When an unknown Hindi word occurs for which all transliteration options are LM-unknown then the best transliteration should be selected. The problem in our original models is that a fixed LM probability ψ is used for LM-unknown transliterations. Hence our model selects the transliteration that has the best $\frac{p_c(h_i,u_i)}{p_c(u_i)}$ score i.e. we maximize $p_c(h_i|u_i)$ instead of $p_c(u_i|h_i)$ (or equivalently $p_c(h_i,u_i)$). The reason is an inconsistency in our models. The language model probability of unknown words is uniform (and equal to ψ) whereas the translation model uses the non-uniform prior probability $p_c(u_i)$ for these words. There is another reason why we can not use the

[13]The translation coefficient λ_1 is same as λ used in previous models and the transliteration coefficient $\lambda_2 = 1 - \lambda$

[14]After optimization we normalize the lambdas to make their sum equal to 1.

value ψ in this case. Our transliterator model also produces space inserted words. The value of ψ is very small because of which transliterations that are actually LM-unknown, but are mistakenly broken into constituents that are LM-known, will always be preferred over their counter parts. An example of this is अमेरिका (America) for which two possible transliterations as given by our model are امیرکا (AmerIkA, without space) and امیر کا (AmerI kA, with space). The latter version is LM-known as its constituents are LM-known. Our models always favor the latter version. Space insertion is an important feature of our transliteration model. We want our transliterator to tackle compound words, derivational affixes, case-markers with nouns that are written as one word in Hindi but as two or more words in Urdu. Examples were already shown in section 3's footnote.

We eliminate the inconsistency by using $p_c(u_i)$ as the 0-gram back-off probability distribution in the language model. For an LM-unknown transliterations we now get in Model-1:

$$
\begin{aligned}
& p(u_i|u_{i-k}^{i-1})[\lambda p_w(h_i|u_i) + (1-\lambda)\frac{p_c(h_i,u_i)}{p_c(u_i)}] \\
&= p(u_i|u_{i-k}^{i-1})[(1-\lambda)\frac{p_c(h_i,u_i)}{p_c(u_i)}] \\
&= \prod_{j=0}^{k} \alpha(u_{i-j}^{i-1}) p_c(u_i)[(1-\lambda)\frac{p_c(h_i,u_i)}{p_c(u_i)}] \\
&= \prod_{j=0}^{k} \alpha(u_{i-j}^{i-1})[(1-\lambda) p_c(h_i,u_i)]
\end{aligned}
$$

where $\prod_{j=0}^{k} \alpha(u_{i-j}^{i-1})$ is just the constant that SRILM returns for unknown words. The last line of the calculation shows that we simply drop $p_c(u_i)$ if u_i is LM-unknown and use the constant $\prod_{j=0}^{k} \alpha(u_{i-j}^{i-1})$ instead of ψ. A similar calculation for Model-2 gives $\prod_{j=0}^{k} \alpha(u_{i-j}^{i-1}) p_c(h_i,u_i)$.

5.3 Heuristic-3

This heuristic discusses a flaw in Model-2. For transliteration options that are TM-unknown, the $p_w(h,u)$ and $p_w(u)$ factors becomes zero and the translation model probability as given by equation (13) becomes:

$$\frac{(1-\lambda)p_c(h_i,u_i)}{(1-\lambda)p_c(u_i)} = \frac{p_c(h_i,u_i)}{p_c(u_i)}$$

In such cases the λ factor cancels out and no weighting of word translation vs. transliteration occurs anymore. As a result of this, transliterations are sometimes incorrectly favored over their translation alternatives.

In order to remedy this problem we assign a minimal probability β to the word-based prior $p_w(u_i)$ in case of TM-unknown transliterations, which prevents it from ever being zero. Because of this addition the translation model probability for LM-unknown words becomes:

$$\frac{(1-\lambda)p_c(h_i,u_i)}{\lambda\beta + (1-\lambda)p_c(u_i)} \text{ where } \beta = \frac{1}{\text{Urdu Types in TM}}$$

6 Final Results

This section shows the improvement in BLEU score by applying heuristics and combinations of heuristics in both the models. Tables 5 and 6 show the improvements achieved by using the different heuristics and modifications discussed in section 5. We refer to the results as $M_x H_y$ where x denotes the model number, 1 for the conditional probability model and 2 for the joint probability model and y denotes a heuristic or a combination of heuristics applied to that model[15].

Both heuristics (H_1 and H_2) show improvements over their base models M_1 and M_2. Heuristic-1 shows notable improvement for both models in parts of test data which has high number of common vocabulary words. Using heuristic 2 we were able to properly score LM-unknown transliterations against each other. Using these heuristics together we obtain a gain of 0.75 over M-1 and a gain of 1.29 over M-2.

Heuristic-3 remedies the flaw in M_2 by assigning a special value to the word-based prior $p_w(u_i)$ for TM-unknown words which prevents the cancelation of interpolating parameter λ. M_2 combined with heuristic 3 (M_2H_3) results in a 1.47

[15]For example M_1H_1 refers to the results when heuristic-1 is applied to model-1 whereas M_2H_{12} refers to the results when heuristics 1 and 2 are together applied to model 2.

BLEU point improvement and combined with all the heuristics (M_2H_{123}) gives an overall gain of 1.95 BLEU points and is close to our best results (M_1H_{12}). We also performed significance test by concatenating all the fold results. Both our best systems M_1H_{12} and M_2H_{123} are statistically significant ($p < 0.05$)[16] over all the baselines discussed in section 4.2.2.

One important issue that has not been investigated yet is that BLEU has not yet been shown to have good performance in morphologically rich target languages like Urdu, but there is no metric known to work better. We observed that sometimes on data where the translators preferred to translate rather than doing transliteration our system is penalized by BLEU even though our output string is a valid translation. For other parts of the data where the translators have heavily used transliteration, the system may receive a higher BLEU score. We feel that this is an interesting area of research for automatic metric developers, and that a large scale task of translation to Urdu which would involve a human evaluation campaign would be very interesting.

7 Sample Output

This section gives two examples showing how our model ($M1H2$) performs disambiguation. Given below are some test sentences that have Hindi homonyms (underlined in the examples) along with Urdu output given by our system. In the first example (given in Figure 1) Hindi word शेर can be transliterated to شیر (Lion) or شعر (Verse) depending upon the context. Our model correctly identifies which transliteration to choose given the context.

In the second example (shown in Figure 2) Hindi word शान्ती can be translated to سکون (peace, s@kun) when it is a common noun but transliterated to شانتی (Shanti, SAnt_di) when it is a proper name. Our model successfully decides whether to translate or transliterate given the context.

8 Conclusion

We have presented a novel way to integrate transliterations into machine translation. In closely related language pairs such as Hindi-Urdu with a significant amount of vocabulary overlap, transliteration can be very effective in machine translation for more than just translating OOV words. We have addressed two problems. First, transliteration helps overcome the problem of data sparsity and noisy alignments. We are able to generate word translations that are unseen in the translation corpus but known to the language model. Additionally, we can generate novel transliterations (that are LM-Unknown). Second, generating multiple transliterations for homograph Hindi words and using language model context helps us solve the problem of disambiguation. We found that the joint probability model performs almost as well as the conditional probability model but that it was more complex to make it work well.

Training Phrase Translation Models with Leaving-One-Out

Abstract

Several attempts have been made to learn phrase translation probabilities for phrase-based statistical machine translation that go beyond pure counting of phrases in word-aligned training data. Most approaches report problems with over-fitting. We describe a novel leaving-one-out approach to prevent over-fitting that allows us to train phrase models that show improved translation performance on the WMT08 Europarl German-English task. In contrast to most previous work where phrase models were trained separately from other models used in translation, we include all components such as single word lexica and reordering models in training. Using this consistent training of phrase models we are able to achieve improvements of up to 1.4 points in BLEU. As a side effect, the phrase table size is reduced by more than 80%.

1 Introduction

A phrase-based SMT system takes a source sentence and produces a translation by segmenting the sentence into phrases and translating those phrases separately (Koehn et al., 2003). The phrase translation table, which contains the bilingual phrase pairs and the corresponding translation probabilities, is one of the main components of an SMT system. The most common method for obtaining the phrase table is heuristic extraction from automatically word-aligned bilingual training data (Och et al., 1999). In this method, all phrases of the sentence pair that match constraints given by the alignment are extracted. This includes overlapping phrases. At extraction time it does not matter, whether the phrases are extracted from a highly probable phrase alignment or from an unlikely one.

Phrase model probabilities are typically defined as relative frequencies of phrases extracted from word-aligned parallel training data. The joint counts $C(\tilde{f}, \tilde{e})$ of the source phrase $\tilde{f}$ and the target phrase $\tilde{e}$ in the entire training data are normalized by the marginal counts of source and target phrase to obtain a conditional probability

$$p_H(\tilde{f}|\tilde{e}) = \frac{C(\tilde{f}, \tilde{e})}{C(\tilde{e})}. \quad (1)$$

The translation process is implemented as a weighted log-linear combination of several models $h_m(e_1^I, s_1^K, f_1^J)$ including the logarithm of the phrase probability in source-to-target as well as in target-to-source direction. The phrase model is combined with a language model, word lexicon models, word and phrase penalty, and many others. (Och and Ney, 2004) The best translation $\hat{e}_1^{\hat{I}}$ as defined by the models then can be written as

$$\hat{e}_1^{\hat{I}} = \underset{I, e_1^I}{\operatorname{argmax}} \left\{ \sum_{m=1}^{M} \lambda_m h_m(e_1^I, s_1^K, f_1^J) \right\} \quad (2)$$

In this work, we propose to directly train our phrase models by applying a forced alignment procedure where we use the decoder to find a phrase alignment between source and target sentences of the training data and then updating phrase translation probabilities based on this alignment. In contrast to heuristic extraction, the proposed method provides a way of consistently training and using phrase models in translation. We use a modified version of a phrase-based decoder to perform the forced alignment. This way we ensure that all models used in training are identical to the ones used at decoding time. An illustration of the basic

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 475–484,
Uppsala, Sweden, 11-16 July 2010.

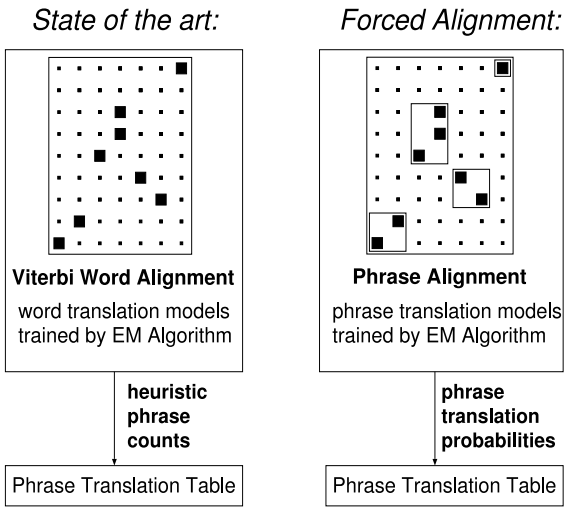

Figure 1: Illustration of phrase training with forced alignment.

idea can be seen in Figure 1. In the literature this method by itself has been shown to be problematic because it suffers from over-fitting (DeNero et al., 2006), (Liang et al., 2006). Since our initial phrases are extracted from the same training data, that we want to align, very long phrases can be found for segmentation. As these long phrases tend to occur in only a few training sentences, the EM algorithm generally overestimates their probability and neglects shorter phrases, which better generalize to unseen data and thus are more useful for translation. In order to counteract these effects, our training procedure applies leaving-one-out on the sentence level. Our results show, that this leads to a better translation quality.

Ideally, we would produce all possible segmentations and alignments during training. However, this has been shown to be infeasible for real-world data (DeNero and Klein, 2008). As training uses a modified version of the translation decoder, it is straightforward to apply pruning as in regular decoding. Additionally, we consider three ways of approximating the full search space:

1. the single-best Viterbi alignment,
2. the n-best alignments,
3. all alignments remaining in the search space after pruning.

The performance of the different approaches is measured and compared on the German-English Europarl task from the *ACL 2008 Workshop on Statistical Machine Translation* (WMT08). Our results show that the proposed phrase model training improves translation quality on the test set by 0.9 BLEU points over our baseline. We find that by interpolation with the heuristically extracted phrases translation performance can reach up to 1.4 BLEU improvement over the baseline on the test set.

After reviewing the related work in the following section, we give a detailed description of phrasal alignment and leaving-one-out in Section 3. Section 4 explains the estimation of phrase models. The empirical evaluation of the different approaches is done in Section 5.

2 Related Work

It has been pointed out in literature, that training phrase models poses some difficulties. For a generative model, (DeNero et al., 2006) gave a detailed analysis of the challenges and arising problems. They introduce a model similar to the one we propose in Section 4.2 and train it with the EM algorithm. Their results show that it can not reach a performance competitive to extracting a phrase table from word alignment by heuristics (Och et al., 1999).

Several reasons are revealed in (DeNero et al., 2006). When given a bilingual sentence pair, we can usually assume there are a number of equally correct phrase segmentations and corresponding alignments. For example, it may be possible to transform one valid segmentation into another by splitting some of its phrases into sub-phrases or by shifting phrase boundaries. This is different from word-based translation models, where a typical assumption is that each target word corresponds to only one source word. As a result of this ambiguity, different segmentations are recruited for different examples during training. That in turn leads to over-fitting which shows in overly determinized estimates of the phrase translation probabilities. In addition, (DeNero et al., 2006) found that the trained phrase table shows a highly peaked distribution in opposition to the more flat distribution resulting from heuristic extraction, leaving the decoder only few translation options at decoding time.

Our work differs from (DeNero et al., 2006) in a number of ways, addressing those problems.

To limit the effects of over-fitting, we apply the leaving-one-out and cross-validation methods in training. In addition, we do not restrict the training to phrases consistent with the word alignment, as was done in (DeNero et al., 2006). This allows us to recover from flawed word alignments.

In (Liang et al., 2006) a discriminative translation system is described. For training of the parameters for the discriminative features they propose a strategy they call *bold updating*. It is similar to our forced alignment training procedure described in Section 3.

For the hierarchical phrase-based approach, (Blunsom et al., 2008) present a discriminative rule model and show the difference between using only the viterbi alignment in training and using the full sum over all possible derivations.

Forced alignment can also be utilized to train a phrase segmentation model, as is shown in (Shen et al., 2008). They report small but consistent improvements by incorporating this segmentation model, which works as an additional prior probability on the monolingual target phrase.

In (Ferrer and Juan, 2009), phrase models are trained by a semi-hidden Markov model. They train a conditional "inverse" phrase model of the target phrase given the source phrase. Additionally to the phrases, they model the segmentation sequence that is used to produce a phrase alignment between the source and the target sentence. They used a phrase length limit of 4 words with longer phrases not resulting in further improvements. To counteract over-fitting, they interpolate the phrase model with IBM Model 1 probabilities that are computed on the phrase level. We also include these word lexica, as they are standard components of the phrase-based system.

It is shown in (Ferrer and Juan, 2009), that Viterbi training produces almost the same results as full Baum-Welch training. They report improvements over a phrase-based model that uses an inverse phrase model and a language model. Experiments are carried out on a custom subset of the English-Spanish Europarl corpus.

Our approach is similar to the one presented in (Ferrer and Juan, 2009) in that we compare Viterbi and a training method based on the Forward-Backward algorithm. But instead of focusing on the statistical model and relaxing the translation task by using monotone translation only, we use a full and competitive translation system as starting point with reordering and all models included.

In (Marcu and Wong, 2002), a joint probability phrase model is presented. The learned phrases are restricted to the most frequent n-grams up to length 6 and all unigrams. Monolingual phrases have to occur at least 5 times to be considered in training. Smoothing is applied to the learned models so that probabilities for rare phrases are non-zero. In training, they use a greedy algorithm to produce the Viterbi phrase alignment and then apply a hill-climbing technique that modifies the Viterbi alignment by merge, move, split, and swap operations to find an alignment with a better probability in each iteration. The model shows improvements in translation quality over the single-word-based IBM Model 4 (Brown et al., 1993) on a subset of the Canadian Hansards corpus.

The joint model by (Marcu and Wong, 2002) is refined by (Birch et al., 2006) who use high-confidence word alignments to constrain the search space in training. They observe that due to several constraints and pruning steps, the trained phrase table is much smaller than the heuristically extracted one, while preserving translation quality.

The work by (DeNero et al., 2008) describes a method to train the joint model described in (Marcu and Wong, 2002) with a Gibbs sampler. They show that by applying a prior distribution over the phrase translation probabilities they can prevent over-fitting. The prior is composed of IBM1 lexical probabilities and a geometric distribution over phrase lengths which penalizes long phrases. The two approaches differ in that we apply the leaving-one-out procedure to avoid over-fitting, as opposed to explicitly defining a prior distribution.

3 Alignment

The training process is divided into three parts. First we obtain all models needed for a normal translations system. We perform minimum error rate training with the downhill simplex algorithm (Nelder and Mead, 1965) on the development data to obtain a set of scaling factors that achieve a good BLEU score. We then use these models and scaling factors to do a forced alignment, where we compute a phrase alignment for the training data. From this alignment we then estimate new phrase models, while keeping all other models un-

changed. In this section we describe our forced alignment procedure that is the basic training procedure for the models proposed here.

3.1 Forced Alignment

The idea of forced alignment is to perform a phrase segmentation and alignment of each sentence pair of the training data using the full translation system as in decoding. What we call segmentation and alignment here corresponds to the "concepts" used by (Marcu and Wong, 2002). We apply our normal phrase-based decoder on the source side of the training data and constrain the translations to the corresponding target sentences from the training data.

Given a source sentence f_1^J and target sentence e_1^I, we search for the best phrase segmentation and alignment that covers both sentences. A segmentation of a sentence into K phrase is defined by

$$k \rightarrow s_k := (i_k, b_k, j_k), \text{ for } k = 1, \ldots, K$$

where for each segment i_k is last position of kth target phrase, and (b_k, j_k) are the start and end positions of the source phrase aligned to the kth target phrase. Consequently, we can modify Equation 2 to define the best segmentation of a sentence pair as:

$$\hat{s}_1^{\hat{K}} = \underset{K, s_1^K}{\operatorname{argmax}} \left\{ \sum_{m=1}^{M} \lambda_m h_m(e_1^I, s_1^K, f_1^J) \right\} \quad (3)$$

The identical models as in search are used: conditional phrase probabilities $p(\tilde{f}_k|\tilde{e}_k)$ and $p(\tilde{e}_k|\tilde{f}_k)$, within-phrase lexical probabilities, distance-based reordering model as well as word and phrase penalty. A language model is not used in this case, as the system is constrained to the given target sentence and thus the language model score has no effect on the alignment.

In addition to the phrase matching on the source sentence, we also discard all phrase translation candidates, that do not match any sequence in the given target sentence.

Sentences for which the decoder can not find an alignment are discarded for the phrase model training. In our experiments, this is the case for roughly 5% of the training sentences.

3.2 Leaving-one-out

As was mentioned in Section 2, previous approaches found over-fitting to be a problem in phrase model training. In this section, we describe a leaving-one-out method that can improve the phrase alignment in situations, where the probability of rare phrases and alignments might be overestimated. The training data that consists of N parallel sentence pairs f_n and e_n for $n = 1, \ldots, N$ is used for both the initialization of the translation model $p(\tilde{f}|\tilde{e})$ and the phrase model training. While this way we can make full use of the available data and avoid unknown words during training, it has the drawback that it can lead to over-fitting. All phrases extracted from a specific sentence pair f_n, e_n can be used for the alignment of this sentence pair. This includes longer phrases, which only match in very few sentences in the data. Therefore those long phrases are trained to fit only a few sentence pairs, strongly overestimating their translation probabilities and failing to generalize. In the extreme case, whole sentences will be learned as phrasal translations. The average length of the used phrases is an indicator of this kind of over-fitting, as the number of matching training sentences decreases with increasing phrase length. We can see an example in Figure 2. Without leaving-one-out the sentence is segmented into a few long phrases, which are unlikely to occur in data to be translated. Phrase boundaries seem to be unintuitive and based on some hidden structures. With leaving-one-out the phrases are shorter and therefore better suited for generalization to unseen data.

Previous attempts have dealt with the over-fitting problem by limiting the maximum phrase length (DeNero et al., 2006; Marcu and Wong, 2002) and by smoothing the phrase probabilities by lexical models on the phrase level (Ferrer and Juan, 2009). However, (DeNero et al., 2006) experienced similar over-fitting with short phrases due to the fact that the same word sequence can be segmented in different ways, leading to specific segmentations being learned for specific training sentence pairs. Our results confirm these findings. To deal with this problem, instead of simple phrase length restriction, we propose to apply the leaving-one-out method, which is also used for language modeling techniques (Kneser and Ney, 1995).

When using leaving-one-out, we modify the phrase translation probabilities for each sentence pair. For a training example f_n, e_n, we have to remove all phrases $C_n(\tilde{f}, \tilde{e})$ that were extracted from this sentence pair from the phrase counts that

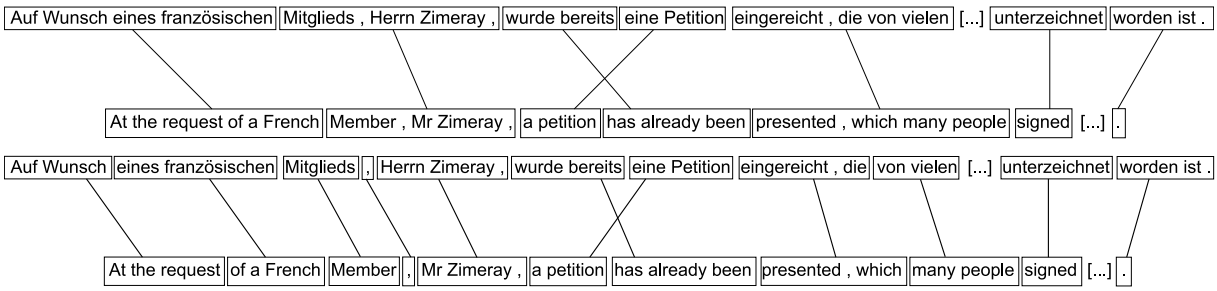

Figure 2: Segmentation example from forced alignment. Top: without leaving-one-out. Bottom: with leaving-one-out.

we used to construct our phrase translation table. The same holds for the marginal counts $C_n(\tilde{e})$ and $C_n(\tilde{f})$. Starting from Equation 1, the leaving-one-out phrase probability for training sentence pair n is

$$p_{l1o,n}(\tilde{f}|\tilde{e}) = \frac{C(\tilde{f},\tilde{e}) - C_n(\tilde{f},\tilde{e})}{C(\tilde{e}) - C_n(\tilde{e})} \quad (4)$$

To be able to perform the re-computation in an efficient way, we store the source and target phrase marginal counts for each phrase in the phrase table. A phrase extraction is performed for each training sentence pair separately using the same word alignment as for the initialization. It is then straightforward to compute the phrase counts after leaving-one-out using the phrase probabilities and marginal counts stored in the phrase table.

While this works well for more frequent observations, singleton phrases are assigned a probability of zero. We refer to singleton phrases as phrase pairs that occur only in one sentence. For these sentences, the decoder needs the singleton phrase pairs to produce an alignment. Therefore we retain those phrases by assigning them a positive probability close to zero. We evaluated with two different strategies for this, which we call standard and length-based leaving-one-out. Standard leaving-one-out assigns a fixed probability α to singleton phrase pairs. This way the decoder will prefer using more frequent phrases for the alignment, but is able to resort to singletons if necessary. However, we found that with this method longer singleton phrases are preferred over shorter ones, because fewer of them are needed to produce the target sentence. In order to better generalize to unseen data, we would like to give the preference to shorter phrases. This is done by length-based leaving-one-out, where singleton phrases are assigned the probability $\beta^{(|\tilde{f}|+|\tilde{e}|)}$ with the source and target phrase lengths $|\tilde{f}|$ and $|\tilde{e}|$ and fixed $\beta < 1$. In our experiments we set $\alpha = e^{-20}$ and $\beta = e^{-5}$. Table 1 shows the decrease in average source phrase length by application of leaving-one-out.

Table 1: Avg. source phrase lengths in forced alignment without leaving-one-out and with standard and length-based leaving-one-out.

	avg. phrase length
without l1o	2.5
standard l1o	1.9
length-based l1o	1.6

3.3 Cross-validation

For the first iteration of the phrase training, leaving-one-out can be implemented efficiently as described in Section 3.2. For higher iterations, phrase counts obtained in the previous iterations would have to be stored on disk separately for each sentence and accessed during the forced alignment process. To simplify this procedure, we propose a cross-validation strategy on larger batches of data. Instead of recomputing the phrase counts for each sentence individually, this is done for a whole batch of sentences at a time. In our experiments, we set this batch-size to 10000 sentences.

3.4 Parallelization

To cope with the runtime and memory requirements of phrase model training that was pointed out by previous work (Marcu and Wong, 2002; Birch et al., 2006), we parallelized the forced alignment by splitting the training corpus into blocks of 10k sentence pairs. From the initial phrase table, each of these blocks only loads the phrases that are required for alignment. The align-

ment and the counting of phrases are done separately for each block and then accumulated to build the updated phrase model.

4 Phrase Model Training

The produced phrase alignment can be given as a single best alignment, as the n-best alignments or as an alignment graph representing all alignments considered by the decoder. We have developed two different models for phrase translation probabilities which make use of the force-aligned training data. Additionally we consider smoothing by different kinds of interpolation of the generative model with the state-of-the-art heuristics.

4.1 Viterbi

The simplest of our generative phrase models estimates phrase translation probabilities by their relative frequencies in the Viterbi alignment of the data, similar to the heuristic model but with counts from the phrase-aligned data produced in training rather than computed on the basis of a word alignment. The translation probability of a phrase pair $(\tilde{f}, \tilde{e})$ is estimated as

$$p_{FA}(\tilde{f}|\tilde{e}) = \frac{C_{FA}(\tilde{f}, \tilde{e})}{\sum_{\tilde{f}'} C_{FA}(\tilde{f}', \tilde{e})} \quad (5)$$

where $C_{FA}(\tilde{f}, \tilde{e})$ is the count of the phrase pair $(\tilde{f}, \tilde{e})$ in the phrase-aligned training data. This can be applied to either the Viterbi phrase alignment or an n-best list. For the simplest model, each hypothesis in the n-best list is weighted equally. We will refer to this model as the *count* model as we simply count the number of occurrences of a phrase pair. We also experimented with weighting the counts with the estimated likelihood of the corresponding entry in the the n-best list. The sum of the likelihoods of all entries in an n-best list is normalized to 1. We will refer to this model as the *weighted count* model.

4.2 Forward-backward

Ideally, the training procedure would consider all possible alignment and segmentation hypotheses. When alternatives are weighted by their posterior probability. As discussed earlier, the run-time requirements for computing all possible alignments is prohibitive for large data tasks. However, we can approximate the space of all possible hypotheses by the search space that was used for the alignment. While this might not cover all phrase translation probabilities, it allows the search space and translation times to be feasible and still contains the most probable alignments. This search space can be represented as a graph of partial hypotheses (Ueffing et al., 2002) on which we can compute expectations using the Forward-Backward algorithm. We will refer to this alignment as the *full* alignment. In contrast to the method described in Section 4.1, phrases are weighted by their posterior probability in the word graph. As suggested in work on minimum Bayes-risk decoding for SMT (Tromble et al., 2008; Ehling et al., 2007), we use a global factor to scale the posterior probabilities.

4.3 Phrase Table Interpolation

As (DeNero et al., 2006) have reported improvements in translation quality by interpolation of phrase tables produced by the generative and the heuristic model, we adopt this method and also report results using log-linear interpolation of the estimated model with the original model.

The log-linear interpolations $p_{int}(\tilde{f}|\tilde{e})$ of the phrase translation probabilities are estimated as

$$p_{int}(\tilde{f}|\tilde{e}) = \Big(p_H(\tilde{f}|\tilde{e})\Big)^{1-\omega} \cdot \Big(p_{gen}(\tilde{f}|\tilde{e})\Big)^{(\omega)} \quad (6)$$

where ω is the interpolation weight, p_H the heuristically estimated phrase model and p_{gen} the count model. The interpolation weight ω is adjusted on the development corpus. When interpolating phrase tables containing different sets of phrase pairs, we retain the intersection of the two.

As a generalization of the fixed interpolation of the two phrase tables we also experimented with adding the two trained phrase probabilities as additional features to the log-linear framework. This way we allow different interpolation weights for the two translation directions and can optimize them automatically along with the other feature weights. We will refer to this method as *feature-wise combination*. Again, we retain the intersection of the two phrase tables. With good log-linear feature weights, feature-wise combination should perform at least as well as fixed interpolation. However, the results presented in Table 5

Table 2: Statistics for the Europarl German-English data

		German	English
TRAIN	Sentences	1 311 815	
	Run. Words	34 398 651	36 090 085
	Vocabulary	336 347	118 112
	Singletons	168 686	47 507
DEV	Sentences	2 000	
	Run. Words	55 118	58 761
	Vocabulary	9 211	6 549
	OOVs	284	77
TEST	Sentences	2 000	
	Run. Words	56 635	60 188
	Vocabulary	9 254	6 497
	OOVs	266	89

show a slightly lower performance. This illustrates that a higher number of features results in a less reliable optimization of the log-linear parameters.

5 Experimental Evaluation

5.1 Experimental Setup

We conducted our experiments on the German-English data published for the *ACL 2008 Workshop on Statistical Machine Translation* (WMT08). Statistics for the Europarl data are given in Table 2.

We are given the three data sets $TRAIN$, DEV and $TEST$. For the heuristic phrase model, we first use GIZA++ (Och and Ney, 2003) to compute the word alignment on $TRAIN$. Next we obtain a phrase table by extraction of phrases from the word alignment. The scaling factors of the translation models have been optimized for BLEU on the DEV data.

The phrase table obtained by heuristic extraction is also used to initialize the training. The forced alignment is run on the training data $TRAIN$ from which we obtain the phrase alignments. Those are used to build a phrase table according to the proposed generative phrase models. Afterward, the scaling factors are trained on DEV for the new phrase table. By feeding back the new phrase table into forced alignment we can reiterate the training procedure. When training is finished the resulting phrase model is evaluated on DEV and $TEST$. Additionally, we can apply smoothing by interpolation of the new phrase table with the original one estimated heuristically, retrain the scaling factors and evaluate afterwards.

Table 3: Comparison of different training setups for the count model on DEV.

leaving-one-out	max phr.len.	BLEU	TER
baseline	6	25.7	61.1
none	2	25.2	61.3
	3	25.7	61.3
	4	25.5	61.4
	5	25.5	61.4
	6	25.4	61.7
standard	6	26.4	60.9
length-based	6	26.5	60.6

The baseline system is a standard phrase-based SMT system with eight features: phrase translation and word lexicon probabilities in both translation directions, phrase penalty, word penalty, language model score and a simple distance-based reordering model. The features are combined in a log-linear way. To investigate the generative models, we replace the two phrase translation probabilities and keep the other features identical to the baseline. For the feature-wise combination the two generative phrase probabilities are added to the features, resulting in a total of 10 features. We used a 4-gram language model with modified Kneser-Ney discounting for all experiments. The metrics used for evaluation are the case-sensitive BLEU (Papineni et al., 2002) score and the translation edit rate (TER) (Snover et al., 2006) with one reference translation.

5.2 Results

In this section, we investigate the different aspects of the models and methods presented before. We will focus on the proposed leaving-one-out technique and show that it helps in finding good phrasal alignments on the training data that lead to improved translation models. Our final results show an improvement of 1.4 BLEU over the heuristically extracted phrase model on the test data set.

In Section 3.2 we have discussed several methods which aim to overcome the over-fitting prob-

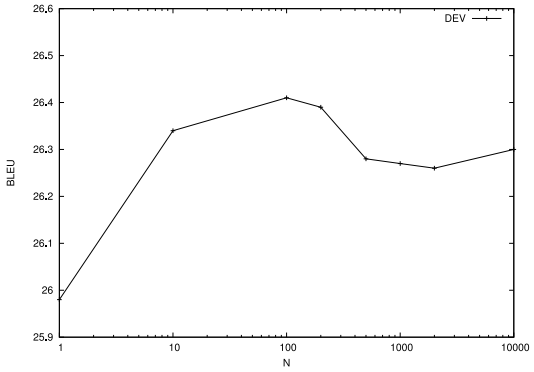

Figure 3: Performance on DEV in BLEU of the count model plotted against size n of n-best list on a logarithmic scale.

lems described in (DeNero et al., 2006). Table 3 shows translation scores of the count model on the development data after the first training iteration for both leaving-one-out strategies we have introduced and for training without leaving-one-out with different restrictions on phrase length. We can see that by restricting the source phrase length to a maximum of 3 words, the trained model is close to the performance of the heuristic phrase model. With the application of leaving-one-out, the trained model is superior to the baseline, the length-based strategy performing slightly better than standard leaving-one-out. For these experiments the count model was estimated with a 100-best list.

The count model we describe in Section 4.1 estimates phrase translation probabilities using counts from the n-best phrase alignments. For smaller n the resulting phrase table contains fewer phrases and is more deterministic. For higher values of n more competing alignments are taken into account, resulting in a bigger phrase table and a smoother distribution. We can see in Figure 3 that translation performance improves by moving from the Viterbi alignment to n-best alignments. The variations in performance with sizes between $n = 10$ and $n = 10000$ are less than 0.2 BLEU. The maximum is reached for $n = 100$, which we used in all subsequent experiments. An additional benefit of the count model is the smaller phrase table size compared to the heuristic phrase extraction. This is consistent with the findings of (Birch et al., 2006). Table 4 shows the phrase table sizes for different n. With $n = 100$ we retain only 17% of the original phrases. Even for the full model, we do not retain all phrase table entries. Due to pruning in the forced alignment step, not all translation options are considered. As a result experiments can be done more rapidly and with less resources than with the heuristically extracted phrase table. Also, our experiments show that the increased performance of the count model is partly derived from the smaller phrase table size. In Table 5 we can see that the performance of the heuristic phrase model can be increased by 0.6 BLEU on $TEST$ by filtering the phrase table to contain the same phrases as the count model and reoptimizing the log-linear model weights. The experiments on the number of different alignments taken into account were done with standard leaving-one-out.

Table 4: Phrase table size of the count model for different n-best list sizes, the full model and for heuristic phrase extraction.

N	# phrases	% of full table
1	4.9M	5.3
10	8.4M	9.1
100	15.9M	17.2
1000	27.1M	29.2
10000	40.1M	43.2
full	59.6M	64.2
heuristic	92.7M	100.0

The final results are given in Table 5. We can see that the count model outperforms the baseline by 0.8 BLEU on DEV and 0.9 BLEU on $TEST$ after the first training iteration. The performance of the filtered baseline phrase table shows that part of that improvement derives from the smaller phrase table size. Application of cross-validation (cv) in the first iteration yields a performance close to training with leaving-one-out (l1o), which indicates that cross-validation can be safely applied to higher training iterations as an alternative to leaving-one-out. The weighted count model clearly under-performs the simpler count model. A second iteration of the training algorithm shows nearly no changes in BLEU score, but a small improvement in TER. Here, we used the phrase table trained with leaving-one-out in the first iteration and applied cross-validation in the second iteration. Log-linear interpolation of the count model with the heuristic yields a further increase, showing an improvement of 1.3 BLEU on DEV and 1.4 BLEU on $TEST$ over the baseline. The interpo-

Table 5: Final results for the heuristic phrase table filtered to contain the same phrases as the count model (baseline filt.), the count model trained with leaving-one-out (l1o) and cross-validation (cv), the weighted count model and the full model. Further, scores for fixed log-linear interpolation of the count model trained with leaving-one-out with the heuristic as well as a feature-wise combination are shown. The results of the second training iteration are given in the bottom row.

	DEV		TEST	
	BLEU	TER	BLEU	TER
baseline	25.7	61.1	26.3	60.9
baseline filt.	26.0	61.6	26.9	61.2
count (l1o)	26.5	60.6	27.2	60.5
count (cv)	26.4	60.7	27.0	60.7
weight. count	25.9	61.4	26.4	61.3
full	26.3	60.0	27.0	60.2
fixed interpol.	**27.0**	**59.4**	**27.7**	**59.2**
feat. comb.	26.8	60.1	27.6	59.9
count, iter. 2	26.4	60.3	27.2	60.0

lation weight is adjusted on the development set and was set to $\omega = 0.6$. Integrating both models into the log-linear framework (feat. comb.) yields a BLEU score slightly lower than with fixed interpolation on both DEV and $TEST$. This might be attributed to deficiencies in the tuning procedure. The full model, where we extract all phrases from the search graph, weighted with their posterior probability, performs comparable to the count model with a slightly worse BLEU and a slightly better TER.

6 Conclusion

We have shown that training phrase models can improve translation performance on a state-of-the-art phrase-based translation model. This is achieved by training phrase translation probabilities in a way that they are consistent with their use in translation. A crucial aspect here is the use of leaving-one-out to avoid over-fitting. We have shown that the technique is superior to limiting phrase lengths and smoothing with lexical probabilities alone.

While models trained from Viterbi alignments already lead to good results, we have demonstrated that considering the 100-best alignments allows to better model the ambiguities in phrase segmentation.

The proposed techniques are shown to be superior to previous approaches that only used lexical probabilities to smooth phrase tables or imposed limits on the phrase lengths. On the WMT08 Europarl task we show improvements of 0.9 BLEU points with the trained phrase table and 1.4 BLEU points when interpolating the newly trained model with the original, heuristically extracted phrase table. In TER, improvements are 0.4 and 1.7 points.

In addition to the improved performance, the trained models are smaller leading to faster and smaller translation systems.

Abstract

The Viterbi algorithm is the conventional decoding algorithm most widely adopted for sequence labeling. Viterbi decoding is, however, prohibitively slow when the label set is large, because its time complexity is quadratic in the number of labels. This paper proposes an exact decoding algorithm that overcomes this problem. A novel property of our algorithm is that it efficiently reduces the labels to be decoded, while still allowing us to check the optimality of the solution. Experiments on three tasks (POS tagging, joint POS tagging and chunking, and supertagging) show that the new algorithm is several orders of magnitude faster than the basic Viterbi and a state-of-the-art algorithm, CARPEDIEM (Esposito and Radicioni, 2009).

1 Introduction

In the past decade, sequence labeling algorithms such as HMMs, CRFs, and Collins' perceptrons have been extensively studied in the field of NLP (Rabiner, 1989; Lafferty et al., 2001; Collins, 2002). Now they are indispensable in a wide range of NLP tasks including chunking, POS tagging, NER and so on (Sha and Pereira, 2003; Tsuruoka and Tsujii, 2005; Lin and Wu, 2009).

One important task in sequence labeling is how to find the most probable label sequence from among all possible ones. This task, referred to as decoding, is usually carried out using the Viterbi algorithm (Viterbi, 1967). The Viterbi algorithm has $O(NL^2)$ time complexity,[1] where N is the input size and L is the number of labels. Although the Viterbi algorithm is generally efficient, it becomes prohibitively slow when dealing with a large number of labels, since its computational cost is quadratic in L (Dietterich et al., 2008).

Unfortunately, several sequence-labeling problems in NLP involve a large number of labels. For example, there are more than 40 and 2000 labels in POS tagging and supertagging, respectively (Brants, 2000; Matsuzaki et al., 2007). These tasks incur much higher computational costs than simpler tasks like NP chunking. What is worse, the number of labels grows drastically if we jointly perform multiple tasks. As we shall see later, we need over 300 labels to reduce joint POS tagging and chunking into the single sequence labeling problem. Although joint learning has attracted much attention in recent years, how to perform decoding efficiently still remains an open problem.

In this paper, we present a new decoding algorithm that overcomes this problem. The proposed algorithm has three distinguishing properties: (1) It is much more efficient than the Viterbi algorithm when dealing with a large number of labels. (2) It is an exact algorithm, that is, the optimality of the solution is always guaranteed unlike approximate algorithms. (3) It is automatic, requiring no task-dependent hyperparameters that have to be manually adjusted.

Experiments evaluate our algorithm on three tasks: POS tagging, joint POS tagging and chunking, and supertagging[2]. The results demonstrate that our algorithm is up to several orders of magnitude faster than the basic Viterbi algorithm and a state-of-the-art algorithm (Esposito and Radicioni, 2009); it makes exact decoding practical even in labeling problems with a large label set.

2 Preliminaries

We first provide a brief overview of sequence labeling and introduce related work.

[1] The first-order Markov assumption is made throughout this paper, although our algorithm is applicable to higher-order Markov models as well.

[2] Our implementation is available at http://www.tkl.iis.u-tokyo.ac.jp/~kaji/staggered

Uppsala, Sweden, 11-16 July 2010.

2.1 Models

Sequence labeling is the problem of predicting label sequence $\boldsymbol{y} = \{y_n\}_{n=1}^N$ for given token sequence $\boldsymbol{x} = \{x_n\}_{n=1}^N$. This is typically done by defining a score function $f(\boldsymbol{x}, \boldsymbol{y})$ and locating the best label sequence: $\boldsymbol{y}_{max} = \operatorname{argmax}_{\boldsymbol{y}} f(\boldsymbol{x}, \boldsymbol{y})$. The form of $f(\boldsymbol{x}, \boldsymbol{y})$ is dependent on the learning model used. Here, we introduce two models widely used in the literature.

Generative models HMM is the most famous generative model for labeling token sequences (Rabiner, 1989). In HMMs, the score function $f(\boldsymbol{x}, \boldsymbol{y})$ is the joint probability distribution over $(\boldsymbol{x}, \boldsymbol{y})$. If we assume a one-to-one correspondence between the hidden states and the labels, the score function can be written as:

$$\begin{aligned} f(\boldsymbol{x}, \boldsymbol{y}) &= \log p(\boldsymbol{x}, \boldsymbol{y}) \\ &= \log p(\boldsymbol{x}|\boldsymbol{y}) + \log p(\boldsymbol{y}) \\ &= \sum_{n=1}^{N} \log p(x_n|y_n) + \sum_{n=1}^{N} \log p(y_n|y_{n-1}). \end{aligned}$$

The parameters $\log p(x_n|y_n)$ and $\log p(y_n|y_{n-1})$ are usually estimated using maximum likelihood or the EM algorithm. Since parameter estimation lies outside the scope of this paper, a detailed description is omitted.

Discriminative models Recent years have seen the emergence of discriminative training methods for sequence labeling (Lafferty et al., 2001; Tasker et al., 2003; Collins, 2002; Tsochantaridis et al., 2005). Among them, we focus on the perceptron algorithm (Collins, 2002). Although we do not discuss the other discriminative models, our algorithm is equivalently applicable to them. The major difference between those models lies in parameter estimation; the decoding process is virtually the same.

In the perceptron, the score function $f(\boldsymbol{x}, \boldsymbol{y})$ is given as $f(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{w} \cdot \boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y})$ where $\boldsymbol{w}$ is the weight vector, and $\boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y})$ is the feature vector representation of the pair $(\boldsymbol{x}, \boldsymbol{y})$. By making the first-order Markov assumption, we have

$$\begin{aligned} f(\boldsymbol{x}, \boldsymbol{y}) &= \boldsymbol{w} \cdot \boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y}) \\ &= \sum_{n=1}^{N} \sum_{k=1}^{K} w_k \phi_k(\boldsymbol{x}, y_{n-1}, y_n), \end{aligned}$$

where $K = |\phi(\boldsymbol{x}, \boldsymbol{y})|$ is the number of features, ϕ_k is the k-th feature function, and w_k is the weight corresponding to it. Parameter $\boldsymbol{w}$ can be estimated in the same way as in the conventional perceptron algorithm. See (Collins, 2002) for details.

2.2 Viterbi decoding

Given the score function $f(\boldsymbol{x}, \boldsymbol{y})$, we have to locate the best label sequence. This is usually performed by applying the Viterbi algorithm. Let $\omega(y_n)$ be the best score of the partial label sequence ending with y_n. The idea of the Viterbi algorithm is to use dynamic programming to compute $\omega(y_n)$. In HMMs, $\omega(y_n)$ can be can be defined as

$$\max_{y_{n-1}} \{\omega(y_{n-1}) + \log p(y_n|y_{n-1})\} + \log p(x_n|y_n).$$

Using this recursive definition, we can evaluate $\omega(y_n)$ for all y_n. This results in the identification of the best label sequence.

Although the Viterbi algorithm is commonly adopted in past studies, it is not always efficient. The computational cost of the Viterbi algorithm is $O(NL^2)$, where N is the input length and L is the number of labels; it is efficient enough if L is small. However, if there are many labels, the Viterbi algorithm becomes prohibitively slow because of its quadratic dependence on L.

2.3 Related work

To the best of our knowledge, the Viterbi algorithm is the only algorithm widely adopted in the NLP field that offers exact decoding. In other communities, several exact algorithms have already been proposed for handling large label sets. While they are successful to some extent, they demand strong assumptions that are unusual in NLP. Moreover, none were challenged with standard NLP tasks.

Felzenszwalb et al. (2003) presented a fast inference algorithm for HMMs based on the assumption that the hidden states can be embedded in a grid space, and the transition probability corresponds to the distance on that space. This type of probability distribution is not common in NLP tasks. Lifshits et al. (2007) proposed a compression-based approach to speed up HMM decoding. It assumes that the input sequence is highly repetitive. Amongst others, CARPEDIEM (Esposito and Radicioni, 2009) is the algorithm closest to our work. It accelerates decoding by assuming that the adjacent labels are not strongly correlated. This assumption is appropriate for

some NLP tasks. For example, as suggested in (Liang et al., 2008), adjacent labels do not provide strong information in POS tagging. However, the applicability of this idea to other NLP tasks is still unclear.

Approximate algorithms, such as beam search or island-driven search, have been proposed for speeding up decoding. Tsuruoka and Tsujii (2005) proposed easiest-first deterministic decoding. Siddiqi and Moore (2005) presented the parameter tying approach for fast inference in HMMs. A similar idea was applied to CRFs as well (Cohn, 2006; Jeong et al., 2009).

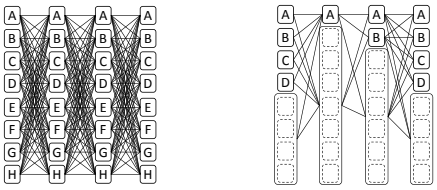
In general, approximate algorithms have the advantage of speed over exact algorithms. However, both types of algorithms are still widely adopted by practitioners, since exact algorithms have merits other than speed. First, the optimality of the solution is always guaranteed. It is hard for most of the approximate algorithms to even bound the error rate. Second, approximate algorithms usually require hyperparameters, which control the trade-off between accuracy and efficiency (e.g., beam width), and these have to be manually adjusted. On the other hand, most of the exact algorithms, including ours, do not require such a manual effort.

Despite these advantages, exact algorithms are rarely used when dealing with a large number of labels. This is because exact algorithms become considerably slower than approximate algorithms in such situations. The paper presents an exact algorithm that avoids this problem; it provides the research community with another option for handling a lot of labels.

3 Algorithm

This section presents the new decoding algorithm. The key is to reduce the number of labels examined. Our algorithm locates the best label sequence by iteratively solving labeling problems with a reduced label set. This results in significant time savings in practice, because each iteration becomes much more efficient than solving the original labeling problem. More importantly, our algorithm always obtains the exact solution. This is because the algorithm allows us to check the optimality of the solution achieved by using only the reduced label set.

In the following discussions, we restrict our focus to HMMs for presentation clarity. Extension to the perceptron algorithm is presented in Section 4.



(a) (b)

Figure 1: (a) An example of a lattice, where the letters {A, B, C, D, E, F, G, H} represent labels associated with nodes. (b) The degenerate lattice.

3.1 Degenerate lattice

We begin by introducing the *degenerate lattice*, which plays a central role in our algorithm. Consider the lattice in Figure 1(a). Following convention, we regard each path on the lattice as a label sequence. Note that the label set is {A, B, C, D, E, F, G, H}. By aggregating several nodes in the same column of the lattice, we can transform the original lattice into a simpler form, which we call the degenerate lattice (Figure 1(b)).

Let us examine the intuition behind the degenerate lattice. Aggregating nodes can be viewed as grouping several labels into a new one. Here, a label is referred to as an *active label* if it is not aggregated (e.g., A, B, C, and D in the first column of Figure 1(b)), and otherwise as an *inactive label* (i.e., dotted nodes). The new label, which is made by grouping the inactive labels, is referred to as a *degenerate label* (i.e., large nodes covering the dotted ones). Two degenerate labels can be seen as equivalent if their corresponding inactive label sets are the same (e.g., degenerate labels in the first and the last column). In this approach, each path of the degenerate lattice can also be interpreted as a label sequence. In this case, however, the label to be assigned is either an active label or a degenerate label.

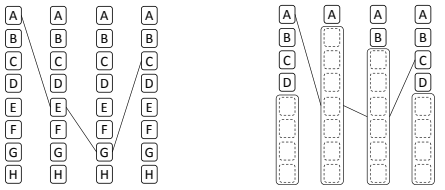
We then define the parameters associated with degenerate label z. For reasons that will become clear later, they are set to the maxima among the parameters of the inactive labels:

$$\log p(x|z) = \max_{y' \in I(z)} \log p(x|y'), \quad (1)$$

$$\log p(z|y) = \max_{y' \in I(z)} \log p(y'|y), \quad (2)$$

$$\log p(y|z) = \max_{y' \in I(z)} \log p(y|y'), \quad (3)$$

$$\log p(z|z') = \max_{y' \in I(z), y'' \in I(z')} \log p(y'|y''), \quad (4)$$



(a) (b)

Figure 2: (a) The path $\boldsymbol{y}$ = {A, E, G, C} of the original lattice. (b) The path $\boldsymbol{z}$ of the degenerate lattice that corresponds to $\boldsymbol{y}$.

where y is an active label, z and z' are degenerate labels, and $I(z)$ denotes one-to-one mapping from z to its corresponding inactive label set.

The degenerate lattice has an important property which is the key to our algorithm:

Lemma 1. *If the best path of the degenerate lattice does not include any degenerate label, it is equivalent to the best path of the original lattice.*

Proof. Let $\boldsymbol{z}_{max}$ be the best path of the degenerate lattice. Our goal is to prove that if $\boldsymbol{z}_{max}$ does not include any degenerate label, then

$$\forall \boldsymbol{y} \in Y, \quad \log p(\boldsymbol{x}, \boldsymbol{y}) \leq \log p(\boldsymbol{x}, \boldsymbol{z}_{max}) \qquad (5)$$

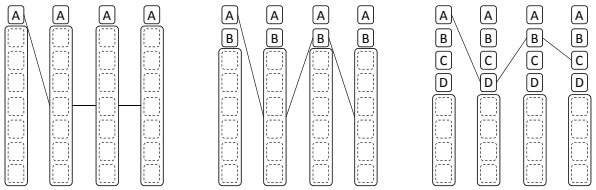
where Y is the set of all paths on the original lattice. We prove this by partitioning Y into two disjoint sets: Y_0 and Y_1, where Y_0 is the subset of Y appearing in the degenerate lattice. Notice that $\boldsymbol{z}_{max} \in Y_0$. Since $\boldsymbol{z}_{max}$ is the best path of the degenerate lattice, we have

$$\forall \boldsymbol{y} \in Y_0, \quad \log p(\boldsymbol{x}, \boldsymbol{y}) \leq \log p(\boldsymbol{x}, \boldsymbol{z}_{max}).$$

The equation holds when $\boldsymbol{y} = \boldsymbol{z}_{max}$. We next examine the label sequence $\boldsymbol{y}$ such that $\boldsymbol{y} \in Y_1$. For each path $\boldsymbol{y} \in Y_1$, there exists a unique path $\boldsymbol{z}$ on the degenerate lattice that corresponds to $\boldsymbol{y}$ (Figure 2). Therefore, we have

$$\forall \boldsymbol{y} \in Y_1, \ \exists \boldsymbol{z} \in Z, \ \log p(\boldsymbol{x}, \boldsymbol{y}) \leq \log p(\boldsymbol{x}, \boldsymbol{z}) < \log p(\boldsymbol{x}, \boldsymbol{z}_{max})$$

where Z is the set of all paths of the degenerate lattice. The inequality $\log p(\boldsymbol{x}, \boldsymbol{y}) \leq \log p(\boldsymbol{x}, \boldsymbol{z})$ can be proved by using Equations (1)-(4). Using these results, we can complete (5). □



(a) (b) (c)

Figure 3: (a) The best path of the initial degenerate lattice, which is denoted by the line, is located. (b) The active labels are expanded and the best path is searched again. (c) The best path without degenerate labels is obtained.

3.2 Staggered decoding

Now we can describe our algorithm, which we call *staggered decoding*. The algorithm successively constructs degenerate lattices and checks whether the best path includes degenerate labels. In building each degenerate lattice, labels with high probability $p(y)$, estimated from training data, are preferentially selected as the active label; the expectation is that such labels are likely to belong to the best path. The algorithm is detailed as follows:

Initialization step The algorithm starts by building a degenerate lattice in which there is only one active label in each column. We select label y with the highest $p(y)$ as the active label.

Search step The best path of the degenerate lattice is located (Figure 3(a)). This is done by using the Viterbi algorithm (and pruning technique, as we describe in Section 3.3). If the best path does not include any degenerate label, we can terminate the algorithm since it is identical with the best path of the original lattice according to Lemma 1. Otherwise, we proceed to the next step.

Expansion step We double the number of the active labels in the degenerate lattice. The new active labels are selected from the current inactive label set in descending order of $p(y)$. If the inactive label set becomes empty, we simply reconstructed the original lattice. After expanding the active labels, we go back to the previous step (Figure 3(b)). This procedure is repeated until the termination condition in the search step is satisfied, i.e., the best path has no degenerate label (Figure 3(c)).

Compared to the Viterbi algorithm, staggered decoding requires two additional computations for

training. First, we have to estimate $p(y)$ so as to select active labels in the initialization and expansion step. Second, we have to compute the parameters regarding degenerate labels according to Equations (1)-(4). Both impose trivial computation costs.

3.3 Pruning

To achieve speed-up, it is crucial that staggered decoding efficiently performs the search step. For this purpose, we can basically use the Viterbi algorithm. In earlier iterations, the Viterbi algorithm is indeed efficient because the label set to be handled is much smaller than the original one. In later iterations, however, our algorithm drastically increases the number of labels, making Viterbi decoding quite expensive.

To handle this problem, we propose a method of pruning the lattice nodes. This technique is motivated by the observation that the degenerate lattice shares many active labels with the previous iteration. In the remainder of Section3.3, we explain the technique by taking the following steps:

- Section 3.3.1 examines a lower bound l such that $l \leq \max_{\boldsymbol{y}} \log p(\boldsymbol{x}, \boldsymbol{y})$.
- Section 3.3.2 examines the maximum score $\textsc{Max}(y_n)$ in case token x_n takes label y_n:

$$\textsc{Max}(y_n) = \max_{y'_n = y_n} \log p(\boldsymbol{x}, \boldsymbol{y}').$$

- Section 3.3.3 presents our pruning procedure. The idea is that if $\textsc{Max}(y_n) < l$, then the node corresponding to y_n can be removed from consideration.

3.3.1 Lower bound

Lower bound l can be trivially calculated in the search step. This can be done by retaining the best path among those consisting of only active labels. The score of that path is obviously the lower bound. Since the search step is repeated until the termination criteria is met, we can update the lower bound at every search step. As the iteration proceeds, the degenerate lattice becomes closer to the original one, so the lower bound becomes tighter.

3.3.2 Maximum score

The maximum score $\textsc{Max}(y_n)$ can be computed from the original lattice. Let $\omega(y_n)$ be the best score of the partial label sequence ending with y_n. Presuming that we traverse the lattice from left to right, $\omega(y_n)$ can be defined as

$$\max_{y_{n-1}} \{\omega(y_{n-1}) + \log p(y_n | y_{n-1})\} + \log p(x_n | y_n).$$

If we traverse the lattice from right to left, an analogous score $\bar{\omega}(y_n)$ can be defined as

$$\log p(x_n | y_n) + \max_{y_{n+1}} \{\bar{\omega}(y_{n+1}) + \log p(y_n | y_{n+1})\}.$$

Using these two scores, we have

$$\textsc{Max}(y_n) = \omega(y_n) + \bar{\omega}(y_n) - \log p(x_n | y_n).$$

Notice that updating $\omega(y_n)$ or $\bar{\omega}(y_n)$ is equivalent to the forward or backward Viterbi algorithm, respectively.

Although it is expensive to compute $\omega(y_n)$ and $\bar{\omega}(y_n)$, we can efficiently estimate their upper bounds. Let $\lambda(y_n)$ and $\bar{\lambda}(y_n)$ be scores analogous to $\omega(y_n)$ and $\bar{\omega}(y_n)$ that are computed using the degenerate lattice. We have $\omega(y_n) \leq \lambda(y_n)$ and $\bar{\omega}(y_n) \leq \bar{\lambda}(y_n)$, by following similar discussions as raised in the proof of Lemma 1. Therefore, we can still check whether $\textsc{Max}(y_n)$ is smaller than l by using $\lambda(y_n)$ and $\bar{\lambda}(y_n)$:

$$\begin{aligned} \textsc{Max}(y_n) &= \omega(y_n) + \bar{\omega}(y_n) - \log p(x_n | y_n) \\ &\leq \lambda(y_n) + \bar{\lambda}(y_n) - \log p(x_n | y_n) \\ &< l. \end{aligned}$$

For the sake of simplicity, we assume that y_n is an active label. Although we do not discuss the other cases, our pruning technique is also applicable to them. We just point out that, if y_n is an inactive label, then there exists a degenerate label z_n in the n-th column such that $y_n \in I(z_n)$, and we can use $\lambda(z_n)$ and $\bar{\lambda}(z_n)$ instead of $\lambda(y_n)$ and $\bar{\lambda}(y_n)$.

We compute $\lambda(y_n)$ and $\bar{\lambda}(y_n)$ by using the forward and backward Viterbi algorithm, respectively. In the search step immediately following initialization, we perform the forward Viterbi algorithm to find the best path, that is, $\lambda(y_n)$ is updated for all y_n. In the next search step, the backward Viterbi algorithm is carried out, and $\bar{\lambda}(y_n)$ is updated. In the succeeding search steps, these updates are alternated. As the algorithm progresses, $\lambda(y_n)$ and $\bar{\lambda}(y_n)$ become closer to $\omega(y_n)$ and $\bar{\omega}(y_n)$.

3.3.3 Pruning procedure

We make use of the bounds in pruning the lattice nodes. To do this, we keep the values of l, $\lambda(y_n)$

and $\bar{\lambda}(y_n)$. They are set as $l = -\infty$ and $\lambda(y_n) = \bar{\lambda}(y_n) = \infty$ in the initialization step, and are updated in the search step. The lower bound l is updated at the end of the search step, while $\lambda(y_n)$ and $\bar{\lambda}(y_n)$ can be updated during the running of the Viterbi algorithm. When $\lambda(y_n)$ or $\bar{\lambda}(y_n)$ is changed, we check whether $\textsc{Max}(y_n) < l$ holds and the node is pruned if the condition is met.

3.4 Analysis

We provide here a theoretical analysis of staggered decoding. In the following proofs, L, V, and N represent the number of original labels, the number of distinct tokens, and the length of input token sequence, respectively. To simplify the discussion, we assume that $\log_2 L$ is an integer (e.g., $L = 64$).

We first introduce three lemmas:

Lemma 2. *Staggered decoding requires at most* $(\log_2 L + 1)$ *iterations to terminate.*

Proof. We have 2^{m-1} active labels in the m-th search step ($m = 1, 2 \ldots$), which means we have L active labels and no degenerate labels in the $(\log_2 L + 1)$-th search step. Therefore, the algorithm always terminates within $(\log_2 L + 1)$ iterations. □

Lemma 3. *The number of degenerate labels is* $\log_2 L$.

Proof. Since we create one new degenerate label in all but the last expansion step, we have $\log_2 L$ degenerate labels. □

Lemma 4. *The Viterbi algorithm requires* $O(L^2 + LV)$ *memory space and has* $O(NL^2)$ *time complexity.*

Proof. Since we need $O(L^2)$ and $O(LV)$ space to keep the transition and emission probability matrices, we need $O(L^2 + LV)$ space to perform the Viterbi algorithm. The time complexity of the Viterbi algorithm is $O(NL^2)$ since there are NL nodes in the lattice and it takes $O(L)$ time to evaluate the score of each node. □

The above statements allow us to establish our main results:

Theorem 1. *Staggered decoding requires* $O(L^2 + LV)$ *memory space.*

Proof. Since we have L original labels and $\log_2 L$ degenerate labels, staggered decoding requires $O((L+\log_2 L)^2 + (L+\log_2 L)V) = O(L^2 + LV)$ memory space to perform Viterbi decoding in the search step. □

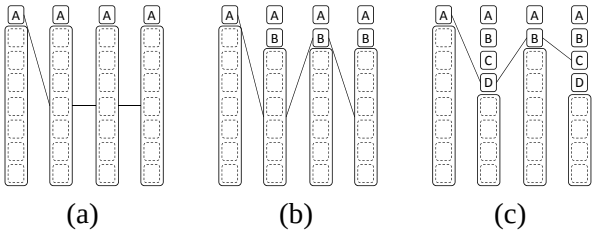


Figure 4: Staggered decoding with column-wise expansion: (a) The best path of the initial degenerate lattice, which does not pass through the degenerate label in the first column. (b) Column-wise expansion is performed and the best path is searched again. Notice that the active label in the first column is not expanded. (c) The final result.

Theorem 2. *Staggered decoding has* $O(N)$ *best case time complexity and* $O(NL^2)$ *worst case time complexity.*

Proof. To perform the m-th search step, staggered decoding requires the order of $O(N4^{m-1})$ time because we have 2^{m-1} active labels. Therefore, it has $O(\sum_{m=1}^{M} N4^{m-1})$ time complexity if it terminates after the M-th search step. In the best case, $M = 1$, the time complexity is $O(N)$. In the worst case, $M = \log_2 L + 1$, the time complexity is the order of $O(NL^2)$ because $\sum_{m=1}^{\log_2 L+1} N4^{m-1} < \frac{4}{3}NL^2$. □

Theorem 1 shows that staggered decoding asymptotically requires the same order of memory space as the Viterbi algorithm. Theorem 2 reveals that staggered decoding has the same order of time complexity as the Viterbi algorithm even in the worst case.

3.5 Heuristic techniques

We present two heuristic techniques for further speeding up our algorithm.

First, we can initialize the value of lower bound l by selecting a path from the original lattice in some way, and then computing the score of that path. In our experiments, we use the path located by the left-to-right deterministic decoding (i.e., beam search with a beam width of 1). Although this method requires an additional cost to locate the path, it is very effective in practice. If l is initialized in this manner, the best case time complexity of our algorithm becomes $O(NL)$.

The second technique is for the expansion step. Instead of the expansion technique described in Section 3.2, we can expand the active labels in a heuristic manner to keep the number of active labels small:

Column-wise expansion step We double the number of the active labels in the column only if the best path of the degenerate lattice passes through the degenerate label of that column (Figure 4).

A drawback of this strategy is that the algorithm requires $N(\log_2 L+1)$ iterations in the worst case. As the result, we can no longer derive a reasonable upper bound for the time complexity. Nevertheless, column-wise expansion is highly effective in practice as we will demonstrate in the experiment. Note that Theorem 1 still holds true even if we use column-wise expansion.

4 Extension to the Perceptron

The discussion we have made so far can be applied to perceptrons. This can be clarified by comparing the score functions $f(\boldsymbol{x}, \boldsymbol{y})$. In HMMs, the score function can be written as

$$\sum_{n=1}^{N} \Big\{ \log(x_n|y_n) + \log(y_n|y_{n-1}) \Big\}.$$

In perceptrons, on the other hand, it is given as

$$\sum_{n=1}^{N} \Big\{ \sum_k w_k^1 \phi_k^1(\boldsymbol{x}, y_n) + \sum_k w_k^2 \phi_k^2(\boldsymbol{x}, y_{n-1}, y_n) \Big\}$$

where we explicitly distinguish the unigram feature function ϕ_k^1 and bigram feature function ϕ_k^2. Comparing the form of the two functions, we can see that our discussion on HMMs can be extended to perceptrons by substituting $\sum_k w_k^1 \phi_k^1(\boldsymbol{x}, y_n)$ and $\sum_k w_k^2 \phi_k^2(\boldsymbol{x}, y_{n-1}, y_n)$ for $\log p(x_n|y_n)$ and $\log p(y_n|y_{n-1})$.

However, implementing the perceptron algorithm is not straightforward. The problem is that it is difficult, if not impossible, to compute $\sum_k w_k^1 \phi_k^1(\boldsymbol{x}, y)$ and $\sum_k w_k^2 \phi_k^2(\boldsymbol{x}, y, y')$ offline because they are dependent on the entire token sequence $\boldsymbol{x}$, unlike $\log p(x|y)$ and $\log p(y|y')$. Consequently, we cannot evaluate the maxima analogous to Equations (1)-(4) offline either.

For unigram features, we compute the maximum, $\max_y \sum_k w_k^1 \phi_k^1(\boldsymbol{x}, y)$, as a preprocess in the initialization step (cf. Equation (1)). This preprocess requires $O(NL)$ time, which is negligible compared with the cost required by the Viterbi algorithm.

Unfortunately, we cannot use the same technique for computing $\max_{y,y'} \sum_k w_k^2 \phi_k^2(\boldsymbol{x}, y, y')$ because a similar computation would take $O(NL^2)$ time (cf. Equation (4)). For bigram features, we compute its upper bound offline. For example, the following bound was proposed by Esposito and Radicioni (2009):

$$\max_{y,y'} \sum_k w_k^2 \phi_k^2(\boldsymbol{x}, y, y') \leq \max_{y,y'} \sum_k w_k^2 \delta(0 < w_k^2)$$

where $\delta(\cdot)$ is the delta function and the summations are taken over all feature functions associated with both y and y'. Intuitively, the upper bound corresponds to an ideal case in which all features with positive weight are activated.[3] It can be computed without any task-specific knowledge.

In practice, however, we can compute better bounds based on task-specific knowledge. The simplest case is that the bigram features are independent of the token sequence $\boldsymbol{x}$. In such a situation, we can trivially compute the exact maxima offline, as we did in the case of HMMs. Fortunately, such a feature set is quite common in NLP problems and we could use this technique in our experiments. Even if bigram features are dependent on $\boldsymbol{x}$, it is still possible to compute better bounds if several features are mutually exclusive, as discussed in (Esposito and Radicioni, 2009).

Finally, it is worth noting that we can use staggered decoding in training perceptrons as well, although such application lies outside the scope of this paper. The algorithm does not support training acceleration for other discriminative models.

5 Experiments and Discussion

5.1 Setting

The proposed algorithm was evaluated with three tasks: POS tagging, joint POS tagging and chunking (called joint tagging for short), and supertagging. To reduce joint tagging into a single sequence labeling problem, we produced the labels by concatenating the POS tag and the chunk tag (BIO format), e.g., NN/B-NP. In the two tasks other than supertagging, the input token is the word. In supertagging, the token is the pair of the word and its oracle POS tag.

[3] We assume binary feature functions.

Table 1: Decoding speed (sent./sec).

	POS tagging	Joint tagging	Supertagging
VITERBI	4000	77	1.1
CARPEDIEM	8600	51	0.26
SD	8800	850	121
SD+C-EXP.	**14,000**	**1600**	**300**

Table 2: The average number of iterations.

	POS tagging	Joint tagging	Supertagging
SD	6.02	8.15	10.0
SD+C-EXP.	6.12	8.62	10.6

Table 3: Training time.

	POS tagging	Joint tagging	Supertagging
VITERBI	100 sec.	20 min.	100 hour
SD+C-EXP.	37 sec.	1.5 min.	5.3 hour

The data sets we used for the three experiments are the Penn TreeBank (PTB) corpus, CoNLL 2000 corpus, and an HPSG treebank built from the PTB corpus (Matsuzaki et al., 2007). We used sections 02-21 of PTB for training, and section 23 for testing. The number of labels in the three tasks is 45, 319 and 2602, respectively.

We used the perceptron algorithm for training. The models were averaged over 10 iterations (Collins, 2002). For features, we basically followed previous studies (Tsuruoka and Tsujii, 2005; Sha and Pereira, 2003; Ninomiya et al., 2006). In POS tagging, we used unigrams of the current and its neighboring words, word bigrams, prefixes and suffixes of the current word, capitalization, and tag bigrams. In joint tagging, we also used the same features. In supertagging, we used POS unigrams and bigrams in addition to the same features other than capitalization.

As the evaluation measure, we used the average decoding speed (sentences/sec) to two significant digits over five trials. To strictly measure the time spent for decoding, we ignored the preprocessing time, that is, the time for loading the model file and converting the features (i.e., strings) into integers. We note that the accuracy was comparable to the state-of-the-art in the three tasks: 97.08, 93.21, and 91.20% respectively.

5.2 Results and discussions

Table 1 presents the performance of our algorithm. SD represents the proposed algorithm without column-wise expansion, while SD+C-EXP. uses column-wise expansion. For comparison, we present the results of two baseline algorithms as well: VITERBI and CARPEDIEM (Esposito and Radicioni, 2009). In almost all settings, we see that both of our algorithms outperformed the other two. We also find that SD+C-EXP. performed consistently better than SD. This indicates the effectiveness of column-wise expansion.

Following VITERBI, CARPEDIEM is the most relevant algorithm, for sequence labeling in NLP, as discussed in Section 2.3. However, our results demonstrated that CARPEDIEM worked poorly in two of the three tasks. We consider this is because the transition information is crucial for the two tasks, and the assumption behind CARPEDIEM is violated. In contrast, the proposed algorithms performed reasonably well for all three tasks, demonstrating the wide applicability of our algorithm.

Table 2 presents the average iteration numbers of SD and SD+C-EXP. We can observe that the two algorithms required almost the same number of iterations on average, although the iteration number is not tightly bounded if we use column-wise expansion. This indicates that SD+C-EXP. virtually avoided performing extra iterations, while heuristically restricting active label expansion.

Table 3 compares the training time spent by VITERBI and SD+C-EXP. Although speeding up perceptron training is a by-product, it is interesting to see that our algorithm is in fact effective at reducing the training time as well. The result also indicates that the speed-up is more significant at test time. This is probably because the model is not predictive enough at the beginning of training, and the pruning is not that effective.

5.3 Comparison with approximate algorithm

Table 4 compares two exact algorithms (VITERBI and SD+E-XP.) with beam search, which is the approximate algorithm widely adopted for sequence labeling in NLP. For this experiment, the beam width, B, was exhaustively calibrated: we tried B = $\{1, 2, 4, 8, ...\}$ until the beam search achieved comparable accuracy to the exact algorithms, i.e., the difference fell below 0.1 in our case.

We see that there is a substantial difference in the performance between VITERBI and BEAM. On the other hand, SD+C-EXP. reached speeds very close to those of BEAM. In fact, they achieved comparable performance in our experiment. These results demonstrate that we could successfully bridge the gap in the performance be-

Table 4: Comparison with beam search (sent./sec).

	POS tagging	Joint tagging	Supertagging
VITERBI	4000	77	1.1
SD+C-EXP.	14,000	1600	**300**
BEAM	**18,000**	**2400**	180

tween exact and approximate algorithms, while retaining the advantages of exact algorithms.

6 Relation to coarse-to-fine approach

Before concluding remarks, we briefly examine the relationship between staggered decoding and coarse-to-fine PCFG parsing (2006). In coarse-to-fine parsing, the candidate parse trees are pruned by using the parse forest produced by a coarse-grained PCFG. Since the degenerate label can be interpreted as a coarse-level label, one may consider that staggered decoding is an instance of coarse-to-fine approach. While there is some resemblance, there are at least two essential differences. First, coarse-to-fine approach is a heuristic pruning, that is, it is not an exact algorithm. Second, our algorithm does not always perform decoding at the fine-grained level. It is designed to be able to stop decoding at the coarse-level.

7 Conclusions

The sequence labeling algorithm is indispensable to modern statistical NLP. However, the Viterbi algorithm, which is the standard decoding algorithm in NLP, is not efficient when we have to deal with a large number of labels. In this paper we presented staggered decoding, which provides a principled way of resolving this problem. We consider that it is a real alternative to the Viterbi algorithm in various NLP tasks.

An interesting future direction is to extend the proposed technique to handle more complex structures than the Markov chains, including semi-Markov models and factorial HMMs (Sarawagi and Cohen, 2004; Sutton et al., 2004). We hope this work opens a new perspective on decoding algorithms for a wide range of NLP problems, not just sequence labeling.

Acknowledgement

We wish to thank the anonymous reviewers for their helpful comments, especially on the computational complexity of our algorithm. We also thank Yusuke Miyao for providing us with the HPSG Treebank data.

Abstract

We combine two complementary ideas for learning supertaggers from highly ambiguous lexicons: grammar-informed tag transitions and models minimized via integer programming. Each strategy on its own greatly improves performance over basic expectation-maximization training with a bitag Hidden Markov Model, which we show on the CCGbank and CCG-TUT corpora. The strategies provide further error reductions when combined. We describe a new two-stage integer programming strategy that efficiently deals with the high degree of ambiguity on these datasets while obtaining the full effect of model minimization.

1 Introduction

Creating accurate part-of-speech (POS) taggers using a tag dictionary and unlabeled data is an interesting task with practical applications. It has been explored at length in the literature since Merialdo (1994), though the task setting as usually defined in such experiments is somewhat artificial since the tag dictionaries are derived from tagged corpora. Nonetheless, the methods proposed apply to realistic scenarios in which one has an electronic part-of-speech tag dictionary or a hand-crafted grammar with limited coverage.

Most work has focused on POS-tagging for English using the Penn Treebank (Marcus et al., 1993), such as (Banko and Moore, 2004; Goldwater and Griffiths, 2007; Toutanova and Johnson, 2008; Goldberg et al., 2008; Ravi and Knight, 2009). This generally involves working with the standard set of 45 POS-tags employed in the Penn Treebank. The most ambiguous word has 7 different POS tags associated with it. Most methods have employed some variant of Expectation Maximization (EM) to learn parameters for a bigram or trigram Hidden Markov Model (HMM). Ravi and Knight (2009) achieved the best results thus far (92.3% word token accuracy) via a Minimum Description Length approach using an integer program (IP) that finds a minimal bigram grammar that obeys the tag dictionary constraints and covers the observed data.

A more challenging task is learning supertaggers for lexicalized grammar formalisms such as Combinatory Categorial Grammar (CCG) (Steedman, 2000). For example, CCGbank (Hockenmaier and Steedman, 2007) contains 1241 distinct supertags (lexical categories) and the most ambiguous word has 126 supertags. This provides a much more challenging starting point for the semi-supervised methods typically applied to the task. Yet, this is an important task since creating grammars and resources for CCG parsers for new domains and languages is highly labor- and knowledge-intensive. Baldridge (2008) uses grammar-informed initialization for HMM tag transitions based on the universal combinatory rules of the CCG formalism to obtain 56.1% accuracy on ambiguous word tokens, a large improvement over the 33.0% accuracy obtained with uniform initialization for tag transitions.

The strategies employed in Ravi and Knight (2009) and Baldridge (2008) are complementary. The former reduces the model size globally given a data set, while the latter biases bitag transitions toward those which are more likely based on a universal grammar without reference to any data. In this paper, we show how these strategies may be combined straightforwardly to produce improvements on the task of learning supertaggers from lexicons that have not been filtered in any way.[1] We demonstrate their cross-lingual effectiveness on CCGbank (English) and the Italian CCG-TUT

[1]See Banko and Moore (2004) for a description of how many early POS-tagging papers in fact used a number of heuristic cutoffs that greatly simplify the problem.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 495–503,
Uppsala, Sweden, 11-16 July 2010.

corpus (Bos et al., 2009). We find a consistent improved performance by using each of the methods compared to basic EM, and further improvements by using them in combination.

Applying the approach of Ravi and Knight (2009) naively to CCG supertagging is intractable due to the high level of ambiguity. We deal with this by defining a new two-stage integer programming formulation that identifies minimal grammars efficiently and effectively.

2 Data

CCGbank. CCGbank was created by semi-automatically converting the Penn Treebank to CCG derivations (Hockenmaier and Steedman, 2007). We use the standard splits of the data used in semi-supervised tagging experiments (e.g. Banko and Moore (2004)): sections 0-18 for training, 19-21 for development, and 22-24 for test.

CCG-TUT. CCG-TUT was created by semi-automatically converting dependencies in the Italian Turin University Treebank to CCG derivations (Bos et al., 2009). It is much smaller than CCGbank, with only 1837 sentences. It is split into three sections: newspaper texts (NPAPER), civil code texts (CIVIL), and European law texts from the JRC-Acquis Multilingual Parallel Corpus (JRC). For test sets, we use the first 400 sentences of NPAPER, the first 400 of CIVIL, and all of JRC. This leaves 409 and 498 sentences from NPAPER and CIVIL, respectively, for training (to acquire a lexicon and run EM). For evaluation, we use two different settings of train/test splits:

TEST 1 Evaluate on the NPAPER section of *test* using a lexicon extracted only from NPAPER section of *train*.

TEST 2 Evaluate on the entire *test* using lexicons extracted from (a) NPAPER + CIVIL, (b) NPAPER, and (c) CIVIL.

Table 1 shows statistics for supertag ambiguity in CCGbank and CCG-TUT. As a comparison, the POS word token ambiguity in CCGbank is 2.2: the corresponding value of 18.71 for supertags is indicative of the (challenging) fact that supertag ambiguity is greatest for the most frequent words.

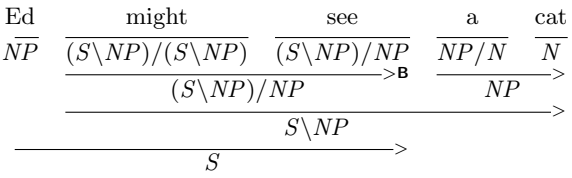
Data	Distinct	Max	Type ambig	Tok ambig
CCGbank	1241	126	1.69	18.71
CCG-TUT				
NPAPER+CIVIL	849	64	1.48	11.76
NPAPER	644	48	1.42	12.17
CIVIL	486	39	1.52	11.33

Table 1: Statistics for the *training* data used to extract lexicons for CCGbank and CCG-TUT. **Distinct**: # of distinct lexical categories; **Max**: # of categories for the most ambiguous word; **Type ambig**: per word type category ambiguity; **Tok ambig**: per word token category ambiguity.

3 Grammar informed initialization for supertagging

Part-of-speech tags are atomic labels that in and of themselves encode no internal structure. In contrast, supertags are detailed, structured labels; a universal set of grammatical rules defines how categories may combine with one another to project syntactic structure.[2] Because of this, properties of the CCG formalism itself can be used to constrain learning—prior to considering any particular language, grammar or data set. Baldridge (2008) uses this observation to create grammar-informed tag transitions for a bitag HMM supertagger based on two main properties. First, categories differ in their complexity and less complex categories tend to be used more frequently. For example, two categories for *buy* in CCGbank are (S[dcl]\NP)/NP and ((((S[b]\NP)/PP)/PP)/(S[adj]\NP))/NP; the former occurs 33 times, the latter once. Second, categories indicate the form of categories found adjacent to them; for example, the category for sentential complement verbs ((S\NP)/S) expects an NP to its left and an S to its right.

Categories combine via rules such as application and composition (see Steedman (2000) for details). Given a lexicon containing the categories for each word, these allow derivations like:



Other derivations are possible. In fact, every pair of adjacent words above may be combined directly. For example, *see* and *a* may combine through forward composition to produce the category (S\NP)/N, and *Ed*'s category may type-raise to S/(S\NP) and compose with *might*'s category.

Baldridge uses these properties to define tag

[2]Note that supertags can be lexical categories of CCG (Steedman, 2000), elementary trees of Tree-adjoining Grammar (Joshi, 1988), or types in a feature hierarchy as in Head-driven Phrase Structure Grammar (Pollard and Sag, 1994).

transition distributions that have higher likelihood for simpler categories that are able to combine. For example, for the distribution $p(t_i|t_{i-1}{=}NP)$, (S\NP)\NP is more likely than ((S\NP)/(N/N))\NP because both categories may combine with a preceding NP but the former is simpler. In turn, the latter is more likely than NP: it is more complex but can combine with the preceding NP. Finally, NP is more likely than (S/NP)/NP since neither can combine, but NP is simpler.

By starting EM with these tag transition distributions and an unfiltered lexicon (word-to-supertag dictionary), Baldridge obtains a tagging accuracy of 56.1% on ambiguous words—a large improvement over the accuracy of 33.0% obtained by starting with uniform transition distributions. We refer to a model learned from basic EM (uniformly initialized) as EM, and to a model with grammar-informed initialization as EM_{GI}.

4 Minimized models for supertagging

The idea of searching for minimized models is related to classic Minimum Description Length (MDL) (Barron et al., 1998), which seeks to select a small model that captures the most regularity in the observed data. This modeling strategy has been shown to produce good results for many natural language tasks (Goldsmith, 2001; Creutz and Lagus, 2002; Ravi and Knight, 2009). For tagging, the idea has been implemented using Bayesian models with priors that indirectly induce sparsity in the learned models (Goldwater and Griffiths, 2007); however, Ravi and Knight (2009) show a better approach is to directly minimize the model using an integer programming (IP) formulation. Here, we build on this idea for supertagging.

There are many challenges involved in using IP minimization for supertagging. The 1241 distinct supertags in the tagset result in 1.5 million tag bigram entries in the model and the dictionary contains almost 3.5 million word/tag pairs that are relevant to the test data. The set of 45 POS tags for the same data yields 2025 tag bigrams and 8910 dictionary entries. We also wish to scale our methods to larger data settings than the 24k word tokens in the test data used in the POS tagging task.

Our objective is to find the smallest supertag grammar (of tag bigram types) that explains the entire text while obeying the lexicon's constraints. However, the original IP method of Ravi and Knight (2009) is intractable for supertagging, so we propose a new two-stage method that scales to the larger tagsets and data involved.

4.1 IP method for supertagging

Our goal for supertagging is to build a minimized model with the following objective:

> $IP_{original}$: Find the smallest supertag grammar (i.e., tag bigrams) that can explain the entire text (the test word token sequence).

Using the full grammar and lexicon to perform model minimization results in a very large, difficult to solve integer program involving billions of variables and constraints. This renders the minimization objective $IP_{original}$ intractable. One way of combating this is to use a reduced grammar and lexicon as input to the integer program. We do this without further supervision by using the HMM model trained using basic EM: entries are pruned based on the tag sequence it predicts on the test data. This produces an *observed* grammar of distinct tag bigrams (G_{obs}) and lexicon of observed lexical assignments (L_{obs}). For CCGbank, G_{obs} and L_{obs} have 12,363 and 18,869 entries, respectively—far less than the millions of entries in the full grammar and lexicon.

Even though EM minimizes the model somewhat, many bad entries remain in the grammar. We prune further by supplying G_{obs} and L_{obs} as input (G, L) to the IP-minimization procedure. However, even with the EM-reduced grammar and lexicon, the IP-minimization is still very hard to solve. We thus split it into two stages. The first stage (Minimization 1) finds the smallest grammar $G_{min1} \subset G$ that explains the set of word bigram *types* observed in the data rather than the word sequence itself, and the second (Minimization 2) finds the smallest augmentation of G_{min1} that explains the full word sequence.

Minimization 1 (MIN1). We begin with a simpler minimization problem than the original one ($IP_{original}$), with the following objective:

> $IP_{\text{min 1}}$: Find the smallest set of tag bigrams $G_{min1} \subset G$, such that there is at least one tagging assignment possible for every word bigram type observed in the data.

We formulate this as an integer program, creating binary variables $gvar_i$ for every tag bigram $g_i = t_j t_k$ in G. Binary link variables connect tag bigrams with word bigrams; these are restricted

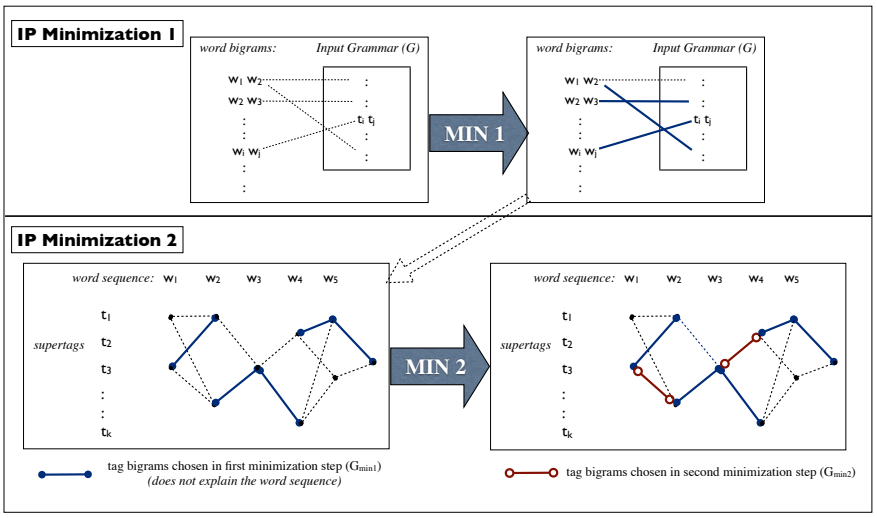


Figure 1: Two-stage IP method for selecting minimized models for supertagging.

to the set of links that respect the lexicon L provided as input, i.e., there exists a link variable $link_{jklm}$ connecting tag bigram $t_j t_k$ with word bigram $w_l w_m$ only if the word/tag pairs (w_l, t_j) and (w_m, t_k) are present in L. The entire integer programming formulation is shown Figure 2.

The IP solver[3] solves the above integer program and we extract the set of tag bigrams G_{min1} based on the activated grammar variables. For the CCGbank test data, MIN1 yields 2530 tag bigrams. However, a second stage is needed since there is no guarantee that G_{min1} can explain the test data: it contains tags for all word bigram types, but it cannot necessarily tag the full word sequence. Figure 1 illustrates this. Using only tag bigrams from MIN1 (shown in blue), there is no fully-linked tag path through the network. There are missing links between words w_2 and w_3 and between words w_3 and w_4 in the word sequence. The next stage fills in these missing links.

Minimization 2 (MIN2). This stage uses the original minimization formulation for the supertagging problem $IP_{original}$, again using an integer programming method similar to that proposed by Ravi and Knight (2009). If applied to the observed grammar G_{obs}, the resulting integer program is hard to solve.[4] However, by using the partial solution G_{min1} obtained in MIN1 the IP optimization speeds up considerably. We implement this by fixing the values of all binary grammar variables present in G_{min1} to 1 before optimization. This reduces the search space significantly, and CPLEX finishes in just a few hours. The details of this method are described below.

Minimize: $\sum_{\forall g_i \in G} gvar_i$

Subject to constraints:

1. For every word bigram $w_l w_m$, there exists at least one tagging that respects the lexicon L.

$$\sum_{\forall\ t_j \in L(w_l),\ t_k \in L(w_m)} link_{jklm} \geq 1$$

where $L(w_l)$ and $L(w_m)$ represent the set of tags seen in the lexicon for words w_l and w_m respectively.

2. The link variable assignments are constrained to respect the grammar variables chosen by the integer program.

$$link_{jklm} \leq gvar_i$$

where $gvar_i$ is the binary variable corresponding to tag bigram $t_j t_k$ in the grammar G.

Figure 2: IP formulation for Minimization 1.

We instantiate binary variables $gvar_i$ and $lvar_i$ for every tag bigram (in G) and lexicon entry (in L). We then create a network of possible taggings for the word token sequence $w_1 w_2 .... w_n$ in the corpus and assign a binary variable to each link in the network. We name these variables $link_{cjk}$, where c indicates the column of the link's source in the network, and j and k represent the link's source and destination (i.e., $link_{cjk}$ corresponds to tag bigram $t_j t_k$ in column c). Next, we formulate the integer program given in Figure 3.

Figure 1 illustrates how MIN2 augments the grammar G_{min1} (links shown in blue) with addi-

[3] We use the commercial CPLEX solver.

[4] The solver runs for days without returning a solution.

Minimize: $\sum_{\forall g_i \in G} gvar_i$

Subject to constraints:

1. Chosen link variables form a left-to-right path through the tagging network.

$$\forall_{c=1..n-2} \forall_k \sum_j link_{cjk} = \sum_j link_{(c+1)kj}$$

2. Link variable assignments should respect the chosen grammar variables.

$$\text{for every link: } link_{cjk} \leq gvar_i$$

where $gvar_i$ corresponds to tag bigram $t_j t_k$

3. Link variable assignments should respect the chosen lexicon variables.

$$\text{for every link: } link_{cjk} \leq lvar_{w_c t_j}$$

$$\text{for every link: } link_{cjk} \leq lvar_{w_{c+1} t_k}$$

where w_c is the c^{th} word in the word sequence $w_1 ... w_n$, and $lvar_{w_c t_j}$ is the binary variable corresponding to the word/tag pair w_c/t_j in the lexicon L.

4. The final solution should produce at least one complete tagging path through the network.

$$\sum_{\forall_{j,k}} link_{1jk} \geq 1$$

5. Provide minimized grammar from MIN1as partial solution to the integer program.

$$\forall_{g_i \in G_{min1}} gvar_i = 1$$

Figure 3: IP formulation for Minimization 2.

tional tag bigrams (shown in red) to form a complete tag path through the network. The minimized grammar set in the final solution G_{min2} contains only 2810 entries, significantly fewer than the original grammar G_{obs}'s 12,363 tag bigrams.

We note that the two-stage minimization procedure proposed here is not guaranteed to yield the optimal solution to our original objective $IP_{original}$. On the simpler task of unsupervised POS tagging with a dictionary, we compared our method versus *directly* solving $IP_{original}$ and found that the minimization (in terms of grammar size) achieved by our method is close to the optimal solution for the original objective and yields the same tagging accuracy far more efficiently.

Fitting the minimized model. The IP-minimization procedure gives us a minimal grammar, but does not fit the model to the data. In order to estimate probabilities for the HMM model for supertagging, we use the EM algorithm but with certain restrictions. We build the transition model using only entries from the minimized grammar set G_{min2}, and instantiate an emission model using the word/tag pairs seen in L (provided as input to the minimization procedure). All the parameters in the HMM model are initialized with uniform probabilities, and we run EM for 40 iterations. The trained model is used to find the Viterbi tag sequence for the corpus. We refer to this model (where the EM output (G_{obs}, L_{obs}) was provided to the IP-minimization as initial input) as **EM+IP**.

Bootstrapped minimization. The quality of the observed grammar and lexicon improves considerably at the end of a single EM+IP run. Ravi and Knight (2009) exploited this to iteratively improve their POS tag model: since the first minimization procedure is seeded with a noisy grammar and tag dictionary, iterating the IP procedure with progressively better grammars further improves the model. We do likewise, bootstrapping a new EM+IP run using as input, the observed grammar G_{obs} and lexicon L_{obs} from the last tagging output of the previous iteration. We run this until the chosen grammar set G_{min2} does not change.[5]

4.2 Minimization with grammar-informed initialization

There are two complementary ways to use grammar-informed initialization with the IP-minimization approach: (1) using EM_{GI} output as the starting grammar/lexicon and (2) using the tag transitions directly in the IP objective function. The first takes advantage of the earlier observation that the quality of the grammar and lexicon provided as initial input to the minimization procedure can affect the quality of the final supertagging output. For the second, we modify the objective function used in the two IP-minimization steps to be:

$$\text{Minimize: } \sum_{\forall g_i \in G} w_i \cdot gvar_i \qquad (1)$$

where, G is the set of tag bigrams provided as input to IP, $gvar_i$ is a binary variable in the integer program corresponding to tag bigram $(t_{i-1}, t_i) \in G$, and w_i is negative logarithm of $p_{gii}(t_i|t_{i-1})$ as given by Baldridge (2008).[6] All other parts of

[5] In our experiments, we run three bootstrap iterations.

[6] Other numeric weights associated with the tag bigrams could be considered, such as 0/1 for uncombin-

the integer program including the constraints remain unchanged, and, we acquire a final tagger in the same manner as described in the previous section. In this way, we combine the minimization and GI strategies into a single objective function that finds a minimal grammar set while keeping the more likely tag bigrams in the chosen solution. **EM$_{GI}$+IP$_{GI}$** is used to refer to the method that uses GI information in both ways: EM$_{GI}$ output as the starting grammar/lexicon *and* GI weights in the IP-minimization objective.

5 Experiments

We compare the four strategies described in Sections 3 and 4, summarized below:

EM HMM uniformly initialized, EM training.

EM+IP IP minimization using initial grammar provided by EM.

EM$_{GI}$ HMM with grammar-informed initialization, EM training.

EM$_{GI}$+IP$_{GI}$ IP minimization using initial grammar/lexicon provided by EM$_{GI}$ and additional grammar-informed IP objective.

For EM+IP and EM$_{GI}$+IP$_{GI}$, the minimization and EM training processes are iterated until the resulting grammar and lexicon remain unchanged. Forty EM iterations are used for all cases.

We also include a baseline which randomly chooses a tag from those associated with each word in the lexicon, averaged over three runs.

Accuracy on ambiguous word tokens. We evaluate the performance in terms of tagging accuracy with respect to gold tags for ambiguous words in held-out test sets for English and Italian. We consider results with and without punctuation.[7]

Recall that unlike much previous work, we do not collect the lexicon (tag dictionary) from the test set: this means the model must handle unknown words and the possibility of having missing lexical entries for covering the test set.

Precision and recall of grammar and lexicon. In addition to accuracy, we measure precision and recall for each model on the observed bitag grammar and observed lexicon on the test set. We calculate them as follows, for an observed grammar or lexicon X:

$$Precision = \frac{|\{X\} \cap \{Observed_{gold}\}|}{|\{X\}|}$$

$$Recall = \frac{|\{X\} \cap \{Observed_{gold}\}|}{|\{Observed_{gold}\}|}$$

This provides a measure of model performance on bitag *types* for the grammar and lexical entry *types* for the lexicon, rather than tokens.

Model	ambig	ambig -punc	all	all -punc
Random	17.9	16.2	27.4	21.9
EM	38.7	35.6	45.6	39.8
EM+IP	52.1	51.0	57.3	53.9
EM$_{GI}$	56.3	59.4	61.0	61.7
EM$_{GI}$+IP$_{GI}$	**59.6**	**62.3**	**63.8**	**64.3**

Table 2: Supertagging accuracy for CCGbank sections 22-24. Accuracies are reported for four settings—(1) *ambiguous* word tokens in the test corpus, (2) ambiguous word tokens, ignoring punctuation, (3) *all* word tokens, and (4) all word tokens except punctuation.

5.1 English CCGbank results

Accuracy on ambiguous tokens. Table 2 gives performance on the CCGbank test sections. All models are well above the random baseline, and both of the strategies individually boost performance over basic EM by a large margin. For the models using GI, accuracy ignoring punctuation is higher than for all almost entirely due to the fact that "." has the supertags "." and S, and the GI gives a preference to S since it can in fact combine with other categories, unlike "."—the effect is that nearly every sentence-final period (˜5.5k tokens) is tagged S rather than ".".

EM$_{GI}$ is more effective than EM+IP; however, it should be kept in mind that IP-minimization is a general technique that can be applied to any sequence prediction task, whereas grammar-informed initialization may be used only with tasks in which the interactions of adjacent labels may be derived from the labels themselves. Interestingly, the gap between the two approaches is greater when punctuation is ignored (51.0 vs. 59.4)—this is unsurprising because, as noted already, punctuation supertags are not actual cate-

able/combinable bigrams.

[7]The reason for this is that the "categories" for punctuation in CCGbank are for the most part not actual categories; for example, the period "." has the categories "." and "S". As such, these supertags are outside of the categorial system: their use in derivations requires phrase structure rules that are not derivable from the CCG combinatory rules.

	EM	EM+IP	EM$_{GI}$	EM$_{GI}$+IP$_{GI}$
Grammar				
Precision	7.5	32.9	52.6	68.1
Recall	26.9	13.2	34.0	19.8
Lexicon				
Precision	58.4	63.0	78.0	80.6
Recall	50.9	56.0	71.5	67.6

Table 3: Comparison of grammar/lexicon observed in the *model tagging* vs. *gold tagging* in terms of precision and recall measures for supertagging on CCGbank data.

gories, so EM$_{GI}$ is unable to model their distribution. Most importantly, the complementary effects of the two approaches can be seen in the improved results for EM$_{GI}$+IP$_{GI}$, which obtains about 3% better accuracy than EM$_{GI}$.

Accuracy on all tokens. Table 2 also gives performance when taking all tokens into account. The HMM when using full supervision obtains 87.6% accuracy (Baldridge, 2008),[8] so the accuracy of 63.8% achieved by EM$_{GI}$+IP$_{GI}$ nearly halves the gap between the supervised model and the 45.6% obtained by basic EM semi-supervised model.

Effect of GI information in EM and/or IP-minimization stages. We can also consider the effect of GI information in *either* EM training *or* IP-minimization to see whether it can be effectively exploited in both. The latter, EM+IP$_{GI}$, obtains 53.2/51.1 for all/no-punc—a small gain compared to EM+IP's 52.1/51.0. The former, EM$_{GI}$+IP, obtains 58.9/61.6—a much larger gain. Thus, the better starting point provided by EM$_{GI}$ has more impact than the integer program that includes GI in its objective function. However, we note that it should be possible to exploit the GI information more effectively in the integer program than we have here. Also, our best model, EM$_{GI}$+IP$_{GI}$, uses GI information in both stages to obtain our best accuracy of 59.6/62.3.

P/R for grammars and lexicons. We can obtain a more-fine grained understanding of how the models differ by considering the precision and recall values for the grammars and lexicons of the different models, given in Table 3. The basic EM model has very low precision for the grammar, indicating it proposes many unnecessary bitags; it achieves better recall because of the sheer number of bitags it proposes (12,363). EM+IP prunes that set of bitags considerably, leading to better precision at the cost of recall. EM$_{GI}$'s higher recall and precision indicate the tag transition distributions do capture general patterns of linkage between adjacent CCG categories, while EM ensures that the data filters out combinable, but unnecessary, bitags. With EM$_{GI}$+IP$_{GI}$, we again see that IP-minimization prunes even more entries, improving precision at the loss of some recall.

Similar trends are seen for precision and recall on the lexicon. IP-minimization's pruning of inappropriate taggings means more common words are not assigned highly infrequent supertags (boosting precision) while unknown words are generally assigned more sensible supertags (boosting recall). EM$_{GI}$ again focuses taggings on combinable contexts, boosting precision and recall similarly to EM+IP, but in greater measure. EM$_{GI}$+IP$_{GI}$ then prunes some of the spurious entries, boosting precision at some loss of recall.

Tag frequencies predicted on the test set. Table 4 compares gold tags to tags generated by all four methods for the frequent and highly ambiguous words *the* and *in*. Basic EM wanders far away from the gold assignments; it has little guidance in the very large search space available to it. IP-minimization identifies a smaller set of tags that better matches the gold tags; this emerges because other determiners and prepositions evoke similar, but not identical, supertags, and the grammar minimization pushes (but does not force) them to rely on the same supertags wherever possible. However, the proportions are incorrect; for example, the tag assigned most frequently to *in* is ((S\NP)\(S\NP))/NP though (NP\NP)/NP is more frequent in the test set. EM$_{GI}$'s tags correct that balance and find better proportions, but also some less common categories, such as (((N/N)\(N/N))\((N/N)\(N/N)))/N, sneak in because they combine with frequent categories like N/N and N. Bringing the two strategies together with EM$_{GI}$+IP$_{GI}$ filters out the unwanted categories while getting better overall proportions.

5.2 Italian CCG-TUT results

To demonstrate that both methods and their combination are language independent, we apply them to the Italian CCG-TUT corpus. We wanted to evaluate performance out-of-the-box because

[8] A state-of-the-art, fully-supervised maximum entropy tagger (Clark and Curran, 2007) (which also uses part-of-speech labels) obtains 91.4% on the same train/test split.

Recall	18.4	15.9	24.9	22.7
Lexicon				
Precision	51.2	52.0	54.8	55.1
Recall	43.6	42.8	46.0	44.9

Table 6: Comparison of grammar/lexicon observed in the *model tagging* vs. *gold tagging* in terms of precision and recall measures for supertagging on CCG-TUT.

bootstrapping a supertagger for a new language is one of the main use scenarios we envision: in such a scenario, there is no development data for changing settings and parameters. Thus, we determined a train/test split beforehand and ran the methods exactly as we had for CCGbank.

The results, given in Table 5, demonstrate the same trends as for English: basic EM is far more accurate than random, EM+IP adds another 8-10% absolute accuracy, and EM$_{GI}$ adds an additional 8-10% again. The combination of the methods generally improves over EM$_{GI}$, except when the lexicon is extracted from NPAPER+CIVIL. Table 6 gives precision and recall for the grammars and lexicons for CCG-TUT—the values are lower than for CCGbank (in line with the lower baseline), but exhibit the same trends.

6 Conclusion

We have shown how two complementary strategies—grammar-informed tag transitions and IP-minimization—for learning of supertaggers from highly ambiguous lexicons can be straightforwardly integrated. We verify the benefits of both cross-lingually, on English and Italian data. We also provide a new two-stage integer programming setup that allows model minimization to be tractable for supertagging without sacrificing the quality of the search for minimal bitag grammars.

The experiments in this paper use large lexicons, but the methodology will be particularly useful in the context of bootstrapping from smaller ones. This brings further challenges; in particular, it will be necessary to identify novel entries consisting of seen word and seen category and to predict unseen, but valid, categories which are needed to explain the data. For this, it will be necessary to forgo the assumption that the provided lexicon is always obeyed. The methods we introduce here should help maintain good accuracy while opening up these degrees of freedom. Because the lexicon *is* the grammar in CCG, learning new word-category associations is grammar generalization and is of interest for grammar acquisition.

Finally, such lexicon refinement and generalization is directly relevant for using CCG in syntax-based machine translation models (Hassan et al., 2009). Such models are currently limited to languages for which corpora annotated with CCG derivations are available. Clark and Curran (2006) show that CCG parsers can be learned from sentences labeled with just supertags—without full derivations—with little loss in accuracy. The improvements we show here for learning supertaggers from lexicons without labeled data may be able to help create annotated resources more efficiently, or enable CCG parsers to be learned with less human-coded knowledge.

Abstract

Conditional Random Fields (CRFs) are a widely-used approach for supervised sequence labelling, notably due to their ability to handle large description spaces and to integrate structural dependency between labels. Even for the simple linear-chain model, taking structure into account implies a number of parameters and a computational effort that grows quadratically with the cardinality of the label set. In this paper, we address the issue of training very large CRFs, containing up to hundreds output labels and several billion features. Efficiency stems here from the sparsity induced by the use of a ℓ^1 penalty term. Based on our own implementation, we compare three recent proposals for implementing this regularization strategy. Our experiments demonstrate that very large CRFs can be trained efficiently and that very large models are able to improve the accuracy, while delivering compact parameter sets.

1 Introduction

Conditional Random Fields (CRFs) (Lafferty et al., 2001; Sutton and McCallum, 2006) constitute a widely-used and effective approach for supervised structure learning tasks involving the mapping between complex objects such as strings and trees. An important property of CRFs is their ability to handle large and redundant feature sets and to integrate structural dependency between output labels. However, even for simple *linear chain* CRFs, the complexity of learning and inference grows quadratically with respect to the number of output labels and so does the number of *structural features*, ie. features testing adjacent pairs of labels. Most empirical studies on CRFs thus either consider tasks with a restricted output space (typically in the order of few dozens of output labels), heuristically reduce the use of features, especially of features that test pairs of adjacent labels[1], and/or propose heuristics to simulate contextual dependencies, via extended tests on the observations (see discussions in, eg., (Punyakanok et al., 2005; Liang et al., 2008)). Limitating the feature set or the number of output labels is however frustrating for many NLP tasks, where the type and number of potentially relevant features are very large. A number of studies have tried to alleviate this problem. Pal et al. (2006) propose to use a "sparse" version of the forward-backward algorithm during training, where sparsity is enforced through beam pruning. Related ideas are discussed by Dietterich et al. (2004); by Cohn (2006), who considers "generalized" feature functions; and by Jeong et al. (2009), who use approximations to simplify the forward-backward recursions. In this paper, we show that the sparsity that is induced by ℓ^1-penalized estimation of CRFs can be used to reduce the total training time, while yielding extremely compact models. The benefits of sparsity are even greater during inference: less features need to be extracted and included in the potential functions, speeding up decoding with a lesser memory footprint. We study and compare three different ways to implement ℓ^1 penalty for CRFs that have been introduced recently: orthant-wise Quasi Newton (Andrew and Gao, 2007), stochastic gradient descent (Tsuruoka et al., 2009) and coordinate descent (Sokolovska et al., 2010), concluding that these methods have complemen-

[1] In CRFsuite (Okazaki, 2007), it is even impossible to jointly test a pair of labels and a test on the observation, bigrams feature are only of the form $f(y_{t-1}, y_t)$.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 504–513,
Uppsala, Sweden, 11-16 July 2010.

tary strengths and weaknesses. Based on an efficient implementation of these algorithms, we were able to train very large CRFs containing more than a hundred of output labels and up to several billion features, yielding results that are as good or better than the best reported results for two NLP benchmarks, text phonetization and part-of-speech tagging.

Our contribution is therefore twofold: firstly a detailed analysis of these three algorithms, discussing implementation, convergence and comparing the effect of various speed-ups. This comparison is made fair and reliable thanks to the reimplementation of these techniques in the same software package. Second, the experimental demonstration that using large output label sets is doable and that very large feature sets actually help improve prediction accuracy. In addition, we show how sparsity in *structured feature sets* can be used in incremental training regimes, where long-range features are progressively incorporated in the model insofar as the shorter range features have proven useful.

The rest of the paper is organized as follows: we first recall the basics of CRFs in Section 2, and discuss three ways to train CRFs with a ℓ^1 penalty in Section 3. We then detail several implementation issues that need to be addressed when dealing with massive feature sets in Section 4. Our experiments are reported in Section 5. The main conclusions of this study are drawn in Section 6.

2 Conditional Random Fields

In this section, we recall the basics of Conditional Random Fields (CRFs) (Lafferty et al., 2001; Sutton and McCallum, 2006) and introduce the notations that will be used throughout.

2.1 Basics

CRFs are based on the following model

$$p_\theta(\mathbf{y}|\mathbf{x}) = \frac{1}{Z_\theta(\mathbf{x})} \exp\left\{\sum_{k=1}^{K} \theta_k F_k(\mathbf{x},\mathbf{y})\right\} \quad (1)$$

where $\mathbf{x} = (x_1, \ldots, x_T)$ and $\mathbf{y} = (y_1, \ldots, y_T)$ are, respectively, the input and output sequences[2], and $F_k(\mathbf{x},\mathbf{y})$ is equal to $\sum_{t=1}^{T} f_k(y_{t-1}, y_t, x_t)$, where $\{f_k\}_{1\leq k\leq K}$ is an arbitrary set of feature functions and $\{\theta_k\}_{1\leq k\leq K}$ are the associated parameter values. We denote by Y and X, respectively, the sets in which y_t and x_t take their values. The normalization factor in (1) is defined by

$$Z_\theta(\mathbf{x}) = \sum_{\mathbf{y}\in Y^T} \exp\left\{\sum_{k=1}^{K} \theta_k F_k(\mathbf{x},\mathbf{y})\right\}. \quad (2)$$

The most common choice of feature functions is to use binary tests. In the sequel, we distinguish between two types of feature functions: *unigram features* $f_{y,x}$, associated with parameters $\mu_{y,x}$, and *bigram features* $f_{y',y,x}$, associated with parameters $\lambda_{y',y,x}$. These are defined as

$$f_{y,x}(y_{t-1}, y_t, x_t) = \mathbf{1}(y_t = y, x_t = x)$$
$$f_{y',y,x}(y_{t-1}, y_t, x_t) = \mathbf{1}(y_{t-1} = y', y_t = y, x_t = x)$$

where $\mathbf{1}(\text{cond.})$ is equal to 1 when the condition is verified and to 0 otherwise. In this setting, the number of parameters K is equal to $|Y|^2 \times |X|_{\text{train}}$, where $|\cdot|$ denotes the cardinal and $|X|_{\text{train}}$ refers to the number of configurations of x_t observed during training. Thus, even in moderate size applications, the number of parameters can be very large, mostly due to the introduction of sequential dependencies in the model. This also explains why it is hard to train CRFs with dependencies spanning more than two adjacent labels. Using only unigram features $\{f_{y,x}\}_{(y,x)\in Y\times X}$ results in a model equivalent to a simple bag-of-tokens position-by-position logistic regression model. On the other hand, bigram features $\{f_{y',y,x}\}_{(y,x)\in Y^2\times X}$ are helpful in modelling dependencies between successive labels. The motivations for using simultaneously both types of feature functions are evaluated experimentally in Section 5.

2.2 Parameter Estimation

Given N independent sequences $\{\mathbf{x}^{(i)}, \mathbf{y}^{(i)}\}_{i=1}^{N}$, where $\mathbf{x}^{(i)}$ and $\mathbf{y}^{(i)}$ contain $T^{(i)}$ symbols, conditional maximum likelihood estimation is based on the minimization, with respect to θ, of the negated conditional log-likelihood of the observations

$$l(\theta) = -\sum_{i=1}^{N} \log p_\theta(\mathbf{y}^{(i)}|\mathbf{x}^{(i)}) \quad (3)$$
$$= \sum_{i=1}^{N} \left\{\log Z_\theta(\mathbf{x}^{(i)}) - \sum_{k=1}^{K} \theta_k F_k(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})\right\}$$

This term is usually complemented with an additional regularization term so as to avoid overfitting

[2] Our implementation also includes a special label y_0, that is always observed and marks the beginning of a sequence.

(see Section 3.1 below). The gradient of $l(\theta)$ is

$$\frac{\partial l(\theta)}{\partial \theta_k} = \sum_{i=1}^{N} \sum_{t=1}^{T^{(i)}} \mathrm{E}_{p_\theta(\mathbf{y}|\mathbf{x}^{(i)})}\, f_k(y_{t-1}, y_t, x_t^{(i)}) - \sum_{i=1}^{N} \sum_{t=1}^{T^{(i)}} f_k(y_{t-1}^{(i)}, y_t^{(i)}, x_t^{(i)}) \quad (4)$$

where $\mathrm{E}_{p_\theta(\mathbf{y}|\mathbf{x})}$ denotes the conditional expectation given the observation sequence, i.e.

$$\mathrm{E}_{p_\theta(\mathbf{y}|\mathbf{x})}\, f_k(y_{t-1}, y_t, x_t^{(i)}) = \sum_{(y',y)\in Y^2} f_k(y, y', x_t)\, \mathrm{P}_\theta(y_{t-1} = y', y_t = y|\mathbf{x}) \quad (5)$$

Although $l(\theta)$ is a smooth convex function, its optimum cannot be computed in closed form, and $l(\theta)$ has to be optimized numerically. The computation of its gradient implies to repeatedly compute the conditional expectation in (5) for all input sequences $\mathbf{x}^{(i)}$ and all positions t. The standard approach for computing these expectations is inspired by the forward-backward algorithm for hidden Markov models: using the notations introduced above, the algorithm implies the computation of the forward

$$\begin{cases} \alpha_1(y) = \exp(\mu_{y,x_1} + \lambda_{y_0,y,x_1}) \\ \alpha_{t+1}(y) = \sum_{y'} \alpha_t(y') \exp(\mu_{y,x_{t+1}} + \lambda_{y',y,x_{t+1}}) \end{cases}$$

and backward recursions

$$\begin{cases} \beta_{T_i}(y) = 1 \\ \beta_t(y') = \sum_y \beta_{t+1}(y) \exp(\mu_{y,x_{t+1}} + \lambda_{y',y,x_{t+1}}), \end{cases}$$

for all indices $1 \leq t \leq T$ and all labels $y \in Y$. Then, $Z_\theta(\mathbf{x}) = \sum_y \alpha_T(y)$ and the pairwise probabilities $\mathrm{P}_\theta(y_t = y', y_{t+1} = y|\mathbf{x})$ are given by

$$\alpha_t(y') \exp(\mu_{y,x_{t+1}} + \lambda_{y',y,x_{t+1}}) \beta_{t+1}(y) / Z_\theta(\mathbf{x})$$

These recursions require a number of operations that grows quadratically with $|Y|$.

3 ℓ^1 Regularization in CRFs

3.1 Regularization

The standard approach for parameter estimation in CRFs consists in minimizing the logarithmic loss $l(\theta)$ defined by (3) with an additional ℓ^2 penalty term $\frac{\rho_2}{2}\|\theta\|_2^2$, where ρ_2 is a regularization parameter. The objective function is then a smooth convex function to be minimized over an unconstrained parameter space. Hence, any numerical optimization strategy may be used and practical solutions include limited memory BFGS (L-BFGS) (Liu and Nocedal, 1989), which is used in the popular CRF++ (Kudo, 2005) and CRFsuite (Okazaki, 2007) packages; conjugate gradient (Nocedal and Wright, 2006) and Stochastic Gradient Descent (SGD) (Bottou, 2004; Vishwanathan et al., 2006), used in CRFsgd (Bottou, 2007). The only caveat is to avoid numerical optimizers that require the full Hessian matrix (e.g., Newton's algorithm) due to the size of the parameter vector in usual applications of CRFs.

The most significant alternative to ℓ^2 regularization is to use a ℓ^1 penalty term $\rho_1\|\theta\|_1$: such regularizers are able to yield sparse parameter vectors in which many component have been zeroed (Tibshirani, 1996). Using a ℓ^1 penalty term thus implicitly performs feature selection, where ρ_1 controls the amount of regularization and the number of extracted features. In the following, we will jointly use both penalty terms, yielding the so-called elastic net penalty (Zhou and Hastie, 2005) which corresponds to the objective function

$$l(\theta) + \rho_1\|\theta\|_1 + \frac{\rho_2}{2}\|\theta\|_2^2 \quad (6)$$

The use of both penalty terms makes it possible to control the number of non zero coefficients and to avoid the numerical problems that might occur in large dimensional parameter settings (see also (Chen, 2009)). However, the introduction of a ℓ^1 penalty term makes the optimization of (6) more problematic, as the objective function is no longer differentiable in 0. Various strategies have been proposed to handle this difficulty. We will only consider here exact approaches and will not discuss heuristic strategies such as grafting (Perkins et al., 2003; Riezler and Vasserman, 2004).

3.2 Quasi Newton Methods

To deal with ℓ^1 penalties, a simple idea is that of (Kazama and Tsujii, 2003), originally introduced for maxent models. It amounts to reparameterizing θ_k as $\theta_k = \theta_k^+ - \theta_k^-$, where θ_k^+ and θ_k^- are positive. The ℓ^1 penalty thus becomes $\rho_1(\theta^+ - \theta^-)$. In this formulation, the objective function recovers its smoothness and can be optimized with conventional algorithms, subject to domain constraints. Optimization is straightforward, but the number of parameters is doubled and convergence is slow

(Andrew and Gao, 2007): the procedure lacks a mechanism for zeroing out useless parameters.

A more efficient strategy is the orthant-wise quasi-Newton (OWL-QN) algorithm introduced in (Andrew and Gao, 2007). The method is based on the observation that the ℓ^1 norm is differentiable when restricted to a set of points in which each coordinate never changes its sign (an "orthant"), and that its second derivative is then zero, meaning that the ℓ^1 penalty does not change the Hessian of the objective on each orthant. An OWL-QN update then simply consists in (i) computing the Newton update in a well-chosen orthant; (ii) performing the update, which might cause some component of the parameter vector to change sign; and (iii) projecting back the parameter value onto the initial orthant, thereby zeroing out those components. In (Gao et al., 2007), the authors show that OWL-QN is faster than the algorithm proposed by Kazama and Tsujii (2003) and can perform model selection even in very high-dimensional problems, with no loss of performance compared to the use of ℓ^2 penalty terms.

3.3 Stochastic Gradient Descent

Stochastic gradient (SGD) approaches update the parameter vector based on an crude approximation of the gradient (4), where the computation of expectations only includes a small batch of observations. SGD updates have the following form

$$\theta_k \leftarrow \theta_k + \eta \frac{\partial l(\theta)}{\partial \theta_k}, \tag{7}$$

where η is the learning rate. In (Tsuruoka et al., 2009), various ways of adapting this update to ℓ^1-penalized likelihood functions are discussed. Two effective ideas are proposed: (i) only update parameters that correspond to active features in the current observation, (ii) keep track of the cumulated penalty z_k that θ_k should have received, had the gradient been computed exactly, and use this value to "clip" the parameter value. This is implemented by patching the update (7) as follows

$$\begin{cases} \textbf{if } (\theta_k > 0)\ \theta_k \leftarrow \max(0, \theta_k - z_k) \\ \textbf{else if } (\theta_k < 0)\ \theta_k \leftarrow \min(0, \theta_k - z_k) \end{cases} \tag{8}$$

Based on a study of three NLP benchmarks, the authors of (Tsuruoka et al., 2009) claim this approach to be much faster than the orthant-wise approach and yet to yield very comparable performance, while selecting slightly larger feature sets.

3.4 Block Coordinate Descent

The coordinate descent approach of Dudík et al. (2004) and Friedman et al. (2008) uses the fact that optimizing a mono-dimensional quadratic function augmented with a ℓ^1 penalty can be performed analytically. For arbitrary functions, this idea can be adapted by considering quadratic approximations of the objective around the current value $\bar{\theta}$

$$l_{k,\bar{\theta}}(\theta_k) = \frac{\partial l(\bar{\theta})}{\partial \theta_k}(\theta_k - \bar{\theta}_k) + \frac{1}{2}\frac{\partial^2 l(\bar{\theta})}{\partial \theta_k^2}(\theta_k - \bar{\theta}_k)^2 + \rho_1|\theta_k| + \frac{\rho_2}{2}\theta_k^2 + C^{st} \tag{9}$$

The minimizer of the approximation (9) is simply

$$\theta_k = \frac{s\left\{\frac{\partial^2 l(\bar{\theta})}{\partial \theta_k^2}\bar{\theta}_k - \frac{\partial l(\bar{\theta})}{\partial \theta_k}, \rho_1\right\}}{\frac{\partial^2 l(\bar{\theta})}{\partial \theta_k^2} + \rho_2} \tag{10}$$

where s is the soft-thresholding function

$$s(z, \rho) = \begin{cases} z - \rho & \text{if } z > \rho \\ z + \rho & \text{if } z < -\rho \\ 0 & \text{otherwise} \end{cases} \tag{11}$$

Coordinate descent is ported to CRFs in (Sokolovska et al., 2010). Making this scheme practical requires a number of adaptations, including (i) approximating the second order term in (10), (ii) performing updates *in block*, where a block contains the $|Y| \times |Y + 1|$ features $\nu_{y',y,x}$ and $\lambda_{y,x}$ for a fixed test x on the observation sequence and (iii) approximating the Hessian for a block by its diagonal terms. (ii) is specially critical, as repeatedly cycling over individual features to perform the update (10) is only possible with restricted sets of features. The *block update* schemes uses the fact that all features within a block appear in the same set of sequences, which means that most of the computations needed to perform theses updates can be shared within the block. One advantage of the resulting algorithm, termed BCD in the following, is that the update of θ_k only involves carrying out the forward-backward recursions for the set of sequences that contain symbols x such that at least one $\{f_k(y', y, x)\}_{(y,y') \in Y^2}$ is non null, which can be much smaller than the whole training set.

4 Implementation Issues

Efficiently processing very-large feature and observation sets requires to pay attention to many implementation details. In this section, we present several optimizations devised to speed up training.

4.1 Sparse Forward-Backward Recursions

For all algorithms, the computation time is dominated by the evaluations of the gradient: our implementation takes advantage of the sparsity to accelerate these computations. Assume the set of bigram features $\{\lambda_{y',y,x_{t+1}}\}_{(y',y)\in Y^2}$ is sparse with only $r(x_{t+1}) \ll |Y|^2$ non null values and define the $|Y| \times |Y|$ sparse matrix

$$M_t(y', y) = \exp(\lambda_{y',y,x_t}) - 1.$$

Using M, the forward-backward recursions are

$$\alpha_t(y) = \sum_{y'} u_{t-1}(y') + \sum_{y'} u_{t-1}(y') M_t(y', y)$$
$$\beta_t(y') = \sum_{y} v_{t+1}(y) + \sum_{y} M_{t+1}(y', y) v_{t+1}(y)$$

with $u_{t-1}(y) = \exp(\mu_{y,x_t})\alpha_{t-1}(y)$ and $v_{t+1}(y) = \exp(\mu_{y,x_{t+1}})\beta_{t+1}(y)$. (Sokolovska et al., 2010) explains how computational savings can be obtained using the fact that the vector/matrix products in the recursions above only involve the sparse matrix $M_{t+1}(y', y)$. They can thus be computed with exactly $r(x_{t+1})$ multiplications instead of $|Y|^2$. The same idea can be used when the set $\{\mu_{y,x_{t+1}}\}_{y\in Y}$ of unigram features is sparse. Using this implementation, the complexity of the forward-backward procedure for $\mathbf{x}^{(i)}$ can be made proportional to the average number of active features per position, which can be much smaller than the number of potentially active features.

For BCD, forward-backward can even be made slightly faster. When computing the gradient wrt. features $\lambda_{y,x}$ and $\mu_{y',y,x}$ (for all the values of y and y') for sequence $\mathbf{x}^{(i)}$, assuming that x only occurs once in $\mathbf{x}^{(i)}$ at position t, all that is needed is $\alpha'_t(y), \forall t' \leq t$ and $\beta'_t(y), \forall t' \geq t$. $Z_\theta(\mathbf{x})$ is then recovered as $\sum_y \alpha_t(y)\beta_t(y)$. Forward-backward recursions can thus be truncated: in our experiments, this divided the computational cost by 1,8 on average.

Note finally that forward-backward is performed on a per-observation basis and is easily parallelized (see also (Mann et al., 2009) for more powerful ways to distribute the computation when dealing with very large datasets). In our implementation, it is distributed on all available cores, resulting in significant speed-ups for OWL-QN and L-BFGS; for BCD the gain is less acute, as parallelization only helps when updating the parameters for a block of features that are occur in many sequences; for SGD, with batches of size one, this parallelization policy is useless.

4.2 Scaling

Most existing implementations of CRFs, eg. CRF++ and CRFsgd perform the forward-backward recursions in the log-domain, which guarantees that numerical over/underflows are avoided no matter the length $T^{(i)}$ of the sequence. It is however very inefficient from an implementation point of view, due to the repeated calls to the $\exp()$ and $\log()$ functions. As an alternative way of avoiding numerical problems, our implementation, like crfSuite's, resorts to "scaling", a solution commonly used for HMMs. Scaling amounts to normalizing the values of α_t and β_t to one, making sure to keep track of the cumulated normalization factors so as to compute $Z_\theta(\mathbf{x})$ and the conditional expectations $\mathrm{E}_{p_\theta(\mathbf{y}|\mathbf{x})}$. Also note that in our implementation, all the computations of $\exp(x)$ are vectorized, which provides an additional speed up of about 20%.

4.3 Optimization in Large Parameter Spaces

Processing very large feature vectors, up to billions of components, is problematic in many ways. Sparsity has been used here to speed up forward-backward, but we have made no attempt to accelerate the computation of the OWL-QN updates, which are linear in the size of the parameter vector. Of the three algorithms, BCD is the most affected by increases in the number of features, or more precisely, in the number of *features blocks*, where one block correspond to a specific test of the observation. In the worst case scenario, each block may require to visit all the training instances, yielding terrible computational wastes. In practice though, most blocks only require to process a small fraction of the training set, and the actual complexity depends on the average number of blocks per observations. Various strategies have been tried to further accelerate BCD, such as processing blocks that only visit one observation in parallel and updating simultaneously all the blocks that visit all the training instances, leading to a small speed-up on the POS-tagging task.

Working with billions of features finally requires to worry also about memory usage. In this respect, BCD is the most efficient, as it only requires to store one K-dimensional vector for the parameter itself. SGD requires two such vectors, one for the parameter and one for storing the z_k (see Eq. (8)). In comparison, OWL-QN requires much more memory, due to the internals of the update routines, which require several histories of the parameter vector and of its gradient. Typically, our implementation necessitates in the order of a dozen K-dimensional vectors. Parallelization only makes things worse, as each core will also need to maintain its own copy of the gradient.

5 Experiments

Our experiments use two standard NLP tasks, phonetization and part-of-speech tagging, chosen here to illustrate two very different situations, and to allow for comparison with results reported elsewhere in the literature. Unless otherwise mentioned, the experiments use the same protocol: 10 fold cross validation, where eight folds are used for training, one for development, and one for testing. Results are reported in terms of phoneme error rates or tag error rates *on the test set*.

Comparing run-times can be a tricky matter, especially when different software packages are involved. As discussed above, the observed run-times depend on many small implementation details. As the three algorithms share as much code as possible, we believe the comparison reported hereafter to be fair and reliable. All experiments were performed on a server with 64G of memory and two Xeon processors with 4 cores at 2.27 Ghz. For comparison, all measures of run-times include the cumulated activity of all cores and give very pessimistic estimates of the wall time, which can be up to 7 times smaller. For OWL-QN, we use 5 past values of the gradient to approximate the inverse of the Hessian matrix: increasing this value had no effect on accuracy or convergence and was detrimental to speed; for SGD, the learning rate parameter was tuned manually.

Note that we have not spent much time optimizing the values of ρ_1 and ρ_2. Based on a pilot study on Nettalk, we found that taking $\rho_1 = .5$ and ρ_2 in the order of 10^{-5} to yield nearly optimal performance, and have used these values throughout.

5.1 Tasks and Settings

5.1.1 Nettalk

Our first benchmark is the word phonetization task, using the Nettalk dictionary (Sejnowski and Rosenberg, 1987). This dataset contains approximately 20,000 English word forms, their pronunciation, plus some prosodic information (stress markers for vowels, syllabic parsing for consonants). Grapheme and phoneme strings are aligned at the character level, thanks to the use of a "null sound" in the latter string when it is shorter than the former; likewise, each prosodic mark is aligned with the corresponding letter. We have derived two test conditions from this database. The first one is standard and aims at predicting the pronunciation information only. In this setting, the set of observations (X) contains 26 graphemes, and the output label set contains $|Y| = 51$ phonemes.

The second condition aims at *jointly predicting phonemic and prosodic information*[3]. The reasons for designing this new condition are twofold: firstly, it yields a large set of composite labels ($|Y| = 114$) and makes the problem computationally challenging. Second, it allows to quantify how much the information provided by the prosodic marks help predict the phonemic labels. Both information are quite correlated, as the stress mark and the syllable openness, for instance, greatly influence the realization of some archi-phonemes.

The features used in Nettalk experiments take the form $f_{y,w}$ (unigram) and $f_{y',y,w}$ (bigram), where w is a n-gram of letters. The n-grm feature sets ($n = \{1, 3, 5, 7\}$) includes all features testing embedded windows of k letters, for all $0 \leq k \leq n$; the n-grm- setting is similar, but only includes the window of length n; in the n-grm+ setting, we add features for odd-size windows; in the n-grm++ setting, we add all sequences of letters up to size n occurring in current window. For instance, the active bigram features at position $t = 2$ in the sequence **x**='*lemma*' are as follows: the 3-grm feature set contains $f_{y,y'}$, $f_{y,y',e}$ and $f_{y',y,lem}$; only the latter appears in the 3-grm- setting. In the 3-grm+ feature set, we also have $f_{y',y,le}$ and $f_{y',y,em}$. The 3-grm++ feature set additionally includes $f_{y',y,l}$ and $f_{y',y,m}$. The number of features ranges from 360 thousands (1-grm setting) to 1.6 billion (7-grm).

[3]Given the design of the Nettalk dictionary, this experiment required to modify the original database so as to reassign prosodic marks to phonemes, rather than to letters.

Features	With		Without	
Nettalk				
3-grm	10.74%	$14.3M$	14.59%	$0.3M$
5-grm	8.48%	$132.5M$	11.54%	$2.5M$
POS tagging				
base	2.91%	$436.7M$	3.47%	$70.2M$

Table 1: Features jointly testing label pairs and the observation are useful (error rates and features counts.)

	ℓ^2	ℓ^1-sparse	ℓ^1	% zero
1-grm	84min	41min	57min	44.6%
3-grm-	65min	16min	44min	99.6%
3-grm	72min	48min	58min	19.9%

Table 2: Sparse vs standard forward-backward (training times and percentages of sparsity of M)

5.1.2 Part-of-Speech Tagging

Our second benchmark is a part-of-speech (POS) tagging task using the PennTreeBank corpus (Marcus et al., 1993), which provides us with a quite different condition. For this task, the number of labels is smaller ($|Y| = 45$) than for Nettalk, and the set of observations is much larger ($|X| = 43207$). This benchmark, which has been used in many studies, allows for direct comparisons with other published work. We thus use a standard experimental set-up, where sections 0-18 of the Wall Street Journal are used for training, sections 19-21 for development, and sections 22-24 for testing.

Features are also standard and follow the design of (Suzuki and Isozaki, 2008) and test the current words (as written and lowercased), prefixes and suffixes up to length 4, and typographical characteristics (case, etc.) of the words. Our baseline feature set also contains tests on individual and pairs of words in a window of 5 words.

5.2 Using Large Feature Sets

The first important issue is to assess the benefits of using large feature sets, notably including features testing both a bigram of labels and an observation. Table 1 compares the results obtained with and without these features for various setting (using OWL-QN to perform the optimization), suggesting that for the tasks at hand, these features are actually helping.

	ℓ^2	ℓ^1	Elastic-net
1-grm	17.81%	17.86%	17.79%
3-grm	10.62%	10.74%	10.70%
5-grm	8.50%	8.45%	8.48%

Table 3: Error rates of the three regularizers on the Nettalk task.

5.3 Speed, Sparsity, Convergence

The training speed depends of two main factors: the number of iterations needed to achieve convergence and the computational cost of one iteration. In this section, we analyze and compare the runtime efficiency of the three optimizers.

5.3.1 Convergence

As far as convergence is concerned, the two forms of regularization (ℓ^2 and ℓ^1) yield the same performance (see Table 3), and the three algorithms exhibit more or less the same behavior. They quickly reach an acceptable set of active parameters, which is often several orders of magnitude smaller than the whole parameter set (see results below in Table 4 and 5). Full convergence, reflected by a stabilization of the objective function, is however not so easily achieved. We have often observed a slow, yet steady, decrease of the log-loss, accompanied with a diminution of the number of active features as the number of iterations increases. Based on this observation, we have chosen to stop all algorithms based on their performance on an independent development set, allowing a fair comparison of the overall training time; for OWL-QN, it allowed to divide the total training time by almost 2.

It has finally often been found useful to fine tune the non-zero parameters by running a final handful of L-BFGS iterations using only a small ℓ^2 penalty; at this stage, all the other features are removed from the model. This had a small impact BCD and SGD's performance and allowed them to catch up with OWL-QN's performance.

5.3.2 Sparsity and the Forward-Backward

As explained in section 4.1, the forward-backward algorithm can be written so as to use the sparsity of the matrix $M_{y,y',x}$. To evaluate the resulting speed-up, we ran a series of experiments using Nettalk (see Table 2). In this table, the 3-grm- setting corresponds to maximum sparsity for M, and training with the sparse algorithm is three times faster than with the non-sparse version. Throwing

	Method	Iter.	# Feat.	Error	Time
OWL-QN	1-grm	63.4	4684	17.79%	11min
	7-grm	140.2	38214	8.12%	1h02min
	5-grm+	141.0	43429	7.89%	1h37min
SGD	1-grm	21.4	3540	18.21%	9min
	5-grm+	28.5	34319	8.01%	45min
BCD	1-grm	28.2	5017	18.27%	27min
	7-grm	9.2	3692	8.21%	1h22min
	5-grm+	8.7	47675	7.91%	2h18min

Table 4: Performance on Nettalk

	Method	Error	Time
SGD	5-grm	14.71% / 8.11%	55min
	5-grm+	13.91% / 7.51%	2h45min
BCD	5-grm	14.57% / 8.06%	2h46min
	7-grm	14.12% / 7.86%	3h02min
	5-grm+	13.85% / 7.47%	7h14min
	5-grm++	13.69% / 7.36%	16h03min

Table 5: Performance on Nettalk+prosody. Error is given for both joint labels and phonemic labels.

in more features has the effect of making M much more dense, mitigating the benefits of the sparse recursions. Nevertheless, even for very large feature sets, the percentage of zeros in M averages 20% to 30%, and the sparse version remains 10 to 20% faster than the non-sparse one. Note that the non-sparse version is faster with a ℓ^1 penalty term than with only the ℓ^2 term: this is because $\exp(0)$ is faster to evaluate than $\exp(x)$ when $x \neq 0$.

5.3.3 Training Speed and Test Accuracy

Table 4 displays the results achieved on the Nettalk task. The three algorithms yield very comparable accuracy results, and deliver compact models: for the 5-gram+ setting, only 50,000 out of 250 million features are selected. SGD is the fastest of the three, up to twice as fast as OWL-QN and BCD depending on the feature set. The performance it achieves are consistently slightly worst than the other optimizers, and only catch up when the parameters are fine-tuned (see above). There are not so many comparisons for Nettalk with CRFs, due to the size of the label set. Our results compare favorably with those reported in (Pal et al., 2006), where the accuracy attains 91.7% using 19075 examples for training and 934 for testing, and with those in (Jeong et al., 2009) (88.4% accuracy with 18,000 (2,000) training (test) instances). Table 5 gives the results obtained for the larger Nettalk+prosody task. Here, we only report the results obtained with SGD and BCD. For OWL-QN, the largest model we could handle was the 3-grm model, which contained 69 million features, and took 48min to train. Here again, performance steadily increase with the number of features, showing the benefits of large-scale models. We lack comparisons for this task, which seems considerably harder than the sole phonetization task, and all systems seem to plateau around 13.5% accuracy. Interestingly, simultaneously predicting the phoneme and its prosodic markers allows to improve the accuracy on the prediction of phonemes, which improves of almost a half point as compared to the best Nettalk system.

For the POS tagging task, BCD appears to be unpractically slower to train than the others approaches (SGD takes about 40min to train, OWL-QN about 1 hour) due the simultaneous increase in the sequence length and in the number of observations. As a result, one iteration of BCD typically requires to repeatedly process over and over the same sequences: on average, each sequence is visited 380 times when we use the baseline feature set. This technique should reserved for tasks where the number of blocks is small, or, as below, when memory usage is an issue.

5.4 Structured Feature Sets

In many tasks, the ambiguity of tokens can be reduced by looking up increasingly large windows of local context. This strategy however quickly runs into a combinatorial increase of the number of features. A side note of the Nettalk experiments is that when using embedded features, the active feature set tends to reflect this hierarchical organization. This means that when a feature testing a n-gram is active, in most cases, the features for all embedded k-grams are also selected.

Based on this observation, we have designed an incremental training strategy for the POS tagging task, where more specific features are progressively incorporated into the model if the corresponding less specific feature is active. This experiment used BCD, which is the most memory efficient algorithm. The first iteration only includes tests on the current word. During the second iteration, we add tests on bigram of words, on suffixes and prefixes up to length 4. After four iterations, we throw in features testing word trigrams, subject to the corresponding unigram block being active. After 6 iterations, we finally augment the

model with windows of length 5, subject to the corresponding trigram being active. After 10 iterations, the model contains about 4 billion features, out of which 400,000 are active. It achieves an error rate of 2.63% (resp. 2.78%) on the development (resp. test) data, which compares favorably with some of the best results for this task (for instance (Toutanova et al., 2003; Shen et al., 2007; Suzuki and Isozaki, 2008)).

6 Conclusion and Perspectives

In this paper, we have discussed various ways to train extremely large CRFs with a ℓ^1 penalty term and compared experimentally the results obtained, both in terms of training speed and of accuracy. The algorithms studied in this paper have complementary strength and weaknesses: OWL-QN is probably the method of choice in small or moderate size applications while BCD is most efficient when using very large feature sets combined with limited-size observation alphabets; SGD complemented with fine tuning appears to be the preferred choice in most large-scale applications. Our analysis demonstrate that training large-scale sparse models can be done efficiently and allows to improve over the performance of smaller models. The CRF package developed in the course of this study implements many algorithmic optimizations and allows to design innovative training strategies, such as the one presented in section 5.4. This package is released as open-source software and is available at `http://wapiti.limsi.fr`.

In the future, we intend to study how sparsity can be used to speed-up training in the face of more complex dependency patterns (such as higher-order CRFs or hierarchical dependency structures (Rozenknop, 2002; Finkel et al., 2008). From a performance point of view, it might also be interesting to combine the use of large-scale feature sets with other recent improvements such as the use of semi-supervised learning techniques (Suzuki and Isozaki, 2008) or variable-length dependencies (Qian et al., 2009).

On the Computational Complexity of Dominance Links in Grammatical Formalisms

Sylvain Schmitz
LSV, ENS Cachan & CNRS, France
sylvain.schmitz@lsv.ens-cachan.fr

Abstract

Dominance links were introduced in grammars to model long distance scrambling phenomena, motivating the definition of *multiset-valued linear indexed grammars* (MLIGs) by Rambow (1994b), and inspiring quite a few recent formalisms. It turns out that MLIGs have since been rediscovered and reused in a variety of contexts, and that the complexity of their emptiness problem has become the key to several open questions in computer science. We survey complexity results and open issues on MLIGs and related formalisms, and provide new complexity bounds for some linguistically motivated restrictions.

1 Introduction

Scrambling constructions, as found in German and other SOV languages (Becker et al., 1991; Rambow, 1994a; Lichte, 2007), cause notorious difficulties to linguistic modeling in classical grammar formalisms like HPSG or TAG. A well-known illustration of this situation is given in the following two German sentences for "that Peter has repaired the fridge today" (Lichte, 2007),

dass [Peter] heute [den Kühlschrank] repariert hat
that Peter$_{nom}$ today the fridge$_{acc}$ repaired has

dass [den Kühlschrank] heute [Peter] repariert hat
that the fridge$_{acc}$ today Peter$_{nom}$ repaired has

with a flexible word order between the two complements of *repariert*, namely between the nominative *Peter* and the accusative *den Kühlschrank*.

Rambow (1994b) introduced a formalism, *unordered vector grammars with dominance links* (UVG-dls), for modeling such phenomena. These grammars are defined by vectors of context-free productions along with dominance links that should be enforced during derivations; for instance, Figure 1 shows how a flexible order between the complements of *repariert* could be expressed in an UVG-dl. Similar dominance mechanisms have been employed in various tree description formalisms (Rambow et al., 1995; Rambow et al., 2001; Candito and Kahane, 1998; Kallmeyer, 2001; Guillaume and Perrier, 2010) and TAG extensions (Becker et al., 1991; Rambow, 1994a).

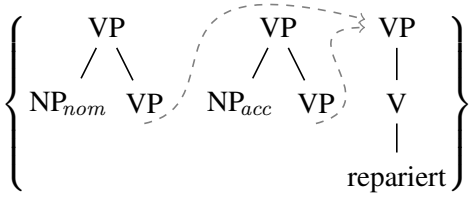

Figure 1: A vector of productions for the verb *repariert* together with its two complements.

However, the prime motivation for this survey is another grammatical formalism defined in the same article: *multiset-valued linear indexed grammars* (Rambow, 1994b, MLIGs), which can be seen as a low-level variant of UVG-dls that uses multisets to emulate unfulfilled dominance links in partial derivations. It is a natural extension of Petri nets, with broader scope than just UVG-dls; indeed, it has been independently rediscovered by de Groote et al. (2004) in the context of linear logic, and by Verma and Goubault-Larrecq (2005) in that of equational theories. Moreover, the decidability of its emptiness problem has proved to be quite challenging and is still uncertain, with several open questions depending on its resolution:

- provability in multiplicative exponential linear logic (de Groote et al., 2004),
- emptiness and membership of abstract categorial grammars (de Groote et al., 2004; Yoshinaka and Kanazawa, 2005),
- emptiness and membership of Stabler (1997)'s minimalist grammars without

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 514–524,
Uppsala, Sweden, 11-16 July 2010.

shortest move constraint (Salvati, 2010),

- satisfiability of first-order logic on data trees (Bojańczyk et al., 2009), and of course
- emptiness and membership for the various formalisms that embed UVG-dls.

Unsurprisingly in the light of their importance in different fields, several authors have started investigating the complexity of decisions problems for MLIGs (Demri et al., 2009; Lazić, 2010). We survey the current state of affairs, with a particular emphasis on two points:

1. the applicability of complexity results to UVG-dls, which is needed if we are to conclude anything on related formalisms with dominance links,
2. the effects of two linguistically motivated restrictions on such formalisms, lexicalization and boundedness/rankedness.

The latter notion is imported from Petri nets, and turns out to offer interesting new complexity trade-offs, as we prove that k-boundedness and k-rankedness are EXPTIME-complete for MLIGs, and that the emptiness and membership problems are EXPTIME-complete for k-bounded MLIGs but PTIME-complete in the k-ranked case. This also implies an EXPTIME lower bound for emptiness and membership in minimalist grammars with shortest move constraint.

We first define MLIGs formally in Section 2 and review related formalisms in Section 3. We proceed with complexity results in Section 4 before concluding in Section 5.

Notations In the following, Σ denotes a finite alphabet, Σ^* the set of finite sentences over Σ, and ε the empty string. The length of a string w is noted $|w|$, and the number of occurrence of a symbol a in w is noted $|w|_a$. A language is formalized as a subset of Σ^*. Let $\mathbb{N}^n$ denote the set of vectors of positive integers of dimension n. The i-th component of a vector $\overline{\mathsf{x}}$ in $\mathbb{N}^n$ is $\overline{\mathsf{x}}(i)$, $\overline{0}$ denotes the null vector, $\overline{1}$ the vector with 1 values, and $\overline{\mathsf{e}}_i$ the vector with 1 as its i-th component and 0 everywhere else. The ordering $\leq$ on $\mathbb{N}^n$ is the componentwise ordering: $\overline{\mathsf{x}} \leq \overline{\mathsf{y}}$ iff $\overline{\mathsf{x}}(i) \leq \overline{\mathsf{y}}(i)$ for all $0 < i \leq n$. The size of a vector refers to the size of its binary encoding: $|\overline{\mathsf{x}}| = \sum_{i=1}^{n} 1 + \max(0, \lfloor \log_2 \overline{\mathsf{x}}(i) \rfloor)$.

We refer the reader unfamiliar with complexity classes and notions such as hardness or LOGSPACE reductions to classical textbooks (e.g. Papadimitriou, 1994).

2 Multiset-Valued Linear Indexed Grammars

Definition 1 (Rambow, 1994b)**.** An n-dimensional *multiset-valued linear indexed grammar* (MLIG) is a tuple $\mathcal{G} = \langle N, \Sigma, P, (S, \overline{\mathsf{x}}_0) \rangle$ where N is a finite set of nonterminal symbols, Σ a finite alphabet disjoint from N, $V = (N \times \mathbb{N}^n) \uplus \Sigma$ the vocabulary, P a finite set of productions in $(N \times \mathbb{N}^n) \times V^*$, and $(S, \overline{\mathsf{x}}_0) \in N \times \mathbb{N}^n$ the start symbol. Productions are more easily written as

$$(A,\overline{\mathsf{x}}) \to u_0(B_1,\overline{\mathsf{x}}_1)u_1 \cdots u_m(B_m,\overline{\mathsf{x}}_m)u_{m+1} \quad (\star)$$

with each u_i in Σ^* and each $(B_i, \overline{\mathsf{x}}_i)$ in $N \times \mathbb{N}^n$.

The *derivation* relation $\Rightarrow$ over sequences in V^* is defined by

$$\delta(A,\overline{\mathsf{y}})\delta' \Rightarrow \delta u_0(B_1,\overline{\mathsf{y}}_1)u_1 \cdots u_m(B_m,\overline{\mathsf{y}}_m)u_{m+1}\delta'$$

if δ and δ' are in V^*, a production of form $(\star)$ appears in P, $\overline{\mathsf{x}} \leq \overline{\mathsf{y}}$, for each $1 \leq i \leq m$, $\overline{\mathsf{x}}_i \leq \overline{\mathsf{y}}_i$, and $\overline{\mathsf{y}} - \overline{\mathsf{x}} = \sum_{i=1}^{m} \overline{\mathsf{y}}_i - \overline{\mathsf{x}}_i$.

The *language* of a MLIG is the set of terminal strings derived from $(S, \overline{\mathsf{x}}_0)$, i.e.

$$L(\mathcal{G}) = \{w \in \Sigma^* \mid (S, \overline{\mathsf{x}}_0) \Rightarrow^* w\}$$

and we denote by $\mathcal{L}(\mathrm{MLIG})$ the class of MLIG languages.

Example 2. To illustrate this definition, and its relevance for free word order languages, consider the 3-dimensional MLIG with productions

$$(S, \overline{0}) \to \varepsilon \mid (S, \overline{1}), \qquad (S, \overline{\mathsf{e}}_1) \to a\,(S, \overline{0}),$$
$$(S, \overline{\mathsf{e}}_2) \to b\,(S, \overline{0}), \qquad (S, \overline{\mathsf{e}}_3) \to c\,(S, \overline{0})$$

and start symbol $(S, \overline{0})$. It generates the MIX language of all sentences with the same number of a, b, and c's (see Figure 2 for an example derivation):

$$L_{\text{mix}} = \{w \in \{a, b, c\}^* \mid |w|_a = |w|_b = |w|_c\}\ .$$

The *size* $|\mathcal{G}|$ of a MLIG $\mathcal{G}$ is essentially the sum of the sizes of each of its productions of form $(\star)$:

$$|\overline{\mathsf{x}}_0| + \sum_{P} \left(m + 1 + |\overline{\mathsf{x}}| + \sum_{i=1}^{m} |\overline{\mathsf{x}}_i| + \sum_{i=0}^{m+1} |u_i| \right).$$

2.1 Normal Forms

A MLIG is in *extended two form* (ETF) if all its productions are of form

terminal $(A, \overline{0}) \to a$ or $(A, \overline{0}) \to \varepsilon$, or

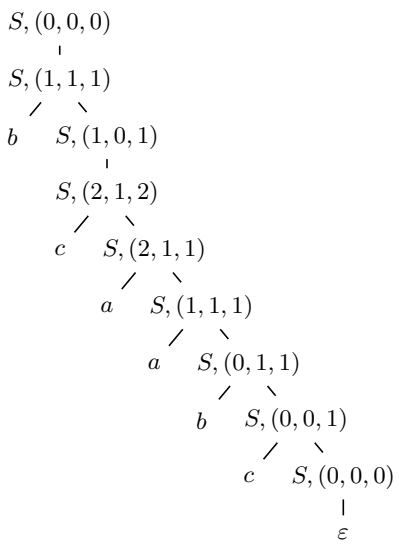

Figure 2: A derivation for $bcaabc$ in the grammar of Example 2.

nonterminal $(A,\overline{\mathsf{x}}) \rightarrow (B_1,\overline{\mathsf{x}}_1)(B_2,\overline{\mathsf{x}}_2)$ or $(A,\overline{\mathsf{x}}) \rightarrow (B_1,\overline{\mathsf{x}}_1)$,

with a in Σ, A, B_1, B_2 in N, and $\overline{\mathsf{x}}$, $\overline{\mathsf{x}}_1$, $\overline{\mathsf{x}}_2$ in $\mathbb{N}^n$. Using standard constructions, any MLIG can be put into ETF in linear time or logarithmic space.

A MLIG is in *restricted index normal form* (RINF) if the productions in P are of form $(A,\overline{0}) \rightarrow \alpha$, $(A,\overline{0}) \rightarrow (B,\overline{\mathsf{e}}_i)$, or $(A,\overline{\mathsf{e}}_i) \rightarrow (B,\overline{0})$, with A, B in N, $0 < i \leq n$, and α in $(\Sigma \cup (N \times \{\overline{0}\}))^*$. The direct translation into RINF proposed by Rambow (1994a) is exponential if we consider a binary encoding of vectors, but using techniques developed for Petri nets (Dufourd and Finkel, 1999), this blowup can be avoided:

Proposition 3. *For any MLIG, one can construct an equivalent MLIG in RINF in logarithmic space.*

2.2 Restrictions

Two restrictions on dominance links have been suggested in an attempt to reduce their complexity, sometimes in conjunction: lexicalization and k-boundedness. We provide here characterizations for them in terms of MLIGs. We can combine the two restrictions, thus defining the class of k-bounded lexicalized MLIGs.

Lexicalization Lexicalization in UVG-dls reflects the strong dependence between syntactic constructions (vectors of productions representing an extended domain of locality) and lexical anchors. We define here a restriction of MLIGs with similar complexity properties:

Definition 4. A terminal derivation $\alpha \Rightarrow^p w$ with w in Σ^* is *c-lexicalized* for some $c > 0$ if $p \leq c \cdot |w|$.[1] A MLIG is *lexicalized* if there exists c such that any terminal derivation starting from $(S,\overline{\mathsf{x}}_0)$ is c-lexicalized, and we denote by $\mathcal{L}(\mathrm{MLIG}_\ell)$ the set of lexicalized MLIG languages.

Looking at the grammar of Example 2, any terminal derivation $(S,\overline{0}) \Rightarrow^p w$ verifies $p = \frac{4 \cdot |w|}{3} + 1$, and the grammar is thus lexicalized.

Boundedness As dominance links model long-distance dependencies, bounding the number of simultaneously pending links can be motivated on competence/performance grounds (Joshi et al., 2000; Kallmeyer and Parmentier, 2008), and on complexity/expressiveness grounds (Søgaard et al., 2007; Kallmeyer and Parmentier, 2008; Chiang and Scheffler, 2008). The *shortest move constraint* (SMC) introduced by Stabler (1997) to enforce a strong form of minimality also falls into this category of restrictions.

Definition 5. A MLIG derivation $\alpha_0 \Rightarrow \alpha_1 \Rightarrow \cdots \Rightarrow \alpha_p$ is of *rank k* for some $k \geq 0$ if, no vector with a sum of components larger than k can appear in any α_j, i.e. for all $\overline{\mathsf{x}}$ in $\mathbb{N}^n$ such that there exist $0 \leq j \leq p$, δ, δ' in V^* and A in N with $\alpha_j = \delta(A,\overline{\mathsf{x}})\delta'$, one has $\sum_{i=1}^n \overline{\mathsf{x}}(i) \leq k$.

A MLIG is *k-ranked* (noted kr-MLIG) if any derivation starting with $\alpha_0 = (S,\overline{\mathsf{x}}_0)$ is of rank k. It is *ranked* if there exists k such that it is k-ranked.

A 0-ranked MLIG is simply a context-free grammar (CFG), and we have more generally the following:

Lemma 6. *Any n-dimensional k-ranked MLIG $\mathcal{G}$ can be transformed into an equivalent CFG $\mathcal{G}'$ in time $O(|\mathcal{G}| \cdot (n+1)^{k^3})$.*

Proof. We assume $\mathcal{G}$ to be in ETF, at the expense of a linear time factor. Each A in N is then mapped to at most $(n+1)^k$ nonterminals $(A,\overline{\mathsf{y}})$ in $N' = N \times \mathbb{N}^n$ with $\sum_{i=1}^n \overline{\mathsf{y}}(i) \leq k$. Finally, for each production $(A,\overline{\mathsf{x}}) \rightarrow (B_1,\overline{\mathsf{x}}_1)(B_2,\overline{\mathsf{x}}_2)$ of P, at most $(n+1)^{k^3}$ choices are possible for productions $(A,\overline{\mathsf{y}}) \rightarrow (B_1,\overline{\mathsf{y}}_1)(B_2,\overline{\mathsf{y}}_2)$ with $(A,\overline{\mathsf{y}})$, $(B_1,\overline{\mathsf{y}}_1)$, and $(B_2,\overline{\mathsf{y}}_2)$ in N'. □

A definition quite similar to k-rankedness can be found in the Petri net literature:

[1] This restriction is slightly stronger than that of *linearly restricted* derivations (Rambow, 1994b), but still allows to capture UVG-dl lexicalization.

Definition 7. A MLIG derivation $\alpha_0 \Rightarrow \alpha_1 \Rightarrow \cdots \Rightarrow \alpha_p$ is *k-bounded* for some $k \geq 0$ if, no vector with a coordinate larger than k can appear in any α_j, i.e. for all $\overline{\mathsf{x}}$ in $\mathbb{N}^n$ such that there exist $0 \leq j \leq p$, δ, δ' in V^* and A in N with $\alpha_j = \delta(A, \overline{\mathsf{x}})\delta'$, and for all $1 \leq i \leq n$, one has $\overline{\mathsf{x}}(i) \leq k$.

A MLIG is *k-bounded* (noted kb-MLIG) if any derivation starting with $\alpha_0 = (S, \overline{\mathsf{x}}_0)$ is k-bounded. It is *bounded* if there exists k such that it is k-bounded.

The SMC in minimalist grammars translates exactly into 1-boundedness of the corresponding MLIGs (Salvati, 2010).

Clearly, any k-ranked MLIG is also k-bounded, and conversely any n-dimensional k-bounded MLIG is (kn)-ranked, thus a MLIG is ranked iff it is bounded. The counterpart to Lemma 6 is:

Lemma 8. *Any n-dimensional k-bounded MLIG $\mathcal{G}$ can be transformed into an equivalent CFG $\mathcal{G}'$ in time $O(|\mathcal{G}| \cdot (k+1)^{n^2})$.*

Proof. We assume $\mathcal{G}$ to be in ETF, at the expense of a linear time factor. Each A in N is then mapped to at most $(k+1)^n$ nonterminals $(A, \overline{\mathsf{y}})$ in $N' = N \times \{0, \ldots, k\}^n$. Finally, for each production $(A, \overline{\mathsf{x}}) \to (B_1, \overline{\mathsf{x}}_1)(B_2, \overline{\mathsf{x}}_2)$ of P, each nonterminal $(A, \overline{\mathsf{y}})$ of N' with $\overline{\mathsf{x}} \leq \overline{\mathsf{y}}$, and each index $0 < i \leq n$, there are at most $k+1$ ways to split $(\overline{\mathsf{y}}(i) - \overline{\mathsf{x}}(i)) \leq k$ into $\overline{\mathsf{y}}_1(i) + \overline{\mathsf{y}}_2(i)$ and span a production $(A, \overline{\mathsf{y}}) \to (B_1, \overline{\mathsf{x}}_1 + \overline{\mathsf{y}}_1)(B_2, \overline{\mathsf{x}}_2 + \overline{\mathsf{y}}_2)$ of P'. Overall, each production is mapped to at most $(k+1)^{n^2}$ context-free productions. □

One can check that the grammar of Example 2 is not bounded (to see this, repeatedly apply production $(S, \overline{0}) \to (S, \overline{1})$), as expected since MIX is not a context-free language.

2.3 Language Properties

Let us mention a few more results pertaining to MLIG languages:

Proposition 9 (Rambow, 1994b)**.** *$\mathcal{L}(\mathrm{MLIG})$ is a substitution closed full abstract family of languages.*

Proposition 10 (Rambow, 1994b)**.** *$\mathcal{L}(\mathrm{MLIG}_\ell)$ is a subset of the context-sensitive languages.*

Natural languages are known for displaying some limited cross-serial dependencies, as witnessed in linguistic analyses, e.g. of Swiss-German (Shieber, 1985), Dutch (Kroch and Santorini, 1991), or Tagalog (Maclachlan and Rambow, 2002). This includes the copy language

$$L_{\text{copy}} = \{ww \mid w \in \{a, b\}^*\} ,$$

which does not seem to be generated by any MLIG:

Conjecture 11 (Rambow, 1994b)**.** *L_{copy} is not in $\mathcal{L}(\mathrm{MLIG})$.*

Finally, we obtain the following result as a consequence of Lemmas 6 and 8:

Corollary 12. *$\mathcal{L}(k\text{r-MLIG}) = \mathcal{L}(k\text{b-MLIG}) = \mathcal{L}(k\text{b-MLIG}_\ell)$ is the set of context-free languages.*

3 Related Formalisms

We review formalisms connected to MLIGs, starting in Section 3.1 with Petri nets and two of their extensions, which turn out to be exactly equivalent to MLIGs. We then consider various linguistic formalisms that employ dominance links (Section 3.2).

3.1 Petri Nets

Definition 13 (Petri, 1962)**.** A marked *Petri net*[2] is a tuple $\mathcal{N} = \langle \mathcal{S}, T, f, \overline{\mathsf{m}}_0 \rangle$ where $\mathcal{S}$ and T are disjoint finite sets of places and transitions, f a flow function from $(\mathcal{S} \times T) \cup (T \times \mathcal{S})$ to $\mathbb{N}$, and $\overline{\mathsf{m}}_0$ an initial marking in $\mathbb{N}^{\mathcal{S}}$. A transition $t \in T$ can be fired in a *marking* $\overline{\mathsf{m}}$ in $\mathbb{N}^{\mathcal{S}}$ if $f(p,t) \geq \overline{\mathsf{m}}(p)$ for all $p \in \mathcal{S}$, and reaches a new marking $\overline{\mathsf{m}}'$ defined by $\overline{\mathsf{m}}'(p) = \overline{\mathsf{m}}(p) - f(p,t) + f(t,p)$ for all $p \in \mathcal{S}$, written $\overline{\mathsf{m}}\ [t\rangle\ \overline{\mathsf{m}}'$. Another view is that place p holds $\overline{\mathsf{m}}(p)$ *tokens*, $f(p,t)$ of which are first removed when firing t, and then $f(t,p)$ added back. Firings are extended to sequences σ in T^* by $\overline{\mathsf{m}}\ [\varepsilon\rangle\ \overline{\mathsf{m}}$, and $\overline{\mathsf{m}}\ [\sigma t\rangle\ \overline{\mathsf{m}}'$ if there exists $\overline{\mathsf{m}}''$ with $\overline{\mathsf{m}}\ [\sigma\rangle\ \overline{\mathsf{m}}''\ [t\rangle\ \overline{\mathsf{m}}'$.

A *labeled* Petri net with reachability acceptance is endowed with a labeling homomorphism $\varphi : T^* \to \Sigma^*$ and a finite acceptance set $F \subseteq \mathbb{N}^{\mathcal{S}}$, defining the language (Peterson, 1981)

$$L(\mathcal{N}, \varphi, F) = \{\varphi(\sigma) \in \Sigma^* \mid \exists \overline{\mathsf{m}} \in F, \overline{\mathsf{m}}_0\ [\sigma\rangle\ \overline{\mathsf{m}}\} .$$

Labeled Petri nets (with acceptance set $\{\overline{0}\}$) are notational variants of *right linear* MLIGs, defined as having production in $(N \times \mathbb{N}^n) \times (\Sigma^* \cup (\Sigma^* \cdot (N \times \mathbb{N}^n)))$. This is is case of the MLIG of Example 2, which is given in Petri net form in Figure 3, where

[2] Petri nets are also equivalent to *vector addition system* (Karp and Miller, 1969, VAS) and *vector addition systems with states* (Hopcroft and Pansiot, 1979, VASS).

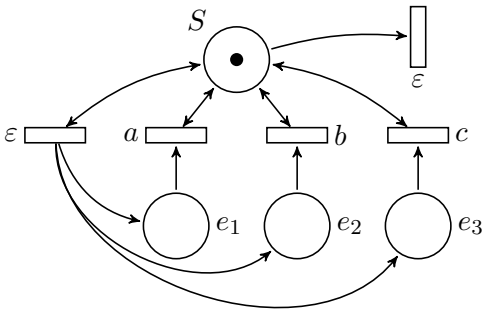

Figure 3: The labeled Petri net corresponding to the right linear MLIG of Example 2.

circles depict places (representing MLIG nonterminals and indices) with black dots for initial tokens (representing the MLIG start symbol), boxes transitions (representing MLIG productions), and arcs the flow values. For instance, production $(S,\overline{\mathsf{e}}_3) \to c\,(S,\overline{0})$ is represented by the rightmost, c-labeled transition, with $f(S,t) = f(e_3,t) = f(t,S) = 1$ and $f(e_1,t) = f(e_2,t) = f(t,e_1) = f(t,e_2) = f(t,e_3) = 0$.

Extensions The subsumption of Petri nets is not innocuous, as it allows to derive lower bounds on the computational complexity of MLIGs. Among several extensions of Petri net with some branching capacity (see e.g. Mayr, 1999; Haddad and Poitrenaud, 2007), two are of singular importance: It turns out that MLIGs in their full generality have since been independently rediscovered under the names *vector addition tree automata* (de Groote et al., 2004, VATA) and *branching VASS* (Verma and Goubault-Larrecq, 2005, BVASS).

Semilinearity Another interesting consequence of the subsumption of Petri nets by MLIGs is that the former generate some non semilinear languages, i.e. with a Parikh image which is not a semilinear subset of $\mathbb{N}^{|\Sigma|}$ (Parikh, 1966). Hopcroft and Pansiot (1979, Lemma 2.8) exhibit an example of a VASS with a non semilinear reachability set, which we translate as a 2-dimensional right linear MLIG with productions[3]

$$(S,\overline{\mathsf{e}}_2) \to (S,\overline{\mathsf{e}}_1), \qquad (S,\overline{0}) \to (A,\overline{0}) \mid (B,\overline{0}),$$
$$(A,\overline{\mathsf{e}}_1) \to (A,2\overline{\mathsf{e}}_2), \qquad (A,\overline{0}) \to a\,(S,\overline{0}),$$
$$(B,\overline{\mathsf{e}}_1) \to b\,(B,\overline{0}) \mid b, \quad (B,\overline{\mathsf{e}}_2) \to b\,(B,\overline{0}) \mid b$$

[3] Adding terminal symbols c in each production would result in a lexicalized grammar, still with a non semilinear language.

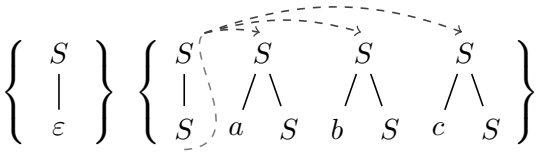

Figure 4: An UVG-dl for L_{mix}.

and $(S,\overline{\mathsf{e}}_2)$ as start symbol, that generates the non semilinear language

$$L_{\text{nsm}} = \{a^n b^m \mid 0 \le n, 0 < m \le 2^n\}\ .$$

Proposition 14 (Hopcroft and Pansiot, 1979)**.** *There exist non semilinear Petri nets languages.*

The non semilinearity of MLIGs entails that of all the grammatical formalisms mentioned next in Section 3.2; this answers in particular a conjecture by Kallmeyer (2001) about the semilinearity of V-TAGs.

3.2 Dominance Links

UVG-dl Rambow (1994b) introduced UVG-dls as a formal model for scrambling and tree description grammars.

Definition 15 (Rambow, 1994b)**.** An *unordered vector grammars with dominance links* (UVG-dl) is a tuple $\mathcal{G} = \langle N, \Sigma, W, S\rangle$ where N and Σ are disjoint finite sets of nonterminals and terminals, $V = N \cup \Sigma$ is the vocabulary, W is a set of vectors of productions with dominance links, i.e. each element of W is a pair (P, D) where each P is a multiset of productions in $N \times V^*$ and D is a relation from nonterminals in the right parts of productions in P to nonterminals in their left parts, and S in N is the start symbol.

A *terminal derivation* of w in Σ^* in an UVG-dl is a context-free derivation of form $S \overset{p_1}{\Rightarrow} \alpha_1 \overset{p_2}{\Rightarrow} \alpha_2 \cdots \alpha_{p-1} \overset{p_p}{\Rightarrow} w$ such that the control word $p_1 p_2 \cdots p_p$ is a permutation of a member of W^* and the dominance relations of W hold in the associated derivation tree. The *language* $L(\mathcal{G})$ of an UVG-dl $\mathcal{G}$ is the set of sentences w with some terminal derivation. We write $\mathcal{L}(\text{UVG-dl})$ for the class of UVG-dl languages.

An alternative semantics of derivations in UVG-dls is simply their translation into MLIGs: associate with each nonterminal in a derivation the multiset of productions it has to spawn. Figure 4 presents the two vectors of an UVG-dl for the MIX language of Example 2, with dashed arrows indicating dominance links. Observe that production

$S \to S$ in the second vector has to spawn eventually one occurrence of each $S \to aS$, $S \to bS$, and $S \to cS$, which corresponds exactly to the MLIG of Example 2.

The ease of translation from the grammar of Figure 4 into a MLIG stems from the impossibility of splitting any of its vectors (P, D) into two nonempty ones (P_1, D_1) and (P_2, D_2) while preserving the dominance relation, i.e. with $P = P_1 \uplus P_2$ and $D = D_1 \uplus D_2$. This *strictness* property can be enforced without loss of generality since we can always add to each vector (P, D) a production $S \to S$ with a dominance link to each production in P. This was performed on the second vector in Figure 4; remark that the grammar without this addition is an *unordered vector grammar* (Cremers and Mayer, 1974, UVG), and still generates L_{mix}.

Theorem 16 (Rambow, 1994b)**.** *Every MLIG can be transformed into an equivalent UVG-dl in logarithmic space, and conversely.*

Proof sketch. One can check that Rambow (1994b)'s proof of $\mathcal{L}(\text{MLIG}) \subseteq \mathcal{L}(\text{UVG-dl})$ incurs at most a quadratic blowup from a MLIG in RINF, and invoke Proposition 3. More precisely, given a MLIG in RINF, productions of form $(A,\overline{0}) \to \alpha$ with A in N and α in $(\Sigma \cup (N \times \{\overline{0}\}))^*$ form singleton vectors, and productions of form $(A,\overline{0}) \to (B,\overline{\mathsf{e}}_i)$ with A, B in N and $0 < i \leq n$ need to be paired with a production of form $(C,\overline{\mathsf{e}}_i) \to (D,\overline{0})$ for some C and D in N in order to form a vector with a dominance link between B and C.

The converse inclusion and its complexity are immediate when considering strict UVG-dls. □

The restrictions to k-ranked and k-bounded grammars find natural counterparts in strict UVG-dls by bounding the (total) number of pending dominance links in any derivation. Lexicalization has now its usual definition: for every vector $(\{p_{i,1}, \ldots, p_{i,k_i}\}, D_i)$ in W, at least one of the $p_{i,j}$ should contain at least one terminal in its right part—we have then $\mathcal{L}(\text{UVG-dl}_\ell) \subseteq \mathcal{L}(\text{MLIG}_\ell)$.

More on Dominance Links Dominance links are quite common in tree description formalisms, where they were already in use in D-theory (Marcus et al., 1983) and in quasi-tree semantics for fb-TAGs (Vijay-Shanker, 1992). In particular, D-tree substitution grammars are essentially the same as UVG-dls (Rambow et al., 2001), and quite a few other tree description formalisms subsume them (Candito and Kahane, 1998; Kallmeyer, 2001; Guillaume and Perrier, 2010). Another class of grammars are *vector TAGs* (V-TAGs), which extend TAGs and MCTAGs using dominance links (Becker et al., 1991; Rambow, 1994a; Champollion, 2007), subsuming again UVG-dls.

4 Computational Complexity

We study in this section the complexity of several decision problems on MLIGs, prominently of emptiness and membership problems, in the general (Section 4.2), k-bounded (Section 4.3), and lexicalized cases (Section 4.4). Table 1 sums up the known complexity results. Since by Theorem 16 we can translate between MLIGs and UVG-dls in logarithmic space, the complexity results on UVG-dls will be the same.

4.1 Decision Problems

Let us first review some decision problems of interest. In the following, $\mathcal{G}$ denotes a MLIG $\langle N, \Sigma, P, (S, \overline{\mathsf{x}}_0)\rangle$:

boundedness given $\langle\mathcal{G}\rangle$, is $\mathcal{G}$ bounded? As seen in Section 2.2, this is equivalent to rankedness.

***k*-boundedness** given $\langle\mathcal{G}, k\rangle$, k in $\mathbb{N}$, is $\mathcal{G}$ k-bounded? As seen in Section 2.2, this is the same as (kn)-rankedness. Here we will distinguish two cases depending on whether k is encoded in unary or binary.

coverability given $\langle\mathcal{G}, F\rangle$, $\mathcal{G}$ ε-free in ETF and F a finite subset of $N \times \mathbb{N}^n$, does there exist $\alpha = (A_1, \overline{\mathsf{y}}_1) \cdots (A_m, \overline{\mathsf{y}}_m)$ in $(N \times \mathbb{N}^n)^*$ such that $(S, \overline{\mathsf{x}}_0) \Rightarrow^* \alpha$ and for each $0 < j \leq m$ there exists $(A_j, \overline{\mathsf{x}}_j)$ in F with $\overline{\mathsf{x}}_j \leq \overline{\mathsf{y}}_j$?

reachability given $\langle\mathcal{G}, F\rangle$, $\mathcal{G}$ ε-free in ETF and F a finite subset of $N \times \mathbb{N}^n$, does there exist $\alpha = (A_1, \overline{\mathsf{y}}_1) \cdots (A_m, \overline{\mathsf{y}}_m)$ in F^* such that $(S, \overline{\mathsf{x}}_0) \Rightarrow^* \alpha$?

non emptiness given $\langle\mathcal{G}\rangle$, is $L(\mathcal{G})$ non empty?

(uniform) membership given $\langle\mathcal{G}, w\rangle$, w in Σ^*, does w belong to $L(\mathcal{G})$?

Boundedness and k-boundedness are needed in order to prove that a grammar is bounded, and to apply the smaller complexities of Section 4.3. Coverability is often considered for Petri nets, and allows to derive lower bounds on reachability. Emptiness is the most basic static

analysis one might want to perform on a grammar, and is needed for *parsing as intersection* approaches (Lang, 1994), while membership reduces to parsing. Note that we only consider uniform membership, since grammars for natural languages are typically considerably larger than input sentences, and their influence can hardly be neglected.

There are several obvious reductions between reachability, emptiness, and membership. Let $\rightarrow_{\log}$ denote LOGSPACE reductions between decision problems; we have:

Proposition 17.

$$\text{coverability} \rightarrow_{\log} \text{reachability} \quad (1)$$
$$\leftrightarrow_{\log} \text{non emptiness} \quad (2)$$
$$\leftrightarrow_{\log} \text{membership} \quad (3)$$

Proof sketch. For (1), construct a reachability instance $\langle \mathcal{G}', \{(E, \overline{0})\}\rangle$ from a coverability instance $\langle \mathcal{G}, F\rangle$ by adding to $\mathcal{G}$ a fresh nonterminal E and the productions

$$\{(A, \overline{\mathsf{x}}) \to (E, \overline{0}) \mid (A, \overline{\mathsf{x}}) \in F\}$$
$$\cup \{(E, \overline{\mathsf{e}_i}) \to (E, \overline{0}) \mid 0 < i \leq n\} .$$

For (2), from a reachability instance $\langle \mathcal{G}, F\rangle$, remove all terminal productions from $\mathcal{G}$ and add instead the productions $\{(A, \overline{\mathsf{x}}) \to \varepsilon \mid (A, \overline{\mathsf{x}}) \in F\}$; the new grammar $\mathcal{G}'$ has a non empty language iff the reachability instance was positive. Conversely, from a non emptiness instance $\langle \mathcal{G}\rangle$, put the grammar in ETF and define F to match all terminal productions, i.e. $F = \{(A, \overline{\mathsf{x}}) \mid (A, \overline{\mathsf{x}}) \to a \in P, a \in \Sigma \cup \{\varepsilon\}\}$, and then remove all terminal productions in order to obtain a reachability instance $\langle \mathcal{G}', F\rangle$.

For (3), from a non emptiness instance $\langle \mathcal{G}\rangle$, replace all terminals in $\mathcal{G}$ by ε to obtain an empty word membership instance $\langle \mathcal{G}', \varepsilon\rangle$. Conversely, from a membership instance $\langle \mathcal{G}, w\rangle$, construct the intersection grammar $\mathcal{G}'$ with $L(\mathcal{G}') = L(\mathcal{G}) \cap \{w\}$ (Bar-Hillel et al., 1961), which serves as non emptiness instance $\langle \mathcal{G}'\rangle$. □

4.2 General Case

Verma and Goubault-Larrecq (2005) were the first to prove that coverability and boundedness were decidable for BVASS, using a covering tree construction à la Karp and Miller (1969), thus of non primitive recursive complexity. Demri et al. (2009, Theorems 7, 17, and 18) recently proved tight complexity bounds for these problems, extending earlier results by Rackoff (1978) and Lipton (1976) for Petri nets.

Theorem 18 (Demri et al., 2009)**.** *Coverability and boundedness for MLIGs are* 2EXPTIME*-complete.*

Regarding reachability, emptiness, and membership, decidability is still open. A 2EXPSPACE lower bound was recently found by Lazić (2010). If a decision procedure exists, we can expect it to be quite complex, as already in the Petri net case, the complexity of the known decision procedures (Mayr, 1981; Kosaraju, 1982) is not primitive recursive (Cardoza et al., 1976, who attribute the idea to Hack).

4.3 k-Bounded and k-Ranked Cases

Since k-bounded MLIGs can be converted into CFGs (Lemma 8), emptiness and membership problems are decidable, albeit at the expense of an exponential blowup. We know from the Petri net literature that coverability and reachability problems are PSPACE-complete for k-bounded right linear MLIGs (Jones et al., 1977) by a reduction from *linear bounded automaton* (LBA) membership. We obtain the following for k-bounded MLIGs, using a similar reduction from membership in polynomially space bounded *alternating Turing machines* (Chandra et al., 1981, ATM):

Theorem 19. *Coverability and reachability for k-bounded MLIGs are* EXPTIME*-complete, even for fixed $k \geq 1$.*

The lower bound is obtained through an encoding of an instance of the membership problem for ATMs working in polynomial space into an instance of the coverability problem for 1-bounded MLIGs. The upper bound is a direct application of Lemma 8, coverability and reachability being reducible to the emptiness problem for a CFG of exponential size. Theorem 19 also shows the EXPTIME-hardness of emptiness and membership in minimalist grammars with SMC.

Corollary 20. *Let $k \geq 1$; k-boundedness for MLIGs is* EXPTIME*-complete.*

Proof. For the lower bound, consider an instance $\langle \mathcal{G}, F\rangle$ of coverability for a 1-bounded MLIG $\mathcal{G}$, which is EXPTIME-hard according to Theorem 19. Add to the MLIG $\mathcal{G}$ a fresh nonterminal E and the productions

$$\{(A, \overline{\mathsf{x}}) \to (E, \overline{\mathsf{x}}) \mid (A, \overline{\mathsf{x}}) \in F\}$$
$$\cup \{(E, \overline{0}) \to (E, \overline{\mathsf{e}_i}) \mid 0 < i \leq n\} ,$$

which make it non k-bounded iff the coverability instance was positive.

Problem	Lower bound	Upper bound
Petri net k-Boundedness	PSPACE (Jones et al., 1977)	PSPACE (Jones et al., 1977)
Petri net Boundedness	EXPSPACE (Lipton, 1976)	EXPSPACE (Rackoff, 1978)
Petri net {Emptiness, Membership}	EXPSPACE (Lipton, 1976)	Decidable, not primitive recursive (Mayr, 1981; Kosaraju, 1982)
{MLIG, MLIG$_\ell$} k-Boundedness	EXPTIME (Corollary 20)	EXPTIME (Corollary 20)
{MLIG, MLIG$_\ell$} Boundedness	2EXPTIME (Demri et al., 2009)	2EXPTIME (Demri et al., 2009)
{MLIG, MLIG$_\ell$} Emptiness MLIG Membership	2EXPSPACE (Lazić, 2010)	Not known to be decidable
{kb-MLIG, kb-MLIG$_\ell$} Emptiness kb-MLIG Membership	EXPTIME (Theorem 19)	EXPTIME (Theorem 19)
{MLIG$_\ell$, kb-MLIG$_\ell$} Membership	NPTIME (Koller and Rambow, 2007)	NPTIME (trivial)
kr-MLIG {Emptiness, Membership}	PTIME (Jones and Laaser, 1976)	PTIME (Lemma 6)

Table 1: Summary of complexity results.

For the upper bound, apply Lemma 8 with $k' = k + 1$ to construct an $O(|\mathcal{G}| \cdot 2^{n^2 \log_2(k'+1)})$-sized CFG, reduce it in polynomial time, and check whether a nonterminal $(A, \bar{\mathrm{x}})$ with $\bar{\mathrm{x}}(i) = k'$ for some $0 < i \leq n$ occurs in the reduced grammar.

Note that the choice of the encoding of k is irrelevant, as $k = 1$ is enough for the lower bound, and k only logarithmically influences the exponent for the upper bound. □

Corollary 20 also implies the EXPTIME-completeness of k-rankedness, k encoded in unary, if k can take arbitrary values. On the other hand, if k is known to be small, for instance logarithmic in the size of $\mathcal{G}$, then k-rankedness becomes polynomial by Lemma 6.

Observe finally that k-rankedness provides the only tractable class of MLIGs for uniform membership, using again Lemma 6 to obtain a CFG of polynomial size—actually exponential in k, but k is assumed to be fixed for this problem. An obvious lower bound is that of membership in CFGs, which is PTIME-complete (Jones and Laaser, 1976).

4.4 Lexicalized Case

Unlike the high complexity lower bounds of the previous two sections, NPTIME-hardness results for uniform membership have been proved for a number of formalisms related to MLIGs, from the commutative CFG viewpoint (Huynh, 1983; Barton, 1985; Esparza, 1995), or from more specialized models (Søgaard et al., 2007; Champollion, 2007; Koller and Rambow, 2007). We focus here on this last proof, which reduces from the *normal dominance graph configurability* problem (Althaus et al., 2003), as it allows to derive NPTIME-hardness even in highly restricted grammars.

Theorem 21 (Koller and Rambow, 2007)**.** *Uniform membership of $\langle \mathcal{G}, w \rangle$ for $\mathcal{G}$ a 1-bounded, lexicalized, UVG-dl with finite language is* NPTIME*-hard, even for $|w| = 1$.*

Proof sketch. Set S as start symbol and add a production $S \to aA$ to the sole vector of the grammar $\mathcal{G}$ constructed by Koller and Rambow (2007) from a normal dominance graph, with dominance links to all the other productions. Then $\mathcal{G}$ becomes strict, lexicalized, with finite language $\{a\}$ or $\emptyset$, and 1-bounded, such that a belongs to $L(\mathcal{G})$ iff the normal dominance graph is configurable. □

The fact that uniform membership is in NPTIME in the lexicalized case is clear, as we only need to guess nondeterministically a derivation of size linear in $|w|$ and check its correctness.

The weakness of lexicalized grammars is however that their emptiness problem is not any easier to solve! The effect of lexicalization is indeed to break the reduction from emptiness to membership in Proposition 17, but emptiness is as hard as ever, which means that static checks on the grammar might even be undecidable.

5 Conclusion

Grammatical formalisms with dominance links, introduced in particular to model scrambling phenomena in computational linguistics, have deep connections with several open questions in an unexpected variety of fields in computer science. We hope this survey to foster cross-fertilizing exchanges; for instance, is there a relation between

Conjecture 11 and the decidability of reachability in MLIGs? A similar question, whether the language L_{pal} of even 2-letters palindromes was a Petri net language, was indeed solved using the decidability of reachability in Petri nets (Jantzen, 1979), and shown to be strongly related to the latter (Lambert, 1992).

A conclusion with a more immediate linguistic value is that MLIGs and UVG-dls hardly qualify as formalisms for *mildly context-sensitive languages*, claimed by Joshi (1985) to be adequate for modeling natural languages, and "roughly" defined as the extensions of context-free languages that display

1. support for *limited cross-serial dependencies*: seems doubtful, see Conjecture 11,
2. constant growth, a requisite nowadays replaced by *semilinearity*: does not hold, as seen with Proposition 14, and
3. *polynomial recognition* algorithms: holds only for restricted classes of grammars, as seen in Section 4.

Nevertheless, variants such as k-ranked V-TAGs are easily seen to fulfill all the three points above.

Acknowledgements Thanks to Pierre Chambart, Stéphane Demri, and Alain Finkel for helpful discussions, and to Sylvain Salvati for pointing out the relation with minimalist grammars.

Abstract

Linear Context-Free Rewriting Systems (LCFRSs) are a grammar formalism capable of modeling discontinuous phrases. Many parsing applications use LCFRSs where the *fan-out* (a measure of the discontinuity of phrases) does not exceed 2. We present an efficient algorithm for optimal reduction of the length of production right-hand side in LCFRSs with fan-out at most 2. This results in asymptotical running time improvement for known parsing algorithms for this class.

1 Introduction

Linear Context-Free Rewriting Systems (LCFRSs) have been introduced by Vijay-Shanker *et al.* (1987) for modeling the syntax of natural language. The formalism extends the generative capacity of context-free grammars, still remaining far below the class of context-sensitive grammars. An important feature of LCFRSs is their ability to generate discontinuous phrases. This has been recently exploited for modeling phrase structure treebanks with discontinuous constituents (Maier and Søgaard, 2008), as well as non-projective dependency treebanks (Kuhlmann and Satta, 2009).

The maximum number f of tuple components that can be generated by an LCFRS G is called the **fan-out** of G, and the maximum number r of nonterminals in the right-hand side of a production is called the **rank** of G. As an example, context-free grammars are LCFRSs with $f = 1$ and r given by the maximum length of a production right-hand side. Tree adjoining grammars (Joshi and Levy, 1977) can also be viewed as a special kind of LCFRS with $f = 2$, since each auxiliary tree generates two strings, and with r given by the maximum number of adjunction and substitution sites in an elementary tree. Beyond tree adjoining languages, LCFRSs with $f = 2$ can also generate languages in which pair of strings derived from different nonterminals appear in so-called crossing configurations. It has recently been observed that, in this way, LCFRSs with $f = 2$ can model the vast majority of data in discontinuous phrase structure treebanks and non-projective dependency treebanks (Maier and Lichte, 2009; Kuhlmann and Satta, 2009).

Under a theoretical perspective, the parsing problem for LCFRSs with $f = 2$ is NP-complete (Satta, 1992), and in known parsing algorithms the running time is exponentially affected by the rank r of the grammar. Nonetheless, in natural language parsing applications, it is possible to achieve efficient, polynomial parsing if we succeed in reducing the rank r (number of nonterminals in the right-hand side) of individual LCFRSs' productions (Kuhlmann and Satta, 2009). This process is called production **factorization**. Production factorization is very similar to the reduction of a context-free grammar production into Chomsky normal form. However, in the LCFRS case some productions might not be reducible to $r = 2$, and the process stops at some larger value for r, which in the worst case might as well be the rank of the source production (Rambow and Satta, 1999).

Motivated by parsing efficiency, the factorization problem for LCFRSs with $f = 2$ has attracted the attention of many researchers in recent years. Most of the literature has been focusing on binarization algorithms, which attempt to find a reduction to $r = 2$ and return a failure if this is not possible. Gómez-Rodríguez *et al.* (2009) report a general binarization algorithm for LCFRS which, in the case of $f = 2$, works in time $\mathcal{O}(|p|^7)$, where $|p|$ is the size of the input production. A more efficient binarization algorithm for the case $f = 2$ is presented in (Gómez-Rodríguez and Satta, 2009), working in time $\mathcal{O}(|p|)$.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 525–533,
Uppsala, Sweden, 11-16 July 2010.

In this paper we are interested in general factorization algorithms, i.e., algorithms that find factorizations with the smallest possible rank (not necessarily $r = 2$). We present a novel technique that solves the general factorization problem in time $\mathcal{O}(|p|^2)$ for LCFRSs with $f = 2$.

Strong generative equivalence results between LCFRS and other finite copying parallel rewriting systems have been discussed in (Weir, 1992) and in (Rambow and Satta, 1999). Through these equivalence results, we can transfer the factorization techniques presented in this article to other finite copying parallel rewriting systems.

2 LCFRSs

In this section we introduce the basic notation for LCFRS and the notion of production factorization.

2.1 Definitions

Let Σ_T be a finite alphabet of terminal symbols. As usual, Σ_T^* denotes the set of all finite strings over Σ_T, including the empty string ε. For integer $k \geq 1$, $(\Sigma_T^*)^k$ denotes the set of all tuples $(w_1, \ldots, w_k)$ of strings $w_i \in \Sigma_T^*$. In what follows we are interested in functions mapping several tuples of strings in Σ_T^* into tuples of strings in Σ_T^*. Let r and f be two integers, $r \geq 0$ and $f \geq 1$. We say that a function g has **rank** r if there exist integers $f_i \geq 1$, $1 \leq i \leq r$, such that g is defined on $(\Sigma_T^*)^{f_1} \times (\Sigma_T^*)^{f_2} \times \cdots \times (\Sigma_T^*)^{f_r}$. We also say that g has **fan-out** f if the range of g is a subset of $(\Sigma_T^*)^f$. Let y_h, x_{ij}, $1 \leq h \leq f$, $1 \leq i \leq r$ and $1 \leq j \leq f_i$, be string-valued variables. A function g as above is said to be **linear regular** if it is defined by an equation of the form

$$g(\langle x_{11}, \ldots, x_{1f_1} \rangle, \ldots, \langle x_{r1}, \ldots, x_{rf_r} \rangle) = \\ = \langle y_1, \ldots, y_f \rangle, \quad (1)$$

where $\langle y_1, \ldots, y_f \rangle$ represents some grouping into f sequences of all and only the variables appearing in the left-hand side of (1) (without repetitions) along with some additional terminal symbols (with possible repetitions).

For a mathematical definition of LCFRS we refer the reader to (Weir, 1992, p. 137). Informally, in a LCFRS every nonterminal symbol A is associated with an integer $\varphi(A) \geq 1$, called its fan-out, and it generates tuples in $(\Sigma_T^*)^{\varphi(A)}$. Productions in a LCFRS have the form

$$p: \quad A \rightarrow g(B_1, B_2, \ldots, B_{\rho(p)}),$$

where $\rho(p) \geq 0$, A and B_i, $1 \leq i \leq \rho(p)$, are nonterminal symbols, and g is a linear regular function having rank $\rho(p)$ and fan-out $\varphi(A)$, defined on $(\Sigma_T^*)^{\varphi(B_1)} \times \cdots \times (\Sigma_T^*)^{\varphi(B_{\rho(p)})}$ and taking values in $(\Sigma_T^*)^{\varphi(A)}$. The basic idea underlying the rewriting relation associated with LCFRS is that production p applies to any sequence of string tuples generated by the B_i's, and provides a new string tuple in $(\Sigma_T^*)^{\varphi(A)}$ obtained through function g. We say that $\varphi(p) = \varphi(A)$ is the **fan-out** of p, and $\rho(p)$ is the **rank** of p.

Example 1 Let L be the language $L = \{a^n b^n a^m b^m a^n b^n a^m b^m \mid n, m \geq 1\}$. A LCFRS generating L is defined by means of the nonterminals S, $\varphi(S) = 1$, and A, $\varphi(A) = 2$, and the productions in figure 1. Observe that nonterminal A generates all tuples of the form $\langle a^n b^n, a^n b^n \rangle$. □

Recognition and parsing for a given LCFRS can be carried out in polynomial time on the length of the input string. This is usually done by exploiting standard dynamic programming techniques; see for instance (Seki et al., 1991).[1] However, the polynomial degree in the running time is a monotonically strictly increasing function that depends on both the rank and the fan-out of the productions in the grammar. To optimize running time, one can then recast the source grammar in such a way that the value of the above function is kept to a minimum. One way to achieve this is by factorizing the productions of a LCFRS, as we now explain.

2.2 Factorization

Consider a LCFRS production of the form $p: \quad A \rightarrow g(B_1, B_2, \ldots, B_{\rho(p)})$, where g is specified as in (1). Let also $\mathcal{C}$ be a subset of $\{B_1, B_2, \ldots, B_{\rho(p)}\}$ such that $|\mathcal{C}| \neq 0$ and $|\mathcal{C}| \neq \rho(p)$. We let $\Sigma_{\mathcal{C}}$ be the alphabet of all variables x_{ij} defined as in (1), for all values of i and j such that $B_i \in \mathcal{C}$ and $1 \leq j \leq f_i$. For each i with $1 \leq i \leq f$, we rewrite each string y_i in (1) in a form $y_i = y'_{i0} z_{i1} y'_{i1} \cdots y'_{id_{i-1}} z_{id_i} y'_{id_i}$, with $d_i \geq 0$, such that the following conditions are all met:

- each z_{ij}, $1 \leq j \leq d_i$, is a string with one or more occurrences of variables, all in $\Sigma_{\mathcal{C}}$;
- each y'_{ij}, $1 \leq j \leq d_i - 1$, is a non-empty string with no occurrences of symbols in $\Sigma_{\mathcal{C}}$;
- y'_{0j} and y'_{0d_i} are (possibly empty) strings with no occurrences of symbols in $\Sigma_{\mathcal{C}}$.

[1] In (Seki et al., 1991) a syntactic variant of LCFRS is used, called multiple context-free grammars.

$$
\begin{array}{ll}
S \rightarrow g_S(A, A), & g_S(\langle x_{11}, x_{12}\rangle, \langle x_{21}, x_{22}\rangle) = \langle x_{11}x_{21}x_{12}x_{22}\rangle; \\
A \rightarrow g_A(A), & g_A(\langle x_{11}, x_{12}\rangle) = \langle ax_{11}b, ax_{12}b\rangle; \\
A \rightarrow g'_A(), & g'_A() = \langle ab, ab\rangle.
\end{array}
$$

Figure 1: A LCFRS for language $L = \{a^n b^n a^m b^m a^n b^n a^m b^m \mid n, m \geq 1\}$.

Let $c = |\mathcal{C}|$ and $\overline{c} = \rho(p) - |\mathcal{C}|$. Assume that $\mathcal{C} = \{B_{h_1}, \ldots, B_{h_c}\}$, and $\{B_1, \ldots, B_{\rho(p)}\} - \mathcal{C} = \{B_{h'_1}, \ldots, B_{h'_{\overline{c}}}\}$. We introduce a fresh nonterminal C with $\varphi(C) = \sum_{i=1}^{f} d_i$ and replace production p in our grammar by means of the two new productions $p_1 : C \rightarrow g_1(B_{h_1}, \ldots, B_{h_c})$ and $p_2 : A \rightarrow g_2(C, B_{h'_1}, \ldots, B_{h'_{\overline{c}}})$. Functions g_1 and g_2 are defined as:

$$
\begin{array}{l}
g_1(\langle x_{h_1 1}, \ldots, x_{h_1 f_{h_1}}\rangle, \ldots, \langle x_{h_c 1}, \ldots, x_{h_c f_{h_c}}\rangle) \\
\quad = \langle z_{11}, \cdots, z_{1d_1}, z_{21}, \cdots, z_{fd_f}\rangle; \\
g_2(\langle x_{h'_1 1}, \ldots, x_{h'_1 f_{h'_1}}\rangle, \ldots, \langle x_{h'_{\overline{c}} 1}, \ldots, x_{h'_{\overline{c}} f_{h'_{\overline{c}}}}\rangle) \\
\quad = \langle y'_{10}, \ldots, y'_{1d_1}, y'_{20}, \ldots, y'_{fd_f}\rangle.
\end{array}
$$

Note that productions p_1 and p_2 have rank strictly smaller than the source production p. Furthermore, if it is possible to choose set $\mathcal{C}$ in such a way that $\sum_{i=0}^{f} d_i \leq f$, then the fan-out of p_1 and p_2 will be no greater than the fan-out of p.

We can iterate the procedure above as many times as possible, under the condition that the fan-out of the productions does not increase.

Example 2 Let us consider the following production with rank 4:

$$
\begin{array}{l}
A \rightarrow g_S(B, C, D, E), \\
\quad g_A(\langle x_{11}, x_{12}\rangle, \langle x_{21}, x_{22}\rangle, \langle x_{31}, x_{32}\rangle, \langle x_{41}, x_{42}\rangle) \\
\quad\quad = \langle x_{11}x_{21}x_{31}x_{41}x_{12}x_{42}, x_{22}x_{32}\rangle.
\end{array}
$$

Applyng the above procedure twice, we obtain a factorization consisting of three productions with rank 2 (variables have been renamed to reflect our conventions):

$$
\begin{array}{l}
A \rightarrow g_A(A_1, A_2), \\
\quad g_A(\langle x_{11}, x_{12}\rangle, \langle x_{21}, x_{22}\rangle) \\
\quad\quad = \langle x_{11}x_{21}x_{12}, x_{22}\rangle; \\
A_1 \rightarrow g_{A_1}(B, E), \\
\quad g_{A_1}(\langle x_{11}, x_{12}\rangle, \langle x_{21}, x_{22}\rangle) = \langle x_{11}, x_{21}x_{12}x_{22}\rangle; \\
A_2 \rightarrow g_{A_2}(C, D), \\
\quad g_{A_2}(\langle x_{11}, x_{12}\rangle, \langle x_{21}, x_{22}\rangle) = \langle x_{11}x_{21}, x_{12}x_{22}\rangle.
\end{array}
$$

□

The factorization procedure above should be applied to all productions of a LCFRS with rank larger than two. This might result in an asymptotic improvement of the running time of existing dynamic programming algorithms for parsing based on LCFRS.

The factorization technique we have discussed can also be viewed as a generalization of well-known techniques for casting context-free grammars into binary forms. These are forms where no more than two nonterminal symbols are found in the right-hand side of productions of the grammar; see for instance (Harrison, 1978). One important difference is that, while production factorization into binary form is always possible in the context-free case, for LCFRS there are worst case grammars in which rank reduction is not possible at all, as shown in (Rambow and Satta, 1999).

3 A graph-based representation for LCFRS productions

Rather than factorizing LCFRS productions directly, in this article we work with a more abstract representation of productions based on graphs. From now on we focus on LCFRS whose nonterminals and productions all have fan-out smaller than or equal to 2. Consider then a production $p : A \rightarrow g(B_1, B_2, \ldots, B_{\rho(p)})$, with $\varphi(A), \varphi(B_i) \leq 2$, $1 \leq i \leq \rho(p)$, and with g defined as

$$
\begin{array}{l}
g(\langle x_{11}, \ldots, x_{1\varphi(B_1)}\rangle, \ldots \\
\quad \ldots, \langle x_{\rho(p)1}, \ldots, x_{\rho(p)\varphi(B_{\rho(p)})}\rangle) \\
\quad = \langle y_1, \ldots, y_{\varphi(A)}\rangle.
\end{array}
$$

In what follows, if $\varphi(A) = 1$ then $\langle y_1, \ldots, y_{\varphi(A)}\rangle$ should be read as $\langle y_1\rangle$ and $y_1 \cdots y_{\varphi(A)}$ should be read as y_1. The same convention applies to all other nonterminals and tuples.

We now introduce a special kind of undirected graph that is associated with a linear order defined over the set of its vertices. The **p-graph** associated with production p is a triple $(V_p, E_p, \prec_p)$ such that

- $V_p = \{x_{ij} \mid 1 \leq i \leq \rho(p),\ \varphi(B_i) = 2,\ 1 \leq j \leq \varphi(B_i)\}$ is a set of vertices;[2]

[2]Here we are overloading symbols x_{ij}. It will always be clear from the context whether x_{ij} is a string-valued variable or a vertex in a p-graph.

- $E_p = \{(x_{i1}, x_{i2}) \mid x_{i1}, x_{i2} \in V_p\}$ is a set of undirected edges;
- for $x, x' \in V_p$, $x \prec_p x'$ if $x \neq x'$ and the (unique) occurrence of x in $y_1 \cdots y_{\varphi(A)}$ precedes the (unique) occurrence of x'.

Note that in the above definition we are ignoring all string-valued variables x_{ij} associated with nonterminals B_i with $\varphi(B_i) = 1$. This is because nonterminals with fan-out one can always be treated as in the context-free grammar case, as it will be explained later.

Example 3 The p-graph associated with the LCFRS production in Example 2 is shown in Figure 2. Circled sets of edges indicate the factorization in that example. □

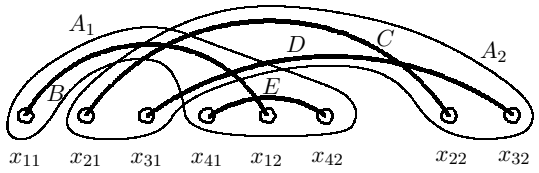

Figure 2: The p-graph associated with the LCFRS production in Example 2.

We close this section by introducing some additional notation related to p-graphs that will be used throughout this paper. Let $E \subseteq E_p$ be some set of edges. The **cover** set for E is defined as $V(E) = \{x \mid (x, x') \in E\}$ (recall that our edges are unordered pairs, so (x, x') and (x', x) denote the same edge). Conversely, let $V \subseteq V_p$ be some set of vertices. The **incident** set for V is defined as $E(V) = \{(x, x') \mid (x, x') \in E_p,\ x \in V\}$.

Assume $\varphi(p) = 2$, and let $x_1, x_2 \in V_p$. If x_1 and x_2 do not occur both in the same string y_1 or y_2, then we say that there is a **gap** between x_1 and x_2. If $x_1 \prec_p x_2$ and there is no gap between x_1 and x_2, then we write $[x_1, x_2]$ to denote the set $\{x_1, x_2\} \cup \{x \mid x \in V_p,\ x_1 \prec_p x \prec_p x_2\}$. For $x \in V_p$ we also let $[x, x] = \{x\}$. A set $[x, x']$ is called a **range**. Let r and r' be two ranges. The pair (r, r') is called a **tandem** if the following conditions are both satisfied: (i) $r \cup r'$ is not a range, and (ii) there exists some edge $(x, x') \in E_p$ with $x \in r$ and $x' \in r'$. Note that the first condition means that r and r' are disjoint sets and, for any pair of vertices $x \in r$ and $x' \in r'$, either there is a gap between x and x' or else there exists some $x_g \in V_p$ such that $x \prec_p x_g \prec_p x'$ and $x_g \notin r \cup r'$.

A set of edges $E \subseteq E_p$ is called a **bundle** with fan-out one if $V(E) = [x_1, x_2]$ for some $x_1, x_2 \in V_p$, i.e., $V(E)$ is a range. Set E is called a bundle with fan-out two if $V(E) = [x_1, x_2] \cup [x_3, x_4]$ for some $x_1, x_2, x_3, x_4 \in V_p$, and $([x_1, x_2], [x_3, x_4])$ is a tandem. Note that if E is a bundle with fan-out two with $V(E) = [x_1, x_2] \cup [x_3, x_4]$, then neither $E([x_1, x_2])$ nor $E([x_3, x_4])$ are bundles with fan-out one, since there is at least one edge incident upon a vertex in $[x_1, x_2]$ and a vertex in $[x_3, x_4]$. We also use the term bundle to denote a bundle with fan-out either one or two.

Intuitively, in a p-graph associated with a LCFRS production p, a bundle E with fan-out f and with $|E| > 1$ identifies a set of nonterminals $\mathcal{C}$ in the right-hand side of p that can be factorized into a new production. The nonterminals in $\mathcal{C}$ are then replaced in p by a fresh nonterminal C with fan-out f, as already explained. Our factorization algorithm is based on efficient methods for the detection of bundles with fan-out one and two.

4 The algorithm

In this section we provide an efficient, recursive algorithm for the decomposition of a p-graph into bundles, which corresponds to factorizing the represented LCFRS production.

4.1 Overview of the algorithm

The basic idea underlying our graph-based algorithm can be described as follows. We want to compute an optimal hierarchical decomposition of an input bundle with fan-out 1 or 2. This decomposition can be represented by a tree, in which each node N corresponds to a bundle (the root node corresponds to the input bundle) and the daughters of N represent the bundles in which N is immediately decomposed. The decomposition is optimal in so far as the maximum arity of the decomposition tree is as small as possible. As already explained above, this decomposition represents a factorization of some production p of a LCFRS, resulting in optimal rank reduction. All the internal nodes in the decomposition represent fresh nonterminals that will be created during the factorization process.

The construction of the decomposition tree is carried out recursively. For a given bundle with fan-out 1 or 2, we apply a procedure for decomposing this bundle in its immediate sub-bundles with fan-out 1 or 2, in an optimal way. Then,

we recursively apply our procedure to the obtained sub-bundles. Recursion stops when we reach bundles containing only one edge (which correspond to the nonterminals in the right-hand side of the input production). We shall prove that the result is an optimal decomposition.

The procedure for computing an optimal decomposition of a bundle F into its immediate sub-bundles, which we describe in the first part of this section, can be sketched as follows. First, we identify and temporarily remove all maximal bundles with fan-out 1 (Section 4.3). The result is a new bundle F' which is a subset of the original bundle, and has the same fan-out. Next, we identify all sub-bundles with fan-out 2 in F' (Section 4.4). We compute the optimal decomposition of F', resting on the hypothesis that there are no sub-bundles with fan-out 1. Each resulting sub-bundle is later expanded with the maximal sub-bundles with fan-out 1 that have been previously removed. This results in a "first level" decomposition of the original bundle F. We then recursively decompose all individual sub-bundles of F, including the bundles with fan-out 1 that have been later attached.

4.2 Backward and forward quantities

For a set $V \subseteq V_p$ of vertices, we write $\max(V)$ (resp. $\min(V)$) the maximum (resp. minimum) vertex in V w.r.t. the $\prec_p$ total order.

Let $r = [x_1, x_2]$ be a range. We write $r.left = x_1$ and $r.right = x_2$. The set of backward edges for r is defined as $B_r = \{(x, x') \,|\, (x, x') \in E_r,\ x \prec_p r.left,\ x' \in r\}$. The set of forward edges for r is defined symmetrically as $F_r = \{(x, x') \,|\, (x, x') \in E_r,\ x \in r,\ r.right \prec_p x'\}$. For $E \in \{B_r, F_r\}$ we also define $L(E) = \{x \,|\, (x, x') \in E,\ x \prec_p x'\}$ and $R(E) = \{x' \,|\, (x, x') \in E,\ x \prec_p x'\}$.

Let us assume $B_r \neq \emptyset$. We write $r.b.left = \min(L(B_r))$. Intuitively, $r.b.left$ is the leftmost vertex of the p-graph that is located at the left of range r and that is connected to some vertex in r through some edge. Similarly, we write $r.b.right = \max(L(B_r))$. If $B_r = \emptyset$, then we set $r.b.left = r.b.right = \bot$. Quantities $r.b.left$ and $r.b.right$ are called **backward** quantities.

We also introduce **local backward** quantities, defined as follows. We write $r.lb.left = \min(R(B_r))$. Intuitively, $r.lb.left$ is the leftmost vertex among all those vertices in r that are connected to some vertex to the left of r. Similarly, we write $r.lb.right = \max(R(B_r))$. If $B_r = \emptyset$, then we set $r.lb.left = r.lb.right = \bot$.

We define **forward** and **local forward** quantities in a symmetrical way.

The backward quantities $r.b.left$ and $r.b.right$ and the local backward quantities $r.lb.left$ and $r.lb.right$ for all ranges r in the p-graph can be computed efficiently as follows. We process ranges in increasing order of size, expanding each range r by one unit at a time by adding a new vertex at its right. Backward and local backward quantities for the expanded range can be expressed as a function of the same quantities for r. Therefore if we store our quantities for previously processed ranges, each new range can be annotated with the desired quantities in constant time. This algorithm runs in time $\mathcal{O}(n^2)$, where n is the number of vertices in V_p. This is an optimal result, since $\mathcal{O}(n^2)$ is also the size of the output.

We compute in a similar way the forward quantities $r.f.left$ and $r.f.right$ and the local forward quantities $r.lf.left$ and $r.lf.right$, this time expanding each range by one unit at its left.

4.3 Bundles with fan-out one

The detection of bundles with fan-out 1 within the p-graph can be easily performed in $\mathcal{O}(n^2)$, where n is the number of its vertices. Indeed, the incident set $E(r)$ of a range r is a bundle with fan-out one if and only if $r.b.left = r.f.left = \bot$. This immediately follows from the definitions given in Section 4.2. It is therefore possible to check all ranges the one after the other, once the backward and forward properties have been computed. These checks take constant time for each of the $\Theta(n^2)$ ranges, hence the quadratic complexity.

We now remove from F all bundles with fan-out 1 from the original bundle F. The result is the new bundle F', that has no sub-bundles with fan-out 1.

4.4 Bundles with fan-out two

Efficient detection of bundles with fan-out two in F' is considerably more challenging. A direct generalization of the technique proposed for detecting bundles with fan-out 1 would use the following property, that is also a direct corollary of the definitions in Section 4.2: the incident set $E(r \cup r')$ of a tandem (r, r') is a bundle with fan-out two if and only if all of the following conditions hold: (i) $r.b.left = r'.f.left = \bot$, (ii) $r.f.left \in r'$, $r.f.right \in r'$, (iii) $r'.b.left \in r$, $r'.b.right \in r$.

However, checking all $\mathcal{O}(n^4)$ tandems the one after the other would require time $\mathcal{O}(n^4)$. Therefore, preserving the quadratic complexity of the overall algorithm requires a more complex representation.

From now on, we assume that $V_p = \{x_1, \ldots, x_n\}$, and we write $[i, j]$ as a shorthand for the range $[x_i, x_j]$.

First, we need to compute an additional data structure that will store local backward figures in a convenient way. Let us define the **expansion table** T as follows: for a given range $r' = [i', j']$, $T(r')$ is the set of all ranges $r = [i, j]$ such that $r.lb.left = i'$ and $r.lb.right = j'$, ordered by increasing left boundary i. It turns out that the construction of such a table can be achieved in time $\mathcal{O}(n^2)$. Moreover, it is possible to compute in $\mathcal{O}(n^2)$ an auxiliary table T' that associates with r the first range r'' in $T([r.f.left, r.f.right])$ such that $r''.b.right \geq r$. Therefore, either $(r, T'(r))$ anchors a valid bundle, or there is no bundle E such that the first component of $V(E)$ is r.

We now have all the pieces to extract bundles with fan-out 2 in time $\mathcal{O}(n^2)$. We proceed as follows. For each range $r = [i, j]$:

- We first retrieve $r' = [r.f.left, r.f.right]$ in constant time.
- Then, we check in constant time whether $r'.b.left$ lies within r. If it doesn't, r is not the first part of a valid bundle with fan-out 2, and we move on to the next range r.
- Finally, for each r'' in the ordered set $T(r')$, starting with $T'(r)$, we check whether $r''.b.right$ is inside r. If it is not, we stop and move on to the next range r. If it is, we output the valid bundle (r, r'') and move on to the next element in $T(r')$. Indeed, in case of a failure, the backward edge that relates a vertex in r'' with a vertex outside r will still be included in all further elements in $T(r')$ since $T(r')$ is ordered by increasing left boundary. This step costs a constant time for each success, and a constant time for the unique failure, if any.

This algorithm spends a constant time on each range plus a constant time on each bundle with fan-out 2. We shall prove in Section 5 that there are $\mathcal{O}(n^2)$ bundles with fan-out 2. Therefore, this algorithm runs in time $\mathcal{O}(n^2)$.

Now that we have extracted all bundles, we need to extract an optimal decomposition of the input bundle F', i.e., a minimal size partition of all n elements (edges) in the input bundle such that each of these partition is a bundle (with fan-out 2, since bundles with fan-out 1 are excluded, except for the input bundle). By definition, a partition has minimal size if there is no other partition it is a refinment of.[3]

4.5 Extracting an optimal decomposition

We have constructed the set of all (fan-out 2) sub-bundles of F'. We now need to build one optimal decomposition of F' into sub-bundles. We need some more theoretical results on the properties of bundles.

Lemma 1 *Let E_1 and E_2 be two sub-bundles of F' (with fan-out 2) that have non-empty intersection, but that are not included the one in the other. Then $E_1 \cup E_2$ is a bundle (with fan-out 2).*

PROOF This lemma can be proved by considering all possible respective positions of the covers of E_1 and E_2, and discarding all situations that would lead to the existence of a fan-out 1 sub-bundle. ■

Theorem 1 *For any bundle E, either it has at least one binary decomposition, or all its decompositions are refinements of a unique optimal one.*

PROOF Let us suppose that E has no binary decomposition. Its cover corresponds to the tandem $(r, r') = ([i, j], [i', j'])$. Let us consider two different decompositions of E, that correspond respectively to decompositions of the range r in two sets of sub-ranges of the form $[i, k_1], [k_1 + 1, k_2], \ldots, [k_m, j]$ and $[i, k'_1], [k'_1 + 1, k'_2], \ldots, [k'_{m'}, j]$. For simplifying the notations, we write $k_0 = k'_0 = i$ and $k_{m+1} = k_{m'+1} = j$. Since $k_0 = k'_0$, there exist an index $p > 0$ such that for any $l < p$, $k_l = k'_l$, but $k_p \neq k'_p$: p is the index that identifies the first discrepancy between both decomposition. Since $k_{m+1} = k_{m'+1}$, there must exist $q \leq m$ and $q' \leq m'$ such that q and q' are strictly greater than p and that are the minimal indexes such that $k_q = k'_{q'}$. By definition, all bundles of the form $E_{[k_{l-1}, k_l]}$ ($p \leq l \leq q$) have a non-empty intersection with at least one bundle of the form $E_{[k'_{l-1}, k'_l]}$

[3] The term "refinement" is used in the usual way concerning partitions, i.e., a partition P_1 is a refinement of another one P_2 if all constituents in P_1 are constituents of P_2, or belongs to a subset of the partition P_1 that is a partition of one element of P_2.

($p \leq l \leq q'$). The reverse is true as well. Applying Lemma 1, this shows that $E([k_{p+1}, k_q])$ is a bundle with fan-out 2. Therefore, by replacing all ranges involved in this union in one decomposition or the other, we get a third decomposition for which the two initial ones are strict refinements. This is a contradiction, which concludes the proof. ∎

Lemma 2 *Let $E = V(r \cup r')$ be a bundle, with $r = [i, j]$. We suppose it has a unique (non-binary) optimal decomposition, which decomposes $[i, j]$ into $[i, k_1], [k_1 + 1, k_2], \ldots, [k_m, j]$. There exist no range $r'' \subset r$ such that (i) $E_{r''}$ is a bundle and (ii) $\exists l$, $1 \leq l \leq m$ such that $[k_l, k_{l+1}] \subset r''$.*

PROOF Let us consider a range r'' that would contradict the lemma. The union of r'' and of the ranges in the optimal decomposition that have a non-empty intersection with r'' is a fan-out 2 bundle that includes at least two elements of the optimal decomposition, but that is strictly included in E because the decomposition is not binary. This is a contradiction. ∎

Lemma 3 *Let $E = V(r, r')$ be a bundle, with $r = [i, j]$. We suppose it has a binary (optimal) decomposition (not necessarily unique). Let $r'' = [i, k]$ be the largest range starting in i such that $k < j$ and such that it anchors a bundle, namely $E(r'')$. Then $E(r'')$ and $E([k + 1, j])$ form a binary decomposition of E.*

PROOF We need to prove that $E([k + 1, j])$ is a bundle. Each (optimal) binary decomposition of E decomposes r in 1, 2 or 3 sub-ranges. If no optimal decomposition decomposes r in at least 2 sub-ranges, then the proof given here can be adapted by reasoning on r' instead of r. We now suppose that at least one of them decomposes r in at least 2 sub-ranges. Therefore, it decomposes r in $[i, k_1]$ and $[k_1 + 1, j]$ or in $[i, k_1]$, $[k_1 + 1, k_2]$ and $[k_2 + 1, j]$. We select one of these optimal decomposition by taking one such that k_1 is maximal. We shall now distinguish between two cases.

First, let us suppose that r is decomposed into two sub-ranges $[i, k_1]$ and $[k_1 + 1, j]$ by the selected optimal decomposition. Obviously, $E([i, k_1])$ is a "crossing" bundle, i.e., the right component of its cover is is a sub-range of r'. Since r is decomposed in two sub-ranges, it is necessarily the same for r'. Therefore, $E([i, k_1])$ has a cover of the form $[i, k_1] \cup [i', k'_1]$ or $[i, k_1] \cup [k'_1 + 1, j]$. Since r'' includes $[i, k_1]$, $E(r'')$ has a cover of the form $[i, k] \cup [i', k']$ or $[i, k] \cup [k' + 1, j]$. This means that r' is decomposed by $E(r'')$ in only 2 ranges, namely the right component of $E(r'')$'s cover and another range, that we can call r'''. Since $r \setminus r'' = [k + 1, j]$ may not anchor a bundle with fan-out 1, it must contain at least one crossing edge. All such edges necessarily fall within r'''. Conversely, any crossing edge that falls inside r''' necessarily has its other end inside $[k + 1, j]$. Which means that $E(r'')$ and $E(r''')$ form a binary decomposition of E. Therefore, by definition of k_1, $k = k_1$.

Second, let us suppose that r is decomposed into 3 sub-ranges by the selected original decomposition (therefore, r' is not decomposed by this decomposition). This means that this decomposition involves a bundle with a cover of the form $[i, k_1] \cup [k_2 + 1, j]$ and another bundle with a cover of the form $[k_1 + 1, k_2] \cup r'$ (this bundle is in fact $E(r')$). If $k \geq k_2$, then the left range of both members of the original decomposition are included in r'', which means that $E(r'') = E$, and therefore $r'' = r$ which is excluded. Note that k is at least as large as k_1 (since $[i, k_1]$ is a valid "range starting in i such that $k < j$ and such that it anchors a bundle"). Therefore, we have $k_1 \leq k < k_2$. Therefore, $E([i, k_1]) \subset E(r'')$, which means that all edges anchored inside $[k_2 + 1, j])$ are included in $E(r'')$. Hence, $E(r'')$ can not be a crossing bundle without having a left component that is $[i, j]$, which is excluded (it would mean $E(r'') = E$). This means that $E(r'')$ is a bundle with a cover of the form $[i, k] \cup [k' + 1, j]$. Which means that $E(r')$ is in fact the bundle whose cover is $[k + 1, k' + 1] \cup r'$. Hence, $E(r'')$ and $E(r')$ form a binary decomposition of E. Hence, by definition of k_1, $k = k_1$. ∎

As an immediate consequence of Lemmas 2 and 3, our algorithm for extracting the optimal decomposition for F' consists in applying the following procedure recursively, starting with F', and repeating it on each constructed sub-bundle E, until sub-bundles with only one edge are reached.

Let $E = E(r, r')$ be a bundle, with $r = [i, j]$. One optimal decomposition of E can be obtained as follows. One selects the bundle with a left component starting in i and with the maximum length, and iterating this selection process until r is covered. The same is done with r'. We retain the optimal among both resulting decompositions (or one of them if they are both optimal). Note that this

decomposition is unique if and only if it has four components or more; it can not be ternary; it may be binary, and in this case it may be non-unique.

This algorithm gives us a way to extract an optimal decomposition of F' in linear time w.r.t. the number of sub-bundles in this optimal decomposition. The only required data structure is, for each i (resp. k), the list of bundles with a cover of the form $[i,j] \cup [k,l]$ ordered by decreasing j (resp. l). This can trivially be constructed in time $\mathcal{O}(n^2)$ from the list of all bundles we built in time $\mathcal{O}(n^2)$ in the previous section. Since the number of bundles is bounded by $\mathcal{O}(n^2)$ (as mentioned above and proved in Section 5), this means we can extract an optimal decomposition for F' in $\mathcal{O}(n^2)$.

Similar ideas apply to the simpler case of the decomposition of bundles with fan-out 1.

4.6 The main decomposition algorithm

We now have to generalize our algorithm in order to handle the possible existence of fan-out 1 bundles. We achieve this by using the fan-out 2 algorithm recursively. First, we extract and remove (maximal) bundles with fan-out 1 from F, and recursively apply to each of them the complete algorithm. What remains is F', which is a set of bundles with no sub-bundles with fan-out 1. This means we can apply the algorithm presented above. Then, for each bundle with fan-out 1, we group it with a randomly chosen adjacent bundle with fan-out 2, which builds an expanded bundle with fan-out 2, which has a binary decomposition into the original bundle with fan-out 2 and the bundle with fan-out 1.

5 Time complexity analysis

In Section 4, we claimed that there are no more than $\mathcal{O}(n^2)$ bundles. In this section we sketch the proof of this result, which will prove the quadratic time complexity of our algorithm.

Let us compute an upper bound on the number of bundles with fan-out two that can be found within the p-graph processed in Section 4.5, i.e., a p-graph with no fan-out 1 sub-bundle.

Let $E, E' \subseteq E_p$ be bundles with fan-out two. If $E \subset E'$, then we say that E' **expands** E. E' is said to **immediately** expand E, written $E \rightarrow E'$, if E' expands E and there is no bundle E'' such that E'' expands E and E' expands E''.

Let us represent bundles and the associated immediate expansion relation by means of a graph. Let $\mathcal{E}$ denote the set of all bundles (with fan-out two) in our p-graph. The **e-graph** associated with our LCFRS production p is the directed graph with vertices $\mathcal{E}$ and edges defined by the relation $\rightarrow$. For $E \in \mathcal{E}$, we let $out(E) = \{E' \mid E \rightarrow E'\}$ and $in(E) = \{E' \mid E' \rightarrow E\}$.

Lack of space prevents us from providing the proof of the following property. For any $E \in \mathcal{E}$ that contains more than one edge, $|out(E)| \leq 2$ and $|in(E)| \geq 2$. This allows us to prove our upper bound on the size of $\mathcal{E}$.

Theorem 2 *The e-graph associated with an* LCFRS *production p has at most n^2 vertices, where n is the rank of p.*

PROOF Consider the e-graph associated with production p, with set of vertices $\mathcal{E}$. For a vertex $E \in \mathcal{E}$, we define the **level** of E as the number $|E|$ of edges in the corresponding bundle from the p-graph associated with p. Let d be the maximum level of a vertex in $\mathcal{E}$. We thus have $1 \leq d \leq n$. We now prove the following claim. For any integer k with $1 \leq k \leq d$, the set of vertices in $\mathcal{E}$ with level k has no more than n elements.

For $k = 1$, since there are no more than n edges in such a p-graph, the statement holds.

We can now consider all vertices in $\mathcal{E}$ with level $k > 1$ ($k \leq d$). Let $\mathcal{E}^{(k-1)}$ be the set of all vertices in $\mathcal{E}$ with level smaller than or equal to $k-1$, and let us call $T^{(k-1)}$ the set of all edges in the e-graph that are leaving from some vertex in $\mathcal{E}^{(k-1)}$. Since for each bundle E in $\mathcal{E}^{(k-1)}$ we know that $|out(E)| \leq 2$, we have $|T^{(k-1)}| \leq 2|\mathcal{E}^{(k-1)}|$.

The number of vertices in $\mathcal{E}^{(k)}$ with level larger than one is at least $|\mathcal{E}^{(k-1)}| - n$. Since for each $E \in \mathcal{E}^{(k-1)}$ we know that $|in(E)| \geq 2$, we conclude that at least $2(|\mathcal{E}^{(k-1)}| - n)$ edges in $T^{(k-1)}$ must end up at some vertex in $\mathcal{E}^{(k)}$. Let T be the set of edges in $T^{(k-1)}$ that impinge on some vertex in $\mathcal{E} \setminus \mathcal{E}^{(k)}$. Thus we have $|T| \leq 2|\mathcal{E}^{(k-1)}| - 2(|\mathcal{E}^{(k-1)}| - n) = 2n$. Since the vertices of level k in $\mathcal{E}$ must have incoming edges from set T, and because each of them have at least 2 incoming edges, there cannot be more than n such vertices. This concludes the proof of our claim.

Since the the level of a vertex in $\mathcal{E}$ is necessarily lower than n, this completes the proof. ∎

The overall complexity of the complete algorithm can be computed by induction. Our induction hypothesis is that for $m < n$, the time complexity is in $\mathcal{O}(m^2)$. This is obviously true for $n = 1$ and $n = 2$. Extracting the bundles

with fan-out 1 costs $\mathcal{O}(n^2)$. These bundles are of length $n_1 \dots n_m$. Extracting bundles with fan-out 2 costs $\mathcal{O}((n - n_1 - \dots - n_m)^2)$. Applying recursively the algorithm to bundles with fan-out 1 costs $\mathcal{O}(n_1^2) + \dots + \mathcal{O}(n_m^2)$. Therefore, the complexity is in $\mathcal{O}(n^2) + \mathcal{O}((n - n_1 - \dots - n_m)^2) + \sum_{i=1}^{n} \mathcal{O}(n_i) = \mathcal{O}(n^2) + \mathcal{O}(\sum_{i=1}^{n} n_i) = \mathcal{O}(n^2)$.

6 Conclusion

We have introduced an efficient algorithm for optimal reduction of the rank of LCFRSs with fan-out at most 2, that runs in quadratic time w.r.t. the rank of the input grammar. Given the fact that fan-out 1 bundles can be attached to any adjacent bundle in our factorization, we can show that our algorithm also optimizes time complexity for known tabular parsing algorithms for LCFRSs with fan-out 2.

As for general LCFRS, it has been shown by Gildea (2010) that rank optimization and time complexity optimization are not equivalent. Furthermore, all known algorithms for rank or time complexity optimization have an exponential time complexity (Gómez-Rodríguez et al., 2009).

Abstract

Combinatory Categorial Grammar (CCG) is generally construed as a fully lexicalized formalism, where all grammars use one and the same universal set of rules, and cross-linguistic variation is isolated in the lexicon. In this paper, we show that the weak generative capacity of this 'pure' form of CCG is strictly smaller than that of CCG with grammar-specific rules, and of other mildly context-sensitive grammar formalisms, including Tree Adjoining Grammar (TAG). Our result also carries over to a multi-modal extension of CCG.

1 Introduction

Combinatory Categorial Grammar (CCG) (Steedman, 2001; Steedman and Baldridge, 2010) is an expressive grammar formalism with formal roots in combinatory logic (Curry et al., 1958) and links to the type-logical tradition of categorial grammar (Moortgat, 1997). It has been successfully used for a wide range of practical tasks, such as data-driven parsing (Hockenmaier and Steedman, 2002; Clark and Curran, 2007), wide-coverage semantic construction (Bos et al., 2004), and the modelling of syntactic priming (Reitter et al., 2006).

It is well-known that CCG can generate languages that are not context-free (which is necessary to capture natural languages), but can still be parsed in polynomial time. Specifically, Vijay-Shanker and Weir (1994) identified a version of CCG that is weakly equivalent to Tree Adjoining Grammar (TAG) (Joshi and Schabes, 1997) and other mildly context-sensitive grammar formalisms, and can generate non-context-free languages such as $a^n b^n c^n$. The generative capacity of CCG is commonly attributed to its flexible *composition* rules, which allow it to model more complex word orders that context-free grammar can.

The discussion of the (weak and strong) generative capacity of CCG and TAG has recently been revived (Hockenmaier and Young, 2008; Koller and Kuhlmann, 2009). In particular, Koller and Kuhlmann (2009) have shown that CCGs that are *pure* (i.e., they can only use generalized composition rules, and there is no way to restrict the instances of these rules that may be used) and *first-order* (i.e., all argument categories are atomic) can *not* generate $a^n b^n c^n$. This shows that the generative capacity of at least first-order CCG crucially relies on its ability to restrict rule instantiations, and is at odds with the general conception of CCG as a fully lexicalized formalism, in which all grammars use one and the same set of universal rules. A question then is whether the result carries over to pure CCG with higher-order categories.

In this paper, we answer this question to the positive: We show that the weak generative capacity of general pure CCG is still strictly smaller than that of the formalism considered by Vijay-Shanker and Weir (1994); composition rules can only achieve their full expressive potential if their use can be restricted. Our technical result is that every language L that can be generated by a pure CCG has a context-free sublanguage $L' \subseteq L$ such that every string in L is a permutation of a string in L', and vice versa. This means that $a^n b^n c^n$, for instance, cannot be generated by pure CCG, as it does not have any (non-trivial) permutation-equivalent sublanguages. Conversely, we show that there are still languages that can be generated by pure CCG but not by context-free grammar.

We then show that our permutation language lemma also holds for pure *multi-modal* CCG as defined by Baldridge and Kruijff (2003), in which the use of rules can be controlled through the lexicon entries by assigning types to slashes. Since this extension was intended to do away with the need for grammar-specific rule restrictions, it comes as quite a surprise that pure multi-modal

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 534–543,
Uppsala, Sweden, 11-16 July 2010.

CCG in the style of Baldridge and Kruijff (2003) is still less expressive than the CCG formalism used by Vijay-Shanker and Weir (1994). This means that word order in CCG cannot be fully lexicalized with the current formal tools; some ordering constraints must be specified via language-specific combination rules and not in lexicon entries. On the other hand, as pure multi-modal CCG has been successfully applied to model the syntax of a variety of natural languages, another way to read our results is as contributions to a discussion about the exact expressiveness needed to model natural language.

The remainder of this paper is structured as follows. In Section 2, we introduce the formalism of *pure* CCG that we consider in this paper, and illustrate the relevance of rule restrictions. We then study the generative capacity of pure CCG in Section 3; this section also presents our main result. In Section 4, we show that this result still holds for multi-modal CCG. Section 5 concludes the paper with a discussion of the relevance of our findings.

2 Combinatory Categorial Grammar

We start by providing formal definitions for categories, syntactic rules, and grammars, and then discuss the relevance of rule restrictions for CCG.

2.1 Categories

Given a finite set A of *atomic categories*, the *set of categories over* A is the smallest set C such that $A \subseteq C$, and $(\mathsf{x}/\mathsf{y}), (\mathsf{x}\backslash\mathsf{y}) \in C$ whenever $\mathsf{x}, \mathsf{y} \in C$. A category x/y represents a function that seeks a string with category y to the right (indicated by the forward slash) and returns a new string with category x; a category $\mathsf{x}\backslash\mathsf{y}$ instead seeks its argument to the left (indicated by the backward slash). In the remainder of this paper, we use lowercase sans-serif letters such as $\mathsf{x}, \mathsf{y}, \mathsf{z}$ as variables for categories, and the vertical bar $|$ as a variable for slashes. In order to save some parentheses, we understand slashes as left-associative operators, and write a category such as $(\mathsf{x}/\mathsf{y})\backslash\mathsf{z}$ as $\mathsf{x}/\mathsf{y}\backslash\mathsf{z}$.

The list of *arguments* of a category c is defined recursively as follows: If c is atomic, then it has no arguments. If $\mathsf{c} = \mathsf{x}|\mathsf{y}$ for some categories x and y, then the arguments of c are the slashed category $|\mathsf{y}$, plus the arguments of x. We number the arguments of a category from outermost to innermost. The *arity* of a category is the number of its arguments. The *target* of a category c is the atomic category that remains when stripping c of its arguments.

x/y	y	$\Rightarrow$	x	forward application $>$
y	$\mathsf{x}\backslash\mathsf{y}$	$\Rightarrow$	x	backward application $<$
x/y	y/z	$\Rightarrow$	x/z	forward harmonic composition $>\mathsf{B}$
$\mathsf{y}\backslash\mathsf{z}$	$\mathsf{x}\backslash\mathsf{y}$	$\Rightarrow$	$\mathsf{x}\backslash\mathsf{z}$	backward harmonic composition $<\mathsf{B}$
x/y	$\mathsf{y}\backslash\mathsf{z}$	$\Rightarrow$	$\mathsf{x}\backslash\mathsf{z}$	forward crossed composition $>\mathsf{B}_\times$
y/z	$\mathsf{x}\backslash\mathsf{y}$	$\Rightarrow$	x/z	backward crossed composition $<\mathsf{B}_\times$

Figure 1: The core set of rules of CCG.

2.2 Rules

The syntactic rules of CCG are directed versions of combinators in the sense of combinatory logic (Curry et al., 1958). Figure 1 lists a core set of commonly assumed rules, derived from functional application and the B combinator, which models functional composition. When talking about these rules, we refer to the premise containing the argument $|\mathsf{y}$ as the *primary premise*, and to the other premise as the *secondary premise* of the rule.

The rules in Figure 1 can be generalized into composition rules of higher degrees. These are defined as follows, where $n \geq 0$ and β is a variable for a sequence of n arguments.

x/y	$\mathsf{y}\beta$	$\Rightarrow$	$\mathsf{x}\beta$	generalized forward composition $>^n$
$\mathsf{y}\beta$	$\mathsf{x}\backslash\mathsf{y}$	$\Rightarrow$	$\mathsf{x}\beta$	generalized backward composition $<^n$

We call the value n the *degree* of the composition rule. Note that the rules in Figure 1 are the special cases for $n = 0$ and $n = 1$.

Apart from the core rules given in Figure 1, some versions of CCG also use rules derived from the S and T combinators of combinatory logic, called *substitution* and *type-raising*, the latter restricted to the lexicon. However, since our main point of reference in this paper, the CCG formalism defined by Vijay-Shanker and Weir (1994), does *not* use such rules, we will not consider them here, either.

2.3 Grammars and Derivations

With the set of rules in place, we can define a *pure combinatory categorial grammar* (PCCG) as a construct $G = (A, \Sigma, L, \mathsf{s})$, where A is an alphabet of *atomic categories*, $\mathsf{s} \in A$ is a distinguished atomic category called the *final category*, Σ is a finite set of *terminal symbols*, and L is a finite relation between symbols in Σ and categories over A, called the *lexicon*. The elements of the lexicon L are called *lexicon entries*, and we represent them using the notation $\sigma \vdash \mathsf{x}$, where $\sigma \in \Sigma$ and x is a category over A. A category that occurs in a lexicon entry is called a *lexical category*.

A derivation in a grammar G can be represented as a *derivation tree* as follows. Given a string $w \in \Sigma^*$, we choose a lexicon entry for each occurrence of a symbol in w, line up the respective lexical categories from left to right, and apply admissible rules to adjacent pairs of categories. After the application of a rule, only the conclusion is available for future applications. We iterate this process until we end up with a single category. The string w is called the *yield* of the resulting derivation tree. A derivation tree is *complete*, if the last category is the final category of G. The *language generated by* G, denoted by $L(G)$, is formed by the yields of all complete derivation trees.

2.4 Degree Restrictions

Work on CCG generally assumes an upper bound on the degree of composition rules that can be used in derivations. We also employ this restriction, and only consider grammars with compositions of some bounded (but arbitrary) degree $n \geq 0$.[1] CCG with unbounded-degree compositions is more expressive than bounded-degree CCG or TAG (Weir and Joshi, 1988).

Bounded-degree grammars have a number of useful properties, one of which we mention here. The following lemma rephrases Lemma 3.1 in Vijay-Shanker and Weir (1994).

Lemma 1 *For every grammar G, every argument in a derivation of G is the argument of some lexical category of G.*

As a consequence, there is only a finite number of categories that can occur as arguments in some derivation. In the presence of a bound on the degree of composition rules, this implies the following:

Lemma 2 *For every grammar G, there is a finite number of categories that can occur as secondary premises in derivations of G.*

Proof. The arity of a secondary premise c can be written as $m + n$, where m is the arity of the first argument of the corresponding primary premise, and n is the degree of the rule applied. Since each argument is an argument of some lexical category of G (Lemma 1), and since n is assumed to be bounded, both m and n are bounded. Hence, there is a bound on the number of choices for c. ∎

Note that the number of categories that can occur as *primary* premises is generally unbounded even in a grammar with bounded degree.

[1] For practical grammars, $n \leq 4$.

2.5 Rule Restrictions

The rule set of pure CCG is universal: the difference between the grammars of different languages should be restricted to different choices of categories in the lexicon. This is what makes pure CCG a lexicalized grammar formalism (Steedman and Baldridge, 2010). However, most practical CCG grammars rely on the possibility to exclude or restrict certain rules. For example, Steedman (2001) bans the rule of forward crossed composition from his grammar of English, and stipulates that the rule of backward crossed composition may be applied only if both of its premises share the common target category s, representing sentences. Exclusions and restrictions of rules are also assumed in much of the language-theoretic work on CCG. In particular, they are essential for the formalism used in the aforementioned equivalence proof for CCG and TAG (Vijay-Shanker and Weir, 1994).

To illustrate the formal relevance of rule restrictions, suppose that we wanted to write a pure CCG that generates the language

$$L_3 \;=\; \{\, a^n b^n c^n \mid n \geq 1 \,\},$$

which is not context-free. An attempt could be

$$G_1 \;=\; (\{\mathsf{s},\mathsf{a},\mathsf{b},\mathsf{c}\},\{a,b,c\},L,\mathsf{s}),$$

where the lexicon L is given as follows:

$$a \vdash \mathsf{a}\,,\; b \vdash \mathsf{s/c\backslash a}\,,\; b \vdash \mathsf{b/c\backslash a}\,,$$
$$b \vdash \mathsf{s/c/b\backslash a}\,,\; b \vdash \mathsf{s/c/b\backslash a}\,,\; c \vdash \mathsf{c}\,.$$

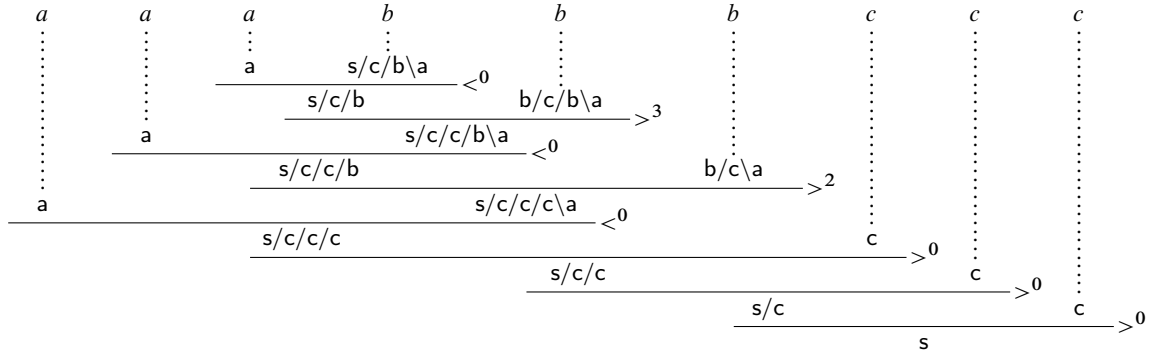
From a few sample derivations like the one given in Figure 2a, we can convince ourselves that G_1 generates all strings of the form $a^n b^n c^n$, for any $n \geq 1$. However, a closer inspection reveals that it also generates other, unwanted strings—in particular, strings of the form $(ab)^n c^n$, as witnessed by the derivation given in Figure 2b.

Now suppose that we would have a way to only allow those instances of generalized composition in which the secondary premise has the form $\mathsf{b/c/b\backslash a}$ or $\mathsf{b/c\backslash a}$. Then the compositions

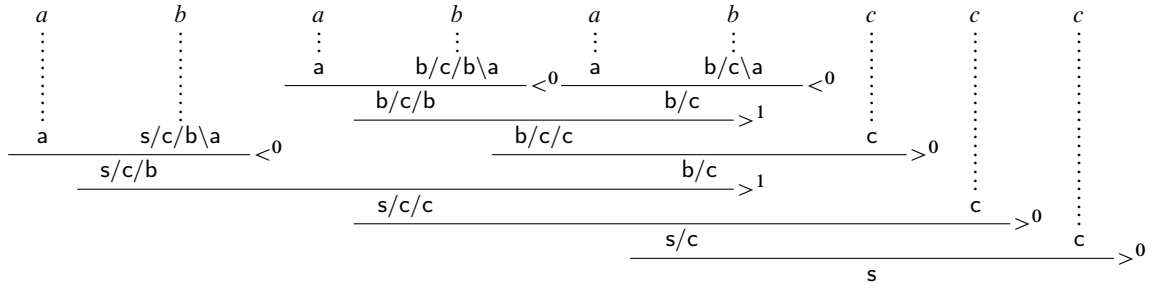
$$\frac{\mathsf{b/c/b}\quad\mathsf{b/c}}{\mathsf{b/c/c}}\,{>}^1 \quad\text{and}\quad \frac{\mathsf{s/c/b}\quad\mathsf{b/c}}{\mathsf{s/c/c}}\,{>}^1$$

would be disallowed, and it is not hard to see that G_1 would generate exactly $a^n b^n c^n$.

As we will show in this paper, our attempt to capture L_3 with a pure CCG grammar failed not only because we could not think of one: L_3 cannot be generated by *any* pure CCG.



(a) Derivation of the string $aaabbbccc$.



(b) Derivation of the string $abababccc$.

Figure 2: Two derivations of the grammar G_1.

3 The Generative Capacity of Pure CCG

We will now develop a formal argument showing that rule restrictions increase the weak generative capacity of CCG. We will first prove that pure CCG is still more expressive than context-free grammar. We will then spend the rest of this section working towards the result that pure CCG is strictly less expressive than CCG with rule restrictions. Our main technical result will be the following:

Theorem 1 *Every language that can be generated by a pure CCG has a Parikh-equivalent context-free sublanguage.*

Here, two languages L and L' are called *Parikh-equivalent* if every string in L is the permutation of a string in L' and vice versa.

3.1 CFG $\subsetneq$ PCCG

Proposition 1 *The class of languages generated by pure CCG properly includes the class of context-free languages.*

Proof. To see the inclusion, it suffices to note that pure CCG when restricted to application rules is the same as *AB-grammar*, the classical categorial formalism investigated by Ajdukiewicz and Bar-Hillel (Bar-Hillel et al., 1964). This formalism is weakly equivalent to context-free grammar.

To see that the inclusion is proper, we can go back to the grammar G_1 that we gave in Section 2.5. We have already discussed that the language L_3 is included in $L(G_1)$. We can also convince ourselves that all strings generated by the grammar G_1 have an equal number of as, bs and cs. Consider now the regular language $R = a^*b^*c^*$. From our observations, it follows that $L(G_1) \cap R = L_3$. Since context-free languages are closed under intersection with regular languages, we find that $L(G_1)$ can be context-free only if L_3 is. Since L_3 is not context-free, we therefore conclude that $L(G_1)$ is not context-free, either. ∎

Two things are worth noting. First, our result shows that the ability of CCG to generate non-context-free languages does not hinge on the availability of substitution and type-raising rules: The derivations of G_1 only use generalized compositions. Neither does it require the use of functional argument categories: The grammar G_1 is *first-order* in the sense of Koller and Kuhlmann (2009).

Second, it is important to note that if the composition degree n is restricted to 0 or 1, pure CCG actually collapses to context-free expressive power. This is clear for $n = 0$ because of the equivalence to AB grammar. For $n = 1$, observe that the arity of the result of a composition is at most as high as

that of each premise. This means that the arity of any derived category is bounded by the maximal arity of lexical categories in the grammar, which together with Lemma 1 implies that there is only a finite set of derivable categories. The set of all valid derivations can then be simulated by a context-free grammar. In the presence of rules with $n \geq 2$, the arities of derived categories can grow unboundedly.

3.2 Active and Inactive Arguments

In the remainder of this section, we will develop the proof of Theorem 1, and use it to show that the generative capacity of PCCG is strictly smaller than that of CCG with rule restrictions. For the proof, we adopt a certain way to view the information flow in CCG derivations. Consider the following instance of forward harmonic composition:

$$\mathsf{a/b}\ \ \mathsf{b/c}\ \Rightarrow\ \mathsf{a/c}$$

This rule should be understood as obtaining its conclusion $\mathsf{a/c}$ from the primary premise $\mathsf{a/b}$ by the removal of the argument $\mathsf{/b}$ and the subsequent transfer of the argument $\mathsf{/c}$ from the secondary premise. With this picture in mind, we will view the two occurrences of $\mathsf{/c}$ in the secondary premise and in the conclusion as two occurrences of one and the same argument. Under this perspective, in a given derivation, an argument has a lifespan that starts in a lexical category and ends in one of two ways: either in the primary or in the secondary premise of a composition rule. If it ends in a primary premise, it is because it is matched against a subcategory of the corresponding secondary premise; this is the case for the argument $\mathsf{/b}$ in the example above. We will refer to such arguments as *active*. If an argument ends its life in a secondary premise, it is because it is consumed as part of a higher-order argument. This is the case for the argument $\mathsf{/c}$ in the secondary premise of the following rule instance:

$$\mathsf{a/(b/c)}\ \ \mathsf{b/c/d}\ \Rightarrow\ \mathsf{a/d}$$

(Recall that we assume that slashes are left-associative.) We will refer to such arguments as *inactive*. Note that the status of an argument as either active or inactive is not determined by the grammar, but depends on a concrete derivation.

The following lemma states an elementary property in connection with active and inactive arguments, which we will refer to as *segmentation*:

Lemma 3 *Every category that occurs in a CCG derivation has the general form* $\mathsf{a}\alpha\beta$*, where* a *is an atomic category,* α *is a sequence of inactive arguments, and* β *is a sequence of active arguments.*

Proof. The proof is by induction on the depth of a node in the derivation. The property holds for the root (which is labeled with the final category), and is transferred from conclusions to premises. ∎

3.3 Transformation

The fundamental reason for why the example grammar G_1 from Section 2.5 overgenerates is that in the absence of rule restrictions, we have no means to control the point in a derivation at which a category combines with its arguments. Consider the examples in Figure 2: It is because we cannot ensure that the bs finish combining with the other bs before combining with the cs that the undesirable word order in Figure 2b has a derivation. To put it as a slogan: Permuting the words allows us to saturate arguments prematurely.

In this section, we show that this property applies to all pure CCGs. More specifically, we show that, in a derivation of a pure CCG, almost all active arguments of a category can be saturated before that category is used as a secondary premise; at most one active argument must be transferred to the conclusion of that premise. Conversely, any derivation that still contains a category with at least two active arguments can be transformed into a new derivation that brings us closer to the special property just characterized.

We formalize this transformation by means of a system of rewriting rules in the sense of Baader and Nipkow (1998). The rules are given in Figure 3. To see how they work, let us consider the first rule, R1; the other ones are symmetric. This rules states that, whenever we see a derivation in which a category of the form $\mathsf{x/y}$ (here marked as **A**) is combined with a category of the form $\mathsf{y}\beta\mathsf{/z}$ (marked as **B**), and the result of this combination is combined with a category of the form $\mathsf{z}\gamma$ (**C**), then the resulting category can also be obtained by 'rotating' the derivation to first saturate $\mathsf{/z}$ by combining **B** with **C**, and only then do the combination with **A**. When applying these rotations exhaustively, we end up with a derivation in which almost all active arguments of a category are saturated before that category is used as a secondary premise. Applying the transformation to the derivation in Figure 2a, for instance, yields the derivation in Figure 2b.

We need the following result for some of the lemmas we prove below. We call a node in a deriv-

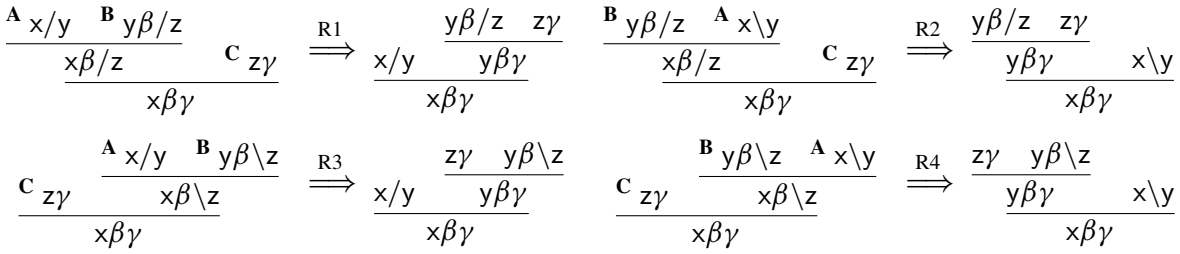


Figure 3: Rewriting rules used in the transformation. Here, γ represents a (possibly empty) sequence of arguments, and β represents a sequence of arguments in which the first (outermost) argument is active.

ation *critical* if its corresponding category contains more than one active argument and it is the secondary premise of a rule. We say that u is a *highest* critical node if there is no other critical node whose distance to the root is shorter.

Lemma 4 *If u is a highest critical node, then we can apply one of the transformation rules to the grandparent of u.*

Proof. Suppose that the category at u has the form $\mathsf{y}\beta/\mathsf{z}$, where $/\mathsf{z}$ is an active argument, and the first argument in β is active as well. (The other possible case, in which the relevant occurrence has the form $\mathsf{y}\beta\backslash\mathsf{z}$, can be treated symmetrically.) Since u is a secondary premise, it is involved in an inference of one of the following two forms:

$$\frac{\mathsf{x}/\mathsf{y} \quad \mathsf{y}\beta/\mathsf{z}}{\mathsf{x}\beta/\mathsf{z}} \qquad \frac{\mathsf{y}\beta/\mathsf{z} \quad \mathsf{x}\backslash\mathsf{y}}{\mathsf{x}\beta/\mathsf{z}}$$

Since u is a highest critical node, the conclusion of this inference is not a critical node itself; in particular, it is not a secondary premise. Therefore, the above inferences can be extended as follows:

$$\frac{\dfrac{\mathsf{x}/\mathsf{y} \quad \mathsf{y}\beta/\mathsf{z}}{\mathsf{x}\beta/\mathsf{z}} \quad \mathsf{z}\gamma}{\mathsf{x}\beta\gamma} \qquad \frac{\dfrac{\mathsf{y}\beta/\mathsf{z} \quad \mathsf{x}\backslash\mathsf{y}}{\mathsf{x}\beta/\mathsf{z}} \quad \mathsf{z}\gamma}{\mathsf{x}\beta\gamma}$$

These partial derivations match the left-hand side of the rewriting rules R1 and R2, respectively. Hence, we can apply a rewriting rule to the derivation. ∎

We now show that the transformation is well-defined, in the sense that it terminates and transforms derivations of a grammar G into new derivations of G.

Lemma 5 *The rewriting of a derivation tree ends after a finite number of steps.*

Proof. We assign natural numbers to the nodes of a derivation tree as follows. Each leaf node is assigned the number 0. For an inner node u, which corresponds to the conclusion of a composition rule, let m, n be the numbers assigned to the nodes corresponding to the primary and secondary premise, respectively. Then u is assigned the number $1 + 2m + n$. Suppose now that we have associated premise **A** with the number x, premise **B** with the number y, and premise **C** with the number z. It is then easy to verify that the conclusion of the partial derivation on the left-hand side of each rule has the value $3 + 4x + 2y + z$, while the conclusion of the right-hand side has the value $2 + 2x + 2y + z$. Thus, each step decreases the value of a derivation tree under our assignment by the amount $1 + 2x$. Since this value is positive for all choices of x, the rewriting ends after a finite number of steps. ∎

To convince ourselves that our transformation does not create ill-formed derivations, we need to show that none of the rewriting rules necessitates the use of composition operations whose degree is higher than the degree of the operations used in the original derivation.

Lemma 6 *Applying the rewriting rules from the top down does not increase the degree of the composition operations.*

Proof. The first composition rule used in the left-hand side of each rewriting rule has degree $|\beta| + 1$, the second rule has degree $|\gamma|$; the first rule used in the right-hand side has degree $|\gamma|$, the second rule has degree $|\beta| + |\gamma|$. To prove the claim, it suffices to show that $|\gamma| \leq 1$. This is a consequence of the following two observations.

1. In the category $\mathsf{x}\beta\gamma$, the arguments in γ occur on top of the arguments in β, the first of which is active. Using the segmentation property stated in Lemma 3, we can therefore infer that γ does not contain any inactive arguments.

2. Because we apply rules top-down, premise **B** is a highest critical node in the derivation (by Lemma 4). This means that the category at premise **C** contains at most one active argument; otherwise, premise **C** would be a critical node closer to the root than premise **B**. ∎

We conclude that, if we rewrite a derivation d of G top-down until exhaustion, then we obtain a new valid derivation d'. We call all derivations d' that we can build in this way *transformed*. It is easy to see that a derivation is transformed if and only if it contains no critical nodes.

3.4 Properties of Transformed Derivations

The special property established by our transformation has consequences for the generative capacity of pure CCG. In particular, we will now show that the set of all transformed derivations of a given grammar yields a context-free language. The crucial lemma is the following:

Lemma 7 *For every grammar G, there is some $k \geq 0$ such that no category in a transformed derivation of G has arity greater than k.*

Proof. The number of inactive arguments in the primary premise of a rule does not exceed the number of inactive arguments in the conclusion. In a transformed derivation, a symmetric property holds for active arguments: Since each secondary premise contains at most one active argument, the number of active arguments in the conclusion of a rule is not greater than the number of active arguments in its primary premise. Taken together, this implies that the arity of a category that occurs in a transformed derivation is bounded by the sum of the maximal arity of a lexical category (which bounds the number of active arguments), and the maximal arity of a secondary premise (which bounds the number of inactive arguments). Both of these values are bounded in G. ∎

Lemma 8 *The yields corresponding to the set of all transformed derivations of a pure CCG form a context-free language.*

Proof. Let G be a pure CCG. We construct a context-free grammar G_T that generates the yields of the set of all transformed derivations of G.

As the set of terminals of G_T, we use the set of terminals of G. To form the set of nonterminals, we take all categories that can occur in a transformed derivation of G, and mark each argument as either 'active' ($+$) or 'inactive' ($-$), in all possible ways that respect the segmentation property stated in Lemma 3. Note that, because of Lemma 7 and Lemma 1, the set of nonterminals is finite. As the start symbol, we use s, the final category of G.

The set of productions of G_T is constructed as follows. For each lexicon entry $\sigma \vdash \mathsf{c}$ of G, we include all productions of the form $x \to \sigma$, where x is some marked version of c. These productions represent all valid guesses about the activity of the arguments of c during a derivation of G. The remaining productions encode all valid instantiations of composition rules, keeping track of active and inactive arguments to prevent derivations with critical nodes. More specifically, they have the form

$$\mathsf{x}\beta \to \mathsf{x}/\mathsf{y}^+\ \mathsf{y}\beta \quad \text{or} \quad \mathsf{x}\beta \to \mathsf{y}\beta\ \mathsf{x}\backslash\mathsf{y}^+\,,$$

where the arguments in the y-part of the secondary premise are all marked as inactive, the sequence β contains at most one argument marked as active, and the annotations of the left-hand side nonterminal are copied over from the corresponding annotations on the right-hand side.

The correctness of the construction of G_T can be proved by induction on the length of a transformed derivation of G on the one hand, and the length of a derivation of G_T on the other hand. ∎

3.5 PCCG $\subsetneq$ CCG

We are now ready to prove our main result, repeated here for convenience.

Theorem 1 *Every language that can be generated by a pure CCG grammar has a Parikh-equivalent context-free sublanguage.*

Proof. Let G be a pure CCG, and let L_T be the set of yields of the transformed derivations of G. Inspecting the rewriting rules, it is clear that every string of $L(G)$ is the permutation of a string in L_T: the transformation only rearranges the yields. By Lemma 8, we also know that L_T is context-free. Since every transformed derivation is a valid derivation of G, we have $L_T \subseteq L(G)$. ∎

As an immediate consequence, we find:

Proposition 2 *The class of languages generated by pure CCG cannot generate all languages that can be generated by CCG with rule restrictions.*

Proof. The CCG formalism considered by Vijay-Shanker and Weir (1994) can generate the non-context-free language L_3. However, the only Parikh-equivalent sublanguage of that language is L_3 itself. From Theorem 1, we therefore conclude that L_3 cannot be generated by pure CCG. ∎

In the light of the equivalence result established by Vijay-Shanker and Weir (1994), this means that pure CCG cannot generate all languages that can be generated by TAG.

4 Multi-Modal CCG

We now extend Theorem 1 to multi-modal CCG. We will see that at least for a popular version of multi-modal CCG, the B&K-CCG formalism presented by Baldridge and Kruijff (2003), the proof can be adapted quite straightforwardly. This means that even B&K-CCG becomes less expressive when rule restrictions are disallowed.

4.1 Multi-Modal CCG

The term 'multi-modal CCG' (MM-CCG) refers to a family of extensions to CCG which attempt to bring some of the expressive power of Categorial Type Logic (Moortgat, 1997) into CCG. Slashes in MM-CCG have *slash types*, and rules can be restricted to only apply to arguments that have slashes of the correct type. The idea behind this extension is that many constraints that in ordinary CCG can only be expressed in terms of rule restrictions can now be specified in the lexicon entries by giving the slashes the appropriate types.

The most widely-known version of multi-modal CCG is the formalism defined by Baldridge and Kruijff (2003) and used by Steedman and Baldridge (2010); we refer to it as B&K-CCG. This formalism uses an inventory of four slash types, $\{\star, \times, \diamond, \cdot\}$, arranged in a simple type hierarchy: $\star$ is the most general type, $\cdot$ the most specific, and $\times$ and $\diamond$ are in between. Every slash in a B&K-CCG lexicon is annotated with one of these slash types.

The combinatory rules in B&K-CCG, given in Figure 4, are defined to be sensitive to the slash types. In particular, slashes with the types $\diamond$ and $\times$ can only be eliminated by harmonic and crossed compositions, respectively.[2] Thus, a grammar writer can constrain the application of harmonic and crossed composition rules to certain categories by assigning appropriate types to the slashes of this category in the lexicon. Application rules apply to slashes of any type. As before, we call an MM-CCG grammar *pure* if it only uses application and generalized compositions, and does not provide means to restrict rule applications.

[2] Our definitions of generalized harmonic and crossed composition are the same as the ones used by Hockenmaier and Young (2008), but see the discussion in Section 4.3.

$x/_\star y \;\; y \Rightarrow x$		forward application
$y \;\; x\backslash_\star y \Rightarrow x$		backward application
$x/_\diamond y \;\; y/_\diamond z\beta \Rightarrow x/_\diamond z\beta$		forward harmonic composition
$x/_\times y \;\; y\backslash_\times z\beta \Rightarrow x\backslash_\times z\beta$		forward crossed composition
$y\backslash_\diamond z\beta \;\; x\backslash_\diamond y \Rightarrow x\backslash_\diamond z\beta$		backward harmonic composition
$y/_\times z\beta \;\; x\backslash_\times y \Rightarrow x/_\times z\beta$		backward crossed composition

Figure 4: Rules in B&K-CCG.

4.2 Rule Restrictions in B&K-CCG

We will now see what happens to the proof of Theorem 1 in the context of pure B&K-CCG. There is only one point in the entire proof that could be damaged by the introduction of slash types, and that is the result that if a transformation rule from Figure 3 is applied to a correct derivation, then the result is also grammatical. For this, it must not only be the case that the degree on the composition operations is preserved (Lemma 6), but also that the transformed derivation remains consistent with the slash types. Slash types make the derivation process sensitive to word order by restricting the use of compositions to categories with the appropriate type, and the transformation rules permute the order of the words in the string. There is a chance therefore that a transformed derivation might not be grammatical in B&K-CCG.

We now show that this does not actually happen, for rule R3; the other three rules are analogous. Using s_1, s_2, s_3 as variables for the relevant slash types, rule R3 appears in B&K-CCG as follows:

$$\dfrac{z\gamma \quad \dfrac{x/_{s_1} y \quad y|_{s_2} w\beta\backslash_{s_3} z}{x|_{s_2} w\beta\backslash_{s_3} z}}{x|_{s_2} w\beta\gamma} \overset{\text{R3}}{\Longrightarrow} \dfrac{x/_{s_1} y \quad \dfrac{z\gamma \quad y|_{s_2} w\beta\backslash_{s_3} z}{y|_{s_2} w\beta\gamma}}{x|_{s_2} w\beta\gamma}$$

Because the original derivation is correct, we know that, if the slash of w is forward, then s_1 and s_2 are subtypes of $\diamond$; if the slash is backward, they are subtypes of $\times$. A similar condition holds for s_3 and the first slash in γ; if γ is empty, then s_3 can be anything because the second rule is an application.

After the transformation, the argument $/_{s_1} y$ is used to compose with $y|_{s_2} w\beta\gamma$. The direction of the slash in front of the w is the same as before, so the (harmonic or crossed) composition is still compatible with the slash types s_1 and s_2. An analogous argument shows that the correctness of combining $\backslash_{s_3} z$ with γ carries over from the left to the right-hand side. Thus the transformation maps grammatical derivations into grammatical derivations. The rest of the proof in Section 3 continues to work literally, so we have the following result:

Theorem 2 *Every language that can be generated by a pure B&K-CCG grammar contains a Parikh-equivalent context-free sublanguage.*

This means that pure B&K-CCG is just as unable to generate L_3 as pure CCG is. In other words, the weak generative capacity of CCG with rule restrictions, and in particular that of the formalism considered by Vijay-Shanker and Weir (1994), is strictly greater than the generative capacity of pure B&K-CCG—although we conjecture (but cannot prove) that pure B&K-CCG is still more expressive than pure non-modal CCG.

4.3 Towards More Expressive MM-CCGs

To put the result of Theorem 2 into perspective, we will now briefly consider ways in which B&K-CCG might be modified in order to obtain a pure multi-modal CCG that is weakly equivalent to CCG in the style of Vijay-Shanker and Weir (1994). Such a modification would have to break the proof in Section 4.2, which is harder than it may seem at first glance. For instance, simply assuming a more complex type system will not do it, because the arguments $\backslash_{s_3}\mathsf{z}$ and $/_{s_1}\mathsf{y}$ are eliminated using the same rules in the original and the transformed derivations, so if the derivation step was valid before, it will still be valid after the transformation. Instead, we believe that it is necessary to make the composition rules sensitive to the categories inside β and γ instead of only the arguments $\backslash_{s_3}\mathsf{z}$ and $/_{s_1}\mathsf{y}$, and we can see two ways how to do this.

First, one could imagine a version of multi-modal CCG with unary modalities that can be used to mark certain category occurrences. In such an MM-CCG, the composition rules for a certain slash type could be made sensitive to the presence or absence of unary modalities in β. Say for instance that the slash type s_1 in the modalized version of R3 in Section 4.2 would require that no category in the secondary argument is marked with the unary modality '$\Box$', but β contains a category marked with '$\Box$'. Then the transformed derivation would be ungrammatical.

A second approach concerns the precise definition of the generalized composition rules, about which there is a surprising degree of disagreement. We have followed Hockenmaier and Young (2008) in classifying instances of generalized forward composition as harmonic if the innermost slash of the secondary argument is forward and crossed if it is backward. However, generalized forward composition is sometimes only accepted as harmonic if *all* slashes of the secondary argument are forward (see e.g. Baldridge (2002) (40, 41), Steedman (2001) (19)). At the same time, based on the principle that CCG rules should be derived from proofs of Categorial Type Logic as Baldridge (2002) does, it can be argued that generalized composition rules of the form $\mathsf{x/y}\ \ \mathsf{y/z\backslash w} \Rightarrow \mathsf{x/z\backslash w}$, which we have considered as harmonic, should actually be classified as crossed, due to the presence of a slash of opposite directionality in front of the w. This definition would break our proof. Thus our result might motivate further research on the 'correct' definition of generalized composition rules, which might then strengthen the generative capacity of pure MM-CCG.

5 Conclusion

In this paper, we have shown that the weak generative capacity of pure CCG and even pure B&K-CCG crucially depends on the ability to restrict the application of individual rules. This means that these formalisms cannot be fully lexicalized, in the sense that certain languages can only be described by selecting language-specific rules.

Our result generalizes Koller and Kuhlmann's (2009) result for pure *first-order* CCG. Our proof is not as different as it looks at first glance, as their construction of mapping a CCG derivation to a valency tree and back to a derivation provides a different transformation on derivation trees. Our transformation is also technically related to the normal form construction for CCG parsing presented by Eisner (1996).

Of course, at the end of the day, the issue that is more relevant to computational linguistics than a formalism's ability to generate artificial languages such as L_3 is how useful it is for modeling *natural* languages. CCG, and multi-modal CCG in particular, has a very good track record for this. In this sense, our formal result can also be understood as a contribution to a discussion about the expressive power that is needed to model natural languages.

Acknowledgments

We have profited enormously from discussions with Jason Baldridge and Mark Steedman, and would also like to thank the anonymous reviewers for their detailed comments.

epitler,lannie,nenkova@seas.upenn.edu

Abstract

To date, few attempts have been made to develop and validate methods for automatic evaluation of linguistic quality in text summarization. We present the first systematic assessment of several diverse classes of metrics designed to capture various aspects of well-written text. We train and test linguistic quality models on consecutive years of NIST evaluation data in order to show the generality of results. For grammaticality, the best results come from a set of syntactic features. Focus, coherence and referential clarity are best evaluated by a class of features measuring local coherence on the basis of cosine similarity between sentences, coreference information, and summarization specific features. Our best results are 90% accuracy for pairwise comparisons of competing systems over a test set of several inputs and 70% for ranking summaries of a specific input.

1 Introduction

Efforts for the development of automatic text summarizers have focused almost exclusively on improving content selection capabilities of systems, ignoring the linguistic quality of the system output. Part of the reason for this imbalance is the existence of ROUGE (Lin and Hovy, 2003; Lin, 2004), the system for automatic evaluation of content selection, which allows for frequent evaluation during system development and for reporting results of experiments performed outside of the annual NIST-led evaluations, the Document Understanding Conference (DUC)[1] and the Text Analysis Conference (TAC)[2]. Few metrics, however, have been proposed for evaluating linguistic quality and none have been validated on data from NIST evaluations.

In their pioneering work on automatic evaluation of summary coherence, Lapata and Barzilay (2005) provide a correlation analysis between human coherence assessments and (1) semantic relatedness between adjacent sentences and (2) measures that characterize how mentions of the same entity in different syntactic positions are spread across adjacent sentences. Several of their models exhibit a statistically significant agreement with human ratings and complement each other, yielding an even higher correlation when combined.

Lapata and Barzilay (2005) and Barzilay and Lapata (2008) both show the effectiveness of entity-based coherence in evaluating summaries. However, fewer than five automatic summarizers were used in these studies. Further, both sets of experiments perform evaluations of mixed sets of human-produced and machine-produced summaries, so the results may be influenced by the ease of discriminating between a human and machine written summary. Therefore, we believe it is an open question how well these features predict the quality of automatically generated summaries.

In this work, we focus on linguistic quality evaluation for *automatic systems only*. We analyze how well different types of features can rank good and poor machine-produced summaries. Good performance on this task is the most desired property of evaluation metrics during system development. We begin in Section 2 by reviewing the various aspects of linguistic quality that are relevant for machine-produced summaries and currently used in manual evaluations. In Section 3, we introduce and motivate diverse classes of features to capture vocabulary, sentence fluency, and local coherence properties of summaries. We evaluate the predictive power of these linguistic quality metrics by training and testing models on consecutive years of NIST evaluations (data described

Uppsala, Sweden, 11-16 July 2010.

in Section 4). We test the performance of different sets of features separately and in combination with each other (Section 5). Results are presented in Section 6, showing the robustness of each class and their abilities to reproduce human rankings of systems and summaries with high accuracy.

2 Aspects of linguistic quality

We focus on the five aspects of linguistic quality that were used to evaluate summaries in DUC: grammaticality, non-redundancy, referential clarity, focus, and structure/coherence.[3] For each of the questions, all summaries were manually rated on a scale from 1 to 5, in which 5 is the best.

The exact definitions that were provided to the human assessors are reproduced below.

Grammaticality: The summary should have no datelines, system-internal formatting, capitalization errors or obviously ungrammatical sentences (e.g., fragments, missing components) that make the text difficult to read.

Non-redundancy: There should be no unnecessary repetition in the summary. Unnecessary repetition might take the form of whole sentences that are repeated, or repeated facts, or the repeated use of a noun or noun phrase (e.g., "Bill Clinton") when a pronoun ("he") would suffice.

Referential clarity: It should be easy to identify who or what the pronouns and noun phrases in the summary are referring to. If a person or other entity is mentioned, it should be clear what their role in the story is. So, a reference would be unclear if an entity is referenced but its identity or relation to the story remains unclear.

Focus: The summary should have a focus; sentences should only contain information that is related to the rest of the summary.

Structure and Coherence: The summary should be well-structured and well-organized. The summary should not just be a heap of related information, but should build from sentence to sentence to a coherent body of information about a topic.

These five questions get at different aspects of what makes a well-written text. We therefore predict each aspect of linguistic quality separately.

3 Indicators of linguistic quality

Multiple factors influence the linguistic quality of text in general, including: word choice, the reference form of entities, and local coherence. We extract features which serve as proxies for each of the factors mentioned above (Sections 3.1 to 3.5). In addition, we investigate some models of grammaticality (Chae and Nenkova, 2009) and coherence (Graesser et al., 2004; Soricut and Marcu, 2006; Barzilay and Lapata, 2008) from prior work (Sections 3.6 to 3.9).

[3] `http://www-nlpir.nist.gov/projects/duc/duc2006/quality-questions.txt`

All of the features we investigate can be computed automatically directly from text, but some require considerable linguistic processing. Several of our features require a syntactic parse. To extract these, all summaries were parsed by the Stanford parser (Klein and Manning, 2003).

3.1 Word choice: language models

Psycholinguistic studies have shown that people read frequent words and phrases more quickly (Haberlandt and Graesser, 1985; Just and Carpenter, 1987), so the words that appear in a text might influence people's perception of its quality. Language models (LM) are a way of computing how familiar a text is to readers using the distribution of words from a large background corpus. Bigram and trigram LMs additionally capture grammaticality of sentences using properties of local transitions between words. For this reason, LMs are widely used in applications such as generation and machine translation to guide the production of sentences. Judging from the effectiveness of LMs in these applications, we expect that they will provide a strong baseline for the evaluation of at least some of the linguistic quality aspects.

We built unigram, bigram, and trigram language models with Good-Turing smoothing over the New York Times (NYT) section of the English Gigaword corpus (over 900 million words). We used the SRI Language Modeling Toolkit (Stolcke, 2002) for this purpose. For each of the three ngram language models, we include the *min*, *max*, and *average* log probability of the sentences contained in a summary, as well as the *overall log probability* of the entire summary.

3.2 Reference form: Named entities

This set of features examines whether named entities have informative descriptions in the summary. We focus on named entities because they appear often in summaries of news documents and are often not known to the reader beforehand. In addition, first mentions of entities in text introduce the entity into the discourse and so must be informative and properly descriptive (Prince, 1981; Fraurud, 1990; Elsner and Charniak, 2008).

We run the Stanford Named Entity Recognizer (Finkel et al., 2005) and record the number of *PERSONs*, *ORGANIZATIONs*, and *LOCATIONs*.

First mentions to people Feature exploration on our development set found that under-specified

references to people are much more disruptive to a summary than short references to organizations or locations. In fact, prior work in Nenkova and McKeown (2003) found that summaries that have been rewritten so that first mentions of people are informative descriptions and subsequent mentions are replaced with more concise reference forms are overwhelmingly preferred to summaries whose entity references have not been rewritten.

In this class, we include features that reflect the modification properties of noun phrases (NPs) in the summary that are first mentions to people. Noun phrases can include pre-modifiers, appositives, prepositional phrases, etc. Rather than prespecifying all the different ways a person expression can be modified, we hoped to discover the best patterns automatically, by including features for the average number of *each Part of Speech (POS) tag occurring before*, *each syntactic phrase occurring before*[4], *each POS tag occurring after*, and *each syntactic phrase occurring after* the head of the first mention NP for a PERSON. To measure if the lack of pre or post modification is particularly detrimental, we also include the proportion of PERSON first mention NPs *with no words before* and *with no words after* the head of the NP.

Summarization specific Most summarization systems today are *extractive* and create summaries using complete sentences from the source documents. A subsequent mention of an entity in a *source document* which is extracted to be the first mention of the entity in the *summary* is probably not informative enough. For each type of named entity (PERSON, ORGANIZATION, LOCATION), we separately record the number of instances which appear as first mentions in the summary but correspond to non-first mentions in the source documents.

3.3 Reference form: NP syntax

Some summaries might not include people and other named entities at all. To measure how entities are referred to more generally, we include features about the overall syntactic patterns found in NPs: the average number of *each POS tag* and *each syntactic phrase* occurring inside NPs.

[4]We define a linear order based on a preorder traversal of the tree, so syntactic phrases which dominate the head are considered occurring before the head.

3.4 Local coherence: Cohesive devices

In coherent text, constituent clauses and sentences are related and depend on each other for their interpretation. Referring expressions such as pronouns link the current utterance to those where the entities were previously mentioned. In addition, discourse connectives such as “but” or “because” relate propositions or events expressed by different clauses or sentences. Both these categories are known cohesive or linking devices in human-produced text (Halliday and Hasan, 1976). The mere presence of such items in a text would be indicative of better structure and coherence.

We compute a number of shallow features that provide a cheap way of capturing the above intuitions: the number of *demonstratives*, *pronouns*, and *definite descriptions* as well as the number of *sentence-initial discourse connectives*.

3.5 Local coherence: Continuity

This class of linguistic quality indicators is a combination of factors related to coreference, adjacent sentence similarity, and summary-specific context of surface cohesive devices.

Summarization specific Extractive multi-document summaries often lack appropriate antecedents for pronouns and proper context for the use of discourse connectives.

In fact, early work in summarization (Paice, 1980; Paice, 1990) has pointed out that the presence of cohesive devices described in the previous section might in fact be the source of problems. A manual analysis of automatic summaries (Otterbacher et al., 2002) also revealed that anaphoric references that cannot be resolved and unclear discourse relations constitute more than 30% of all revisions required to manually rewrite summaries into a more coherent form.

To identify these potential problems, we adapt the features for surface cohesive devices to indicate whether referring expressions and discourse connectives appear in the summary with the same context as in the input documents.

For each of the cohesive devices discussed in Section 3.4—*demonstratives*, *pronouns*, *definite descriptions*, and *sentence-initial discourse connectives*—we compare the previous sentence in the summary with the previous sentence in the input article. Two features are computed for each type of cohesive device: (1) number of times the preceding sentence in the summary is the same

as the preceding sentence in the input and (2) the number of times the preceding sentence in summary is different from that in the input. Since the previous sentence in the input text often contains the antecedent of pronouns in the current sentence, if the previous sentence from the input is also included in the summary, the pronoun is highly likely to have a proper antecedent.

We also compute the proportion of adjacent sentences in the summary that were extracted from the same input document.

Coreference Steinberger et al. (2007) compare the coreference chains in input documents and in summaries in order to locate potential problems. We instead define a set of more general features related to coreference that are not specific to summarization and are applicable for any text. Our features check the existence of proper antecedents for pronouns in the summary without reference to the text of the input documents.

We use the publicly available pronoun resolution system described in Charniak and Elsner (2009) to mark possible antecedents for pronouns in the summary. We then compute as features the number of times an antecedent for a pronoun was found *in the previous sentence*, *in the same sentence*, or *neither*. In addition, we modified the pronoun resolution system to also output the probability of the most likely antecedent and include the *average antecedent probability* for the pronouns in the text. Automatic coreference systems are trained on human-produced texts and we expect their accuracies to drop when applied to automatically generated summaries. However, the predictions and confidence scores still reflect whether or not possible antecedents exist in previous sentences that match in gender/number, and so may still be useful for coherence evaluation.

Cosine similarity We use cosine similarity to compute the overlap of words in adjacent sentences s_i and s_{i+1} as a measure of continuity.

$$cos\theta = \frac{v_{s_i}.v_{s_{i+1}}}{||v_{s_i}||||v_{s_{i+1}}||} \quad (1)$$

The dimensions of the two vectors (v_{s_i} and $v_{s_{i+1}}$) are the total number of word types from both sentences s_i and s_{i+1}. Stop words were retained. The value of each dimension for a sentence is the number of tokens of that word type in that sentence. We compute the *min*, *max*, and *average* value of cosine similarity over the entire summary.

While some repetition is beneficial for cohesion, too much repetition leads to redundancy in the summary. Cosine similarity is thus indicative of both continuity and redundancy.

3.6 Sentence fluency: Chae and Nenkova (2009)

We test the usefulness of a suite of 38 shallow syntactic features studied by Chae and Nenkova (2009). These features are weakly but significantly correlated with the fluency of machine translated sentences. These include *sentence length*, *number of fragments*, *average lengths of the different types of syntactic phrases*, *total length of modifiers in noun phrases*, and various other syntactic features. We expect that these structural features will be better at detecting ungrammatical sentences than the local language model features.

Since all of these features are calculated over individual sentences, we use the average value over all the sentences in a summary in our experiments.

3.7 Coh-Metrix: Graesser et al. (2004)

The Coh-Metrix tool[5] provides an implementation of 54 features known in the psycholinguistic literature to correlate with the coherence of human-written texts (Graesser et al., 2004). These include commonly used readability metrics based on sentence length and number of syllables in constituent words. Other measures implemented in the system are surface text properties known to contribute to text processing difficulty. Also included are measures of cohesion between adjacent sentences such as similarity under a latent semantic analysis (LSA) model (Deerwester et al., 1990), stem and content word overlap, syntactic similarity between adjacent sentences, and use of discourse connectives. Coh-Metrix has been designed with the goal of capturing properties of coherent text and has been used for grade level assessment, predicting student essay grades, and various other tasks. Given the heterogeneity of features in this class, we expect that they will provide reasonable accuracies for all the linguistic quality measures. In particular, the overlap features might serve as a measure of redundancy and local coherence.

[5] `http://cohmetrix.memphis.edu/`

3.8 Word coherence: Soricut and Marcu (2006)

Word co-occurrence patterns across adjacent sentences provide a way of measuring local coherence that is not linguistically informed but which can be easily computed using large amounts of unannotated text (Lapata, 2003; Soricut and Marcu, 2006). Word coherence can be considered as the analog of language models at the inter-sentence level. Specifically, we used the two features introduced by Soricut and Marcu (2006).

Soricut and Marcu (2006) make an analogy to machine translation: two words are likely to be translations of each other if they often appear in *parallel* sentences; in texts, two words are likely to signal local coherence if they often appear in *adjacent* sentences. The two features we computed are *forward likelihood*, the likelihood of observing the words in sentence s_i conditioned on s_{i-1}, and *backward likelihood*, the likelihood of observing the words in sentence s_i conditioned on sentence s_{i+1}. "Parallel texts" of 5 million adjacent sentences were extracted from the NYT section of GigaWord. We used the GIZA++[6] implementation of IBM Model 1 to align the words in adjacent sentences and obtain all relevant probabilities.

3.9 Entity coherence: Barzilay and Lapata (2008)

Linguistic theories, and Centering theory (Grosz et al., 1995) in particular, have hypothesized that the properties of the transition of attention from entities in one sentence to those in the next, play a major role in the determination of local coherence. Barzilay and Lapata (2008), inspired by Centering, proposed a method to compute the local coherence of texts on the basis of the sequences of entity mentions appearing in them.

In their Entity Grid model, a text is represented by a matrix with rows corresponding to each sentence in a text, and columns to each entity mentioned anywhere in the text. The value of a cell in the grid is the entity's grammatical role in that sentence (Subject, Object, Neither, or Absent). An entity transition is a particular entity's role in two adjacent sentences. The actual entity coherence features are the fraction of each type of these transitions in the entire entity grid for the text. One would expect that coherent texts would contain a certain distribution of entity transitions which would differ from those in incoherent sequences.

We use the Brown Coherence Toolkit[7] (Elsner et al., 2007) to construct the grids. The tool does not perform full coreference resolution. Instead, noun phrases are considered to refer to the same entity if their heads are identical.

Entity coherence features are the only ones that have been previously applied with success for predicting summary coherence. They can therefore be considered to be the state-of-the-art approach for automatic evaluation of linguistic quality.

4 Summarization data

For our experiments, we use data from the multi-document summarization tasks of the Document Understanding Conference (DUC) workshops (Over et al., 2007).

Our training and development data comes from DUC 2006 and our test data from DUC 2007. These were the most recent years in which the summaries were evaluated according to specific linguistic quality questions. Each input consists of a set of 25 related documents on a topic and the target length of summaries is 250 words.

In DUC 2006, there were 50 inputs to be summarized and 35 summarization systems which participated in the evaluation. This included 34 automatic systems submitted by participants, and a baseline system that simply extracted the leading sentences from the most recent article. In DUC 2007, there were 45 inputs and 32 different summarization systems. Apart from the leading sentences baseline, a high performance automatic summarizer from a previous year was also used as a baseline. All these automatic systems are included in our evaluation experiments.

4.1 System performance on linguistic quality

Each summary was evaluated according to the five linguistic quality questions introduced in Section 2: grammaticality, non-redundancy, referential clarity, focus, and structure. For each of these questions, all summaries were manually rated on a scale from 1 to 5, in which 5 is the best.

The distributions of system scores in the 2006 data are shown in Figure 1. Systems are currently the worst at structure, middling at referential clarity, and relatively better at grammaticality, focus,

Focus					.80 *

Table 1: Spearman correlations between the manual ratings for systems averaged over the 50 inputs in 2006; * $p < .05$

and non-redundancy. Structure is the aspect of linguistic quality where there is the most room for improvement. The only system with an average structure score above 3.5 in DUC 2006 was the leading sentences baseline system.

As can be expected, people are unlikely to be able to focus on a single aspect of linguistic quality exclusively while ignoring the rest. Some of the linguistic quality ratings are significantly correlated with each other, particularly referential clarity, focus, and structure (Table 1).

More importantly, the systems that produce summaries with good content[8] are not necessarily the systems producing the most readable summaries. Notice from the first row of Table 1 that none of the system rankings based on these measures of linguistic quality are significantly *positively* correlated with system rankings of content. The development of automatic linguistic quality measurements will allow researchers to optimize both content and linguistic quality.

[8]as measured by summary responsiveness ratings on a 1 to 5 scale, without regard to linguistic quality

5 Experimental setup

We use the summaries from DUC 2006 for training and feature development and DUC 2007 served as the test set. Validating the results on consecutive years of evaluation is important, as results that hold for the data in one year might not carry over to the next, as happened for example in Conroy and Dang (2008)'s work.

Following Barzilay and Lapata (2008), we report summary ranking accuracy as the fraction of correct pairwise rankings in the test set.

We use a Ranking SVM (SVM^{light} (Joachims, 2002)) to score summaries using our features. The Ranking SVM seeks to minimize the number of discordant pairs (pairs in which the gold standard has x_1 ranked strictly higher than x_2, but the learner ranks x_2 strictly higher than x_1). The output of the ranker is always a real valued score, so a global rank order is always obtained. The default regularization parameter was used.

5.1 Combining predictions

To combine information from the different feature classes, we train a meta ranker using the predictions from each class as features.

First, we use a leave-one out (jackknife) procedure to get the predictions of our features for the entire 2006 data set. To predict rankings of systems on one input, we train all the individual rankers, one for each of the classes of features introduced above, on data from the remaining inputs. We then apply these rankers to the summaries produced for the held-out input. By repeating this process for each input in turn, we obtain the predicted scores for each summary.

Once this is done, we use these predicted scores as features for the meta ranker, which is trained on all 2006 data. To test on a new summary pair in 2007, we first apply each individual ranker to get its predictions, and then apply the meta ranker.

In either case (meta ranker or individual feature class), all training is performed on 2006 data, and all testing is done on 2007 data which guarantees the results generalize well at least from one year of evaluation to the next.

5.2 Evaluation of rankings

We examine the predictive power of our features for each of the five linguistic quality questions in two settings. In *system-level* evaluation, we would like to rank all participating systems according to

their performance on the entire test set. In *input-level* evaluation, we would like to rank all summaries produced for a single given input.

For input-level evaluation, the pairs are formed from summaries of the *same input*. Pairs in which the gold standard ratings are tied are not included. After removing the ties, the test set consists of 13K to 16K pairs for each linguistic quality question. Note that there were 45 inputs and 32 automatic systems in DUC 2007. So, there are a total of $45 \cdot \binom{32}{2} = 22,320$ possible summary pairs.

For system-level evaluation, we treat the real-valued output of the SVM ranker for each summary as the linguistic quality score. The 45 individual scores for summaries produced by a given system are averaged to obtain an overall score for the system. The gold-standard system-level quality rating is equal to the *average human ratings* for the system's summaries over the 45 inputs. At the system level, there are about 500 non-tied pairs in the test set for each question.

For both evaluation settings, a random baseline which ranked the summaries in a random order would have an expected pairwise accuracy of 50%.

6 Results and discussion

6.1 System-level evaluation

System-level accuracies for each class of features are shown in Table 2. All classes of features perform well, with at least a 20% absolute increase in accuracy over the random baseline (50% accuracy). For each of the linguistic quality questions, the corresponding best class of features gives prediction accuracies around 90%. In other words, if these features were used to fully automatically compare systems that participated in the 2007 DUC evaluation, only one out of ten comparisons would have been incorrect. These results set a high standard for future work on automatic system-level evaluation of linguistic quality.

The state-of-the-art entity coherence features perform well but are not the best for any of the five aspects of linguistic quality. As expected, sentence fluency is the best feature class for grammaticality. For all four other questions, the best feature set is Continuity, which is a combination of summarization specific features, coreference features and cosine similarity of adjacent sentences. Continuity features outperform entity coherence by 3 to 4% absolute difference on referential quality, focus, and coherence. Accuracies from the language model features are within 1% of entity coherence for these three aspects of summary quality.

Feature set	Gram.	Redun.	Ref.	Focus	Struct.
Lang. models	87.6	83.0	91.2	85.2	86.3
Named ent.	78.5	83.6	82.1	74.0	69.6
NP syntax	85.0	83.8	87.0	76.6	79.2
Coh. devices	82.1	79.5	82.7	82.3	83.7
Continuity	88.8	**88.5**	**92.9**	**89.2**	**91.4**
Sent. fluency	**91.7**	78.9	87.6	82.3	84.9
Coh-Metrix	87.2	86.0	88.6	83.9	86.3
Word coh.	81.7	76.0	87.8	81.7	79.0
Entity coh.	90.2	88.1	89.6	85.0	87.1
Meta ranker	**92.9**	87.9	91.9	87.8	90.0

Table 2: System-level prediction accuracies (%)

Coh-Metrix, which has been proposed as a comprehensive characterization of text, does not perform as well as the language model and the entity coherence classes, which contain considerably fewer features related to only one aspect of text.

The classes of features specific to named entities and noun phrase syntax are the weakest predictors. It is apparent from the results that continuity, entity coherence, sentence fluency and language models are the most powerful classes of features that should be used in automation of evaluation and against which novel predictors of text quality should be compared.

Combining all feature classes with the meta ranker only yields higher results for grammaticality. For the other aspects of linguistic quality, it is better to use Continuity by itself to rank systems.

One certainly unexpected result is that features designed to capture one aspect of well-written text turn out to perform well for other questions as well. For instance, entity coherence and continuity features predict grammaticality with very high accuracy of around 90%, and are surpassed only by the sentence fluency features. These findings warrant further investigation because we would not expect characteristics of local transitions indicative of text structure to have anything to do with sentence grammaticality or fluency. The results are probably due to the significant correlation between structure and grammaticality (Table 1).

6.2 Input-level evaluation

The results of the input-level ranking experiments are shown in Table 3. Understandably, input-level prediction is more difficult and the results are lower compared to the system-level predictions: even with wrong predictions for some of the summaries by two systems, the overall judgment that

one system is better than the other over the entire test set can still be accurate.

While for system-level predictions the meta ranker was only useful for grammaticality, at the input level it outperforms every individual feature class for each of the five questions, obtaining accuracies around 70%.

These input-level accuracies compare favorably with automatic evaluation metrics for other natural language processing tasks. For example, at the 2008 ACL Workshop on Statistical Machine Translation, all fifteen automatic evaluation metrics, including variants of BLEU scores, achieved between 42% and 56% pairwise accuracy with human judgments at the sentence level (Callison-Burch et al., 2008).

As in system-level prediction, for referential clarity, focus, and structure, the best feature class is Continuity. Sentence fluency again is the best class for identifying grammaticality.

Coh-Metrix features are now best for determining redundancy. Both Coh-Metrix and Continuity (the top two features for redundancy) include overlap measures between adjacent sentences, which serve as a good proxy for redundancy.

Surprisingly, the *relative* performance of the feature classes at input level is not the same as for system-level prediction. For example, the language model features, which are the second best class for the system-level, do not fare as well at the input-level. Word co-occurrence which obtained good accuracies at the system level is the least useful class at the input level with accuracies just above chance in all cases.

6.3 Components of continuity

The class of features capturing sentence-to-sentence continuity in the summary (Section 3.5) are the most effective for predicting referential clarity, focus, and structure at the input level. We now investigate to what extent each of its components–summary-specific features, coreference, and cosine similarity between adjacent sentences–contribute to performance.

Results obtained after excluding each of the components of continuity is shown in Table 4; each line in the table represents Continuity minus a feature subclass. Removing cosine overlap causes the largest drop in prediction accuracy, with results about 10% lower than those for the complete Continuity class. Summary specific features, which compare the context of a sentence in the summary with the context in the original document where it appeared, also contribute substantially to the success of the Continuity class in predicting structure and referential clarity. Accuracies drop by about 7% when these features are excluded. However, the coreference features do not seem to contribute much towards predicting summary linguistic quality. The accuracies of the Continuity class are not affected at all when these coreference features are not included.

Feature set	Gram.	Redun.	Ref.	Focus	Struct.
Lang. models	66.3	57.6	62.2	60.5	62.5
Named ent.	52.9	54.4	60.0	54.1	52.5

Table 3: Input-level prediction accuracies (%)

6.4 Impact of summarization methods

In this paper, we have discussed an analysis of the outputs of current research systems. Almost all of these systems still use *extractive* methods. The summarization specific continuity features reward systems that include the necessary preceding context from the original document. These features have high prediction accuracies (Section 6.3) of *linguistic quality*, however note that the supporting context could often contain less important *content*. Therefore, there is a tension between strategies for optimizing linguistic quality and for optimizing content, which warrants the development of abstractive methods.

As the field moves towards more *abstractive* summaries, we expect to see differences in both a) summary linguistic quality and b) the features predictive of linguistic aspects.

As discussed in Section 4.1, systems are currently worst at structure/coherence. However, grammaticality will become more of an issue as systems use sentence compression (Knight and Marcu, 2002), reference rewriting (Nenkova and McKeown, 2003), and other techniques to produce their own sentences.

The number of discourse connectives is currently significantly *negatively* correlated with structure/coherence (Spearman correlation of r =

	Ref.	Focus	Struct.
Continuity	69.7	65.4	70.4
- Sum-specific	63.9	64.2	63.5
- Coref	70.1	65.2	70.6
- Cosine	60.2	56.6	60.7

Table 4: Ablation within the Continuity class; pairwise accuracy for input-level predictions (%)

-.06, p = .008 on DUC 2006 system summaries). This can be explained by the fact that they often lack proper context in an extractive summary. However, an *abstractive* system could plan a discourse structure and insert appropriate connectives (Saggion, 2009). In this case, we would expect the presence of discourse connectives to be a mark of a well-written summary.

6.5 Results on human-written abstracts

Since abstractive summaries would have markedly different properties from extracts, it would be interesting to know how well these sets of features would work for predicting the quality of machine-produced abstracts. However, since current systems are extractive, such a data set is not available.

Therefore we experiment on *human-written* abstracts to get an estimate of the expected performance of our features on abstractive system summaries. In both DUC 2006 and DUC 2007, ten NIST assessors wrote summaries for the various inputs. There are four human-written summaries for each input and these summaries were judged on the same five linguistic quality aspects as the machine-written summaries. We train on the human-written summaries from DUC 2006 and test on the human-written summaries from DUC 2007, using the same set-up as in Section 5.

These results are shown in Table 5. We only report results on the input level, as we are interested in distinguishing between the quality of the summaries, not the NIST assessors' writing skills.

Except for grammaticality, the prediction accuracies of the best feature classes for human abstracts are better than those at input level for machine extracts. This result is promising, as it shows that similar features for evaluating linguistic quality will be valid for abstractive summaries as well.

Note however that the relative performance of the feature sets changes between the machine and human results. While for the machines Continuity feature class is the best predictor of referential clarity, focus, and structure (Table 3), for humans, language models and sentence fluency are best for these three aspects of linguistic quality. A possible explanation for this difference could be that in system-produced extracts, incoherent organization influences human perception of linguistic quality to a great extent and so local coherence features turned out very predictive. But in human summaries, sentences are clearly well-organized and here, continuity features appear less useful. Sentence level fluency seems to be more predictive of the linguistic quality of these summaries.

Feature set	Gram.	Redun.	Ref.	Focus	Struct.
Lang. models	52.1	60.8	76.5	**71.9**	**78.4**
Named ent.	62.5	66.7	47.1	43.9	59.1

Table 5: Input-level prediction accuracies for human-written summaries (%)

7 Conclusion

We have presented an analysis of a wide variety of features for the linguistic quality of summaries. Continuity between adjacent sentences was consistently indicative of the quality of machine generated summaries. Sentence fluency was useful for identifying grammaticality. Language model and entity coherence features also performed well and should be considered in future endeavors for automatic linguistic quality evaluation.

The high prediction accuracies for input-level evaluation and the even higher accuracies for system-level evaluation confirm that questions regarding the linguistic quality of summaries can be answered reasonably using existing computational techniques. Automatic evaluation will make testing easier during system development and enable reporting results obtained outside of the cycles of NIST evaluation.

Abstract

Identifying background (context) information in scientific articles can help scholars understand major contributions in their research area more easily. In this paper, we propose a general framework based on probabilistic inference to extract such context information from scientific papers. We model the sentences in an article and their lexical similarities as a *Markov Random Field* tuned to detect the patterns that context data create, and employ a *Belief Propagation* mechanism to detect likely context sentences. We also address the problem of generating surveys of scientific papers. Our experiments show greater pyramid scores for surveys generated using such context information rather than citation sentences alone.

1 Introduction

In scientific literature, scholars use citations to refer to external sources. These secondary sources are essential in comprehending the new research. Previous work has shown the importance of citations in scientific domains and indicated that citations include survey-worthy information (Siddharthan and Teufel, 2007; Elkiss et al., 2008; Qazvinian and Radev, 2008; Mohammad et al., 2009; Mei and Zhai, 2008).

A citation to a paper in a scientific article may contain explicit information about the cited research. The following example is an excerpt from a CoNLL paper[1] that contains information about Eisner's work on bottom-up parsers and the notion of span in parsing:

"*Another use of bottom-up is due to* **Eisner (1996)**, *who introduced the notion of a span.*"

[1]Buchholz and Marsi "CoNLL-X Shared Task On Multilingual Dependency Parsing", CoNLL 2006

However, the citation to a paper may not always include explicit information about the cited paper:

"*This approach is one of those described in* **Eisner (1996)**"

Although this sentence alone does not provide any information about the cited paper, it suggests that its surrounding sentences describe the proposed approach in Eisner's paper:

> "*... In an all pairs approach, every possible pair of two tokens in a sentence is considered and some score is assigned to the possibility of this pair having a (directed) dependency relation. Using that information as building blocks, the parser then searches for the best parse for the sentence. This approach is one of those described in* **Eisner (1996)**."

We refer to such *implicit citations* that contain information about a specific secondary source but do not explicitly cite it, as sentences with *context* information or *context sentences* for short. We look at the patterns that such sentences create and observe that context sentences occur with-ing a small neighborhood of explicit citations. We also discuss the problem of extracting context sentences for a source-reference article pair. We propose a general framework that looks at each sentence as a random variable whose value determines its state about the target paper. In summary, our proposed model is based on the probabilistic inference of these random variables using graphical models. Finally we give evidence on how such sentences can help us produce better surveys of research areas. The rest of this paper is organized as follows. Preceded by a review of prior work in Section 2, we explain the data collection and our annotation process in Section 3. Section 4 explains our methodology and is followed by experimental setup in Section 5.

2 Prior Work

Analyzing the structure of scientific articles and their relations has received a lot of attention recently. The structure of citation and collaboration networks has been studied in (Teufel et al., 2006; Newman, 2001), and summarization of scientific documents is discussed in (Teufel and Moens, 2002). In addition, there is some previous work on the importance of citation sentences. Elkiss et al, (Elkiss et al., 2008) perform a large-scale study on citations in the free PubMed Central (PMC) and show that they contain information that may not be present in abstracts. In other work, Nanba et al, (Nanba and Okumura, 1999; Nanba et al., 2004b; Nanba et al., 2004a) analyze citation sentences and automatically categorize them in order to build a tool for survey generation.

The text of scientific citations has been used in previous research. Bradshaw (Bradshaw, 2002; Bradshaw, 2003) uses citations to determine the content of articles. Similarly, the text of citation sentences has been directly used to produce summaries of scientific papers in (Qazvinian and Radev, 2008; Mei and Zhai, 2008; Mohammad et al., 2009). Determining the scientific attribution of an article has also been studied before. Siddharthan and Teufel (Siddharthan and Teufel, 2007; Teufel, 2005) categorize sentences according to their role in the author's argument into predefined classes: Own, Other, Background, Textual, Aim, Basis, Contrast.

Little work has been done on automatic citation extraction from research papers. Kaplan et al, (Kaplan et al., 2009) introduces "citation-site" as a block of text in which the cited text is discussed. The mentioned work uses a machine learning method for extracting citations from research papers and evaluates the result using 4 annotated articles.

In our work we use graphical models to extract context sentences. Graphical models have a number of properties and corresponding techniques and have been used before on Information Retrieval tasks. Romanello et al, (Romanello et al., 2009) use Conditional Random Fields (CRF) to extract references from unstructured text in digital libraries of classic texts. Similar work include term dependency extraction (Metzler and Croft, 2005), query expansion (Metzler and Croft, 2007), and automatic feature selection (Metzler, 2007).

3 Data

The ACL Anthology Network (AAN)[2] is a collection of papers from the ACL Anthology[3] published in the Computational Linguistics journal and proceedings from ACL conferences and workshops and includes more than $14,000$ papers over a period of four decades (Radev et al., 2009). AAN includes the citation network of the papers in the ACL Anthology. The papers in AAN are publicly available in text format retrieved by an OCR process from the original pdf files, and are segmented into sentences.

To build a corpus for our experiments we picked 10 recently published papers from various areas in NLP[4], each of which had references for a total of 203 candidate paper-reference pairs. Table 1 lists these papers together with their authors, titles, publication year, number of references, number of references within AAN, and the number of sen-

[4]Regardless of data selection, the methodology in this work is applicable to any of the papers in AAN.

L&P	S&al	Sentence
		. . .
$\mathcal{C}$	$\mathcal{C}$	Jacquemin (1999) and Barzilay and McKeown (2001) identify phrase level paraphrases, while **Lin and Pantel (2001)** and **Shinyama et al. (2002)** acquire structural paraphrases encoded as templates.
1	1	These latter are the most closely related to the sentence-level paraphrases we desire, and so we focus in this section on template-induction approaches.
$\mathcal{C}$	0	**Lin and Pantel (2001)** extract inference rules, which are related to paraphrases (for example, X wrote Y implies X is the author of Y), to improve question answering.
1	0	They assume that paths in dependency trees that take similar arguments (leaves) are close in meaning.
1	0	However, only two-argument templates are considered.
0	$\mathcal{C}$	**Shinyama et al. (2002)** also use dependency-tree information to extract templates of a limited form (in their case, determined by the underlying information extraction application).
1	1	Like us (and unlike Lin and Pantel, who employ a single large corpus), they use articles written about the same event in different newspapers as data.
1	1	Our approach shares two characteristics with the two methods just described: pattern comparison by analysis of the patterns respective arguments, and use of nonparallel corpora as a data source.
0	0	However, extraction methods are not easily extended to generation methods.
1	1	One problem is that their templates often only match small fragments of a sentence.
1	1	While this is appropriate for other applications, deciding whether to use a given template to generate a paraphrase requires information about the surrounding context provided by the entire sentence.
		. . .

Table 2: Part of the annotation for N03-1003 with respect to two of its references "Lin and Pantel (2001)" (the first column) "Shinyama et al. (2002)" (the second column). $\mathcal{C}$s indicate explicit citations, 1s indicate implicit citations and 0s are none.

tences.

3.1 Annotation Process

We annotated the sentences in each paper from Table 1. Each *annotation instance* in our setting corresponds to a paper-reference pair, and is a vector in which each dimension corresponds to a sentence and is marked with a $\mathcal{C}$ if it explicitly cites the reference, and with a 1 if it implicitly talks about it. All other sentences are marked with 0s. Table 2 shows a portion of two separate annotation instances of N03-1003 corresponding to two of its references. Our annotation has resulted in 203 annotation instances each corresponding to one paper-reference pair. The goal of this work is to automatically identify all context sentences, which are marked as "1".

3.1.1 Inter-judge Agreement

We also asked a neutral annotator[5] to annotate two of our datasets that are marked with $*$ in Table 1. For each paper-reference pair, the annotator was provided with a vector in which explicit citations were already marked with $\mathcal{C}$s. The annotation guidelines instructed the annotator to look at each explicit citation sentence, and read up to 15 sentences before and after, then mark context sentences around that sentence with 1s. Next, the 29 annotation instances done by the external annotator were compared with the corresponding annotations that we did, and the Kappa coefficient (κ) was calculated. The κ statistic is formulated as

$$\kappa = \frac{\Pr(a) - \Pr(e)}{1 - \Pr(e)}$$

where $Pr(a)$ is the relative observed agreement among raters, and $Pr(e)$ is the probability that annotators agree by chance if each annotator is randomly assigning categories. To calculate κ, we ignored all explicit citations (since they were provided to the external annotator) and used the binary categories (i.e., 1 for context sentences, and 0 otherwise) for all other sentences. Table 3 shows the annotation vector size (i.e., number of sentences), number of annotation instances (i.e., number of references), and average κ for each set. The average κ is above 0.85 in both cases, suggesting that the annotation process has a low degree of subjectivity and can be considered reliable.

ACL-ID	vector size	# Annotations	$\overline{\kappa}$

N03-2016*	92	8	0.853 ± 0.35

Table 3: Average κ coefficient as inter-judge agreement for annotations of two sets

3.2 Analysis

In this section we describe our analysis. First, we look at the number of explicit citations each reference has received in a paper. Figure 1 (a) shows the histogram corresponding to this distribution. It indicates that the majority of references get cited in only 1 sentence in a scientific article, while the maximum being 9 in our collected dataset with only 1 instance (i.e., there is only 1 reference that gets cited 9 times in a paper). Moreover, the data exhibits a highly positive-skewed distribution. This is illustrated on a log-log scale in Figure 1 (b). This highly skewed distribution indicates that the majority of references get cited only once in a citing paper. The very small number of citing sentences can not make a full inventory of the contributions of the cited paper, and therefore, extracting explicit citations alone without context

[5] Someone not involved with the paper but an expert in NLP.

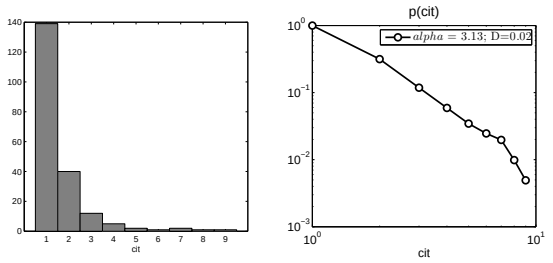
sentences may result in information loss about the contributions of the cited paper.



a b

Figure 1: (a) Histogram of the number of different citations to each reference in a paper. (b) The distribution observed for the number of different citations on a log-log scale.

Next, we investigate the distance between context sentences and the closest citations. For each context sentence, we find its distance to the closets context sentence or explicit citation. Formally, we define the *gap* to be the number of sentences between a context sentence (marked with 1) and the closest context sentence or explicit citation (marked with either C or 1) to it. For example, the second column of Table 2 shows that there is a gap of size 1 in the 9^{th} sentence in the set of context and citation sentences about Shinyama et al. (2002). Table 4 shows the distribution of gap sizes in the annotated data. This observation suggests that the majority of context sentences directly occur after or before a citation or another context sentence. However, it shows that gaps between sentences describing a cited paper actually exist, and a proposed method should have the capability to capture them.

4 Proposed Method

In this section we propose our methodology that enables us to identify the context information of a cited paper. Particularly, the task is to assign a binary label X_C to each sentence S_i from a paper S, where $X_C = 1$ shows a context sentence related to a given cited paper, C. To solve this problem we propose a systematic way to model the network level relationship between consecutive sentences. In summary, each sentence is represented with a node and is given two scores (context, non-context), and we update these scores to be in harmony with the neighbors' scores.

A particular class of graphical models known as *Markov Random Fields* (MRFs) are suited for solving inference problems with uncertainty in observed data. The data is modeled as an undirected graph with two types of nodes: hidden and observed. Observed nodes represent values that are known from the data. Each hidden node x_u, corresponding to an observed node y_u, represents the true state underlying the observed value. The state of a hidden node is related to the value of its corresponding observed node as well as the states of its neighboring hidden nodes.

The *local Markov property* of an MRF indicates that a variable is conditionally independent on all other variables given its neighbors: $x_v \perp\!\!\!\perp x_{V \setminus cl(v)} | x_{ne(v)}$, where $ne(v)$ is the set of neighbors of v, and $cl(v) = \{v\} \cup ne(v)$ is the closed neighborhood of v. Thus, the state of a node is assumed to statistically depend only upon its hidden node and each of its neighbors, and independent of any other node in the graph given its neighbors.

Dependencies in an MRF are represented using two functions: *Compatibility function (ψ)* and *Potential function (ϕ)*. $\psi_{uv}(x_c, x_d)$ shows the edge potential of an edge between two nodes u, v of classes x_c and x_d. Large values of ψ_{uv} would indicate a strong association between x_c and x_d at nodes u, v. The Potential function, $\phi_i(x_c, y_c)$, shows the statistical dependency between x_c and y_c at each node i assumed by the MRF model.

In order to find the marginal probabilities of x_is in a MRF we can use *Belief Propagation (BP)* (Yedidia et al., 2003). If we assume the y_is are fixed and show $\phi_i(x_i, y_i)$ by $\phi_i(x_i)$, we can find the joint probability distribution for unknown variables x_i as

$$p(\{x\}) = \frac{1}{Z} \prod_{ij} \psi_{ij}(x_i, x_j) \prod_i \phi_i(x_i)$$

In the BP algorithm a set of new variables m is introduced where $m_{ij}(x_j)$ is the message passed from i to j about what state x_j should be in. Each message, $m_{ij}(x_j)$, is a vector with the same dimensionality of x_j in which each dimension shows i's opinion about j being in the corresponding class. Therefore each message could be considered as a probability distribution and its components should sum up to 1. The final belief at a

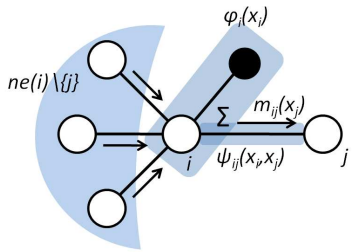


Figure 2: The illustration of the message updating rule. Elements that make up the message from a node i to another node j: messages from i's neighbors, local evidence at i, and propagation function between i, j summed over all possible states of node i.

node i, in the BP algorithm, is also a vector with the same dimensionality of messages, and is proportional to the local evidence as well as all messages from the node's neighbors:

$$b_i(x_i) \leftarrow k\phi_i(x_i) \prod_{j \in ne(i)} m_{ji}(x_i) \quad (1)$$

where k is the normalization factor of the beliefs about different classes. The message passed from i to j is proportional to the propagation function between i, j, the local evidence at i, and all messages sent to i from its neighbors except j:

$$m_{ij}(x_j) \leftarrow \sum_{x_i} \phi_i(x_i)\psi_{ij}(x_i, x_j) \prod_{k \in ne(i)\backslash j} m_{ki}(x_i) \quad (2)$$

Figure 2 illustrates the message update rule.

Convergence can be determined based on a variety of criteria. It can occur when the maximum change of any message between iteration steps is less than some threshold. Convergence is guaranteed for trees but not for general graphs. However, it typically occurs in practice (McGlohon et al., 2009). Upon convergence, belief scores are determined by Equation 1.

4.1 MRF construction

To find the sentences from a paper that form the context information of a given cited paper, we build an MRF in which a hidden node x_i and an observed node y_i correspond to each sentence. The structure of the graph associated with the MRF is dependent upon the validity of a basic assumption. This assumption indicates that the generation of a sentence (in form of its words) only depends on its surrounding sentences. Said differently, each sentence is written independently of all other sentences given a number of its neighbors. This local dependence assumption can result in a number of different MRFs, each built assuming a dependency between a sentence and all sentences within a particular distance. Figure 3 shows the structure of the two MRFs at either extreme of the local dependence assumption. In Figure 3 a, each sentence only depends on one following and one preceding sentence, while Figure 3 b shows an MRF in which sentences are dependent on each other regardless of their position. We refer to the former by $\mathbf{BP_1}$, and to the latter by $\mathbf{BP_n}$. Generally, we use $\mathbf{BP_i}$ to denote an MRF in which each sentence is connected to i sentences before and after.

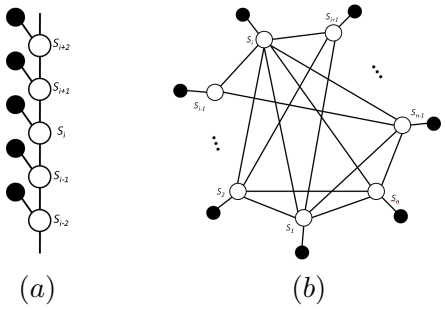

Figure 3: The structure of the MRF constructed based on the independence of non-adjacent sentences; (a) left, each sentence is independent on all other sentences given its immediate neighbors. (b) right, sentences have dependency relationship with each other regardless of their position.

$\psi_{ij}(x_c, x_d)$	$x_d = 0$	$x_d = 1$
$x_c = 0$	0.5	0.5
$x_c = 1$	$1 - S_{ij}$	S_{ij}

Table 5: The compatibility function ψ between any two nodes in the MRFs from the sentences in scientific papers

4.2 Compatibility Function

The compatibility function of an MRF represents the association between the hidden node classes. A node's belief to be in class 1 is its probability to be included in the context. The belief of a node i, about its neighbor j to be in either classes is assumed to be 0.5 if i is in class 0. In other words, if a node is not part of the context itself, we assume

it has no effect on its neighbors' classes. In contrast, if i is in class 1 its belief about its neighbor j is determined by their mutual lexical similarity. If this similarity is close to 1 it indicates a stronger tie between i, j. However, if i, j are not similar, i's probability of being in class 1, should not affect that of j's. To formalize this assumption we use the sigmoid of the cosine similarity of two sentences to build ψ. More formally, we define S to be

$$S_{ij} = \frac{1}{1 + e^{-cosine(i,j)}}$$

The sigmoid function obtains a value of 0.5 for a cosine of 0 indicating that there is no bias in the association of the two sentences. The matrix in Table 5 shows the compatibility function built based on the above arguments.

4.3 Potential Function

The node potential function of an MRF can incorporate some other features observable from data. Here, the goal is to find all sentences that are about a specific cited paper, without having explicit citations. To build the node potential function of the observed nodes, we use some sentence level features. First, we use the explicit citation as an important feature of a sentence. This feature can affect the belief of the corresponding hidden node, which can in turn affect its neighbors' beliefs. For a given paper-reference pair, we flag (with a 1) each sentence that has an explicit citation to the reference.

The second set of features that we are interested in are discourse-based features. In particular we match each sentence with specific patterns and flag those that match. The first pattern is a bigram in which the first term matches any of "*this; that; those; these; his; her; their; such; previous*", and the second term matches any of "*work; approach; system; method; technique; result; example*". The second pattern includes all sentences that start with "*this; such*".

Finally, the similarity of each sentence to the reference is observable from the data and can be used as a sentence-level feature. Intuitively, if a sentence has higher similarity with the reference paper, it should have a higher potential of being in class 1 or $\mathcal{C}$. The flag of each sentence here is a value between 0 and 1 and is determined by its cosine similarity to the reference. Once the flags for each sentence, S_i are determined, we calculate normalized f_i as the unweighted linear combination of individual features. Based on f_is, we compute the potential function, ϕ, as shown in Table 6.

$\phi_i(x_c, y_c)$	$x_c = 0$	$x_c = 1$
	$1 - f_i$	f_i

Table 6: The node potential function ϕ for each node in the MRFs from the sentences in scientific papers is built using the sentences' flags computed using sentence level features.

5 Experiments

The intrinsic evaluation of our methodology means to directly compare the output of our method with the gold standards obtained from the annotated data. Our methodology finds the sentences that cite a reference implicitly. Therefore the output of the inference method is a vector, υ, of 1's and 0's, whereby a 1 at element i means that sentence i in the source document is a context sentence about the reference while a 0 means an explicit citation or neither. The gold standard for each paper-reference pair, ω (obtained from the annotated vectors in Section 3.1 by changing all $\mathcal{C}$s to 0s), is also a vector of the same format and dimensionality.

Precision, recall, and F_β for this task can be defined as

$$p = \frac{\upsilon \cdot \omega}{\upsilon \cdot \mathbf{1}}; \quad r = \frac{\upsilon \cdot \omega}{\omega \cdot \mathbf{1}}; \quad F_\beta = \frac{(1 + \beta^2) p \cdot r}{\beta^2 p + r} \qquad (3)$$

where $\mathbf{1}$ is a vector of 1's with the same dimensionality and β is a non-negative real number.

5.1 Baseline Methods

The first baseline that we use is an IR-based method. This baseline, $\mathbf{B_1}$, takes explicit citations as an input but use them to find context sentences. Given a paper-reference pair, for each explicit citation sentence, marked with $\mathcal{C}$, $\mathbf{B_1}$ picks its preceding and following sentences if their similarities to that sentence is greater than a cutoff (the median of all such similarities), and repeats this for neighboring sentences of newly marked sentences. Intuitively, $\mathbf{B_1}$ tries to find the best chain (window) around citing sentences.

As the second baseline, we use the hand-crafted discourse based features used in MRF's potential function. Particularly, this baseline, $\mathbf{B_2}$, marks

paper	$\mathbf{B_1}$	$\mathbf{B_2}$	**SVM**	$\mathbf{BP_1}$	$\mathbf{BP_4}$	$\mathbf{BP_n}$

Table 7: Average $F_{\beta=3}$ for similarity based baseline ($\mathbf{B_1}$), discourse-based baseline ($\mathbf{B_2}$), a supervised method (**SVM**) and three MRF-based methods.

each sentence that is within a particular distance (4 in our experiments) of an explicit citation and matches one of the two patterns mentioned in Section 4.3. After marking all such sentences, $\mathbf{B_2}$ also marks all sentences between them and the closest explicit citation, which is no farther than 4 sentences away. This baseline helps us understand how effectively this sentence level feature can work in the absence of other features and the network structure.

Finally, we use a supervised method, **SVM**, to classify sentences as context/non-context. We use 4 features to train the **SVM** model. These 4 features comprise the 3 sentence level features used in MRF's potential function (i.e., similarity to reference, explicit citation, matching certain regular-expressions) and a network level feature: distance to the closes explicit citation. For each source paper, P, we use all other source papers and their source-reference annotation instances to train a model. We then use this model to classify all instances in P. Although the number of references and thus source-reference pairs are different for different papers, this can be considered similar to a 10-fold cross validation scheme, since for each source paper the model is built using all source-reference pairs of all other 9 papers.

We compare these baselines with 3 MRF-based systems each with a different assumption about independence of sentences. $\mathbf{BP_1}$ denotes an MRF in which each sentence is only connected to 1 sentence before and after. In $\mathbf{BP_4}$ locality is more relaxed and each sentence is connected to 4 sentences on each sides. $\mathbf{BP_n}$ denotes an MRF in which all sentences are connected to each other regardless of their position in the paper.

Table 7 shows $F_{\beta=3}$ for our experiments and shows how $\mathbf{BP_4}$ outperforms the other methods on average. The value 4 may suggest the fact that although sentences might be independent of distant sentences, they depend on more than one sentence on each side.

The final experiment we do to intrinsically evaluate the MRF-base method is to compare different sentence-level features. The first feature used to build the potential function is explicit citations. This feature does not directly affect context sentences (i.e., it affects the marginal probability of context sentences through the MRF network connections). Therefore, we do not alter this feature in comparing different features. However, we look at the effect of the second and the third features: hand-crafted regular expression-based features and similarity to the reference. For each paper, we use $\mathbf{BP_4}$ to perform 3 experiments: two in absence of each feature and one including all features. Figure 4 shows the average $F_{\beta=3}$ for each experiment. This plot shows that the features lead to better results when used together.

6 Impact on Survey Generation

We also performed an extrinsic evaluation of our context extraction methodology. Here we show how context sentences add important survey-worthy information to explicit citations. Previous work that generate surveys of scientific topics use the text of citation sentences alone (Mohammad et al., 2009; Qazvinian and Radev, 2008). Here, we show how the surveys generated using citations and their context sentences are better than those generated using citation sentences alone.

We use the data from (Mohammad et al., 2009)

... Naturally, our current work on question answering for the reading comprehension task is most related to those of (Hirschman et al. , 1999; Charniak et al. , 2000; Riloffand Thelen, 2000 ; Wang et al. , 2000). **In fact, all of this body of work as well as ours are evaluated on the same set of test stories, and are developed (or trained) on the same development set of stories.** The work of (Hirschman et al. , 1999) initiated this series of work, and it reported an accuracy of 36.3% on answering the questions in the test stories. **Subsequently, the work of (Riloffand Thelen , 2000) and (Chaxniak et al. , 2000) improved the accuracy further to 39.7% and 41%, respectively. However, all of these three systems used handcrafted, deterministic rules and algorithms**...
...**The cross-model comparison showed that the performance ranking of these models was: U-SVM** $>$ **PatternM** $>$ **S-SVM** $>$ **Retrieval-M.** Compared with retrieval-based [Yang et al. 2003], pattern-based [Ravichandran et al. 2002 and Soubbotin et al. 2002], and deep NLP-based [Moldovan et al. 2002, Hovy et al. 2001; and Pasca et al. 2001] answer selection, machine learning techniques are more effective in constructing QA components from scratch. **These techniques suffer, however, from the problem of requiring an adequate number of handtagged question-answer training pairs. It is too expensive and labor intensive to collect such training pairs for supervised machine learning techniques** ...
... **As expected, the definition and person-bio answer types are covered well by these resources.** The web has been employed for pattern acquisition (Ravichandran et al. , 2003), document retrieval (Dumais et al. , 2002), query expansion (Yang et al. , 2003), structured information extraction, and answer validation (Magnini et al. , 2002). **Some of these approaches enhance existing QA systems, while others simplify the question answering task, allowing a less complex approach to find correct answers** ...

	citation survey	context survey
	QA	
CT nuggets	0.416	**0.634**
AB nuggets	0.397	**0.594**
	DP	
CT nuggets	0.324	**0.379**

Table 9: Pyramid $F_{\beta=3}$ scores of automatic surveys of QA and DP data. The QA surveys are evaluated using nuggets drawn from citation texts (CT), or abstracts (AB), and DP surveys are evaluated using nuggets from citation texts (CT).

that contains two sets of cited papers and corresponding citing sentences, one on Question Answering (QA) with 10 papers and the other on Dependency Parsing (DP) with 16 papers. The QA set contains two different sets of nuggets extracted by experts respectively from paper abstracts and citation sentences. The DP set includes nuggets extracted only from citation sentences. We use these nugget sets, which are provided in form of regular expressions, to evaluate automatically generated summaries. To perform this experiment we needed to build a new corpus that includes context sentences. For each citation sentence, $\mathbf{BP_4}$ is used on the citing paper to extract the proper context. Here, we limit the context size to be 4 on each side. That is, we attach to a citing sentence any of its 4 preceding and following sentences if BP4 marks them as context sentences. Therefore, we build a new corpus in which each explicit citation sentence is replaced with the same sentence attached to at most 4 sentence on each side.

After building the context corpus, we use LexRank (Erkan and Radev, 2004) to generate 2 QA and 2 DP surveys using the citation sentences only, and the new context corpus explained above. LexRank is a multidocument summarization system, which first builds a cosine similarity graph of all the candidate sentences. Once the network is built, the system finds the most central sentences by performing a random walk on the graph. We limit these surveys to be of a maximum length of 1000 words. Table 8 shows a portion of the survey generated from the QA context corpus. This example shows how context sentences add meaningful and survey-worthy information along with citation sentences. Table 9 shows the Pyramid $F_{\beta=3}$ score of automatic surveys of QA and DP

data. The QA surveys are evaluated using nuggets drawn from citation texts (CT), or abstracts (AB), and DP surveys are evaluated using nuggets from citation texts (CT). In all evaluation instances the surveys generated with the context corpora excel at covering nuggets drawn from abstracts or citation sentences.

7 Conclusion

In this paper we proposed a framework based on probabilistic inference to extract sentences that appear in the scientific literature, and which are about a secondary source, but which do not contain explicit citations to that secondary source. Our methodology is based on inference in an MRF built using the similarity of sentences and their lexical features. We show, by numerical experiments, that an MRF in which each sentence is connected to only a few adjacent sentences properly fits this problem. We also investigate the usefulness of such sentences in generating surveys of scientific literature. Our experiments on generating surveys for Question Answering and Dependency Parsing show how surveys generated using such context information along with citation sentences have higher quality than those built using citations alone.

Generating fluent scientific surveys is difficult in absence of sufficient background information. Our future goal is to combine summarization and bibliometric techniques towards building automatic surveys that employ context information as an important part of the generated surveys.

Automatic Generation of Story Highlights

Abstract

In this paper we present a joint content selection and compression model for single-document summarization. The model operates over a phrase-based representation of the source document which we obtain by merging information from PCFG parse trees and dependency graphs. Using an integer linear programming formulation, the model learns to select and combine phrases subject to length, coverage and grammar constraints. We evaluate the approach on the task of generating "story highlights"—a small number of brief, self-contained sentences that allow readers to quickly gather information on news stories. Experimental results show that the model's output is comparable to human-written highlights in terms of both grammaticality and content.

1 Introduction

Summarization is the process of condensing a source text into a shorter version while preserving its information content. Humans summarize on a daily basis and effortlessly, but producing high quality summaries automatically remains a challenge. The difficulty lies primarily in the nature of the task which is complex, must satisfy many constraints (e.g., summary length, informativeness, coherence, grammaticality) and ultimately requires wide-coverage text understanding. Since the latter is beyond the capabilities of current NLP technology, most work today focuses on extractive summarization, where a summary is created simply by identifying and subsequently concatenating the most important sentences in a document.

Without a great deal of linguistic analysis, it is possible to create summaries for a wide range of documents. Unfortunately, extracts are often documents of low readability and text quality and contain much redundant information. This is in marked contrast with hand-written summaries which often combine several pieces of information from the original document (Jing, 2002) and exhibit many rewrite operations such as substitutions, insertions, deletions, or reorderings.

Sentence compression is often regarded as a promising first step towards ameliorating some of the problems associated with extractive summarization. The task is commonly expressed as a word deletion problem. It involves creating a short grammatical summary of a *single* sentence, by removing elements that are considered extraneous, while retaining the most important information (Knight and Marcu, 2002). Interfacing extractive summarization with a sentence compression module could improve the conciseness of the generated summaries and render them more informative (Jing, 2000; Lin, 2003; Zajic et al., 2007).

Despite the bulk of work on sentence compression and summarization (see Clarke and Lapata 2008 and Mani 2001 for overviews) only a handful of approaches attempt to do both in a joint model (Daumé III and Marcu, 2002; Daumé III, 2006; Lin, 2003; Martins and Smith, 2009). One reason for this might be the performance of sentence compression systems which falls short of attaining grammaticality levels of human output. For example, Clarke and Lapata (2008) evaluate a range of state-of-the-art compression systems across different domains and show that machine generated compressions are consistently perceived as worse than the human gold standard. Another reason is the summarization objective itself. If our goal is to summarize news articles, then we may be better off selecting the first n sentences of the document. This "lead" baseline may err on the side of verbosity but at least will be grammatical, and it has indeed proved extremely hard to outperform by more sophisticated methods (Nenkova, 2005).

In this paper we propose a model for sum-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 565–574,
Uppsala, Sweden, 11-16 July 2010.

marization that incorporates compression into the task. A key insight in our approach is to formulate summarization as a *phrase* rather than *sentence* extraction problem. Compression falls naturally out of this formulation as only phrases deemed important should appear in the summary. Obviously, our output summaries must meet additional requirements such as sentence length, overall length, topic coverage and, importantly, grammaticality. We combine phrase and dependency information into a single data structure, which allows us to express grammaticality as constraints across phrase dependencies. We encode these constraints through the use of integer linear programming (ILP), a well-studied optimization framework that is able to search the entire solution space efficiently.

We apply our model to the task of generating highlights for a single document. Examples of CNN news articles with human-authored highlights are shown in Table 1. Highlights give a brief overview of the article to allow readers to quickly gather information on stories, and usually appear as bullet points. Importantly, they represent the gist of the *entire* document and thus often differ substantially from the first n sentences in the article (Svore et al., 2007). They are also highly compressed, written in a telegraphic style and thus provide an excellent testbed for models that generate compressed summaries. Experimental results show that our model's output is comparable to hand-written highlights both in terms of grammaticality and informativeness.

2 Related work

Much effort in automatic summarization has been devoted to sentence extraction which is often formalized as a classification task (Kupiec et al., 1995). Given appropriately annotated training data, a binary classifier learns to predict for each document sentence if it is worth extracting. Surface-level features are typically used to single out important sentences. These include the presence of certain key phrases, the position of a sentence in the original document, the sentence length, the words in the title, the presence of proper nouns, etc. (Mani, 2001; Sparck Jones, 1999).

Relatively little work has focused on extraction methods for units smaller than sentences. Jing and McKeown (2000) first extract sentences, then remove redundant phrases, and use (manual) recombination rules to produce coherent output. Wan and Paris (2008) segment sentences heuristically into clauses *before* extraction takes place, and show that this improves summarization quality. In the context of multiple-document summarization, heuristics have also been used to remove parenthetical information (Conroy et al., 2004; Siddharthan et al., 2004). Witten et al. (1999) (among others) extract keyphrases to capture the gist of the document, without however attempting to reconstruct sentences or generate summaries.

A few previous approaches have attempted to interface sentence compression with summarization. A straightforward way to achieve this is by adopting a two-stage architecture (e.g., Lin 2003) where the sentences are first extracted and then compressed or the other way round. Other work implements a *joint* model where words and sentences are deleted simultaneously from a document. Using a noisy-channel model, Daumé III and Marcu (2002) exploit the discourse structure of a document and the syntactic structure of its sentences in order to decide which constituents to drop but also which discourse units are unimportant. Martins and Smith (2009) formulate a joint sentence extraction and summarization model as an ILP. The latter optimizes an objective function consisting of two parts: an extraction component, essentially a non-greedy variant of maximal marginal relevance (McDonald, 2007), and a sentence compression component, a more compact reformulation of Clarke and Lapata (2008) based on the output of a dependency parser. Compression and extraction models are trained separately in a max-margin framework and then interpolated. In the context of multi-document summarization, Daumé III's (2006) vine-growth model creates summaries incrementally, either by starting a new sentence or by growing already existing ones.

Our own work is closest to Martins and Smith (2009). We also develop an ILP-based compression and summarization model, however, several key differences set our approach apart. Firstly, content selection is performed at the phrase rather than sentence level. Secondly, the combination of phrase and dependency information into a single data structure is new, and important in allowing us to express grammaticality as constraints across phrase dependencies, rather than resorting to a lan-

Most blacks say MLK's vision fulfilled, poll finds	**9/11 billboard draws flak from Florida Democrats, GOP**
WASHINGTON (CNN) – More than two-thirds of African-Americans believe Martin Luther King Jr.'s vision for race relations has been fulfilled, a CNN poll found – a figure up sharply from a survey in early 2008. The CNN-Opinion Research Corp. survey was released Monday, a federal holiday honoring the slain civil rights leader and a day before Barack Obama is to be sworn in as the first black U.S. president. The poll found 69 percent of blacks said King's vision has been fulfilled in the more than 45 years since his 1963 'I have a dream' speech – roughly double the 34 percent who agreed with that assessment in a similar poll taken last March. But whites remain less optimistic, the survey found.	(CNN) – A Florida man is using billboards with an image of the burning World Trade Center to encourage votes for a Republican presidential candidate, drawing criticism for politicizing the 9/11 attacks. 'Please Don't Vote for a Democrat' reads the type over the picture of the twin towers after hijacked airliners hit them on September, 11, 2001. Mike Meehan, a St. Cloud, Florida, businessman who paid to post the billboards in the Orlando area, said former President Clinton should have put a stop to Osama bin Laden and al Qaeda before 9/11. He said a Republican president would have done so.
• *69 percent of blacks polled say Martin Luther King Jr's vision realized.* • *Slim majority of whites say King's vision not fulfilled.* • *King gave his "I have a dream" speech in 1963.*	• *Billboards use image from 9/11 to encourage GOP votes.* • *9/11 image wrong for ad, say Florida political parties.* • *Floridian praises President Bush, says ex-President Clinton failed to stop al Qaeda.*

Table 1: Two example CNN news articles, showing the title and the first few paragraphs, and below, the original highlights that accompanied each story.

guage model. Lastly, our model is more compact, has fewer parameters, and does not require two training procedures. Our approach bears some resemblance to headline generation (Dorr et al., 2003; Banko et al., 2000), although we output several sentences rather than a single one. Headline generation models typically extract individual words from a document to produce a very short summary, whereas we extract phrases and ensure that they are combined into grammatical sentences through our ILP constraints.

Svore et al. (2007) were the first to foreground the highlight generation task which we adopt as an evaluation testbed for our model. Their approach is however a purely extractive one. Using an algorithm based on neural networks and third-party resources (e.g., news query logs and Wikipedia entries) they rank sentences and select the three highest scoring ones as story highlights. In contrast, we aim to generate rather than extract highlights. As a first step we focus on deleting extraneous material, but other more sophisticated rewrite operations (e.g., Cohn and Lapata 2009) could be incorporated into our framework.

3 The Task

Given a document, we aim to produce three or four short sentences covering its main topics, much like the "Story Highlights" accompanying the (online) CNN news articles. CNN highlights are written by humans; we aim to do this automatically.

	Documents	Highlights
Sentences	37.2 ± 39.6	3.5 ± 0.5
Tokens	795.0 ± 744.8	47.0 ± 9.6
Tokens/sentence	22.4 ± 4.2	13.3 ± 1.7

Table 2: Overview statistics on the corpus of documents and highlights (mean and standard deviation). A minority of documents are transcripts of interviews and speeches, and can be very long; this accounts for the very large standard deviation.

Two examples of a news story and its associated highlights, are shown in Table 1. As can be seen, the highlights are written in a compressed, almost telegraphic manner. Articles, auxiliaries and forms of the verb *be* are often deleted. Compression is also achieved through paraphrasing, e.g., substitutions and reorderings. For example, the document sentence "*The poll found 69 percent of blacks said King's vision has been fulfilled.*" is rephrased in the highlight as "*69 percent of blacks polled say Martin Luther King Jr's vision realized.*". In general, there is a fair amount of lexical overlap between document sentences and highlights (42.44%) but the correspondence between document sentences and highlights is not always one-to-one. In the first example in Table 1, the second paragraph gives rise to two highlights. Also note that the highlights need not form a coherent summary, each of them is relatively stand-alone, and there is little co-referencing between them.

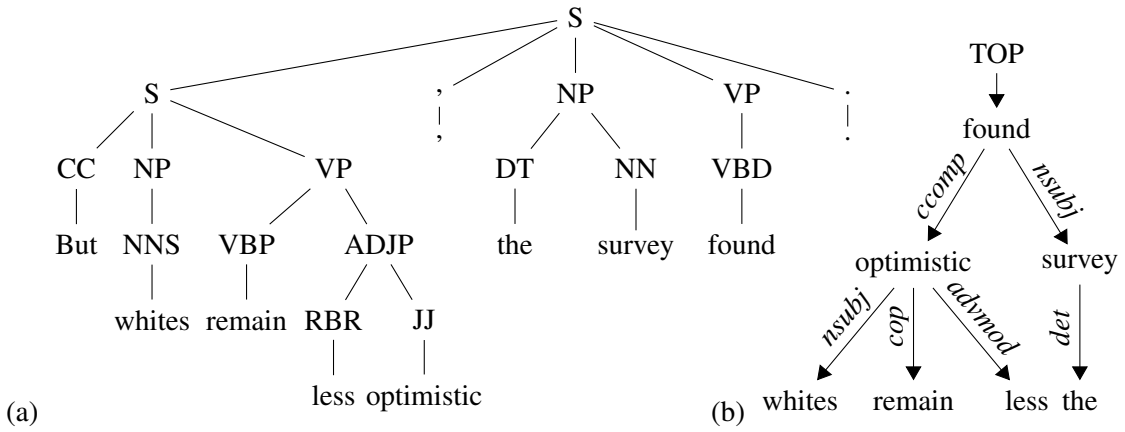

Figure 1: An example phrase structure (a) and dependency (b) tree for the sentence "*But whites remain less optimistic, the survey found.*".

In order to train and evaluate the model presented in the following sections we created a corpus of document-highlight pairs (approximately 9,000) which we downloaded from the CNN.com website.[1] The articles were randomly sampled from the years 2007–2009 and covered a wide range of topics such as business, crime, health, politics, showbiz, etc. The majority were news articles, but the set also contained a mixture of editorials, commentary, interviews and reviews. Some overview statistics of the corpus are shown in Table 2. Overall, we observe a high degree of compression both at the document and sentence level. The highlights summary tends to be ten times shorter than the corresponding article. Furthermore, individual highlights have almost half the length of document sentences.

4 Modeling

The objective of our model is to create the most informative story highlights possible, subject to constraints relating to sentence length, overall summary length, topic coverage, and grammaticality. These constraints are *global* in their scope, and cannot be adequately satisfied by optimizing each one of them individually. Our approach therefore uses an ILP formulation which will provide a globally optimal solution, and which can be efficiently solved using standard optimization tools. Specifically, the model selects phrases from which to form the highlights, and each highlight is created from a single sentence through phrase deletion. The model operates on parse trees augmented with dependency labels. We first describe how we obtain this representation and then move on to discuss the model in more detail.

Sentence Representation We obtain syntactic information by parsing every sentence twice, once with a phrase structure parser and once with a dependency parser. The phrase structure and dependency-based representations for the sentence "*But whites remain less optimistic, the survey found.*" (from Table 1) are shown in Figures 1(a) and 1(b), respectively.

We then combine the output from the two parsers, by mapping the dependencies to the edges of the phrase structure tree in a greedy fashion, shown in Figure 2(a). Starting at the top node of the dependency graph, we choose a node i and a dependency arc to node j. We locate the corresponding words i and j on the phrase structure tree, and locate their nearest shared ancestor p. We assign the label of the dependency $i \rightarrow j$ to the first unlabeled edge from p to j in the phrase structure tree. Edges assigned with dependency labels are shown as dashed lines. These edges are important to our formulation, as they will be represented by binary decision variables in the ILP. Further edges from p to j, and all the edges from p to i, are marked as *fixed* and shown as solid lines. In this way we keep the correct ordering of leaf nodes. Finally, leaf nodes are merged into parent phrases, until each phrase node contains a minimum of two tokens, shown in Figure 2(b). Because of this minimum length rule, it is possible for a merged node to be a clause rather than a phrase, but in the subsequent description we will use the term *phrase* rather loosely to describe any merged leaf node.

[1] The corpus is available from `http://homepages.inf.ed.ac.uk/mlap/resources/index.html`.

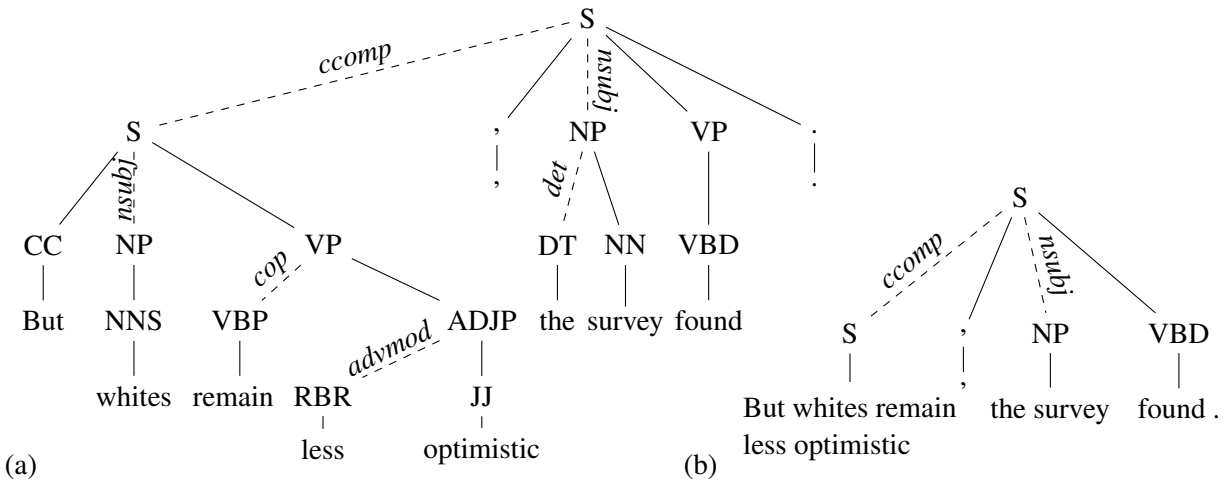

Figure 2: Dependencies are mapped onto phrase structure tree (a) and leaf nodes are merged with parent phrases (b).

ILP model The merged phrase structure tree, such as shown in Figure 2(b), is the actual input to our model. Each phrase in the document is given a *salience score*. We obtain these scores from the output of a supervised machine learning algorithm that predicts for each phrase whether it should be included in the highlights or not (see Section 5 for details). Let $\mathcal{S}$ be the set of sentences in a document, $\mathcal{P}$ be the set of phrases, and $\mathcal{P}_s \subset \mathcal{P}$ be the set of phrases in each sentence $s \in \mathcal{S}$. $\mathcal{T}$ is the set of words with the highest tf.idf scores, and $\mathcal{P}_t \subset \mathcal{P}$ is the set of phrases containing the token $t \in \mathcal{T}$. Let f_i denote the salience score for phrase i, determined by the machine learning algorithm, and l_i is its length in tokens.

We use a vector of binary variables $x \in \{0,1\}^{|\mathcal{P}|}$ to indicate if each phrase is to be within a highlight. These are either top-level nodes in our merged tree representation, or nodes whose edge to the parent has a dependency label (the dashed lines). Referring to our example in Figure 2(b), binary variables would be allocated to the top-level S node, the child S node and the NP node. The vector of auxiliary binary variables $y \in \{0,1\}^{|\mathcal{S}|}$ indicates from which sentences the chosen phrases come (see Equations (1i) and (1j)). Let the sets $\mathcal{D}_i \subset \mathcal{P}, \forall i \in \mathcal{P}$ capture the phrase dependency information for each phrase i, where each set $\mathcal{D}_i$ contains the phrases that depend on the presence of i. Our objective function function is given in Equation (1a): it is the sum of the salience scores of all the phrases chosen to form the highlights of a given document, subject to the constraints in Equations (1b)–(1j). The latter provide a natural way of describing the requirements the output must meet.

$$\max_x \quad \sum_{i \in \mathcal{P}} f_i x_i \tag{1a}$$

$$\text{s.t.} \quad \sum_{i \in \mathcal{P}} l_i x_i \leq L_T \tag{1b}$$

$$\sum_{i \in \mathcal{P}_s} l_i x_i \leq L_M y_s \qquad \forall s \in \mathcal{S} \tag{1c}$$

$$\sum_{i \in \mathcal{P}_s} l_i x_i \geq L_m y_s \qquad \forall s \in \mathcal{S} \tag{1d}$$

$$\sum_{i \in \mathcal{P}_t} x_i \geq 1 \qquad \forall t \in \mathcal{T} \tag{1e}$$

$$x_j \rightarrow x_i \qquad \forall i \in \mathcal{P}, j \in \mathcal{D}_i \tag{1f}$$

$$x_i \rightarrow y_s \qquad \forall s \in \mathcal{S}, i \in \mathcal{P}_s \tag{1g}$$

$$\sum_{s \in \mathcal{S}} y_s \leq N_S \tag{1h}$$

$$x_i \in \{0,1\} \qquad \forall i \in \mathcal{P} \tag{1i}$$

$$y_s \in \{0,1\} \qquad \forall s \in \mathcal{S}. \tag{1j}$$

Constraint (1b) ensures that the generated highlights do not exceed a total budget of L_T tokens. This constraint may vary depending on the application or task at hand. Highlights on a small screen device would presumably be shorter than highlights for news articles on the web. It is also possible to set the length of each highlight to be within the range $[L_m, L_M]$. Constraints (1c) and (1d) enforce this requirement. In particular, these constraints stop highlights formed from sentences at the beginning of the document (which tend to have

high salience scores) from being too long. Equation (1e) is a set-covering constraint, requiring that each of the words in $\mathcal{T}$ appears at least once in the highlights. We assume that words with high tf.idf scores reveal to a certain extent what the document is about. Constraint (1e) ensures that some of these words will be present in the highlights.

We enforce grammatical correctness through constraint (1f) which ensures that the phrase dependencies are respected. Phrases that depend on phrase i are contained in the set $\mathcal{D}_i$. Variable x_i is true, and therefore phrase i will be included, if any of its dependents $x_j \in \mathcal{D}_i$ are true. The phrase dependency constraints, contained in the set $\mathcal{D}_i$ and enforced by (1f), are the result of two rules based on the typed dependency information:

1. Any child node j of the current node i, whose connecting edge $i \rightarrow j$ is of type *nsubj* (nominal subject), *nsubjpass* (passive nominal subject), *dobj* (direct object), *pobj* (preposition object), *infmod* (infinitival modifier), *ccomp* (clausal complement), *xcomp* (open clausal complement), *measure* (measure phrase modifier) and *num* (numeric modifier) must be included if node i is included.

2. The parent node p of the current node i must always be included if i is, unless the edge $p \rightarrow i$ is of type *ccomp* (clausal complement) or *advcl* (adverbial clause), in which case it is possible to include i without including p.

Consider again the example in Figure 2(b). There are only two possible outputs from this sentence. If the phrase "*the survey*" is chosen, then the parent node "*found*" will be included, and from our first rule the *ccomp* phrase must also be included, which results in the output: "*But whites remain less optimistic, the survey found.*" If, on the other hand, the clause "*But whites remain less optimistic*" is chosen, then due to our second rule there is no constraint that forces the parent phrase "*found*" to be included in the highlights. Without other factors influencing the decision, this would give the output: "*But whites remain less optimistic.*" We can see from this example that encoding the possible outputs as decisions on branches of the phrase structure tree provides a more compact representation of many options than would be possible with an explicit enumeration of all possible compressions. Which output is chosen (if any) depends on the scores of the phrases involved, and the influence of the other constraints.

Constraint (1g) tells the ILP to create a highlight if one of its constituent phrases is chosen. Finally, note that a maximum number of highlights N_S can be set beforehand, and (1h) limits the highlights to this maximum.

5 Experimental Set-up

Training We obtained phrase-based salience scores using a supervised machine learning algorithm. 210 document-highlight pairs were chosen randomly from our corpus (see Section 3). Two annotators manually aligned the highlights and document sentences. Specifically, each sentence in the document was assigned one of three alignment labels: must be in the summary (1), could be in the summary (2), and is not in the summary (3). The annotators were asked to label document sentences whose content was identical to the highlights as "must be in the summary", sentences with partially overlapping content as "could be in the summary" and the remainder as "should not be in the summary". Inter-annotator agreement was .82 ($p < 0.01$, using Spearman's ρ rank correlation). The mapping of sentence labels to phrase labels was unsupervised: if the phrase came from a sentence labeled (1), and there was a unigram overlap (excluding stop words) between the phrase and any of the original highlights, we marked this phrase with a positive label. All other phrases were marked negative.

Our feature set comprised surface features such as sentence and paragraph position information, POS tags, unigram and bigram overlap with the title, and whether high-scoring tf.idf words were present in the phrase (66 features in total). The 210 documents produced a training set of 42,684 phrases (3,334 positive and 39,350 negative). We learned the feature weights with a linear SVM, using the software SVM-OOPS (Woodsend and Gondzio, 2009). This tool gave us directly the feature weights as well as support vector values, and it allowed different penalties to be applied to positive and negative misclassifications, enabling us to compensate for the unbalanced data set. The penalty hyper-parameters chosen were the ones that gave the best F-scores, using 10-fold validation.

Highlight generation We generated highlights for a test set of 600 documents. We created and

solved an ILP for each document. Sentences were first tokenized to separate words and punctuation, then parsed to obtain phrases and dependencies as described in Section 4 using the Stanford parser (Klein and Manning, 2003). For each phrase, features were extracted and salience scores calculated from the feature weights determined through SVM training. The distance from the SVM hyperplane represents the salience score. The ILP model (see Equation (1)) was parametrized as follows: the maximum number of highlights N_S was 4, the overall limit on length L_T was 75 tokens, the length of each highlight was in the range of $[8,28]$ tokens, and the topic coverage set $\mathcal{T}$ contained the top 5 tf.idf words. These parameters were chosen to capture the properties seen in the majority of the training set; they were also relaxed enough to allow a feasible solution of the ILP model (with hard constraints) for all the documents in the test set. To solve the ILP model we used the ZIB Optimization Suite software (Achterberg, 2007; Koch, 2004; Wunderling, 1996). The solution was converted into highlights by concatenating the chosen leaf nodes in order. The ILP problems we created had on average 290 binary variables and 380 constraints. The mean solve time was 0.03 seconds.

Summarization In order to examine the generality of our model and compare with previous work, we also evaluated our system on a vanilla summarization task. Specifically, we used the same model (trained on the CNN corpus) to generate summaries for the DUC-2002 corpus[2]. We report results on the entire dataset and on a subset containing 140 documents. This is the same partition used by Martins and Smith (2009) to evaluate their ILP model.[3]

Baselines We compared the output of our model to two baselines. The first one simply selects the "leading" three sentences from each document (without any compression). The second baseline is the output of a sentence-based ILP model, similar to our own, but simpler. The model is given in (2). The binary decision variables $x \in \{0,1\}^{|\mathcal{S}|}$ now represent sentences, and f_i the salience score for each sentence. The objective again is to maximize the total score, but now subject only to tf.idf coverage (2b) and a limit on the number of highlights (2c) which we set to 3. There are no sentence length or grammaticality constraints, as there is no sentence compression.

$$\max_{x} \quad \sum_{i \in \mathcal{S}} f_i x_i \tag{2a}$$

$$\text{s.t.} \quad \sum_{i \in \mathcal{S}_t} x_i \geq 1 \qquad \forall t \in \mathcal{T} \tag{2b}$$

$$\sum_{i \in \mathcal{S}} x_i \leq N_S \tag{2c}$$

$$x_i \in \{0,1\} \qquad \forall i \in \mathcal{S}. \tag{2d}$$

The SVM was trained with the same features used to obtain phrase-based salience scores, but with sentence-level labels (labels (1) and (2) positive, (3) negative).

Evaluation We evaluated summarization quality using ROUGE (Lin and Hovy, 2003). For the highlight generation task, the original CNN highlights were used as the reference. We report unigram overlap (ROUGE-1) as a means of assessing informativeness and the longest common subsequence (ROUGE-L) as a means of assessing fluency.

In addition, we evaluated the generated highlights by eliciting human judgments. Participants were presented with a news article and its corresponding highlights and were asked to rate the latter along three dimensions: informativeness (do the highlights represent the article's main topics?), grammaticality (are they fluent?), and verbosity (are they overly wordy and repetitive?). The subjects used a seven point rating scale. An ideal system would receive high numbers for grammaticality and informativeness and a low number for verbosity. We randomly selected nine documents from the test set and generated highlights with our model and the sentence-based ILP baseline. We also included the original highlights as a gold standard. We thus obtained ratings for 27 (9×3) document-highlights pairs.[4] The study was conducted over the Internet using WebExp (Keller et al., 2009) and was completed by 34 volunteers, all self reported native English speakers.

With regard to the summarization task, following Martins and Smith (2009), we used ROUGE-1 and ROUGE-2 to evaluate our system's output. We also report results with ROUGE-L. Each document in the DUC-2002 dataset is paired with

[3] We are grateful to André Martins for providing us with details of their testing partition.

[4] A Latin square design ensured that subjects did not see two different highlights of the same document.

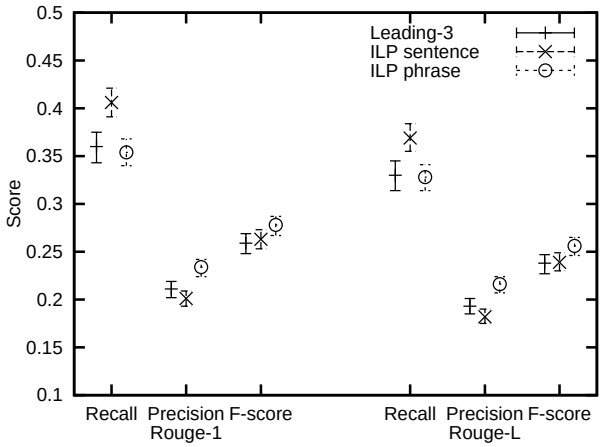

Figure 3: ROUGE-1 and ROUGE-L results for phrase-based ILP model and two baselines, with error bars showing 95% confidence levels.

a human-authored summary (approximately 100 words) which we used as reference.

6 Results

We report results on the highlight generation task in Figure 3 with ROUGE-1 and ROUGE-L (error bars indicate the 95% confidence interval). In both measures, the ILP sentence baseline has the best recall, while the ILP phrase model has the best precision (the differences are statistically significant). F-score is higher for the phrase-based system but not significantly. This can be attributed to the fact that the longer output of the sentence-based model makes the recall task easier. Average highlight lengths are shown in Table 3, and the compression rates they represent. Our phrase model achieves the highest compression rates, whereas the sentence-based model tends to select long sentences even in comparison to the lead baseline. The sentence ILP model outperforms the lead baseline with respect to recall but not precision or F-score. The phrase ILP achieves a significantly better F-score over the lead baseline with both ROUGE-1 and ROUGE-L.

The results of our human evaluation study are summarized in Table 4. There was no statistically significant difference in the grammaticality between the highlights generated by the phrase ILP system and the original CNN highlights (means differences were compared using a Post-hoc Tukey test). The grammaticality of the sentence ILP was significantly higher overall as no compression took place ($\alpha < 0.05$). All three

	s	toks/s	C.R.
Articles	36.5	22.2 ± 4.0	100%
CNN highlights	3.5	13.3 ± 1.7	5.8%
ILP phrase	3.8	18.0 ± 2.9	8.4%
Leading-3	3.0	25.1 ± 7.4	9.3%
ILP sentence	3.0	31.3 ± 7.9	11.6%

Table 3: Comparison of output lengths: number of sentences, tokens per sentence, and compression rate, for CNN articles, their highlights, the ILP phrase model, and two baselines.

Model	Grammar	Importance	Verbosity
CNN highlights	4.85	4.88	3.14
ILP sentence	6.41	5.47	3.97
ILP phrase	5.53	5.05	3.38

Table 4: Average human ratings for original CNN highlights, and two ILP models.

systems performed on a similar level with respect to importance (differences in the means were not significant). The highlights created by the sentence ILP were considered significantly more verbose ($\alpha < 0.05$) than those created by the phrase-based system and the CNN abstractors. Overall, the highlights generated by the phrase ILP model were not significantly different from those written by humans. They capture the same content as the full sentences, albeit in a more succinct manner. Table 5 shows the output of the phrase-based system for the documents in Table 1.

Our results on the complete DUC-2002 corpus are shown in Table 6. Despite the fact that our model has not been optimized for the original task of generating 100-word summaries—instead it is trained on the CNN corpus, and generates highlights—the results are comparable with the best of the original participants[5] in each of the ROUGE measures. Our model is also significantly better than the lead sentences baseline.

Table 7 presents our results on the same DUC-2002 partition (140 documents) used by Martins and Smith (2009). The phrase ILP model achieves a significantly better F-score (for both ROUGE-1 and ROUGE-2) over the lead baseline, the sentence ILP model, and Martins and Smith. We should point out that the latter model is not a straw man. It significantly outperforms a pipeline

[5]The list of participants is on page 12 of the slides available from `http://duc.nist.gov/pubs/2002slides/overview.02.pdf`.

- *More than two-thirds of African-Americans believe Martin Luther King Jr.'s vision for race relations has been fulfilled.*
- *69 percent of blacks said King's vision has been fulfilled in the more than 45 years since his 1963 'I have a dream' speech.*
- *But whites remain less optimistic, the survey found.*

- *A Florida man is using billboards with an image of the burning World Trade Center to encourage votes for a Republican presidential candidate, drawing criticism.*
- *'Please Don't Vote for a Democrat' reads the type over the picture of the twin towers.*
- *Mike Meehan said former President Clinton should have put a stop to Osama bin Laden and al Qaeda before 9/11.*

Table 5: Generated highlights for the stories in Table 1 using the phrase ILP model.

Participant	ROUGE-1	ROUGE-2	ROUGE-L
28	0.464	0.222	0.432
19	0.459	0.221	0.431
21	0.458	0.216	0.426
29	0.449	0.208	0.419
27	0.445	0.209	0.417
Leading-3	0.416	0.200	0.390
ILP phrase	0.454	0.213	0.428

Table 6: ROUGE results on the complete DUC-2002 corpus, including the top 5 original participants. For all results, the 95% confidence interval is $\pm$0.008.

approach that first creates extracts and then compresses them. Furthermore, as a standalone sentence compression system it yields state of the art performance, comparable to McDonald's (2006) discriminative model and superior to Hedge Trimmer (Zajic et al., 2007), a less sophisticated deterministic system.

7 Conclusions

In this paper we proposed a joint content selection and compression model for single-document summarization. A key aspect of our approach is the representation of content by phrases rather than entire sentences. Salient phrases are selected to form the summary. Grammaticality, length and coverage requirements are encoded as constraints in an integer linear program. Applying the model to the generation of "story highlights" (and single document summaries) shows that it is a viable alternative to extraction-based systems. Both ROUGE scores and the results of our human study

	ROUGE-1	ROUGE-2	ROUGE-L
Leading-3	.400 $\pm$ .018	.184 $\pm$ .015	.374 $\pm$ .017
M&S (2009)	.403 $\pm$ .076	.180 $\pm$ .076	—
ILP sentence	.430 $\pm$ .014	.191 $\pm$ .015	.401 $\pm$ .014
ILP phrase	.445 $\pm$ .014	.200 $\pm$ .014	.419 $\pm$ .014

Table 7: ROUGE results on DUC-2002 corpus (140 documents). —: only ROUGE-1 and ROUGE-2 results are given in Martins and Smith (2009).

confirm that our system manages to create summaries at a high compression rate and yet maintain the informativeness and grammaticality of a competitive extractive system. The model itself is relatively simple and knowledge-lean, and achieves good performance without reference to any resources outside the corpus collection.

Future extensions are many and varied. An obvious next step is to examine how the model generalizes to other domains and text genres. Although coherence is not so much of an issue for highlights, it certainly plays a role when generating standard summaries. The ILP model can be straightforwardly augmented with discourse constraints similar to those proposed in Clarke and Lapata (2007). We would also like to generalize the model to arbitrary rewrite operations, as our results indicate that compression rates are likely to improve with more sophisticated paraphrasing.

Abstract

In this paper, we introduce a corpus of consumer reviews from the *rateitall* and the *eopinions* websites annotated with opinion-related information. We present a two-level annotation scheme. In the first stage, the reviews are analyzed at the sentence level for *(i)* relevancy to a given topic, and *(ii)* expressing an evaluation about the topic. In the second stage, on-topic sentences containing evaluations about the topic are further investigated at the expression level for pinpointing the properties (semantic orientation, intensity), and the functional components of the evaluations (opinion terms, targets and holders). We discuss the annotation scheme, the inter-annotator agreement for different subtasks and our observations.

1 Introduction

There has been a huge interest in the automatic identification and extraction of opinions from free text in recent years. Opinion mining spans a variety of subtasks including: creating opinion word lexicons (Esuli and Sebastiani, 2006; Ding et al., 2008), identifying opinion expressions (Riloff and Wiebe, 2003; Fahrni and Klenner, 2008), identifying polarities of opinions in context (Breck et al., 2007; Wilson et al., 2005), extracting opinion targets (Hu and Liu, 2004; Zhuang et al., 2006; Cheng and Xu, 2008) and opinion holders (Kim and Hovy, 2006; Choi et al., 2005).

Data-driven approaches for extracting opinion expressions, their holders and targets require reliably annotated data at the expression level. In previous research, expression level annotation of opinions was extensively investigated on newspaper articles (Wiebe et al., 2005; Wilson and Wiebe, 2005; Wilson, 2008b) and on meeting dialogs (Somasundaran et al., 2008; Wilson, 2008a).

Compared to the newspaper and meeting dialog genres, little corpus-based work has been carried out for interpreting the opinions and evaluations in user-generated discourse. Due to the high popularity of Web 2.0 communities[1], the amount of user-generated discourse and the interest in the analysis of such discourse has increased over the last years. To the best of our knowledge, there are two corpora of user-generated discourse which are annotated for opinion related information at the expression level: The corpus of Hu & Liu (2004) consists of customer reviews about consumer electronics, and the corpus of Zhuang et al. (2006) consists of movie reviews. Both corpora are tailored for application specific needs, therefore, do not contain certain related information explicitly annotated in the discourse, which we consider important (see Section 2). Furthermore, none of these works provide inter-annotator agreement studies.

Our goal is to create sentence and expression level annotated corpus of customer reviews which fulfills the following requirements: (1) It filters individual sentences regarding their topic relevancy and the existence of an opinion or factual information which implies an evaluation. (2) It identifies opinion expressions including the respective opinion target, opinion holder, modifiers, and anaphoric expressions if applicable. (3) The semantic orientation of the opinion expression is identified while considering negation, and the opinion expression is linked to the respective holder and target in the discourse. Such a resource would *(i)* enable novel applications of opinion mining such as a fine-grained identification of opinion properties, e.g. opinion modification detection including negation, and *(ii)* enhance opinion target extraction and the polarity assignment by linking the opinion expression with its target

and providing anaphoric resolutions in discourse.

We present an annotation scheme which fulfills the mentioned requirements, an inter-annotator agreement study, and discuss our observations. The rest of this paper is structured as follows: Section 2 presents the related work. In Sections 3, we describe the annotation scheme. Section 4 presents the data and the annotation study, while Section 5 summarizes the main conclusions.

2 Previous Opinion Annotated Corpora

2.1 Newspaper Articles and Meeting Dialogs

Most prominent work concerning the expression level annotation of opinions is the Multi-Perspective Question Answering (MPQA) corpus[2] (Wiebe et al., 2005). It was extended several times over the last years, either by adding new documents or annotating new types of opinion related information (Wilson and Wiebe, 2005; Stoyanov and Cardie, 2008; Wilson, 2008b). The MPQA annotation scheme builds upon the *private state* notion (Quirk et al., 1985) which describes mental states including opinions, emotions, speculations and beliefs among others. The annotation scheme strives to represent the *private states* in terms of their functional components (i.e. *experiencer* holding an *attitude* towards a *target*). It consists of frames (*direct subjective, expressive subjective element, objective speech event, agent, attitude,* and *target frames*) with slots representing various attributes and properties (e.g.*intensity, nested source*) of the private states.

Wilson (2008a) adapts and extends the concepts from the MPQA scheme to annotate subjective content in meetings (AMI corpus), and creates the AMIDA scheme. Besides subjective utterances, the AMIDA scheme contains *objective polar utterances* which annotates evaluations without expressing explicit opinion expressions.

Somasundaran et al. (2008) proposes *opinion frames* for representing discourse level associations in meeting dialogs. The annotation scheme focuses on two types of opinions, *sentiment* and *arguing*. It annotates the opinion expression and target spans. The *link* and *link type* attributes associate the target with other targets in the discourse through *same* or *alternative* relations. The *opinion frames* are built based on the links between targets. Somasundaran et al. (2008) show that *opinion frames* enable a coherent interpretation of the opinions in discourse and discover implicit evaluations through link transitivity.

Similar to Somasundaran et al. (2008), Asher et al. (2008) performs discourse level analysis of opinions. They propose a scheme which first identifies and assigns categories to the opinion segments as *reporting, judgment, advice,* or *sentiment*; and then links the opinion segments with each other via rhetorical relations including *contrast, correction, support, result*, or *continuation*. However, in contrast to our scheme and other schemes, instead of marking expression boundaries without any restriction they annotate an opinion segment only if it contains an opinion word from their lexicon, or if it has a rhetorical relation to another opinion segment.

2.2 User-generated Discourse

The two annotated corpora of user-generated content and their corresponding annotation schemes are far less complex. Hu & Liu (2004) present a dataset of customer reviews for consumer electronics crawled from amazon.com. The following example shows two annotations taken from the corpus of Hu & Liu (2004):

camera[+2]##This is my first digital camera and what a toy it is...

size[+2][u]##it is small enough to fit easily in a coat pocket or purse.

The corpus provides only target and polarity annotations, and do not contain opinion expression or opinion modifier annotations which lead to these polarity scores. The annotation scheme allows the annotation of implicit features (indicated with the the attribute *[u]*). Implicit features are not resolved to any actual product feature instances in discourse. In fact, the actual positions of the product features (or any anaphoric references to them) are not explicitly marked in the discourse, i.e, it is unclear to which mention of the feature the opinion refers to.

In their paper on movie review mining and summarization, Zhuang et al. (2006) introduce an annotated corpus of movie reviews from the Internet Movie Database. The corpus is annotated regarding movie features and corresponding opinions. The following example shows an annotated sentence:

⟨Sentence⟩I have never encountered a movie whose supporting cast was so perfectly realized.⟨FO Fword="supporting cast" Ftype="PAC" Oword="perfect" Otype="PRO"/⟩⟨/Sentence⟩

[2] http://www.cs.pitt.edu/mpqa/

The movie features (*Fword*) are attributed to one of 20 predefined categories (Ftype). The opinion words (*Oword*) and their semantic orientations (*Otype*) are identified. Possible negations are directly reflected by the semantic orientation, but not explicitly labeled in the sentence. *(PD)* in the following example indicates that the movie feature is referenced by anaphora:

⟨Sentence⟩It is utter nonsense and insulting to my intelligence and sense of history. ⟨FO Fword="film(PD)" Ftype="OA" Oword="nonsense, insulting" Otype="CON"/⟩⟨/Sentence⟩

However, similar to the corpus of Hu & Liu (2004) the referring pronouns are not explicitly marked in discourse. It is therefore neither possible to automatically determine which pronoun creates the link if there are more than one in a sentence, nor it is denoted which antecedent, i.e. the actual mention of the feature in the discourse it relates to.

3 Annotation Scheme

3.1 Opinion versus Polar Facts

The goal of the annotation scheme is to capture the evaluations regarding the topics being discussed in the consumer reviews. The evaluations in consumer reviews are either explicit expressions of opinions, or facts which imply evaluations as discussed below.

Explicit expressions of opinions: Opinions are private states (Wiebe et al., 2005; Quirk et al., 1985) which are not open to objective observation or verification. In this study, we focus on the opinions stating the quality or value of an entity, experience or a proposition from one's perspective. (1) illustrates an example of an explicit expression of an opinion. Similar to Wiebe et al. (2005), we view opinions in terms of their functional components, as *opinion holders*, e.g., the author in (1), holding attitudes (*polarity*), e.g., negative attitude indicated with the word *nightmare*, towards possible *targets*, e.g., *Capella University*.

(1) I had a nightmare with Capella University.[3]

Facts implying evaluations: Besides opinions, there are facts which can be objectively verified, but still imply an evaluation of the quality or value of an entity or a proposition. For instance, consider the snippet below:

[3]We use authentic examples from the corpus without correcting grammatical or spelling errors.

(2) In a 6-week class, I counted 3 comments from the professors directly to me and two directed to my team.
(3) I found that I spent most of my time learning from my fellow students.
(4) A standard response from my professors would be that of a sentence fragment.

The example above provides an evaluation about the professors without stating any explicit expressions of opinions. We call such objectively verifiable, but evaluative sentences *polar facts*. Explicit expressions of opinions typically contain specific cues, i.e. opinion words, loaded with a positive or negative connotation (e.g., *nightmare*). Even when they are taken out of the context in which they appear, they evoke an evaluation. However, evaluations in *polar facts* can only be inferred within the context of the review. For instance, the targets of the implied evalution in the polar facts (2), (3) and (4) are the professors. However, (3) may have been perceived as a positive statement if the review was explaining how good the fellow students were or how the course enforced team work etc.

The annotation scheme consists of two levels. First, the sentence level scheme analyses each sentence in terms of *(i)* its relevancy to the overall topic of the review, and *(ii)* whether it contains an evaluation (an opinion or a *polar fact*) about the topic. Once the on-topic sentences containing evaluations are identified, the expression level scheme first focuses either on marking the text spans of the opinion expressions (if the sentence contains an explicit expression of an opinion) or marking the targets of the *polar facts* (if the sentence is a *polar fact*). Upon marking an opinion expression span, the target and holder of the opinion is marked and linked to the marked opinion expression. Furthermore, the expression level scheme allows assigning polarities to the marked opinion expression spans and targets of the *polar facts*.

The following subsections introduce the sentence and the expression level annotation schemes in detail with examples.

3.2 Sentence Level Annotation

The sentence annotation strives to identify the sentences containing evaluations about the topic. In consumer reviews people occasionally drift off the actual topic being reviewed. For instance, as in (5) taken from a review about an online university, they tend to provide information about their background or other experiences.

(5) I am very fortunate and almost right out of high school

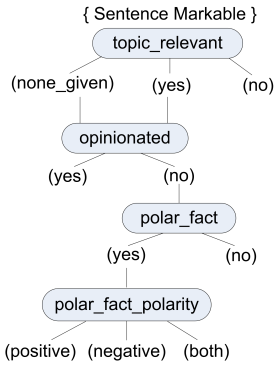

Figure 1: The sentence level annotation scheme

with a very average GPA and only 20; I already make above $45,000 a year as a programmer with a large health care company for over a year and have had 3 promotions up in the first year and a half.

Such sentences do not provide information about the actual topic, but typically serve for justifying the user's point of view or provide a better understanding about her circumstances. However, they are not valuable for an application aiming to extract opinions about a specific topic.

Reviews given to the annotators contain meta information stating the topic, for instance, the name of the university or the service being reviewed. A markable (i.e. an annotation unit) is created for each sentence prior to the annotation process. At this level, the annotation process is therefore a sentence labeling task. The annotators are able to see the whole review, and instructed to label sentences in the context of the whole review. Figure 1 presents the sentence level scheme. Attribute names are marked with oval circles and the possible values are given in parenthesis. The following attributes are used:

topic_relevant attribute is labeled as *yes* if the sentence discusses the given topic itself or its aspects, properties or features as in examples (1)-(4). Other possible values for this attribute include *none_given* which can be chosen in the absence of meta data, or *no* if the sentence drifted off the topic as in example (5).

opinionated attribute is labeled as *yes* if the sentence contains any explicit expressions of opinions about the given topic. This attribute is presented if the *topic_relevant* attribute has been labeled as *none_given* or *yes*. In other words, only the on-topic sentences are considered in this step. Examples (6)-(8) illustrate examples labeled as *topic_relevant=yes* and *opinionated=yes*.

*(6) Many people are knocking Devry but I have seen them to be a very great school. [**Topic:** Devry University]*
*(7) University of Phoenix was a surprising disappointment. [**Topic:** University of Phoenix]*
*(8) Assignments were passed down, but when asked to clarify the assignment because the syllabus had contradicting, poorly worded, information, my professors regularly responded...."refer to the syllabus"....but wait, the syllabus IS the question. [**Topic:** University of Phoenix]*

polar_fact attribute is labeled as *yes* if the sentence is a *polar fact*. This attribute is presented if the *opinionated* attribute has been labeled as *no*. Examples (2)-(4) demonstrate sentences labeled as *topic_relevant=yes, opinionated=no* and *polar_fact=yes*.

polar_fact_polarity attribute represents the polarity of the evaluation in a *polar_fact* sentence. The possible values for this attribute include *positive, negative, both*. The value *both* is intended for the *polar_fact* sentences containing more than one evaluation with contradicting polarities. At the expression level analysis, the targets of the contradicting *polar_fact* evaluations are identified distinctly and assigned polarities of *positive* or *negative* later on. Examples (9)-(11) demonstrate examples of *polar fact* sentences with different values of the attribute *polar_fact_polarity*.

*(9) There are students in the first programming class and after taking this class twice they cannot write a single line of code. **[polar_fact_polarity=negative]***
*(10) The same class (i.e. computer class) being teach at Ivy League schools are being offered at Devry. **[polar_fact_polarity=positive]***
*(11) The lectures are interactive and recorded, but you need a consent from the instructor each time. **[polar_fact_polarity=both]***

3.3 Expression Level Annotation

At the expression level, we focus on the topic relevant sentences containing evaluations, i.e., sentences labeled as *topic_relevant=yes, opinionated=yes* or *topic_relevant=yes, opinionated=no, polar_fact=yes*. If the sentence is a *polar fact*, then the aim is to mark the target and label the polarity of the evaluation. If the sentence is opinionated, then, the aim is to mark the opinion expression span, and label its polarity and strength (i.e. intensity), and to link it to the target and the holder.

Figure 2 presents the expression level scheme. At this stage, annotators mark text spans, and are allowed to assign one of the five labels to the marked span:

The ***polar_target*** is used to label the targets of the evaluations implied by *polar facts*. The *isReference* attribute labels *polar_targets* which are anaphoric references. The *polar_target_polarity*

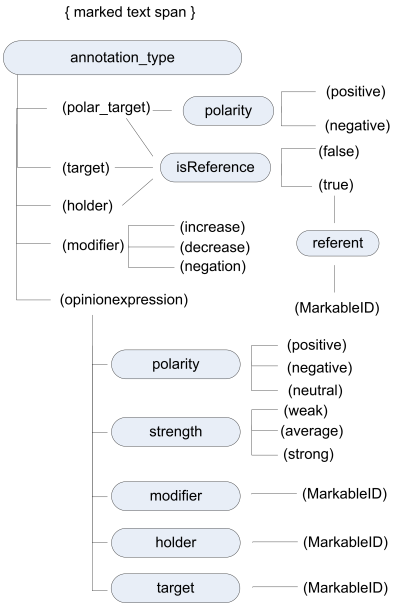

Figure 2: The expression level annotation scheme

attribute is used to label the polarity as *positive* or *negative*. If the *isReference* attribute is labeled as *true*, then the *referent* attribute appears which enables the annotator to resolve the reference to its antecedent. Consider the example sentences (12) and (13) below. The *polar_target* in (13), written bold, is labeled as *isReference=true*, *polar_target_polarity=negative*. To resolve the reference, annotator first creates another *polar_target* markable for the antecedent, namely the bold text span in (12), then, links the antecedent to the *referent* attribute of the *polar_target* in (13).

(12) Since classes already started, ***CTU*** *told me they would extend me so that I could complete the classes and get credit once I got back.*
(13) What ***they*** *didn't tell me is in order to extend, I also had to be enrolled in the next semester.*

The ***target*** annotation represents what the opinion is about. Both *polar_targets* and *targets* can be the topic of the review or different aspects, i.e. features of the topic. Similar to the *polar_targets*, the *isReference* attribute allows the identification of the targets which are anaphoric references and the *referent* attribute links them to their antecedents in the discourse. Bold span in (14) shows an example of a *target* in an opinionated sentence.

(14) Capella U has incredible ***faculty in the Harold Abel School of Psychology****.*

The ***holder*** type represents the holder of an opinion in the discourse and is labeled in the same manner as the *targets* and *polar_targets*. In consumer reviews, *holders* are most of the time the authors of the reviews. To ease the annotation process, the holder is not labeled when this is the author.

The ***modifier*** annotation labels the lexical items, such as *not, very, hardly etc.*, which affect the strength of an opinion or shift its polarity. Upon creation of a *modifier* markable, annotators are asked to choose between *negation, increase, decrease* for identifying the influence of the *modifier* on the opinion. For instance, the marked span in (15) is labeled as *modifier=increase* as it gives the impression that the author is really offended by the negative comments about her university.

(15) I am ***quite honestly*** *appauled by some of the negative comments given for Capella University on this website.*

The ***opinionexpression*** annotation is used to label the opinion terms in the sentence. This markable type has five attributes, three of which, i.e., *modifier*, *holder*, and *target* are pointer attributes to the previously defined markable types. The *polarity* attribute assesses the semantic orientation of the attitude, where the *strength* attribute marks the intensity of this attitude. The *polarity* and *strength* attributes focus solely on the marked *opinionexpression* span, not the whole evaluation implied in the sentence. For instance, the *opinionexpression* span in (16) is labeled as *polarity=negative, strength=average*. We infer the polarity of the evaluation only after considering the *modifier, polarity* and the *strength* attributes together. In (16), the evaluation about the target is strongly negative after considering all three attributes of the *opinionexpression* annotation. In (17), the *polarity* of the *opinionexpression1* itself (*complaints*) is labeled as *negative*. It is linked to the *modifier1* which is labeled as *negation*. *Target1* (*PhD journey*) is linked to the *opinionexpression1*. The overall evaluation regarding the *target1* is positive after applying the affect of the *modifier1* to the *polarity* of the *opinionexpression1*, i.e., after negating the negative polarity.

(16) I am ***quite honestly*** $_{[modifier]}$ ***appauled by*** $_{[opinionexpression]}$ *some of the* ***negative comments given for Capella University on this website*** $_{[target]}$.
(17) I have ***no*** $_{[modifier1]}$ ***complaints*** $_{[opinionexpression1]}$ *about the entire* ***PhD journey*** $_{[target1]}$ *and* ***highly*** $_{[modifier2]}$ ***recommend*** $_{[opinionexpression2]}$ ***this school*** $_{[target2]}$.

Finally, Figure 3 demonstrates all expression level markables created for an opinionated sentence and how they relate to each other.

Figure 3: Expression level annotation example

4 Annotation Study

Each review has been annotated by two annotators independently according to the annotation scheme introduced above. We used the freely available MMAX2[4] annotation tool capable of stand-off multi-level annotations. Annotators were native speaker linguistic students. They were trained on 15 reviews after reading the annotation manual.[5] In the training stage, the annotators discussed with each other if different decisions have been made and were allowed to ask questions to clarify their understanding of the scheme. Annotators had access to the review text as a whole while making their decisions.

4.1 Data

The corpus consists of consumer reviews collected from the review portals *rateitall*[6] and *epinions*[7]. It contains reviews from two domains including online universities, e.g., Capella University, Pheonix, University of Maryland University College etc. and online services, e.g., PayPal, egroups, eTrade, eCircles etc. These two domains were selected with the project-relevant, domain-specific research goals in mind. We selected a specific topic, e.g. Pheonix, if there were more than 3 reviews written about it. Table 1 shows descriptive statistics regarding the data.

We used 118 reviews containing 1151 sentences from the university domain for measuring the sentence and expression level agreements. In the following subsections, we report the inter-annotator agreement (IAA) at each level.

Table 1: Descriptive statistics about the corpus

4.2 Sentence Level Agreement

Sentence level markables were already created automatically prior to the annotation, i.e., the set of annotation units were the same for both annotators. We use Cohen's kappa (κ) (Cohen, 1960) for measuring the IAA. The sentence level annotation scheme has a hierarchical structure. A new attribute is presented based on the decision made for the previous attribute, for instance, *opinionated* attribute is only presented if the *topic_relevant* attribute is labeled as *yes* or *none_given*; *polar_fact* attribute is only presented if the *opinionated* attribute is labeled as *no* etc. We calculate κ for each attribute considering only the markables which were labeled the same by both annotators in the previously required step. Table 2 shows the κ values for each attribute, the size of the markable set on which the value was calculated, and the percentage agreement.

Attribute	Markables	Agr.	κ
topic_relevant	1151	0.89	0.73
opinionated	682	0.80	0.61
polar_fact	258	0.77	0.56
polar_fact_polarity	103	0.96	0.92

Table 2: Sentence level inter-annotator agreement

The agreement for topic relevancy shows that it is possible to label this attribute reliably. The sentences labeled as topic relevant by both annotators correspond to 59% of all sentences, suggesting that people often drift off the topic in consumer reviews. This is usually the case when they provide information about their backgrounds or alternatives to the given topic.

On the other hand, we obtain moderate agreement levels for the *opinionated* and *polar_fact* attributes. 62% of the topic relevant sentences were labeled as opinionated by at least one annotator, and the rest 38% constitute the topic relevant sentences labeled as not opinionated by both annotators. Nonetheless, they still contain evaluations (*polar_facts*), as 15% of the topic relevant sen-

tences were labeled as *polar_facts* by both annotators. When we merge the attributes *opinionated* and *polar_fact* into a single category, we obtain κ of 0.75 and a percentage agreement of 87%. Thus, we conclude that opinion-relevant sentences, either in the form of an explicit expression of opinion or a *polar fact*, can be labeled reliably in consumer reviews. However, there is a thin border between *polar facts* and explicit expressions of opinions.

To the best of our knowledge, similar annotation efforts on consumer or movie reviews do not provide any agreement figures for direct comparison. However, Wiebe et al. (2005) present an annotation study where they mark textual spans for subjective expressions in a newspaper corpus. They report pairwise κ values for three annotators ranging between 0.72 - 0.84 for the sentence level subjective/objective judgments. Wiebe et al. (2005) mark subjective spans, and do not explicitly perform the sentence level labeling task. They calculate the sentence level κ values based on the existence of a subjective expression span in the sentence. Although the task definitions, approaches and the corpora have quite disparate characteristics in both studies, we obtain comparable results when we merge *opinionated* and *polar_fact* categories.

4.3 Expression Level Agreement

At the expression level, annotators focus only on the sentences which were labeled as *opinionated* or *polar_fact* by both annotators. Annotators were instructed to mark text spans, and then, assign them the annotation types such as *polar_target, opinionexpression* etc. (see Figure 2). For calculating the text span agreement, we use the agreement metric presented by Wiebe et al. (2005) and Somasundaran et al. (2008). This metric corresponds to the precision (P) and recall (R) metrics in information retrieval where the decisions of one annotator are treated as the system; the decisions of the other annotator are treated as the gold standard; and the overlapping spans correspond to the correctly retrieved documents.

Somasundaran et al. (2008) present a discourse level annotation study in which opinion and target spans are marked and linked with each other in a meeting transcript corpus. Following Somasundaran et al. (2008), we compute three different measures for the text span agreement: *(i) exact matching* in which the text spans should perfectly match; *(ii) lenient (relaxed) matching* in which the overlap between spans is considered as a match, and *(iii) subset matching* in which a span has to be contained in another span in order to be considered as a match.[8] Agreement naturally increases as we relax the matching constraints. However, there were no differences between the *lenient* and the *subset* agreement values. Therefore, we report only the *exact* and *lenient matching* agreement results for each annotation type in Table 3. The same agreement results for the *lenient* and *subset* matching indicates that inexact matches are still very similar to each other, i.e., at least one span is totally contained in the other.

Somasundaran et al. (2008) do not report any F-measure. However, they report span agreement results in terms of precision and recall ranging between 0.44 - 0.87 for opinion spans and between 0.74 - 0.90 for the target spans. Wiebe et al. (2005) use the *lenient matching* approach for reporting text span agreements ranging between 0.59 - 0.81 for subjective expressions. We obtain higher agreement values for both opinion expression and target spans. We attribute this to the fact that the annotators look for opinion expression and target spans within the opinionated sentences which they agreed upon. Sentence level analysis indeed increases the reliability at the expression level. Compared to the high agreement on marking *target* spans, we obtain lower agreement values on marking *polar_target* spans. We observe that it is easier to attribute explicit expressions of evaluations to topic relevant entities compared to attributing evaluations implied by experiences to specific topic relevant entities in the reviews.

We calculated the agreement on identifying anaphoric references using the method introduced in (Passonneau, 2004) which utilizes Krippendorf's α (Krippendorff, 2004) for computing reliability for coreference annotation. We considered the overlapping *target* and *polar_target* spans together in this calculation, and obtained an α value of 0.29. Compared to Passonneau (α values from 0.46 to 0.74), we obtain a much lower agreement value. This may be due to the different definitions and organizations of the annotation tasks. Passonneau requires prior marking of all noun phrases (or instances which needs to be processed by the an-

[8] An example of *subset matching*: waste of time vs. total waste of time

Span	Exact			Lenient		
	P	R	F	P	R	F
opinionexpression	0.70	0.80	0.75	0.82	0.93	0.87
modifier	0.80	0.82	0.81	0.86	0.86	0.86
target	0.80	0.81	0.80	0.91	0.90	0.91
holder	0.75	0.72	0.73	0.93	0.88	0.91
polar_target	0.67	0.42	0.51	0.75	0.49	0.59

Table 3: Inter-annotator agreement on text spans at the expression level

notator). Annotator's task is to identify whether an instance refers to another marked entity in the discourse, and then, to identify corefering entity chains. However, in our annotation process annotators were tasked to identify only one entity as the referent, and was free to choose it from anywhere in the discourse. In other words, our chains contain only one entity. It is possible that both annotators performed correct resolutions, but still did not overlap with each other, as they resolve to different instances of the same entity in the discourse. We plan to further investigate reference resolution annotation discrepancies and perform corrections in the future.

Some annotation types require additional attributes to be labeled after marking the span. For instance, upon marking a text span as a *polar_target* or an *opinionexpression*, one has to label the *polarity* and *strength*. We consider the overlapping spans for each annotation type and use κ for reporting the agreement on these attributes. Table 4 shows the κ values.

Attribute	Markables	Agr.	κ
polarity	329	0.97	0.94
strength	329	0.74	0.55
modifier	136	0.88	0.77
polar_target_polarity	63	0.80	0.67

Table 4: Inter-annotator agreement at the expression level

We observe that the *strength* of the *opinionexpression* and the *polar_target_polarity* cannot be labeled as reliably as the *polarity* of the *opinionexpression*. 61% of the agreed upon *polar_targets* were labeled as negative by both annotators. On the other hand, only 35% of the agreed upon *opinionexpressions* were labeled as negative by both annotators. There were no neutral instances. This indicates that reviewers tend to report negative experiences using polar facts, probably objectively describing what has happened, but report positive experiences with explicit opinion expressions. Distribution of the *strength* attribute was as follows: *weak* 6%, *average* 54%, and *strong* 40%. The majority of the modifiers were annotated as intensifiers (70%), while 20% of the modifiers were labeled as negation.

4.4 Discussion

We analyzed the discrepancies in the annotations to gain insights about the challenges involved in various opinion related labeling tasks. At the sentence level, there were several trivial cases of disagreement, for instance, failing to recognize topic relevancy when the topic was not mentioned or referenced explicitly in the sentence, as in (18). Occasionally, annotators disagreed about whether a sentence that was written as a reaction to the other reviewers, as in (19), should be considered as topic relevant or not. Another source of disagreement included sentences similar to (20) and (21). One annotator interpreted them as universally true statements regardless of the topic, while the other attributed them to the discussed topic.

(18) Go to a state university if you know whats good for you!
(19) Those with sour grapes couldnt cut it, have an ax to grind, and are devoting their time to smearing the school.
(20) As far as learning, you really have to WANT to learn the material.
(21) On an aside, this type of education is not for the undisciplined learner.

Annotators easily distinguished the evaluations at the sentence level. However, they had difficulties distinguishing between a *polar_fact* and an opinion. For instance, both annotators agreed that the sentences (22) and (23) contain evaluations regarding the topic of the review. However, one annotator interpreted both sentences as objectively verifiable facts giving a positive impression about the school, while the other one treated them as opinions.

(22) All this work in the first 2 Years!
(23) The school has a reputation for making students work really hard.

Sentence level annotation increases the reliability of the expression level annotation in terms of marking text spans. However, annotators often had disagreements on labeling the *strength* attribute. For instance, one annotator labeled the

opinion expression in (24) as *strong*, while the other one labeled it as *average*. We observe that it is not easy to identify trivial causes of disagreements regarding *strength* as its perception by each individual is highly subjective. However, most of the disagreements occurred between *weak* and *average* cases.

(24) the experience that i have when i visit student finance is much ***like going to the dentist****, except when i leave, nothing is ever fixed.*

We did not apply any consolidation steps during our agreement studies. However, a final version of the corpus will be produced by the third judge (one of the co-authors) by consolidating the judgements of the two annotators.

5 Conclusions

We presented a corpus of consumer reviews from the *rateitall* and *eopinions* websites annotated with opinion related information. Existing opinion annotated user-generated corpora suffer from several limitations which result in difficulties for interpreting the experimental results and for performing error analysis. To name a few, they do not explicitly link the functional components of the opinions like targets, holders, or modifiers with the opinion expression; some of them do not mark opinion expression spans, none of them resolves anaphoric references in discourse. Therefore, we introduced a two level annotation scheme consisting of the sentence and expression levels, which overcomes the limitations of the existing review corpora. The sentence level annotation labels sentences for *(i)* relevancy to a given topic, and *(ii)* expressing an evaluation about the topic. Similar to (Wilson, 2008a), our annotation scheme allows capturing evaluations made with factual (objective) sentences. The expression level annotation further investigates on-topic sentences containing evaluations for pinpointing the properties (polarity, strength), and marking the functional components of the evaluations (opinion terms, modifiers, targets and holders), and linking them within a discourse. We applied the annotation scheme to the consumer review genre and presented an extensive inter-annotator study providing insights to the challenges involved in various opinion related labeling tasks in consumer reviews. Similar to the MPQA scheme, which is successfully applied to the newspaper genre, the annotation scheme treats opinions and evaluations as a composition of functional components and it is easily extendable. Therefore, we hypothesize that the scheme can also be applied to other genres with minor extensions or as it is. Finally, the corpus and the annotation manual will be made available at `http://www.ukp.tu-darmstadt.de/research/data/sentiment-analysis`.

Acknowledgements

This research was funded partially by the German Federal Ministry of Economy and Technology under grant 01MQ07012 and partially by the German Research Foundation (DFG) as part of the *Research Training Group on Feedback Based Quality Management in eLearning* under grant 1223. We are very grateful to Sandra Kübler for her help in organizing the annotators, and to Lizhen Qu for his programming support in harvesting the data.

Generating Focused Topic-specific Sentiment Lexicons

Valentin Jijkoun **Maarten de Rijke** **Wouter Weerkamp**
ISLA, University of Amsterdam, The Netherlands
jijkoun,derijke,w.weerkamp@uva.nl

Abstract

We present a method for automatically generating focused and accurate topic-specific subjectivity lexicons from a general purpose polarity lexicon that allow users to pin-point subjective on-topic information in a set of relevant documents. We motivate the need for such lexicons in the field of media analysis, describe a bootstrapping method for generating a topic-specific lexicon from a general purpose polarity lexicon, and evaluate the quality of the generated lexicons both manually and using a TREC Blog track test set for opinionated blog post retrieval. Although the generated lexicons can be an order of magnitude more selective than the general purpose lexicon, they maintain, or even improve, the performance of an opinion retrieval system.

1 Introduction

In the area of *media analysis*, one of the key tasks is collecting detailed information about opinions and attitudes toward specific topics from various sources, both offline (traditional newspapers, archives) and online (news sites, blogs, forums). Specifically, media analysis concerns the following system task: given a topic and list of documents (discussing the topic), find all instances of attitudes toward the topic (e.g., positive/negative sentiments, or, if the topic is an organization or person, support/criticism of this entity). For every such instance, one should identify the source of the sentiment, the polarity and, possibly, subtopics that this attitude relates to (e.g., specific targets of criticism or support). Subsequently, a (human) media analyst must be able to aggregate the extracted information by source, polarity or subtopics, allowing him to build support/criticism networks etc. (Altheide, 1996). Recent advances in language technology, especially in *sentiment analysis*, promise to (partially) automate this task.

Sentiment analysis is often considered in the context of the following two tasks:

- *sentiment extraction*: given a set of textual documents, identify phrases, clauses, sentences or entire documents that express attitudes, and determine the polarity of these attitudes (Kim and Hovy, 2004); and
- *sentiment retrieval*: given a topic (and possibly, a list of documents relevant to the topic), identify documents that express attitudes *toward this topic* (Ounis et al., 2007).

How can technology developed for sentiment analysis be applied to media analysis? In order to use a *sentiment extraction* system for a media analysis problem, a system would have to be able to determine which of the extracted sentiments are actually relevant, i.e., it would not only have to identify specific targets of all extracted sentiments, but also decide which of the targets are relevant for the topic at hand. This is a difficult task, as the relation between a *topic* (e.g., a movie) and specific targets of sentiments (e.g., acting or special effects in the movie) is not always straightforward, in the face of ubiquitous complex linguistic phenomena such as referential expressions ("... this beautifully shot *documentary*") or bridging anaphora ("the *director* did an excellent jobs").

In *sentiment retrieval*, on the other hand, the topic is initially present in the task definition, but it is left to the user to identify sources and targets of sentiments, as systems typically return a list of documents ranked by relevance and opinionatedness. To use a traditional sentiment retrieval system in media analysis, one would still have to manually go through ranked lists of documents returned by the system.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 585–594,
Uppsala, Sweden, 11-16 July 2010.

To be able to support media analysis, we need to combine the specificity of (phrase- or word-level) sentiment analysis with the topicality provided by sentiment retrieval. Moreover, we should be able to identify sources and specific targets of opinions.

Another important issue in the media analysis context is *evidence* for a system's decision. If the output of a system is to be used to inform actions, the system should present evidence, e.g., highlighting words or phrases that indicate a specific attitude. Most modern approaches to sentiment analysis, however, use various flavors of classification, where decisions (typically) come with confidence scores, but without explicit support.

In order to move towards the requirements of media analysis, in this paper we focus on two of the problems identified above: (1) pinpointing evidence for a system's decisions about the presence of sentiment in text, and (2) identifying specific targets of sentiment.

We address these problems by introducing a special type of lexical resource: a topic-specific subjectivity lexicon that indicates specific relevant targets for which sentiments may be expressed; for a given topic, such a lexicon consists of pairs (*syntactic clue*, *target*). We present a method for automatically generating a topic-specific lexicon for a given topic and query-biased set of documents. We evaluate the quality of the lexicon both manually and in the setting of an opinionated blog post retrieval task. We demonstrate that such a lexicon is highly *focused*, allowing one to effectively pinpoint evidence for sentiment, while being competetive with traditional subjectivity lexicons consisting of (a large number of) clue words.

Unlike other methods for topic-specific sentiment analysis, we do not expand a seed lexicon. Instead, we make an existing lexicon more focused, so that it can be used to actually pin-point subjectivity in documents relevant to a given topic.

2 Related Work

Much work has been done in sentiment analysis. We discuss related work in four parts: sentiment analysis in general, domain- and target-specific sentiment analysis, product review mining and sentiment retrieval.

2.1 Sentiment analysis

Sentiment analysis is often seen as two separate steps for determining subjectivity and polarity. Most approaches first try to identify subjective units (documents, sentences), and for each of these determine whether it is positive or negative. Kim and Hovy (2004) select candidate sentiment sentences and use word-based sentiment classifiers to classify unseen words into a negative or positive class. First, the lexicon is constructed from WordNet: from several seed words, the structure of WordNet is used to expand this seed to a full lexicon. Next, this lexicon is used to measure the distance between unseen words and words in the positive and negative classes. Based on word sentiments, a decision is made at the sentence level.

A similar approach is taken by Wilson et al. (2005): a classifier is learnt that distinguishes between polar and neutral sentences, based on a prior polarity lexicon and an annotated corpus. Among the features used are syntactic features. After this initial step, the sentiment sentences are classified as negative or positive; again, a prior polarity lexicon and syntactic features are used. The authors later explored the difference between prior and contextual polarity (Wilson et al., 2009): words that lose polarity in context, or whose polarity is reversed because of context.

Riloff and Wiebe (2003) describe a bootstrapping method to learn subjective extraction patterns that match specific syntactic templates, using a high-precision sentence-level subjectivity classifier and a large unannotated corpus. In our method, we bootstrap from a subjectivity lexicion rather than a classifier, and perform a topic-specific analysis, learning indicators of subjectivity toward a specific topic.

2.2 Domain- and target-specific sentiment

The way authors express their attitudes varies with the domain: An unpredictable movie can be positive, but unpredictable politicians are usually something negative. Since it is unrealistic to construct sentiment lexicons, or manually annotate text for learning, for every imaginable domain or topic, automatic methods have been developed.

Godbole et al. (2007) aim at measuring overall subjectivity or polarity towards a certain entity; they identify sentiments using domain-specific lexicons. The lexicons are generated from manually selected seeds for a broad domain such as *Health* or *Business*, following an approach similar to (Kim and Hovy, 2004). All named entites in a sentence containing a clue from a lexicon are

considered targets of sentiment for counting. Because of the data volume, no expensive linguistic processing is performed.

Choi et al. (2009) advocate a joint topic-sentiment analysis. They identify "sentiment topics," noun phrases assumed to be linked to a sentiment clue in the same expression. They address two tasks: identifying sentiment clues, and classifying sentences into positive, negative, or neutral. They start by selecting initial clues from SentiWordNet, based on sentences with known polarity. Next, the sentiment topics are identified, and based on these sentiment topics and the current list of clues, new potential clues are extracted. The clues can be used to classifiy sentences.

Fahrni and Klenner (2008) identify potential targets in a given domain, and create a target-specific polarity adjective lexicon. To this end, they find targets using Wikipedia, and associated adjectives. Next, the target-specific polarity of adjectives is detemined using Hearst-like patterns.

Kanayama and Nasukawa (2006) introduce polar atoms: minimal human-understandable syntactic structures that specify polarity of clauses. The goal is to learn new domain-specific polar atoms, but these are not target-specific. They use manually-created syntactic patterns to identify atoms and coherency to determine polarity.

In contrast to much of the work in the literature, we need to specialize subjectivity lexicons not for a domain and target, but for "topics."

2.3 Product features and opinions

Much work has been carried out for the task of mining product reviews, where the goal is to identify features of specific products (such as *picture*, *zoom*, *size*, *weight* for digital cameras) and opinions about these specific features in user reviews. Liu et al. (2005) describe a system that identifies such features via rules learned from a manually annotated corpus of reviews; opinions on features are extracted from the structure of reviews (which explicitly separate positive and negative opinions).

Popescu and Etzioni (2005) present a method that identifies product features for using corpus statistics, WordNet relations and morphological cues. Opinions about the features are extracted using a hand-crafted set of syntactic rules.

Targets extracted in our method for a topic are similar to features extracted in review mining for products. However, topics in our setting go beyond concrete products, and the diversity and generality of possible topics makes it difficult to apply such supervised or thesaurus-based methods to identify opinion targets. Moreover, in our method we directly use associations between targets and opinions to extract both.

2.4 Sentiment retrieval

At TREC, the Text REtrieval Conference, there has been interest in a specific type of sentiment analysis: opinion retrieval. This interest materialized in 2006 (Ounis et al., 2007), with the opinionated blog post retrieval task. Finding blog posts that are not just about a topic, but also contain an opinion on the topic, proves to be a difficult task. Performance on the opinion-finding task is dominated by performance on the underlying document retrieval task (the topical baseline).

Opinion finding is often approached as a two-stage problem: (1) identify documents relevant to the query, (2) identify opinions. In stage (2) one commonly uses either a binary classifier to distinguish between opinionated and non-opinionated documents or applies reranking of the initial result list using some opinion score. Opinion add-ons show only slight improvements over relevance-only baselines.

The best performing opinion finding system at TREC 2008 is a two-stage approach using reranking in stage (2) (Lee et al., 2008). The authors use SentiWordNet and a corpus-derived lexicon to construct an opinion score for each post in an initial ranking of blog posts. This opinion score is combined with the relevance score, and posts are reranked according to this new score. We detail this approach in Section 6. Later, the authors use domain-specific opinion indicators (Na et al., 2009), like "interesting story" (movie review), and "light" (notebook review). This domain-specific lexicon is constructed using feedback-style learning: retrieve an initial list of documents and use the top documents as training data to learn an opinion lexicon. Opinion scores per document are then computed as an average of opinion scores over all its words. Results show slight improvements (+3%) on mean average precision.

3 Generating Topic-Specific Lexicons

In this section we describe how we generate a lexicon of subjectivity clues and targets for a given *topic* and a list of *relevant documents* (e.g., re-

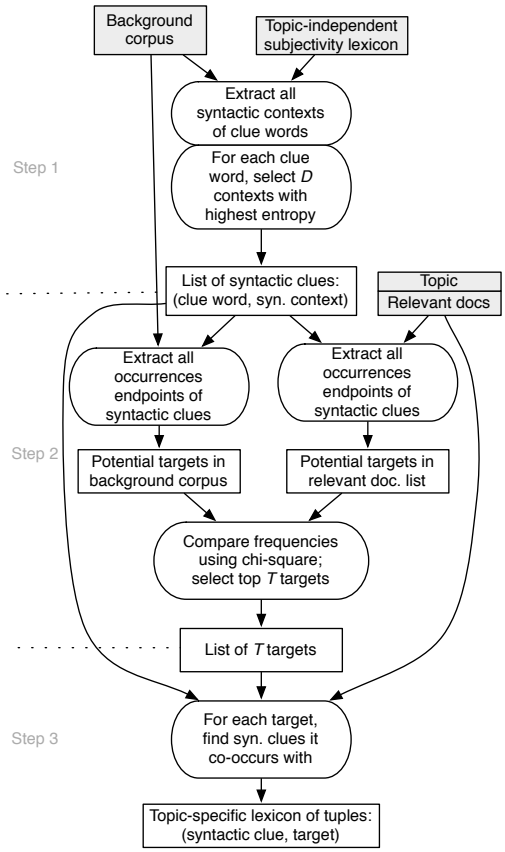

Figure 1: Our method for learning a topic-dependent subjectivity lexicon.

trieved by a search engine for the topic). As an additional resource, we use a large background corpus of text documents of a similar style but with diverse subjects; we assume that the relevant documents are part of this corpus as well. As the background corpus, we used the set of documents from the assessment pools of TREC 2006–2008 opinion retrieval tasks (described in detail in section 4). We use the Stanford lexicalized parser[1] to extract labeled dependency triples (*head, label, modifier*). In the extracted triples, all words indicate their category (*noun, adjective, verb, adverb,* etc.) and are normalized to lemmas.

Figure 1 provides an overview of our method; below we describe it in more detail.

3.1 Step 1: Extracting syntactic contexts

We start with a general domain-independent prior polarity lexicon of 8,821 clue words (Wilson et al., 2005). First, we identify *syntactic contexts* in which specific clue words can be used to express attitude: we try to find how a clue word can be syntactically linked to targets of sentiments. We take a simple definition of the syntactic context: a single labeled directed dependency relation. For every clue word, we extract all syntactic contexts, i.e., all dependencies, in which the word is involved (as head or as modifier) in the background corpus, along with their endpoints. Table 1 shows examples of clue words and contexts that indicate sentiments. For every clue, we only select those contexts that exhibit a high entropy among the lemmas at the other endpoint of the dependencies. E.g., in our background corpus, the verb *to like* occurs 97,179 times with a nominal subject and 52,904 times with a direct object; however, the entropy of lemmas of the subjects is 4.33, compared to 9.56 for the direct objects. In other words, subjects of *like* are more "predictable." Indeed, the pronoun *I* accounts for 50% of subjects, followed by *you* (14%), *they* (4%), *we* (4%) and *people* (2%). The most frequent objects of *like* are *it* (12%), *what* (4%), *idea* (2%), *they* (2%). Thus, objects of *to like* will be preferred by the method.

Our entropy-driven selection of syntactic contexts of a clue word is based on the following assumption:

> *Assumption 1:* In text, targets of sentiments are more diverse than sources of sentiments or other accompanying attributes such as location, time, manner, etc. Therefore targets exhibit higher entropy than other attributes.

For every clue word, we select the top D syntactic contexts whose entropy is at least half of the maximum entropy for this clue.

To summarize, at the end of Step 1 of our method, we have extracted a list of pairs (*clue word, syntactic context*) such that for occurrences of the clue word, the words at the endpoint of the syntactic dependency are likely to be targets of sentiments. We call such a pair a *syntactic clue*.

3.2 Step 2: Selecting potential targets

Here, we use the extracted syntantic clues to identify words that are likely to serve as specific targets for opinions about the topic in the relevant documents. In this work we only consider individual words as potential targets and leave exploring other options (e.g., NPs and VPs as targets) for future work. In extracting targets, we rely on the following assumption:

[1] http://nlp.stanford.edu/software/lex-parser.shtml

Clue word	Syntactic context	Target	Example
to like	has direct object	*u2*	*I do still like U2 very much*
to like	has clausal complement	*criticize*	*I don't like to criticize our intelligence services*
to like	has *about*-modifier	*olympics*	*That's what I like about Winter Olympics*
terrible	is adjectival modifier of	*idea*	*it's a terrible idea to recall judges for...*
terrible	has nominal subject	*shirt*	*And Neil, that shirt is terrible!*
terrible	has clausal complement	*can*	*It is terrible that a small group of extremists can ...*

Table 1: Examples of subjective syntactic contexts of clue words (based on Stanford dependencies).

Assumption 2: The list of relevant documents contains a substantial number of documents on the topic which, moreover, contain sentiments about the topic.

We extract all endpoints of all occurrences of the syntactic clues in the relevant documents, as well as in the background corpus. To identify potential attitude targets in the relevant documents, we compare their frequency in the relevant documents to the frequency in the background corpus using the standard χ^2 statistics. This technique is based on the following assumption:

Assumption 3: Sentiment targets related to the topic occur more often in subjective context in the set of relevant documents, than in the background corpus. In other words, while the background corpus contains sentiments towards very diverse subjects, the relevant documents tend to express attitudes related to the topic.

For every potential target, we compute the χ^2-score and select the top T highest scoring targets.

As the result of Steps 1 and 2, as candidate targets for a given topic, we only select words that occur in subjective contexts, and that do so more often than we would normally expect. Table 2 shows examples of extracted targets for three TREC topics (see below for a description of our experimental data).

3.3 Step 3: Generating topic-specific lexicons

In the last step of the method, we combine clues and targets. For each target identified in Step 2, we take all syntactic clues extracted in Step 1 that co-occur with the target in the relevant documents. The resulting list of triples (*clue word, syntactic context, target*) constitute the lexicon. We conjecture that an occurrence of a lexicon entry in a text indicates, with reasonable confidence, a subjective attitude towards the target.

Topic "Relationship between Abramoff and Bush"
abramoff lobbyist scandal fundraiser bush fund-raiser republican prosecutor tribe swirl corrupt corruption norquist democrat lobbying investigation scanlon reid lawmaker dealings president
Topic "MacBook Pro"
macbook laptop powerbook connector mac processor notebook fw800 spec firewire imac pro machine apple powerbooks ibook ghz g4 ata binary keynote drive modem
Topic: "Super Bowl ads"
ad bowl commercial fridge caveman xl endorsement advertising spot advertiser game super essential celebrity payoff marketing publicity brand advertise watch viewer tv football venue

Table 2: Examples of targets extracted at Step 2.

4 Data and Experimental Setup

We consider two types of evaluation. In the next section, we examine the quality of the lexicons we generate. In the section after that we evaluate lexicons quantitatively using the TREC Blog track benchmark.

For extrinsic evaluation we apply our lexicon generation method to a collection of documents containing opinionated utterances: blog posts. The Blogs06 collection (Macdonald and Ounis, 2006) is a crawl of blog posts from 100,649 blogs over a period of 11 weeks (06/12/2005–21/02/2006), with 3,215,171 posts in total. Before indexing the collection, we perform two preprocessing steps: (i) when extracting plain text from HTML, we only keep block-level elements longer than 15 words (to remove boilerplate material), and (ii) we remove non-English posts using TextCat[2] for language detection. This leaves us with 2,574,356 posts with 506 words per post on average. We index the collection using Indri,[3] version 2.10.

TREC 2006–2008 came with the task of *opinionated blog post retrieval* (Ounis et al., 2007). For each year a set of 50 topics was created, giv-

[2] http://odur.let.rug.nl/~vannoord/TextCat/

[3] http://www.lemurproject.org/indri/

ing us 150 topics in total. Every topic comes with a set of relevance judgments: Given a topic, a blog post can be either (i) nonrelevant, (ii) relevant, but not opinionated, or (iii) relevant and opinionated. TREC topics consist of three fields (*title*, *description*, and *narrative*), of which we only use the *title* field: a query of 1–3 keywords.

We use standard TREC evaluation measures for opinion retrieval: MAP (mean average precision), R-precision (precision within the top R retrieved documents, where R is the number of known relevant documents in the collection), MRR (mean reciprocal rank), P@10 and P@100 (precision within the top 10 and 100 retrieved documents). In the context of media analysis, recall-oriented measures such as MAP and R-precision are more meaningful than the other, early precision-oriented measures. Note that for the opinion retrieval task a document is considered relevant if it is on topic and contains opinions or sentiments towards the topic.

Throughout Section 6 below, we test for significant differences using a two-tailed paired t-test, and report on significant differences for $\alpha = 0.01$ ($^{\blacktriangle}$ and $^{\blacktriangledown}$), and $\alpha = 0.05$ ($^{\triangle}$ and $^{\triangledown}$).

For the quantative experiments in Section 6 we need a topical baseline: a set of blog posts potentially relevant to each topic. For this, we use the Indri retrieval engine, and apply the Markov Random Fields to model term dependencies in the query (Metzler and Croft, 2005) to improve topical retrieval. We retrieve the top 1,000 posts for each query.

5 Qualitative Analysis of Lexicons

Lexicon size (the number of entries) and selectivity (how often entries match in text) of the generated lexicons vary depending on the parameters D and T introduced above. The two rightmost columns of Table 4 show the lexicon size and the average number of matches per topic. Because our topic-specific lexicons consist of triples (*clue word, syntactic context, target*), they actually contain more words than topic-independent lexicons of the same size, but topic-specific entries are more selective, which makes the lexicon more focused. Table 3 compares the application of topic-independent and topic-specific lexicons to on-topic blog text.

We manually performed an explorative error analysis on a small number of documents, annotated using the smallest lexicon in Table 4 for the topic "March of the Pinguins." We assigned 186 matches of lexicon entries in 30 documents into four classes:

There are some *tragic* moments like eggs freezing , and predators *snatching* the females and *little* ones-you know the whole *NATURE* thing ... but this movie is *awesome*	There are some tragic moments l ike eggs freezing , and predators snatching the females and little ones-you know the whole NATURE thing ... but this **movie** is *awesome*
Saturday was more errands, then spent the evening with Dad and Stepmum, and *finally* was *able* to see March of the Penguins, which was *wonderful*. Christmas Day was *lovely*, surrounded by family, *good* food and drink, and *little* L to play with.	Saturday was more errands, then spent the evening with Dad and Stepmum, and finally was able to see March of the **Penguins**, which was *wonderful*. Christmas Day was lovely, surrounded by family, good food and drink, and little L to play with.

Table 3: Posts with highlighted targets (bold) and subjectivity clues (blue) using topic-independent (left) and topic-specific (right) lexicons.

- REL: sentiment towards a relevant target;
- CONTEXT: sentiment towards a target that is irrelevant to the topic due to context (e.g., opinion about a target "film", but refering to a film different from the topic);
- IRREL: sentiment towards irrelevant target (e.g., "game" for a topic about a movie);
- NOSENT: no sentiment at all

In total only 8% of matches were manually classified as REL, with 62% classified as NOSENT, 23% as CONTEXT, and 6% as IRREL. On the other hand, among documents assessed as opionionated by TREC assessors, only 13% did not contain matches of the lexicon entries, compared to 27% of non-opinionated documents, which does indicate that our lexicon does attempt to separate non-opinionated documents from opinionated.

6 Quantitative Evaluation of Lexicons

In this section we assess the quality of the generated topic-specific lexicons numerically and extrinsically. To this end we deploy our lexicons to the task of opinionated blog post retrieval (Ounis et al., 2007). A commonly used approach to this task works in two stages: (1) identify topically relevant blog posts, and (2) classify these posts as being opinionated or not. In stage 2 the standard

approach is to rerank the results from stage 1, instead of doing actual binary classification. We take this approach, as it has shown good performance in the past TREC editions (Ounis et al., 2007) and is fairly straightforward to implement. We also explore another way of using the lexicon: as a source for query expansion (i.e., adding new terms to the original query) in Section 6.2. For all experiments we use the collection described in Section 4.

Our experiments have two goals: to compare the use of topic-independent and topic-specific lexicons for the opinionated post retrieval task, and to examine how different settings for the parameters of the lexicon generation affect the empirical quality.

6.1 Reranking using a lexicon

To rerank a list of posts retrieved for a given topic, we opt to use the method that showed best performance at TREC 2008. The approach taken by Lee et al. (2008) linearly combines a (topical) relevance score with an opinion score for each post. For the opinion score, terms from a (topic-independent) lexicon are matched against the post content, and weighted with the probability of term's subjectivity. Finally, the sum is normalized using the Okapi BM25 framework. The final opinion score S_{op} is computed as in Eq. 1:

$$S_{op}(D) = \frac{Opinion(D) \cdot (k_1 + 1)}{Opinion(D) + k_1 \cdot (1 - b + \frac{b \cdot |D|}{avgdl})}, \quad (1)$$

where k_1, and b are Okapi parameters (set to their default values $k_1 = 2.0$, and $b = 0.75$), $|D|$ is the length of document D, and $avgdl$ is the average document length in the collection. The opinion score $Opinion(D)$ is calculated using Eq. 2:

$$Opinion(D) = \sum_{w \in O} P(sub|w) \cdot n(w, D), \quad (2)$$

where O is the set of terms in the sentiment lexicon, $P(sub|w)$ indicates the probability of term w being subjective, and $n(w, D)$ is the number of times term w occurs in document D. The opinion scoring can weigh lexicon terms differently, using $P(sub|w)$; it normalizes scores to cancel out the effect of varying document sizes.

In our experiments we use the method described above, and plug in the MPQA polarity lexicon.[4] We compare the results of using this topic-independent lexicon to the topic-dependent lexicons our method generates, which are also plugged into the reranking of Lee et al. (2008).

In addition to using Okapi BM25 for opinion scoring, we also consider a simpler method. As we observed in Section 5, our topic-specific lexicons are more selective than the topic-independent lexicon, and a simple number of lexicon matches can give a good indication of opinionatedness of a document:

$$S_{op}(D) = \min(n(O, D), 10)/10, \quad (3)$$

where $n(O, D)$ is the number of matches of the term of sentiment lexicon O in document D.

6.1.1 Results and observations

There are several parameters that we can vary when generating a topic-specific lexicon and when using it for reranking:

D: the number of syntactic contexts per clue
T: the number of extracted targets
$S_{op}(D)$: the opinion scoring function.
α: the weight of the opinion score in the linear combination with the relevance score.

Note that α does not affect the lexicon creation, but only how the lexicon is used in reranking. Since we want to assess the quality of lexicons, not in the opinionated retrieval performance as such, we factor out α by selecting the best setting for each lexicon (including the topic-independent) and each evaluation measure.

In Table 4 we present the results of evaluation of several lexicons in the context of opinionated blog post retrieval.

First, we note that reranking using all lexicons in Table 4 significantly improves over the relevance-only baseline for all evaluation measures. When comparing topic-specific lexicons to the topic-independent one, most of the differences are not statistically significant, which is surprising given the fact that most topic-specific lexicons we evaluated are substantially smaller (see the two rightmost columns in the table). The smallest lexicon in Table 4 is seven times more selective than the general one, in terms of the number of lexicon matches per document.

The only evaluation measure where the topic-independent lexicon consistently outperforms topic-specific ones, is Mean Reciprocal Rank that depends on a single relevant opinionated document high in a ranking. A possible explanation

[4] http://www.cs.pitt.edu/mpqa/

Lexicon			MAP	R-prec	MRR	P@10	P@100	|lexicon|	hits per doc
no reranking			0.2966	0.3556	0.6750	0.4820	0.3666	—	—
topic-independent			0.3182	0.3776	**0.7714**	**0.5607**	0.3980	8,221	36.17
D	T	S_{op}

5	50	count	0.3178	0.3775	0.7246$^{\triangledown}$	0.5560	0.3931	2,784	5.73
5	100	count	0.3178	0.3784	0.7316$^{\triangledown}$	0.5513	0.3961	4,910	10.06
all	50	count	0.3167	0.3753	0.7264$^{\triangledown}$	0.5520	0.3957	4,505	9.34
all	100	count	0.3146	0.3761	0.7283$^{\triangledown}$	0.5347$^{\triangledown}$	0.3955	8,217	16.72
all	50	okapi	0.3129	0.3713	0.7247$^{\blacktriangledown}$	0.5333$^{\triangledown}$	0.3833$^{\triangledown}$	4,505	9.34
all	100	okapi	0.3189	0.3755	0.7162$^{\blacktriangledown}$	0.5473	0.3921	8,217	16.72
all	200	okapi	**0.3229**$^{\blacktriangle}$	**0.3803**	0.7389	0.5547	**0.3987**	14,581	29.14

Table 4: Evaluation of topic-specific lexicons applied to the opinion retrieval task, compared to the topic-independent lexicon. The two rightmost columns show the number of lexicon entries (average per topic) and the number of matches of lexicon entries in blog posts (average for top 1,000 posts).

is that the large general lexicon easily finds a few "obviously subjective" posts (those with heavily used subjective words), but is not better at detecting less obvious ones, as indicated by the recall-oriented MAP and R-precision.

Interestingly, increasing the number of syntactic contexts considered for a clue word (parameter D) and the number of selected targets (parameter T) leads to substantially larger lexicons, but only gives marginal improvements when lexicons are used for opinion retrieval. This shows that our bootstrapping method is effective at filtering out non-relevant sentiment targets and syntactic clues.

The evaluation results also show that the choice of opinion scoring function (Okapi or raw counts) depends on the lexicon size: for smaller, more focused lexicons unnormalized counts are more effective. This also confirms our intuition that for small, focused lexicons simple presence of a sentiment clue in text is a good indication of subjectivity, while for larger lexicons an overall subjectivity scoring of texts has to be used, which can be hard to interpret for (media analysis) users.

6.2 Query expansion with lexicons

In this section we evaluate the quality of targets extracted as part of the lexicons by using them for query expansion. Query expansion is a commonly used technique in information retrieval, aimed at getting a better representation of the user's information need by adding terms to the original retrieval query; for user-generated content, selective query expansion has proved very beneficial (Weerkamp et al., 2009). We hypothesize that if our method manages to identify targets that correspond to issues, subtopics or features associated with the topic, the extracted targets should be good candidates for query expansion. The experiments described below test this hypothesis.

Run	MAP	P@10	MRR
Topical blog post retrieval			
Baseline	0.4086	0.7053	0.7984
Rel. models	0.4017$^{\triangledown}$	0.6867	0.7383$^{\blacktriangledown}$
Subj. targets	0.4190$^{\triangle}$	0.7373$^{\triangle}$	0.8470$^{\triangle}$
Opinion retrieval			
Baseline	0.2966	0.4820	0.6750
Rel. models	0.2841$^{\blacktriangledown}$	0.4467$^{\blacktriangledown}$	0.5479$^{\blacktriangledown}$
Subj. targets	0.3075	0.5227$^{\blacktriangle}$	0.7196

Table 5: Query expansion using relevance models and topic-specific subjectivity targets. Significance tested against the baseline.

For every test topic, we select the 20 top-scoring targets as expansion terms, and use Indri to return 1,000 most relevant documents for the expanded query. We evaluate the resulting ranking using both topical retrieval and opinionated retrieval measures. For the sake of comparison, we also implemented a well-known query expansion method based on Relevance Models (Lavrenko and Croft, 2001): this method has been shown to work well in many settings. Table 5 shows evaluation results for these two query expansion methods, compared to the baseline retrieval run.

The results show that on topical retrieval query expansion using targets significantly improves retrieval performance, while using relevance models actually hurts all evaluation measures. The failure of the latter expansion method can be attributed to the relatively large amount of noise in user-generated content, such as boilerplate

material, timestamps of blog posts, comments etc. (Weerkamp and de Rijke, 2008). Our method uses full syntactic parsing of the retrieved documents, which might substantially reduce the amount of noise since only (relatively) well-formed English sentences are used in lexicon generation.

For opinionated retrieval, target-based expansion also improves over the baseline, although the differences are only significant for P@10. The consistent improvement for topical retrieval suggests that a topic-specific lexicon can be used both for query expansion (as described in this section) and for opinion reranking (as described in Section 6.1). We leave this combination for future work.

7 Conclusions and Future Work

We have described a bootstrapping method for deriving a topic-specific lexicon from a general purpose polarity lexicon. We have evaluated the quality of generated lexicons both manually and using a TREC Blog track test set for opinionated blog post retrieval. Although the generated lexicons can be an order of magnitude more selective, they maintain, or even improve, the performance of an opinion retrieval system.

As to future work, we intend to combine our method with known methods for topic-specific lexicon *expansion* (our method is rather concerned with lexicon "restriction"). Existing sentence- or phrase-level (trained) sentiment classifiers can also be used easily: when collecting/counting targets we can weigh them by "prior" score provided by such classifiers. We also want to look at more complex syntactic patterns: Choi et al. (2009) report that many errors are due to exclusive use of unigrams. We would also like to extend potential opinion targets to include multi-word phrases (NPs and VPs), in addition to individual words. Finally, we do not identify polarity yet: this can be partially inherited from the initial lexicon and refined automatically via bootstrapping.

Abstract

Subjectivity analysis is a rapidly growing field of study. Along with its applications to various NLP tasks, much work have put efforts into multilingual subjectivity learning from existing resources. Multilingual subjectivity analysis requires language-independent criteria for comparable outcomes across languages. This paper proposes to measure the multilanguage-comparability of subjectivity analysis tools, and provides meaningful comparisons of multilingual subjectivity analysis from various points of view.

1 Introduction

The field of NLP has seen a recent surge in the amount of research on subjectivity analysis. Along with its applications to various NLP tasks, there have been efforts made to extend the resources and tools created for the English language to other languages. These endeavors have been successful in constructing lexicons, annotated corpora, and tools for subjectivity analysis in multiple languages.

There are multilingual subjectivity analysis systems available that have been built to monitor and analyze various concerns and opinions on the Internet; among the better known are OASYS from the University of Maryland that analyzes opinions on topics from news article searches in multiple languages (Cesarano et al., 2007)[1] and TextMap, an entity search engine developed by Stony Brook University for sentiment analysis along with other functionalities (Bautin et al., 2008).[2] Though these systems currently rely on English analysis tools and a machine translation (MT) technology to translate other languages into English, up-to-date research provides various ways to analyze subjectivity in multilingual environments.

Given sentiment analysis systems in different languages, there are many situations when the analysis outcomes need to be multilanguage-comparable. For example, it has been common these days for the Internet users across the world to share their views and opinions on various topics including music, books, movies, and global affairs and incidents, and also multinational companies such as Apple and Samsung need to analyze customer feedbacks for their products and services from many countries in different languages. Governments may also be interested in monitoring terrorist web forums or its global reputation. Surveying these opinions and sentiments in various languages involves merging the analysis outcomes into a single database, thereby objectively comparing the result across languages.

If there exists an ideal subjectivity analysis system for each language, evaluating the multilanguage-comparability would be unnecessary because the analysis in each language would correctly identify the exact meanings of all input texts regardless of the language. However, this requirement is not fulfilled with current technology, thus the need for defining and measuring the multilanguage-comparability of subjectivity analysis systems is evident.

This paper proposes to evaluate the multilanguage-comparability of multilingual subjectivity analysis systems. We build a number of subjectivity classifiers that distinguishes subjective texts from objective ones, and measure the multilanguage-comparability according to our proposed evaluation method. Since subjectivity analysis tools in languages other than English are not readily available, we focus our experiments on comparing different methods to build multilingual analysis systems from the resources and systems

created for English. These approaches enable us to extend a monolingual system to many languages with a number of freely available NLP resources and tools.

2 Related Work

Much research have been put into developing methods for multilingual subjectivity analysis recently. With the high availability of subjectivity resources and tools in English, an easy and straightforward approach would be to employ a machine translation (MT) system to translate input texts in target languages into English then carry out the analyses using an existing subjectivity analysis tool (Kim and Hovy, 2006; Bautin et al., 2008; Banea et al., 2008). Mihalcea et al. (2007) and Banea et al. (2008) proposed a number of approaches exploiting a bilingual dictionary, a parallel corpus, and an MT system to port the resources and systems available in English to languages with limited resources.

For subjectivity lexicons translation, Mihalcea et al. (2007) and Wan (2008) used the first sense in a bilingual dictionary, Kim and Hovy (2006) used a parallel corpus and a word alignment tool to extract translation pairs, and Kim et al. (2009) used a dictionary to translate and a link analysis algorithm to refine the matching intensity.

To overcome the shortcomings of available resources and to take advantage of ensemble systems, Wan (2008) and Wan (2009) explored methods for developing a hybrid system for Chinese using English and Chinese sentiment analyzers. Abbasi et al. (2008) and Boiy and Moens (2009) have created manually annotated gold standards in target languages and studied various feature selection and learning techniques in machine learning approaches to analyze sentiments in multilingual web documents.

For learning multilingual subjectivity, the literature tentatively concludes that translating lexicon is less dependable in terms of preserving subjectivity than corpus translation (Mihalcea et al., 2007; Wan, 2008), and though corpus translation results in modest performance degradation, it provides a viable approach because no manual labor is required (Banea et al., 2008; Brooke et al., 2009).

Based on the observation that the performances of subjectivity analysis systems in comparable experimental settings for two languages differ,

Texts with an identical negative sentiment:
* The iPad could cannibalize the e-reader market.
* 아이패드가(iPad) 전자책 시장을(e-reader market) 위축시킬 수 있다(could cannibalize).

Texts with different strengths of positive sentiments:
* Samsung cell phones have excellent battery life.
* 삼성(Samsung) 휴대전화(cell phone) 배터리는(battery) 그럭저럭(somehow or other) 오래간다(last long).

Figure 1: Examples of sentiments in multilingual text

Banea et al. (2008) have attributed the variations in the difficulty level of subjectivity learning to the differences in language construction. Bautin et al. (2008)'s system analyzes the sentiment scores of entities in multilingual news and blogs and adjusted the sentiment scores using entity sentiment probabilities of languages.

3 Multilanguage-Comparability

3.1 Motivation

The quality of a subjectivity analysis tool is measured by its ability to distinguish subjectivity from objectivity and/or positive sentiments from negative sentiments. Additionally, a multilingual subjectivity analysis system is required to generate unbiased analysis results across languages; the system should base its outcome solely on the subjective meanings of input texts irrespective of the language, and the equalities and inequalities of subjectivity labels and intensities must be useful within and throughout the languages.

Let us consider two cases where the pairs of multilingual inputs in English and Korean have identical and different subjectivity meanings (Figure 1). The first pair of texts carry a negative sentiment about how the release of a new electronics device might affect an emerging business market. When a multilanguage-comparable system is inputted with such a pair, its output should appropriately reflect the negative sentiment, and be identical for both texts. The second pair of texts share a similar positive sentiment about a mobile device's battery capacity but with different strengths. A good multilingual system must be able to identify the positive sentiments and distinguish the differences in their intensities.

However, these kinds of conditions cannot be measured with performance evaluations indepen-

dently carried out on each language; A system with a dissimilar ability to analyze subjective expressions from one language to another may deliver opposite labels or biased scores on texts with an identical subjective meaning, and vice versa, but still might produce similar performances on the evaluation data.

Macro evaluations on individual languages cannot provide any conclusions on the system's multilanguage-comparability capability. To measure how much of a system's judgment principles are preserved across languages, an evaluation from a different perspective is necessary.

3.2 Evaluation Approach

An evaluation of multilanguage-comparability may be done in two ways: measuring agreements in the outcomes of a pair of multilingual texts with an identical subjective meaning, or measuring the consistencies in the label and/or accordance in the order of intensity of a pair of texts with different subjectivities.

There are advantages and disadvantages to each approaches. The first approach requires multilingual texts aligned at the level of specificity, for instance, document, sentence and phrase, that the subjectivity analysis system works. Text corpora for MT evaluation such as newspapers, books, technical manuals, and government official records provide a wide variety of parallel texts, typically at the sentence level. Annotating these types of corpus can be efficient; as parallel texts must have identical semantic meanings, subjectivity–related annotations for one language can be projected into other languages without much loss of accuracy.

The latter approach accepts any pair of multilingual texts as long as they are annotated with labels and/or intensity. In this case, evaluating the label consistency of a multilingual system is only as difficult as evaluating that of a monolingual system; we can produce all possible pairs of texts from test corpora annotated with labels for each language. Evaluating with intensity is not easy for the latter approach; if test corpora already exist with intensity annotations for both languages, normalizing the intensity scores to a comparable scale is necessary (yet is uncertain unless every pair is checked manually), otherwise every pair of multilingual texts needs a manual annotation with its relative order of intensity.

In this paper, we utilize the first approach because it provides a more rational means; we can reasonably hypothesize that text translated into another language by a skilled translator carries an identical semantic meaning and thereby conveys identical subjectivity. Therefore the required resource is more easily attained in relatively inexpensive ways.

For evaluation, we measure the consistency in the subjectivity labels and the correlation of subjectivity intensity scores of parallel texts. Section 5.1 describes the details of evaluation metrics.

4 Multilingual Subjectivity System

We create a number of multilingual systems consisting of multiple subsystems each processing a language, where one system analyzes English, and the other systems analyze the Korean, Chinese, and Japanese languages. We try to reproduce a set of systems using diverse methods in order to compare the systems and find out which methods are more suitable for multilanguage-comparability.

4.1 Source Language System

We adopt the three systems described below as our source language systems: a state-of-the-art subjectivity classifier, a corpus-based, and a lexicon-based systems. The resources needed for developing the systems or the system itself are readily available for research purposes. In addition, these systems cover the general spectrum of current approaches to subjectivity analysis.

State-of-the-art (S-SA): OpinionFinder is a publicly-available NLP tool for subjectivity analysis (Wiebe and Riloff, 2005; Wilson et al., 2005).[3] The software and its resources have been widely used in the field of subjectivity analysis, and it has been the de facto standard system against which new systems are validated. We use a high-coverage classifier from the OpinionFinder's two sentence-level subjectivity classifiers. This Naive Bayes classifier builds upon a corpus annotated by a high-precision classifier with the bootstrapping of the corpus and extraction patterns. The classifier assesses a sentence's subjectivity with a label and a score for confidence in its judgment.

Corpus-based (S-CB): The MPQA opinion corpus is a collection of 535 newspaper articles in English annotated with opinions and private states at

[3] http://www.cs.pitt.edu/mpqa/opinionfinderrelease/, version 1.5

the sub-sentence level (Wiebe et al., 2003).[4] We retrieve the sentence level subjectivity labels for 11,111 sentences using the set of rules described in (Wiebe and Riloff, 2005). The corpus provides a relatively balanced corpus with 55% subjective sentences. We train an ML-based classifier using the corpus. Previous studies have found that, among several ML-based approaches, the SVM classifier generally performs well in many subjectivity analysis tasks (Pang et al., 2002; Banea et al., 2008).

We use SVM^{Light} with its default configurations,[5] inputted with a sentence represented as a feature vector of word unigrams and their counts in the sentence. An SVM score (a margin or the distance from a learned decision boundary) with a positive value predicts the input as being subjective, and negative value as objective.

Lexicon-based (S-LB): OpinionFinder contains a list of English subjectivity clue words with intensity labels (Wilson et al., 2005). The lexicon is compiled from several manually and automatically built resources and contains 6885 unique entries.

Riloff and Wiebe (2003) constructed a high-precision classifier for contiguous sentences using the number of strong and weak subjective words in current and nearby sentences. Unlike previous work, we do not (or rather, cannot) maintain assumptions about the proximity of input text. Using the lexicon, we build a simple and high-coverage rule-based subjectivity classifier. Setting the scores of strong and weak subjective words as 1.0 and 0.5, we evaluate the subjectivity of a given sentence as the sum of subjectivity scores; above a threshold, the input is subjective, and otherwise objective. The threshold value is optimized for an F-measure using the MPQA corpus, and is set to 1.0 throughout our experiments.

4.2 Target Language System

To construct a target language system leveraging on available resources in the source language, we consider three approaches from previous literature:

1. translating test sentences in target language into source language and inputting them into a source language system (Kim and Hovy, 2006; Bautin et al., 2008; Banea et al., 2008)
2. translating a source language training corpus into target language and creating a corpus-based system in target language (Banea et al., 2008)
3. translating a subjectivity lexicon from source language to target language and creating a lexicon-based system in target language (Mihalcea et al., 2007)

Each approach has its advantages and disadvantages. The advantage of the first approach is its simple architecture, clear separation of subjectivity and MT systems, and that it has only one subjectivity system, and is thus easier to maintain. Its disadvantage is that the time-consuming MT has to be executed for each text input. In the second and third approaches, a subjectivity system in the target language is constructed sharing corpora, rules, and/or features with the source language system. Later on, it may also include its own set of resources specifically engineered for the target language as a performance improvement. However, keeping the systems up-to-date would require as much effort as the number of languages. All three approaches use MT, and would suffer significantly if the translation results are poor.

Using the first approach, we can easily adopt all three source language systems;

- Target input translated into source, analyzed by source language system **S-SA**
- Target input translated into source, analyzed by source language system **S-CB**
- Target input translated into source, analyzed by source language system **S-LB**

The second and the third approaches are carried out as follows:

Corpus-based (T-CB): We translate the MPQA corpus into the target languages sentence by sentence using a web-based service.[6] Using the same method for **S-CB**, we train an SVM model for each language with the translated training corpora.

Lexicon-based (T-LB): This classifier is identical to **S-LB**, where the English lexicon is replaced by one of the target languages. We automatically translate the lexicon using free bilingual dictionaries.[7] First, the entries in the lexicon are looked

	O	12	383	395
	Total	470	389	859

up in the dictionary, if they are found, we select the first word in the first sense of the definition. If the entry is not in the dictionary, we lemmatize it,[8] then repeat the search. Our simple approach produces moderate-sized lexicons (3,808, 3,980, 3,027 for Korean, Chinese, and Japanese) compared to Mihalcea et al. (2007)'s complicated translation approach (4,983 Romanian words). The threshold values are optimized using the MPQA corpus translated into each target language.[9]

5 Experiment

5.1 Experimental Setup

Test Corpus

Our evaluation corpus consists of 50 parallel newspaper articles from the Donga Daily News Website.[10] The website provides news articles in Korean and their human translations in English, Japanese, and Chinese. We selected articles that contain *Editorial* in its English title from a 30-day period. Three human annotators who are fluent in the two languages manually annotated N-to-N sentence alignments for each language pairs (KR-EN, KR-CH, KR-JP). By keeping only the sentence chunks whose Korean chunk appears in all language pairs, we were left with 859 sentence chunk pairs.

The corpus was preprocessed with NLP tools for each language,[11] and the Korean, Chinese, and Japanese texts were translated into English with the same web-based service used to translate the training corpus in Section 4.2.

Manual Annotation and Agreement Study

To assess the performance of our subjectivity analysis systems, the Korean sentence chunks were manually annotated by two native speakers of Korean with *Subjective* and *Objective* labels (Table 1). A proportion agreement of 0.86 and a kappa value of 0.73 indicate a substantial agreement between the two annotators. We set aside 743 sentence chunks that both annotators agreed on for the automatic evaluation of subjectivity analysis systems, thereby removing the borderline cases, which are difficult even for humans to assess. The corresponding sentence chunks for other languages were extracted and tagged with labels equivalent to Korean chunks.

In addition, to verify how consistently the subjectivity of the original texts is projected to the translated, we carried out another manual annotation and agreement study with Korean and English sentence chunks (Table 2).

Note that our cross-lingual agreement study is similar to the one carried out by Mihalcea et al. (2007), where two annotators labeled the sentence subjectivity of a parallel text in different languages. They reported that, similarly to monolingual annotations, most cases of disagreements on annotations are due to the differences in the annotators' judgments on subjectivity, and the rest from subjective meanings lost in the translation process and figurative language such as irony.

To avoid the role played by annotators' private views from disagreements, the subjectivity of sentence chunks in English were manually annotated by one of the annotators for the Korean text. Judged by the same annotator, we speculate that the disagreement in the annotation should account only for the inconsistency in the subjectivity projection. By proportion, the agreement between the annotation of Korean and English is 0.97, and the kappa is 0.96, suggesting an almost perfect agreement. Only a small number of sentence chunk pairs have inconsistent labels; six chunks in Ko-

Implicit sentiment expressed through translation:
* 시간이 갈수록(with time) 그 격차가(disparity/gap) 벌어지고 있다(widening).
* Worse, the (economic) disparity (between South Korea and North Korea) is worsening with time.

Sentiment lost in translation:
* 인도의 타타 자동차회사는(India's Tata Motors) 2200달러짜리 자동차 나노를(2,200-dollar automobile Nano) 내놓아(presented) 주목을 끌었다 (drew attention).
* India's Tata Motors has produced the 2,200-dollar subcompact Nano.

Figure 2: Excerpts from Donga Daily News with differing sentiments between parallel texts

rean lost subjectivity in translation, and implied subjective meanings in twelve chunks were expressed explicitly through interpretation. Excerpts from our corpus show two such cases (Figure 2).

Evaluation Metrics

To evaluate the multilanguage-comparability of subjectivity analysis systems, we measure 1) how consistently the system assigns subjectivity labels and 2) how closely numeric scores for systems' confidences correlate with regard to parallel texts in different languages.

In particular, we use Cohen's kappa coefficient for the first and Pearson's correlation coefficient for the latter. These widely used metrics provide useful comparability measures for categorical and quantitative data.

Both coefficients are scaled from -1 to $+1$, indicating negative to positive correlations. Kappa measures are corrected for chance, thereby yielding better measurements than agreement by proportion. The characteristics of Pearson's correlation coefficient that it measures linear relationships and is independent of change in origin, scale, and unit comply with our experiments.

5.2 Subjectivity Classification

Our multilingual subjectivity analysis systems were evaluated on the test corpora described in Section 5.1 (Table 3).

Due to the difference in testbeds, the performance of the state-of-the-art English system (**S-SA**) on our corpus is lower by about 10% relatively than the performance reported on the MPQA corpus.[12] However, it still performs sufficiently well and provides the most balanced results among the three source language systems; The corpus-based system (**S-CB**) classifies with a high precision, and the lexicon-based (**S-LB**) with a high recall. The source language systems (**S-SA,-CB,-LB**) lose a small percentage in precision when inputted with translations, but the recalls are generally on a par or even higher in the target languages.

For the systems created from target language resources, Corpus-based systems (**T-CB**) generally perform better than the ones with source language resource (**S-CB**), and lexicon-based systems (**T-LB**) perform worse than (**S-LB**). Similarly to systems with source language resources, **T-CB** classifies with a high precision and **T-LB** with a high recall, but the gap is less. Among the target languages, Korean tends to have a higher precision, and Japanese a higher recall than other languages in most systems.

Overall, **S-SA** provides easy accessibility when analyzing both the source and the target languages, with a balanced precision and recall performance. Among the other approaches, only **T-CB** is better in all measures than **S-SA**, and **S-LB** performs best on F-measure evaluations.

5.3 Multilanguage-Comparability

The evaluation results on multilanguage-comparability are presented in Table 4. The subjectivity analysis systems are evaluated with all language pairs with kappa and Pearson's correlation coefficients. Kappa and Pearson's correlation values are consistent with each other; Pearson's correlation between the two evaluation measures is 0.91.

We observe a distinct contrast in performances between corpus-based systems (**S-CB** and **T-CB**) and lexicon-based systems (**S-LB** and **T-LB**); All corpus-based systems show moderate agreements while agreements on lexicon-based systems are only fair.

Within corpus-based systems, **S-CB** performs better with language pairs that include English, and **T-CB** performs better with language pairs of the target languages.

For lexicon-based systems, systems in the target languages (**T-LB**) performs the worst with only slight to fair agreements between languages. Lexicon-based systems and state-of-the-art systems in the source language (**S-LB** and **S-SA**) result in average performances.

[12] precision, recall, and F-measure of 79.4, 70.6, and 74.7.

Table 3: Performance of subjectivity analysis with precision (P), recall (R), and F-measure (F). S-SA,-CB,-LB systems in Korean, Chinese, Japanese indicate English analysis systems inputted with translations of the target languages into English.

Figure 3: Scatter plots of English (x-axis) and Korean (y-axis) subjectivity scores from state-of-the-art (S-SA), corpus-based (S-CB), and lexicon-based (S-LB) systems of the source language, and corpus-based with translated corpora (T-CB), and lexicon-based with translated lexicon (T-LB) systems. Slanted lines in figures are best-fit lines through the origins.

Figure 3 shows scatter plots of subjectivity scores of our English and Korean test corpora evaluated on different systems; the data points on the first and the third quadrants are occurrences of label agreements, and the second and the fourth are disagreements. Linearly scattered data points are more correlated regardless of the slope.

Figure 3a shows a moderate correlation for multilingual results from the state-of-the-art system (**S-SA**). Agreements on objective instances are clustered together while agreements on subjective instances are diffused over a wide region.

Agreements between the source language corpus-based system (**S-CB**) and the corpus-based system trained with translated resources (**T-CB**) are more distinctively correlated than the results for other pairs of systems (Figures 3b and 3d). We notice that **S-CB** seems to have a lower number of outliers than **T-CB**, but slightly more diffusive.

Lexicon-based systems (**S-LB**, **T-LB**) generate noticeably uncorrelated scores (Figures 3c and 3e). We observe that the results from the English system with translated inputs (**S-LB**) is more correlated than those from systems with translated lexicons (**T-LB**), and that analysis results from both systems are biased toward subjective scores.

6 Discussion

Which approach is most suitable for multilingual subjectivity analysis?

In our experiments, the corpus-based systems trained on corpora translated from English to the target languages (**T-CB**) perform well for subjectivity classification and multilanguage-comparability measures on the whole. However, the methods we employed to expand the languages were naively carried out without much considerations for optimization. Further adjustments could improve the other systems for both classification and multilanguage-comparability performances.

Is there a correlation between classification performance and multilanguage-comparability?

Lexicon-based systems in the source language (**S-LB**) have good overall classification performances, especially on recall and F-measures. However, these systems performs worse on multilanguage-comparability than other systems with poorer classification performances. Intrigued by the observation, we tried to measure which criteria for classification performance influences multilanguage-comparability. We again employed Pearson's correlation metrics to measure the correlations of precision (P), recall (R), and F-measures (F) to kappa (κ) and Pearson's correlation (ρ) values.

Specifically, we measure the correlations between the sums of P, the sums of R, and the sums of F to κ and ρ for all pairs of systems.[13] The correlations of P with κ and ρ are 0.78 and 0.68, R -0.38 and -0.28, and F -0.20 and -0.05. These numbers strongly suggest that multilanguage-comparability correlates with the precisions of classifiers.

However, we cannot always expect a high-precision multilingual subjectivity classifier to be multilanguage-comparable as well. For example, the **S-SA** system has a much higher precision than **S-LB** consistently over all languages, but their multilanguage-comparability performances differed only by small amounts.

7 Conclusion

Multilanguage-comparability is an analysis system's ability to retain its decision criteria across different languages. We implemented a number of previously proposed approaches to learning multilingual subjectivity, and evaluated the systems on multilanguage-comparability as well as classification performance. Our experimental results provide meaningful comparisons of the multilingual subjectivity analysis systems across various aspects.

Also, we developed a multilingual subjectivity evaluation corpus from a parallel text, and studied inter-annotator, inter-language agreements on subjectivity, and observed persistent subjectivity projections from one language to another from a parallel text.

For future work, we aim extend this work to constructing a multilingual sentiment analysis system and evaluate it with multilingual datasets such as product reviews collected from different countries. We also plan to resolve the lexicon-based classifiers' classification bias towards subjective meanings with a list of objective words (Esuli and Sebastiani, 2006) and their multilingual expansion (Kim et al., 2009), and evaluate the multilanguage-comparability of systems constructed with resources from different sources.

[13] Pairs of values such as 71.1 + 70.7 and 0.41 for precisions and Kappa of S-SA for English and Korean.

Abstract

Automatic error detection is desired in the post-processing to improve machine translation quality. The previous work is largely based on confidence estimation using system-based features, such as word posterior probabilities calculated from N-best lists or word lattices. We propose to incorporate two groups of linguistic features, which convey information from outside machine translation systems, into error detection: lexical and syntactic features. We use a maximum entropy classifier to predict translation errors by integrating word posterior probability feature and linguistic features. The experimental results show that 1) linguistic features alone outperform word posterior probability based confidence estimation in error detection; and 2) linguistic features can further provide complementary information when combined with word confidence scores, which collectively reduce the classification error rate by 18.52% and improve the F measure by 16.37%.

1 Introduction

Translation hypotheses generated by a statistical machine translation (SMT) system always contain both correct parts (e.g. words, n-grams, phrases matched with reference translations) and incorrect parts. Automatically distinguishing incorrect parts from correct parts is therefore very desirable not only for post-editing and interactive machine translation (Ueffing and Ney, 2007) but also for SMT itself: either by rescoring hypotheses in the N-best list using the probability of correctness calculated for each hypothesis (Zens and Ney, 2006) or by generating new hypotheses using N-best lists from one SMT system or multiple systems (Akibay et al., 2004; Jayaraman and Lavie, 2005).

In this paper we restrict the "parts" to words. That is, we detect errors at the word level for SMT. A common approach to SMT error detection at the word level is calculating the confidence at which a word is correct. The majority of word confidence estimation methods follows three steps:

1) Calculate features that express the correctness of words either based on SMT model (e.g. translation/language model) or based on SMT system output (e.g. N-best lists, word lattices) (Blatz et al., 2003; Ueffing and Ney, 2007).

2) Combine these features together with a classification model such as multi-layer perceptron (Blatz et al., 2003), Naive Bayes (Blatz et al., 2003; Sanchis et al., 2007), or log-linear model (Ueffing and Ney, 2007).

3) Divide words into two groups (correct translations and errors) by using a classification threshold optimized on a development set.

Sometimes the step 2) is not necessary if only one effective feature is used (Ueffing and Ney, 2007); and sometimes the step 2) and 3) can be merged into a single step if we directly output predicting results from binary classifiers instead of making thresholding decision.

Various features from different SMT models and system outputs are investigated (Blatz et al., 2003; Ueffing and Ney, 2007; Sanchis et al., 2007; Raybaud et al., 2009). Experimental results show that they are useful for error detection. However, it is not adequate to just use these features as discussed in (Shi and Zhou, 2005) because the information that they carry is either from the inner components of SMT systems or from system outputs. To some extent, it has already been considered by SMT systems. Hence finding external information

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 604–611,
Uppsala, Sweden, 11-16 July 2010.

sources from outside SMT systems is desired for error detection.

Linguistic knowledge is exactly such a good choice as an external information source. It has already been proven effective in error detection for speech recognition (Shi and Zhou, 2005). However, it is not widely used in SMT error detection. The reason is probably that people have yet to find effective linguistic features that outperform non-linguistic features such as word posterior probability features (Blatz et al., 2003; Raybaud et al., 2009). In this paper, we would like to show an effective use of linguistic features in SMT error detection.

We integrate two sets of linguistic features into a maximum entropy (MaxEnt) model and develop a MaxEnt-based binary classifier to predict the category (correct or incorrect) for each word in a generated target sentence. Our experimental results show that linguistic features substantially improve error detection and even outperform word posterior probability features. Further, they can produce additional improvements when combined with word posterior probability features.

The rest of the paper is organized as follows. In Section 2, we review the previous work on word-level confidence estimation which is used for error detection. In Section 3, we introduce our linguistic features as well as the word posterior probability feature. In Section 4, we elaborate our MaxEnt-based error detection model which combine linguistic features and word posterior probability feature together. In Section 5, we describe the SMT system which we use to generate translation hypotheses. We report our experimental results in Section 6 and conclude in Section 7.

2 Related Work

In this section, we present an overview of confidence estimation (CE) for machine translation at the word level. As we are only interested in error detection, we focus on work that uses confidence estimation approaches to detect translation errors. Of course, confidence estimation is not limited to the application of error detection, it can also be used in other scenarios, such as translation prediction in an interactive environment (Grandrabur and Foster, 2003) .

In a JHU workshop, Blatz et al. (2003) investigate using neural networks and a naive Bayes classifier to combine various confidence features for confidence estimation at the word level as well as at the sentence level. The features they use for word level CE include word posterior probabilities estimated from N-best lists, features based on SMT models, semantic features extracted from WordNet as well as simple syntactic features, i.e. parentheses and quotation mark check. Among all these features, the word posterior probability is the most effective feature, which is much better than linguistic features such as semantic features, according to their final results.

Ueffing and Ney (2007) exhaustively explore various word-level confidence measures to label each word in a generated translation hypothesis as correct or incorrect. All their measures are based on word posterior probabilities, which are estimated from 1) system output, such as word lattices or N-best lists and 2) word or phrase translation table. Their experimental results show that word posterior probabilities directly estimated from phrase translation table are better than those from system output except for the Chinese-English language pair.

Sanchis et al. (2007) adopt a smoothed naive Bayes model to combine different word posterior probability based confidence features which are estimated from N-best lists, similar to (Ueffing and Ney, 2007).

Raybaud et al. (2009) study several confidence features based on mutual information between words and n-gram and backward n-gram language model for word-level and sentence-level CE. They also explore linguistic features using information from syntactic category, tense, gender and so on. Unfortunately, such linguistic features neither improve performance at the word level nor at the sentence level.

Our work departs from the previous work in two major respects.

- We exploit various linguistic features and show that they are able to produce larger improvements than widely used system-related features such as word posterior probabilities. This is in contrast to some previous work. Yet another advantage of using linguistic features is that they are system-independent, which therefore can be used across different systems.

- We treat error detection as a complete binary classification problem. Hence we di-

rectly output prediction results from our discriminatively trained classifier without optimizing a classification threshold on a distinct development set beforehand.[1] Most previous approaches make decisions based on a pretuned classification threshold τ as follows

$$class = \begin{cases} correct, & \Phi(correct, \theta) > \tau \\ incorrect, & otherwise \end{cases}$$

where Φ is a classifier or a confidence measure and θ is the parameter set of Φ. The performance of these approaches is strongly dependent on the classification threshold.

3 Features

We explore two sets of linguistic features for each word in a machine generated translation hypothesis. The first set of linguistic features are simple lexical features. The second set of linguistic features are syntactic features which are extracted from link grammar parse. To compare with the previously widely used features, we also investigate features based on word posterior probabilities.

3.1 Lexical Features

We use the following lexical features.

- wd: word itself
- pos: part-of-speech tag from a tagger trained on WSJ corpus. [2]

For each word, we look at previous n words/tags and next n words/tags. They together form a word/tag sequence pattern. The basic idea of using these features is that words in rare patterns are more likely to be incorrect than words in frequently occurring patterns. To some extent, these two features have similar function to a target language model or pos-based target language model.

3.2 Syntactic Features

High-level linguistic knowledge such as syntactic information about a word is a very natural and promising indicator to decide whether this word is syntactically correct or not. Words occurring in an ungrammatical part of a target sentence are prone to be incorrect. The challenge of using syntactic knowledge for error detection is that machine-generated hypotheses are rarely fully grammatical. They are mixed with grammatical and ungrammatical parts, which hence are not friendly to traditional parsers trained on grammatical sentences because ungrammatical parts of a machine-generated sentence could lead to a parsing failure.

To overcome this challenge, we select the *Link Grammar* (LG) parser [3] as our syntactic parser to generate syntactic features. The LG parser produces a set of labeled links which connect pairs of words with a link grammar (Sleator and Temperley, 1993).

The main reason why we choose the LG parser is that it provides a robustness feature: *null-link* scheme. The null-link scheme allows the parser to parse a sentence even when the parser can not fully interpret the entire sentence (e.g. including ungrammatical parts). When the parser fail to parse the entire sentence, it ignores one word each time until it finds linkages for remaining words. After parsing, those ignored words are not connected to any other words. We call them *null-linked* words.

Our hypothesis is that null-linked words are prone to be syntactically incorrect. We hence straightforwardly define a syntactic feature for a word w according to its links as follows

$$link(w) = \begin{cases} yes, & w\ has\ links \\ no, & otherwise \end{cases}$$

In Figure 1 we show an example of a generated translation hypothesis with its link parse. Here links are denoted with dotted lines which are annotated with link types (e.g., Jp, Op). Bracketed words, namely "," and "including", are null-linked words.

3.3 Word Posterior Probability Features

Our word posterior probability is calculated on N-best list, which is first proposed by (Ueffing et al., 2003) and widely used in (Blatz et al., 2003; Ueffing and Ney, 2007; Sanchis et al., 2007).

Given a source sentence f, let $\{e_n\}_1^N$ be the N-best list generated by an SMT system, and let e_n^i is the i-th word in e_n. The major work of calculating word posterior probabilities is to find the Levenshtein alignment (Levenshtein, 1966) between the best hypothesis e_1 and its competing hypothesis

[1] This does not mean we do not need a development set. We do validate our feature selection and other experimental settings on the development set.

[2] Available via http://www-tsujii.is.s.u-tokyo.ac.jp/~tsuruoka/postagger/

[3] Available at http://www.link.cs.cmu.edu/link/

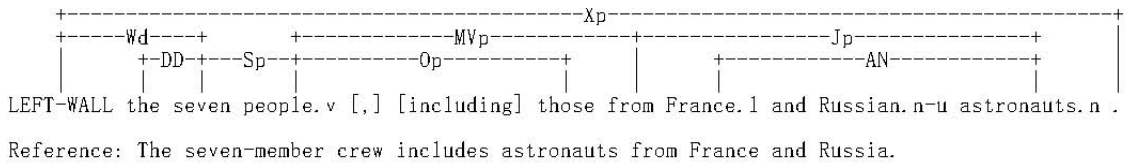

Figure 1: An example of Link Grammar parsing results.

e_n in the N-best list $\{e_n\}_1^N$. We denote the alignment between them as $\ell(e_1, e_n)$. The word in the hypothesis e_n which e_1^i is Levenshtein aligned to is denoted as $\ell_i(e_1, e_n)$.

The word posterior probability of e_1^i is then calculated by summing up the probabilities over all hypotheses containing e_1^i in a position which is Levenshtein aligned to e_1^i.

$$p_{wpp}(e_1^i) = \frac{\sum_{e_n:\, \ell_i(e_1,e_n)=e_1^i} p(e_n)}{\sum_1^N p(e_n)}$$

To use the word posterior probability in our error detection model, we need to make it discrete. We introduce a feature for a word w based on its word posterior probability as follows

$$dwpp(w) = \lfloor -log(p_{wpp}(w))/df \rfloor$$

where df is the discrete factor which can be set to 1, 0.1, 0.01 and so on. "$\lfloor\ \rfloor$" is a rounding operator which takes the largest integer that does not exceed $-log(p_{wpp}(w))/df$. We optimize the discrete factor on our development set and find the optimal value is 1. Therefore a feature "$dwpp = 2$" represents that the logarithm of the word posterior probability is between -3 and -2;

4 Error Detection with a Maximum Entropy Model

As mentioned before, we consider error detection as a binary classification task. To formalize this task, we use a feature vector ψ to represent a word w in question, and a binary variable c to indicate whether this word is correct or not. In the feature vector, we look at 2 words before and 2 words after the current word position $(w_{-2}, w_{-1}, w, w_1, w_2)$. We collect features $\{wd, pos, link, dwpp\}$ for each word among these words and combine them into the feature vector ψ for w. As such, we want the feature vector to capture the contextual environment, e.g., pos sequence pattern, syntactic pattern, where the word w occurs.

For classification, we employ the maximum entropy model (Berger et al., 1996) to predict whether a word w is correct or incorrect given its feature vector ψ.

$$p(c|\psi) = \frac{exp(\sum_i \theta_i f_i(c, \psi))}{\sum_{c'} exp(\sum_i \theta_i f_i(c', \psi))}$$

where f_i is a binary model feature defined on c and the feature vector ψ. θ_i is the weight of f_i. Table 1 shows some examples of our binary model features.

In order to learn the model feature weights θ for probability estimation, we need a training set of m samples $\{\psi^i, c^i\}_1^m$. The challenge of collecting training instances is that the correctness of a word in a generated translation hypothesis is not intuitively clear (Ueffing and Ney, 2007). We will describe the method to determine the correctness of a word in Section 6.1, which is broadly adopted in previous work.

We tune our model feature weights using an off-the-shelf MaxEnt toolkit (Zhang, 2004). To avoid overfitting, we optimize the Gaussian prior on the development set. During test, if the probability $p(correct|\psi)$ is larger than $p(incorrect|\psi)$ according the trained MaxEnt model, the word is labeled as correct otherwise incorrect.

5 SMT System

To obtain machine-generated translation hypotheses for our error detection, we use a state-of-the-art phrase-based machine translation system MOSES (Koehn et al., 2003; Koehn et al., 2007). The translation task is on the official NIST Chinese-to-English evaluation data. The training data consists of more than 4 million pairs of sentences (including 101.93M Chinese words and 112.78M English words) from LDC distributed corpora. Table 2 shows the corpora that we use for the translation task.

We build a four-gram language model using the SRILM toolkit (Stolcke, 2002), which is trained

Feature	Example
wd	$f(c,\psi) = \begin{cases} 1, & \psi.w.wd = ".", c = correct \\ 0, & otherwise \end{cases}$
pos	$f(c,\psi) = \begin{cases} 1, & \psi.w_2.pos = "NN", c = incorrect \\ 0, & otherwise \end{cases}$
$link$	$f(c,\psi) = \begin{cases} 1, & \psi.w.link = no, c = incorrect \\ 0, & otherwise \end{cases}$
$dwpp$	$f(c,\psi) = \begin{cases} 1, & \psi.w_{-2}.dwpp = 2, c = correct \\ 0, & otherwise \end{cases}$

on Xinhua section of the English Gigaword corpus (181.1M words). For minimum error rate tuning (Och, 2003), we use NIST MT-02 as the development set for the translation task. In order to calculate word posterior probabilities, we generate 10,000 best lists for NIST MT-02/03/05 respectively. The performance, in terms of BLEU (Papineni et al., 2002) score, is shown in Table 4.

6 Experiments

We conducted our experiments at several levels. Starting with MaxEnt models with single linguistic feature or word posterior probability based feature, we incorporated additional features incrementally by combining features together. In doing so, we would like the experimental results not only to display the effectiveness of linguistic features for error detection but also to identify the additional contribution of each feature to the task.

6.1 Data Corpus

For the error detection task, we use the best translation hypotheses of NIST MT-02/05/03 generated by MOSES as our training, development, and test corpus respectively. The statistics about these corpora is shown in Table 3. Each translation hypothesis has four reference translations.

	Corpus	Sentences	Words
Training	MT-02	878	24,225
Development	MT-05	1082	31,321
Test	MT-03	919	25,619

Table 3: Corpus statistics (number of sentences and words) for the error detection task.

To obtain the linkage information, we run the LG parser on all translation hypotheses. We find that the LG parser can not fully parse 560 sentences (63.8%) in the training set (MT-02), 731 sentences (67.6%) in the development set (MT-05) and 660 sentences (71.8%) in the test set (MT-03). For these sentences, the LG parser will use the the null-link scheme to generate null-linked words.

To determine the true class of a word in a generated translation hypothesis, we follow (Blatz et al., 2003) to use the word error rate (**WER**). We tag a word as correct if it is aligned to itself in the Levenshtein alignment between the hypothesis and the nearest reference translation that has minimum edit distance to the hypothesis among four reference translations. Figure 2 shows the Levenshtein alignment between a machine-generated hypothesis and its nearest reference translation. The "Class" row shows the label of each word according to the alignment, where "c" and "i" represent *correct* and *incorrect* respectively.

There are several other metrics to tag single words in a translation hypothesis as correct or incorrect, such as **PER** where a word is tagged as correct if it occurs in one of reference translations with the same number of occurrences, **Set** which is a less strict variant of PER, ignoring the number of occurrences per word. In Figure 2, the two words "last year" in the hypothesis will be tagged as correct if we use the PER or Set metric since they do not consider the occurring positions of words. Our

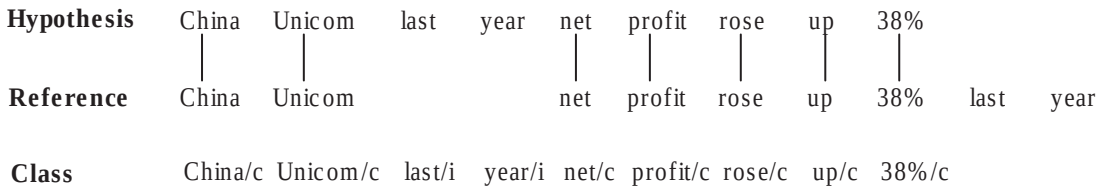

Figure 2: Tagging a word as correct/incorrect according to the Levenshtein alignment.

Corpus	BLEU (%)	RCW (%)
MT-02	33.24	47.76
MT-05	32.03	47.85
MT-03	32.86	47.57

Table 4: Case-insensitive BLEU score and ratio of correct words (RCW) on the training, development and test corpus.

metric corresponds to the **m-WER** used in (Ueffing and Ney, 2007), which is stricter than PER and Set. It is also stricter than normal WER metric which compares each hypothesis to all references, rather than the nearest reference.

Table 4 shows the case-insensitive BLEU score and the percentage of words that are labeled as correct according to the method described above on the training, development and test corpus.

6.2 Evaluation Metrics

To evaluate the overall performance of the error detection, we use the commonly used metric, classification error rate (CER) to evaluate our classifiers. CER is defined as the percentage of words that are wrongly tagged as follows

$$CER = \frac{\text{\# of wrongly tagged words}}{\text{Total \# of words}}$$

The baseline CER is determined by assuming the most frequent class for all words. Since the ratio of correct words in both the development and test set is lower than 50%, the most frequent class is "incorrect". Hence the baseline CER in our experiments is equal to the ratio of correct words as these words are wrongly tagged as incorrect.

We also use precision and recall on errors to evaluate the performance of error detection. Let n_g be the number of words of which the true class is incorrect, n_t be the number of words which are tagged as incorrect by classifiers, and n_m be the number of words tagged as incorrect that are indeed translation errors. The precision Pre is the percentage of words correctly tagged as translation errors.

$$Pre = \frac{n_m}{n_t}$$

The recall Rec is the proportion of actual translation errors that are found by classifiers.

$$Rec = \frac{n_m}{n_g}$$

F measure, the trade-off between precision and recall, is also used.

$$F = \frac{2 \times Pre \times Rec}{Pre + Rec}$$

6.3 Experimental Results

Table 5 shows the performance of our experiments on the error detection task. To compare with previous work using word posterior probabilities for confidence estimation, we carried out experiments using wpp estimated from N-best lists with the classification threshold τ, which was optimized on our development set to minimize CER. A relative improvement of 9.27% is achieved over the baseline CER, which reconfirms the effectiveness of word posterior probabilities for error detection.

We conducted three groups of experiments using the MaxEnt based error detection model with various feature combinations.

- The first group of experiments uses single feature, such as $dwpp$, pos. We find the most effective feature is pos, which achieves a 16.12% relative improvement over the baseline CER and 7.55% relative improvement over the CER of word posterior probability thresholding. Using discrete word posterior probabilities as features in the MaxEnt based error detection model is marginally better than word posterior probability thresholding in terms of CER, but obtains a 13.79% relative improvement in F measure. The syntactic feature $link$ also improves the error detection in terms of CER and particularly recall.

Combination	Features	CER (%)	Pre (%)	Rec (%)	F (%)
Baseline	-	47.57	-	-	-
Thresholding wpp	-	43.16	58.98	58.07	58.52
MaxEnt ($dwpp$)	44	43.07	56.12	81.86	66.59
MaxEnt (wd)	19,164	41.57	58.25	73.11	64.84
MaxEnt (pos)	199	39.90	58.88	79.23	67.55
MaxEnt ($link$)	19	44.31	54.72	89.72	67.98
MaxEnt ($wd + pos$)	19,363	39.43	59.36	78.60	67.64
MaxEnt ($wd + pos + link$)	19,382	39.79	58.74	80.97	68.08
MaxEnt ($dwpp + wd$)	19,208	41.04	57.18	83.75	67.96
MaxEnt ($dwpp + wd + pos$)	19,407	38.88	59.87	78.38	67.88
MaxEnt ($dwpp + wd + pos + link$)	19,426	38.76	59.89	78.94	68.10

Table 5: Performance of the error detection task.

- The second group of experiments concerns with the combination of linguistic features without word posterior probability feature. The combination of lexical features improves both CER and precision over single lexical feature (wd, pos). The addition of syntactic feature $link$ marginally undermines CER but improves recall by a lot.

- The last group of experiments concerns about the additional contribution of linguistic features to error detection with word posterior probability. We added linguistic features incrementally into the feature pool. The best performance was achieved by using all features, which has a relative of improvement of 18.52% over the baseline CER.

The first two groups of experiments show that linguistic features, individually (except for $link$) or by combination, are able to produce much better performance than word posterior probability features in both CER and F measure. The best combination of linguistic features achieves a relative improvement of 8.64% and 15.58% in CER and F measure respectively over word posterior probability thresholding.

The Table 5 also reveals how linguistic features improve error detection. The lexical features (pos, wd) improve precision when they are used. This suggests that lexical features can help the system find errors more accurately. Syntactic features ($link$), on the other hand, improve recall whenever they are used, which indicates that they can help the system find more errors.

We also show the number of features in each combination in Table 5. Except for the wd feature, the pos has the largest number of features, 199, which is a small set of features. This suggests that our error detection model can be learned from a rather small training set.

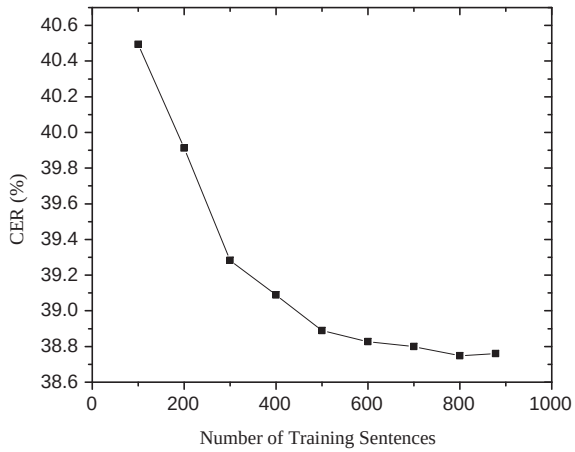

Figure 3: CER vs. the number of training sentences.

Figure 3 shows CERs for the feature combination MaxEnt ($dwpp + wd + pos + link$) when the number of training sentences is enlarged incrementally. CERs drop significantly when the number of training sentences is increased from 100 to 500. After 500 sentences are used, CERs change marginally and tend to converge.

7 Conclusions and Future Work

In this paper, we have presented a maximum entropy based approach to automatically detect errors in translation hypotheses generated by SMT

systems. We incorporate two sets of linguistic features together with word posterior probability based features into error detection.

Our experiments validate that linguistic features are very useful for error detection: 1) they by themselves achieve a higher improvement in terms of both CER and F measure than word posterior probability features; 2) the performance is further improved when they are combined with word posterior probability features.

The extracted linguistic features are quite compact, which can be learned from a small training set. Furthermore, The learned linguistic features are system-independent. Therefore our approach can be used for other machine translation systems, such as rule-based or example-based system, which generally do not produce N-best lists.

Future work in this direction involve detecting particular error types such as incorrect positions, inappropriate/unnecessary words (Elliott, 2006) and automatically correcting errors.

Abstract

The adoption of Machine Translation technology for commercial applications is hampered by the lack of trust associated with machine-translated output. In this paper, we describe TrustRank, an MT system enhanced with a capability to rank the quality of translation outputs from good to bad. This enables the user to set a quality threshold, granting the user control over the quality of the translations.

We quantify the gains we obtain in translation quality, and show that our solution works on a wide variety of domains and language pairs.

1 Introduction

The accuracy of machine translation (MT) software has steadily increased over the last 20 years to achieve levels at which large-scale commercial applications of the technology have become feasible. However, widespread adoption of MT technology remains hampered by the lack of trust associated with machine-translated output. This lack of trust is a normal reaction to the erratic translation quality delivered by current state-of-the-art MT systems. Unfortunately, the lack of predictable quality discourages the adoption of large-scale automatic translation solutions.

Consider the case of a commercial enterprise that hosts reviews written by travellers on its web site. These reviews contain useful information about hotels, restaurants, attractions, etc. There is a large and continuous stream of reviews posted on this site, and the large majority is written in English. In addition, there is a large set of potential customers who would prefer to have these reviews available in their (non-English) native languages. As such, this enterprise presents the perfect opportunity for the deployment of a large-volume MT solution. However, travel reviews present specific challenges: the reviews tend to have poor spelling, loose grammar, and broad topics of discussion. The result is unpredictable levels of MT quality. This is undesirable for the commercial enterprise, who is not content to simply reach a broad audience, but also wants to deliver a high-quality product to that audience.

We propose the following solution. We develop TrustRank, an MT system enhanced with a capability to rank the quality of translation outputs from good to bad. This enables the user to set a quality threshold, granting the user control over the quality of the translations that it employs in its product. With this enhancement, MT adoption stops being a binary should-we-or-shouldn't-we question. Rather, each user can make a personal trade-off between the scope and the quality of their product.

2 Related Work

Work on automatic MT evaluation started with the idea of comparing automatic translations against human-produced references. Such comparisons are done either at lexical level (Papineni et al., 2002; Doddington, 2002), or at linguistically-richer levels using paraphrases (Zhou et al., 2006; Kauchak and Barzilay, 2006), WordNet (Lavie and Agarwal, 2007), or syntax (Liu and Gildea, 2005; Owczarzak et al., 2007; Yang et al., 2008; Amigó et al., 2009). In contrast, we are interested in performing MT quality assessments on documents for which reference translations are not available.

Reference-free approaches to automatic MT quality assessment, based on Machine Learning techniques such as classification (Kulesza and Shieber, 2004), regression (Albrecht and Hwa, 2007), and ranking (Ye et al., 2007; Duh, 2008), have a different focus compared to ours. Their approach, which uses a test set that is held constant and against which various MT systems are mea-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 612–621,
Uppsala, Sweden, 11-16 July 2010.

sured, focuses on evaluating system performance. Similar proposals exist outside the MT field, for instance in syntactic parsing (Ravi et al., 2008). In this case, the authors focus on estimating performance over entire test sets, which in turn is used for evaluating system performance. In contrast, we focus on evaluating the quality of the translations themselves, while the MT system is kept constant.

A considerable amount of work has been done in the related area of confidence estimation for MT, for which Blatz et al. (2004) provide a good overview. The goal of this work is to identify small units of translated material (words and phrases) for which one can be confident in the quality of the translation. Related to this goal, and closest to our proposal, is the work of Gamon et al. (2005) and Specia et al. (2009). They describe Machine Learning approaches (classification and regression, respectively) aimed at predicting which sentences are likely to be well/poorly translated. Our work, however, departs from all these works in several important aspects.

First, we want to make the quality predictions at document-level, as opposed to sentence-level (Gamon et al., 2005; Specia et al., 2009), or word/phrase-level (Blatz et al., 2004; Ueffing and Ney, 2005). Document-level granularity is a requirement for large-scale commercial applications that use fully-automated translation solutions. For these applications, the need to make the distinction between "good translation" and "poor translation" must be done at document level. Otherwise, it is not actionable. In contrast, quality-prediction or confidence estimation at sentence- or word-level fits best a scenario in which automated translation is only a part of a larger pipeline. Such pipelines usually involve human post-editing, and are useful for translation productivity (Lagarda et al., 2009). Such solutions, however, suffer from the inherent volume bottleneck associated with human involvement. Our fully-automated solution targets large volume translation needs, on the order of 10,000 documents/day or more.

Second, we use automatically generated training labels for the supervised Machine Learning approach. In the experiments presented in this paper, we use BLEU scores (Papineni et al., 2002) as training labels. However, they can be substituted with any of the proposed MT metrics that use human-produced references to automatically assess translation quality (Doddington, 2002; Lavie and Agarwal, 2007). In a similar manner, the work of (Specia et al., 2009) uses NIST scores, and the work of (Ravi et al., 2008) uses PARSEVAL scores. The main advantage of this approach is that we can generate quickly and cheaply as many learning examples as needed. Additionally, we can customize the prediction models on a large variety of genres and domains, and quickly scale to multiple language pairs. In contrast, solutions that require training labels produced manually by humans (Gamon et al., 2005; Albrecht and Hwa, 2007) have difficulties producing prediction models fast enough, trained on enough data, and customized for specific domains.

Third, the main metric we use to assess the performance of our solution is targeted directly at measuring translation quality gains. We are interested in the extrinsic evaluation of the quantitative impact of the TrustRank solution, rather than in the intrinsic evaluation of prediction errors (Ravi et al., 2008; Specia et al., 2009).

3 Experimental Framework

3.1 Domains

We are interested in measuring the impact of TrustRank on a variety of genres, domains, and language pairs. Therefore, we set up the experimental framework accordingly. We use three proprietary data sets, taken from the domains of Travel (consumer reviews), Consumer Electronics (customer support for computers, data storage, printers, etc.), and HighTech (customer support for high-tech components). All these data sets come in a variety of European and Asian language pairs. We also use the publicly available data set used in the WMT09 task (Koehn and Haddow, 2009) (a combination of European parliament and news data). Information regarding the sizes of these data sets is provided in Table 2.

3.2 Metrics

We first present the experimental framework designed to answer the main question we want to address: can we automatically produce a ranking for document translations (for which no human-produced references are available), such that the translation quality of the documents at the top of this ranking is higher than the average translation quality? To this end, we use several metrics that can gauge how well we answer this question.

The first metric is Ranking Accuracy (rAcc), see (Gunawardana and Shani, 2009). We are interested in ranking N documents and assigning them into n quantiles. The formula is:

$$\text{rAcc}[n] = \text{Avg}_{i=1}^{n} \frac{\text{TP}_i}{\frac{N}{n}} = \frac{1}{N} \times \Sigma_{i=1}^{n} \text{TP}_i$$

where TP_i (True-Positive$_i$) is the number of correctly-assigned documents in quantile i. Intuitively, this formula is an average of the ratio of documents correctly assigned in each quantile.

The rAcc metric provides easy to understand lowerbounds and upperbounds. For example, with a method that assigns random ranks, when using 4 quantiles, the accuracy is 25% in any of the quantiles, hence an rAcc of 25%. With an oracle-based ranking, the accuracy is 100% in any of the quantiles, hence an rAcc of 100%. Therefore, the performance of any decent ranking method, when using 4 quantiles, can be expected to fall somewhere between these bounds.

The second and main metric is the volume-weighted BLEU gain (vBLEUΔ) metric. It measures the average BLEU gain when trading-off volume for accuracy on a predefined scale. The general formula, for n quantiles, is

$$\text{vBLEU}\Delta[n] = \Sigma_{i=1}^{n-1} w_i \times (\text{BLEU}_{1...i} - \text{BLEU})$$

$$\text{with } w_i = \frac{\frac{i}{n}}{\Sigma_{j=1}^{n-1} \frac{j}{n}} = \frac{i}{\Sigma_{j=1}^{n-1} j} = \frac{2i}{n(n-1)}$$

where $\text{BLEU}_{1...i}$ is the BLEU score of the first i quantiles, and BLEU is the score over all the quantiles. Intuitively, this formula provides a volume-weighted average of the BLEU gain obtained while varying the threshold of acceptance from 1 to n-1. (A threshold of acceptance set to the n-th quantile means accepting all the translations and therefore ignore the rankings, so we do not include it in the average.) Without rankings (or with random ranks), the expected vBLEU$\Delta[n]$ is zero, as the value $\text{BLEU}_{1...i}$ is expected to be the same as the overall BLEU for any i. With oracle ranking, the expected vBLEU$\Delta[n]$ is a positive number representative of the upperbound on the quality of the translations that pass an acceptance threshold. We report the vBLEU$\Delta[n]$ values as signed numbers, both within a domain and when computed as an average across domains.

The choice regarding the number of quantiles is closely related to the choice of setting an acceptance quality threshold. Because we want the solution to stay unchanged while the acceptance quality threshold can vary, we cannot treat this as a classification problem. Instead, we need to provide a complete ranking over an input set of documents. As already mentioned, TrustRank uses a regression method that is trained on BLEU scores as training labels. The regression functions are then used to predict a BLEU-like number for each document in the input set. The rankings are derived trivially from the predicted BLEU numbers, by simply sorting from highest to lowest. Reference ranking is obtained similarly, using actual BLEU scores.

Although we are mainly interested in the ranking problem here, it helps to look at the error produced by the regression models to arrive at a more complete picture. Besides the two metrics for ranking described above, we use the well-known regression metrics MAE (mean absolute error) and TE (test-level error):

$$\text{MAE} = \frac{1}{N} \times \Sigma_{k=1}^{N} |\text{predBLEU}_k - \text{BLEU}_k|$$

$$\text{TE} = \text{predBLEU} - \text{BLEU}$$

where BLEU_k is the BLEU score for document k, predBLEU_k is the predicted BLEU value, and predBLEU is a weighted average of the predicted document-level BLEU numbers over the entire set of N documents.

3.3 Experimental conditions

The MT system used by TrustRank (TrustRank-MT) is a statistical phrase-based MT system similar to (Och and Ney, 2004). As a reference point regarding the performance of this system, we use the official WMT09 parallel data, monolingual data, and development tuning set (news-dev2009a) to train baseline TrustRank-MT systems for each of the ten WMT09 language pairs. Our system produces translations that are competitive with state-of-the-art systems. We show our baseline-system BLEU scores on the official development test set (news-dev2009b) for the WMT09 task in Table 1, along with the BLEU scores reported for the baseline Moses system (Koehn and Haddow, 2009).

For each of the domains we consider, we partition the data sets as follows. We first set aside 3000 documents, which we call the Regression set [1]. The remaining data is called the training MT

[1]For parallel data for which we do not have document

Table 1: BLEU scores (uncased) for the TrustRank-MT system compared to Moses (WMT09 data).

set, on which the MT system is trained. From the Regression set, we set aside 1000 parallel documents to be used as a blind test set (called Regression Test) for our experiments. An additional set of 1000 parallel documents is used as a development set, and the rest of 1000 parallel documents is used as the regression-model training set.

We have also performed learning-curve experiments using between 100 and 2000 documents for regression-model training. We do not go into the details of these experiments here for lack of space. The conclusion derived from these experiments is that 1000 documents is the point where the learning-curves level off.

In Table 2, we provide a few data points with respect to the data size of these sets (tokenized word-count on the source side). We also report the BLEU performance of the TrustRank-MT system on the Regression Test set.

Note that the differences between the BLEU scores reported in Table 1 and the BLEU scores under the WMT09 label in Table 2 reflect differences in the genres of these sets. The official development test set (news-dev2009b) for the WMT09 task is news only. The regression Test sets have the same distribution between Europarl data and news as the corresponding training data set for each language pair.

4 The ranking algorithm

As mentioned before, TrustRank takes a supervised Machine Learning approach. We automatically generate the training labels by computing BLEU scores for every document in the Regression training set.

boundaries, we simply simulate document boundaries after every 10 consecutive sentences.

Table 2: Data sizes and BLEU on Regression Test.

4.1 The learning method

The results we report here are obtained using the freely-available Weka engine [2]. We have compared and contrasted results using all the regression packages offered by Weka, including regression functions based on simple and multiple-feature Linear regression, Pace regression, RBF networks, Isotonic regression, Gaussian Processes, Support Vector Machines (with SMO optimization) with polynomial and RBF kernels, and regression trees such as REP trees and M5P trees. Due to lack of space and the tangential impact on the message of this paper, we do not report

[2] Weka software at http://www.cs.waikato.ac.nz/ml/weka/, version 3.6.1, June 2009.

these contrastive experiments here.

The learning technique that consistently yields the best results is M5P regression trees (weka.classifiers.trees.M5P). Therefore, we report all the results in this paper using this learning method. As an additional advantage, the decision trees and the regression models produced in training are easy to read, understand, and interpret. One can get a good insight into what the impact of a certain feature on a final predicted value is by simply inspecting these trees.

4.2 The features

In contrast to most of the work on confidence estimation (Blatz et al., 2004), the features we use are not internal features of the MT system. Therefore, TrustRank can be applied for a large variety of MT approaches, from statistical-based to rule-based approaches.

The features we use can be divided into text-based, language-model–based, pseudo-reference–based, example-based, and training-data–based feature types. These feature types can be computed either on the source-side (input documents) or on the target-side (translated documents).

Text-based features

These features simply look at the length of the input in terms of (tokenized) number of words. They can be applied on the input, where they induce a correlation between the number of words in the input document and the expected BLEU score for that document size. They can also be applied on the produced output, and learn a similar correlation for the produced translation.

Language-model–based features

These features are among the ones that were first proposed as possible differentiators between good and bad translations (Gamon et al., 2005). They are a measure of how likely a collection of strings is under a language model trained on monolingual data (either on the source or target side).

The language-model–based feature values we use here are computed as document-level perplexity numbers using a 5-gram language model trained on the MT training set.

Pseudo-reference–based features

Previous work has shown that, in the absence of human-produced references, automatically-produced ones are still helpful in differentiating between good and bad translations (Albrecht and Hwa, 2008). When computed on the target side, this type of features requires one or more secondary MT systems, used to generate translations starting from the same input. These pseudo-references are useful in gauging translation convergence, using BLEU scores as feature values. In intuitive terms, their usefulness can be summarized as follows: "if system X produced a translation A and system Y produced a translation B starting from the same input, and A and B are similar, then A is probably a good translation".

An important property here is that systems X and Y need to be as different as possible from each other. This property ensures that a convergence on similar translations is not just an artifact, but a true indication that the translations are correct. The secondary systems we use here are still phrase-based, but equipped with linguistically-oriented modules similar with the ones proposed in (Collins et al., 2005; Xu et al., 2009).

The source-side pseudo-reference–based feature type is of a slightly different nature. It still requires one or more secondary MT systems, but operating in the reverse direction. A translated document produced by the main MT system is fed to the secondary MT system(s), translated back into the original source language, and used as pseudo-reference(s) when computing a BLEU score for the original input. In intuitive terms: "if system X takes document A and produces B, and system X^{-1} takes B and produces C, and A and C are similar, then B is probably a good translation".

Example-based features

For example-based features, we use a development set of 1000 parallel documents, for which we produce translations and compute document-level BLEU scores. We set aside the top-100 BLEU scoring documents and bottom-100 BLEU scoring documents. They are used as positive examples (with better-than-average BLEU) and negative examples (with worse-than-average BLEU), respectively. We define a positive-example–based feature function as a geometric mean of 1-to-4–gram precision scores (i.e., BLEU score without length penalty) between a document (on either source or target side) and the positive examples used as references (similarly for negative-example–based features).

The intuition behind these features can be summarized as follows: "if system X translated docu-

ment A well/poorly, and A and B are similar, then system X probably translates B well/poorly".

Training-data–based features

If the main MT system is trained on a parallel corpus, the data in this corpus can be exploited towards assessing translation quality (Specia et al., 2009). In our context, the documents that make up this corpus can be used in a fashion similar with the positive examples. One type of training-data–based features operates by computing the number of out-of-vocabulary (OOV) tokens with respect to the training data (on either source or target side).

A more powerful type of training-data–based features operates by computing a BLEU score between a document (source or target side) and the training-data documents used as references. Intuitively, we assess the coverage with respect to the training data and correlate it with a BLEU score: "if the n-grams of input document A are well covered by the source-side of the training data, the translation of A is probably good" (on the source side); "if the n-grams in the output translation B are well covered by the target-side of the parallel training data, then B is probably a good translation" (on the target side).

4.3 Results

We are interested in the best performance for TrustRank using the features described above. In this section, we focus on reporting the results obtain for the English-Spanish language pair. In the next section, we report results obtained on all the language pairs we considered.

Before we discuss the results of TrustRank, let us anchor the numerical values using some lower- and upper-bounds. As a baseline, we use a regression function that outputs a constant number for each document, equal to the BLEU score of the Regression Training set. As an upperbound, we use an oracle regression function that outputs a number for each document that is equal to the actual BLEU score of that document. In Table 4, we present the performance of these regression functions across all the domains considered.

As already mentioned, the rAcc values are bounded by the 25% lowerbound and the 100% upperbound. The vBLEUΔ values are bounded by 0 as lowerbound, and some positive BLEU gain value that varies among the domains we considered from +6.4 (Travel) to +13.5 (HiTech).

The best performance obtained by TrustRank for English-Spanish, using all the features described, is presented in Table 3. The ranking accuracy numbers on a per-quantile basis reveals an important property for the approach we advocate. The ranking accuracy on the first quantile Q_1 (identifying the best 25% of the translations) is 52% on average across the domains. For the last quantile Q_4 (identifying the worst 25% of the translations), it is 56%. This is much better than the ranking accuracy for the median-quality translations (35-37% accuracy for the two middle quantiles). This property fits well our scenario, in which we are interested in associating trust in the quality of the translations in the top quantile.

Domain	rAcc	vBLEUΔ[4]	MAE	TE
Baseline				
WMT09	25%	0	9.9	+0.4
Travel	25%	0	8.3	+2.0
Electr.	25%	0	12.2	+2.6
HiTech	25%	0	16.9	+2.4
Dom. avg.	25%	0	11.8	1.9
Oracle				
WMT09	100%	+8.2	0	0
Travel	100%	+6.4	0	0
Electr.	100%	+9.2	0	0
HiTech	100%	+13.5	0	0
Dom. avg.	100%	+9.3	0	0

Table 4: Lower- and upper-bounds for ranking and regression accuracy (English-Spanish).

The quality of the top quantile translations is quantifiable in terms of BLEU gain. The 250 document translations in Q_1 for Travel have a BLEU score of 38.0, a +6.8 BLEU gain compared to the overall BLEU of 31.2 (Q_{1-4}). The Q_1 HiTech translations, with a BLEU of 77.9, have a +18.9 BLEU gain compared to the overall BLEU of 59.0. The TrustRank algorithm allows us to tradeoff quantity versus quality on any scale. The results under the BLEU heading in Table 3 represent an instantiation of this ability to a 3-point scale (Q_1,Q_{1-2},Q_{1-3}). The vBLEUΔ numbers reflect an average of the BLEU gains for this instantiation (e.g., a +11.6 volume-weighted average BLEU gain for the HiTech domain).

We are also interested in the best performance under more restricted conditions, such as time constraints. The assumption we make here is that the translation time dwarfs the time needed for fea-

Domain	Ranking Accuracy					Translation Accuracy					MAE	TE
						BLEU				vBLEUΔ[4]		
	Q_1	Q_2	Q_3	Q_4	rAcc	Q_1	Q_{1-2}	Q_{1-3}	Q_{1-4}			
WMT09	34%	26%	29%	40%	32%	44.8	43.6	42.4	41.1	+2.1	9.6	-0.1
Travel	50%	26%	29%	41%	36%	38.0	35.1	33.0	31.2	+3.4	7.4	-1.9
Electronics	57%	38%	39%	68%	51%	76.1	72.7	69.6	65.2	+6.5	8.4	-2.6
HiTech	65%	48%	49%	75%	59%	77.9	72.7	66.7	59.0	+11.6	8.6	-2.1
Dom. avg.	**52%**	**35%**	**37%**	**56%**	**45%**	-				**+5.9**	**8.5**	**1.7**

Table 3: Detailed performance using all features (English-Spanish).

ture and regression value computation. Therefore, the most time-expensive feature is the source-side pseudo-reference–based feature, which effectively doubles the translation time required. Under the "time-constrained" condition, we exclude this feature and use all of the remaining features. Table 5 presents the results obtained for English-Spanish.

Domain	rAcc	vBLEUΔ[4]	MAE	TE
"Time-constrained" condition				
WMT09	32%	+2.1	9.6	-0.1
Travel	35%	+3.2	7.4	-1.8
Electronics	50%	+6.3	8.4	-2.2
HiTech	59%	+11.6	8.9	-2.1
Dom. avg.	**44%**	**+5.8**	**8.6**	**1.6**

Table 5: "Time-constrained" performance (English-Spanish).

The results presented above allow us to draw a series of conclusions.

Benefits vary by domain

Even with oracle rankings (Table 4), the benefits vary from one domain to the next. For Travel, with an overall BLEU score in the low 30s (31.2), we stand to gain at most +6.4 BLEU points on average (+6.4 vBLEUΔ upperbound). For a domain such as HiTech, even with a high overall BLEU score close to 60 (59.0), we stand to gain twice as much (+13.5 vBLEUΔ upperbound).

Performance varies by domain

As the results in Table 3 show, the best performance we obtain also varies from one domain to the next. For instance, the ranking accuracy for the WMT09 domain is only 32%, while for the HiTech domain is 59%. Also, the BLEU gain for the WMT09 domain is only +2.1 vBLEUΔ (compared to the upperbound vBLEUΔ of +8.2, it is only 26% of the oracle performance). In contrast, the BLEU gain for the HiTech domain is +11.6 vBLEUΔ (compared to the +13.5 vBLEUΔ upperbound, it is 86% of the oracle performance).

Positive feature synergy and overlap

The features we described capture different information, and their combination achieves the best performance. For instance, in the Electronics domain, the best single feature is the target-side n-gram coverage feature, with +5.3 vBLEUΔ. The combination of all features gives a +6.5 vBLEUΔ.

The numbers in Table 3 also show that eliminating some of the features results in lower performance. The rAcc drops from 45% to 44% in under the "time-constraint" condition (Table 5). The difference in the rankings is statistically significant at $p < 0.01$ using the Wilcoxon test (Demšar, 2006).

However, this drop is quantitatively small (1% rAcc drop, -0.1 in vBLEUΔ, averaged across domains). This suggests that, even when eliminating features that by themselves have a good discriminatory power (the source-side pseudo-reference–based feature achieves a +5.0 vBLEUΔ as a single feature in the Electronics domain), the other features compensate to a large degree.

Poor regression performance

By looking at the results of the regression metrics, we conclude that the predicted BLEU numbers are not accurate in absolute value. The aggregated Mean Absolute Error (MAE) is 8.5 when using all the features. This is less than the baseline MAE of 11.8, but it is too high to allow us to confidently use the document-level BLEU numbers as reliable indicators of translation accuracy. The Test Error (TE) numbers are not encouraging either, as the 1.7 TE of TrustRank is close to the baseline TE of 1.9 (see Table 4 for baseline numbers).

5 Large-scale experimental results

In this section, we present the performance of TrustRank on a variety of language pairs (Table 6). We report the BLEU score obtained on our 1000-document regression Test, as well as ranking and regression performance using the rAcc, vBLEUΔ, MAE, and TE metrics.

As the numbers for the ranking and regression metrics show, the same trends we observed for English-Spanish hold for many other language pairs as well. Some domains, such as HiTech, are easier to rank regardless of the language pair, and the quality gains are consistently high (+9.9 average vBLEUΔ for the 5 language pairs considered). Other domains, such as WMT09 and Travel, are more difficult to rank. However, the WMT09 English-Hungarian data set appears to be better suited for ranking, as the vBLEUΔ numbers are higher compared to the rest of the language pairs from this domain (+4.3 vBLEUΔ for Eng-Hun, +7.1 vBLEUΔ for Hun-Eng). For Travel, English-Dutch is also an outlier in terms of quality gains (+12.9 vBLEUΔ).

Overall, the results indicate that TrustRank obtains consistent performance across a large variety of language pairs. Similar with the conclusion for English-Spanish, the regression performance is currently too poor to allow us to confidently use the absolute document-level predicted BLEU numbers as indicators of translation accuracy.

6 Examples and Illustrations

As the experimental results in Table 6 show, the regression performance varies considerably across domains. Even within the same domain, the nature of the material used to perform the experiments can influence considerably the results we obtain. In Figure 1, we plot ⟨BLEU,predBLEU⟩ points for three of our language pairs presented in Table 6: Travel Eng-Fra, Travel Eng-Dut, and HiTech Eng-Rus. These plots illustrate the tendency of the predicted BLEU values to correlate with the actual BLEU scores. The amount of correlation visible in these plots matches the performance numbers provided in Table 6, with Travel Eng-Fra at a lower level of correlation compared to Travel Eng-Dut and HiTech Eng-Rus. The ⟨BLEU,predBLEU⟩ points tend to align along a line at an angle smaller than 45°, an indication of the fact that the BLEU predictions tend to be more conservative compared to the actual BLEU scores. For example, in the Travel Eng-Fra case, the predicted BLEU numbers are spread across a narrower band (95% of the values are in the [19-35] interval), compared to the actual BLEU scores (95% of the values are in the [11-47] interval).

Domain	BLEU	rAcc	vBLEUΔ[4]	MAE	TE
WMT09					
Eng-Spa	41.0	35%	+2.4	9.2	-0.3
Eng-Fra	37.1	37%	+3.3	8.3	-0.5
Eng-Ger	23.7	32%	+1.9	5.8	-0.7
Eng-Cze	10.3	38%	+1.3	3.1	-0.6
Eng-Hun	14.5	55%	+4.3	3.7	-1.1
Spa-Eng	40.1	37%	+3.3	8.1	-0.2
Fra-Eng	37.9	39%	+3.8	10.1	-0.6
Ger-Eng	29.4	36%	+2.7	5.9	-0.9
Cze-Eng	19.7	40%	+2.4	4.3	-0.6
Hun-Eng	24.0	61%	+7.1	4.9	-1.8
Travel					
Eng-Spa	31.2	36%	+3.4	7.4	-1.9
Eng-Fra	27.8	39%	+2.7	6.2	-0.9
Eng-Ita	22.5	39%	+2.4	5.1	+0.0
Eng-Por	41.9	51%	+5.6	8.6	+1.1
Eng-Ger	27.6	37%	+5.7	11.8	-0.4
Eng-Dut	41.9	52%	+12.9	12.9	-0.7
Electronics					
Eng-Spa	65.2	51%	+6.5	8.4	-2.6
Eng-Fra	55.8	49%	+7.7	8.4	-2.3
Eng-Ger	42.1	57%	+8.9	7.4	-1.6
Eng-Chi	63.9	48%	+6.4	8.6	-0.8
Eng-Por	47.9	49%	+6.9	9.0	-1.8
HiTech					
Eng-Spa	59.0	59%	+11.6	8.6	-2.1
Eng-Ger	36.6	62%	+9.2	7.1	-1.0
Eng-Chi	60.3	54%	+7.5	8.4	-1.0
Eng-Rus	39.2	62%	+10.7	8.7	-2.1
Eng-Kor	49.4	61%	+10.5	9.7	-3.2

Table 6: Performance of TrustRank on a variety of domains and language pairs.

These intervals are also useful for gauging the level of difficulty stemming from the nature of the material used to perform the experiments. In the case of Travel Eng-Fra, the actual BLEU scores are clustered in a narrower band (interval [11-47] covers 95% of the values), compared to the actual BLEU scores for Travel Eng-Dut (interval [11-92] covers 95% of the values) and HiTech Eng-Rus (interval [3-80] covers 95% of the values). This

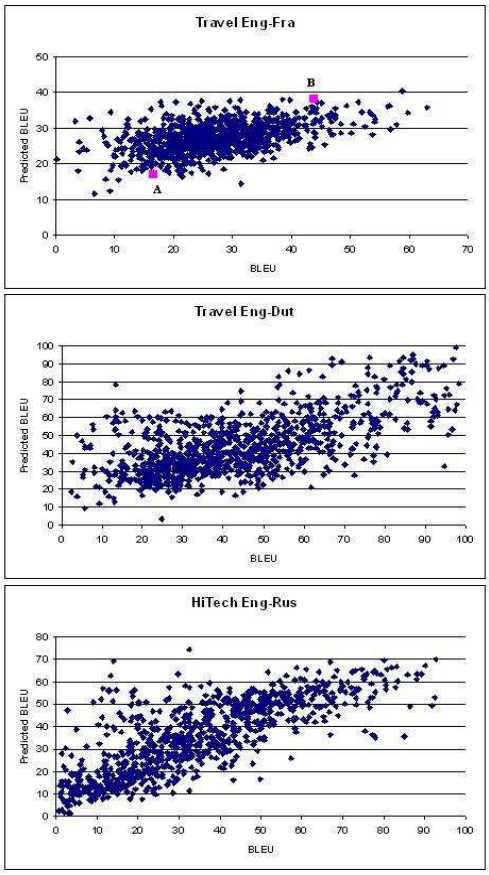

Figure 1: Examples of BLEU versus predBLEU.

means that the documents in the latter cases are easier to distinguish, compared to the documents in Travel Eng-Fra.

To provide an intuitive feel for the difference between the level of translation performance between documents ranked close to the bottom and documents ranked close to the top, we present here two example translations. They are documents that we randomly picked from the bottom 10% and top 10% of the Travel Eng-Fra document set, and they correspond to points A and B in the first plot of Figure 1, respectively. The A-Fra and B-Fra entries below are produced by our Eng-Fra TrustRank-MT system, starting from A-Eng and B-Eng[3], respectively.

A-Eng This will be our 18th year,still love it. Same hotel, room, staff, even other guests from other countries, its lovely to see everyone that you have gotten to know over the years, even if ,you or they ,do not speak each others language. We love the Island some much that, hopefuly, that is where we are retiring to, we do keep looking for that affordable place.

A-Fra Ce sera notre 18ème année, adore. Même hôtel, la chambre, le personnel, même d'autres clients dans d'autres pays, c'est très agréable de voir que tout le monde vous aurais savoir au cours de ces dernières années, même si, ou bien ils vous, ne parlent pas chaque d'autres langues. Nous adorons l'île des que, hopefuly, c'est l'endroit où nous avons retiring, nous ne pour chercher un endroit abordable.

B-Eng Stayed at the Intercontinental for 4 nights. It is in an excellent location, not far from the French Quarter. The rooms are large, clean, and comfortable. The staff is friendly and helpful. Parking is very expensive, around $29. 00 a day. There is a garage next door which is a little more reasonable. I certainly suggest this hotel to others.

B-Fra J'ai séjourné à l'Intercontinental pour 4 nuits. Il est très bien situé, pas loin du Quartier Français. Les chambres sont grandes, propres et confortables. Le personnel est sympa et serviable. Le parking est très cher, autour de 29 $ par jour. Il y a un garage à côté, ce qui est un peu plus raisonnable. Je conseille cet hôtel à d'autres.

Document A-Fra is a poor translation, and is ranked in the bottom 10%, while document B-Fra is a nearly-perfect translation ranked in the top 10%, out of a total of 1000 documents.

7 Conclusions and Future Work

Commercial adoption of MT technology requires trust in the translation quality. Rather than delay this adoption until MT attains a near-human level of sophistication, we propose an interim approach. We present a mechanism that allows MT users to trade quantity for quality, using automatically-determined translation quality rankings.

The results we present in this paper show that document-level translation quality rankings provide quantitatively strong gains in translation quality, as measured by BLEU. A difference of +18.9 BLEU, like the one we obtain for the English-Spanish HiTech domain (Table 3), is persuasive evidence for inspiring trust in the quality of selected translations. This approach enables us to develop TrustRank, a complete MT solution that enhances automatic translation with the ability to identify document subsets containing translations that pass an acceptable quality threshold.

When measuring the performance of our solution across several domains, it becomes clear that some domains allow for more accurate quality prediction than others. Given the immediate benefit that can be derived from increasing the ranking accuracy for translation quality, we plan to open up publicly available benchmark data that can be used to stimulate and rigorously monitor progress in this direction.

[3]We preserved the original writing style of the documents in the source language.

Abstract

We propose a translation recommendation framework to integrate Statistical Machine Translation (SMT) output with Translation Memory (TM) systems. The framework recommends SMT outputs to a TM user when it predicts that SMT outputs are more suitable for post-editing than the hits provided by the TM. We describe an implementation of this framework using an SVM binary classifier. We exploit methods to fine-tune the classifier and investigate a variety of features of different types. We rely on automatic MT evaluation metrics to approximate human judgements in our experiments. Experimental results show that our system can achieve 0.85 precision at 0.89 recall, excluding exact matches. Furthermore, it is possible for the end-user to achieve a desired balance between precision and recall by adjusting confidence levels.

1 Introduction

Recent years have witnessed rapid developments in statistical machine translation (SMT), with considerable improvements in translation quality. For certain language pairs and applications, automated translations are now beginning to be considered acceptable, especially in domains where abundant parallel corpora exist.

However, these advances are being adopted only slowly and somewhat reluctantly in professional localization and post-editing environments. Post-editors have long relied on translation memories (TMs) as the main technology assisting translation, and are understandably reluctant to give them up. There are several simple reasons for this: 1) TMs are useful; 2) TMs represent considerable effort and investment by a company or (even more so) an individual translator; 3) the fuzzy match score used in TMs offers a good approximation of post-editing effort, which is useful both for translators and translation cost estimation and, 4) current SMT translation confidence estimation measures are not as robust as TM fuzzy match scores and professional translators are thus not ready to replace fuzzy match scores with SMT internal quality measures.

There has been some research to address this issue, see e.g. (Specia et al., 2009a) and (Specia et al., 2009b). However, to date most of the research has focused on better confidence measures for MT, e.g. based on training regression models to perform confidence estimation on scores assigned by post-editors (cf. Section 2).

In this paper, we try to address the problem from a different perspective. Given that most post-editing work is (still) based on TM output, we propose to recommend MT outputs which are better than TM hits to post-editors. In this framework, post-editors still work with the TM while benefiting from (better) SMT outputs; the assets in TMs are not wasted and TM fuzzy match scores can still be used to estimate (the upper bound of) post-editing labor.

There are three specific goals we need to achieve within this framework. Firstly, the recommendation should have high precision, otherwise it would be confusing for post-editors and may negatively affect the lower bound of the post-editing effort. Secondly, although we have full access to the SMT system used in this paper, our method should be able to generalize to cases where SMT is treated as a black-box, which is of-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 622–630,
Uppsala, Sweden, 11-16 July 2010.

ten the case in the translation industry. Finally, post-editors should be able to easily adjust the recommendation threshold to particular requirements without having to retrain the model.

In our framework, we recast translation recommendation as a binary classification (rather than regression) problem using SVMs, perform RBF kernel parameter optimization, employ posterior probability-based confidence estimation to support user-based tuning for precision and recall, experiment with feature sets involving MT-, TM- and system-independent features, and use automatic MT evaluation metrics to simulate post-editing effort.

The rest of the paper is organized as follows: we first briefly introduce related research in Section 2, and review the classification SVMs in Section 3. We formulate the classification model in Section 4 and present experiments in Section 5. In Section 6, we analyze the post-editing effort approximated by the TER metric (Snover et al., 2006). Section 7 concludes the paper and points out avenues for future research.

2 Related Work

Previous research relating to this work mainly focuses on predicting the MT quality.

The first strand is confidence estimation for MT, initiated by (Ueffing et al., 2003), in which posterior probabilities on the word graph or N-best list are used to estimate the quality of MT outputs. The idea is explored more comprehensively in (Blatz et al., 2004). These estimations are often used to rerank the MT output and to optimize it directly. Extensions of this strand are presented in (Quirk, 2004) and (Ueffing and Ney, 2005). The former experimented with confidence estimation with several different learning algorithms; the latter uses word-level confidence measures to determine whether a particular translation choice should be accepted or rejected in an interactive translation system.

The second strand of research focuses on combining TM information with an SMT system, so that the SMT system can produce better target language output when there is an exact or close match in the TM (Simard and Isabelle, 2009). This line of research is shown to help the performance of MT, but is less relevant to our task in this paper.

A third strand of research tries to incorporate confidence measures into a post-editing environment. To the best of our knowledge, the first paper in this area is (Specia et al., 2009a). Instead of modeling on translation quality (often measured by automatic evaluation scores), this research uses regression on both the automatic scores and scores assigned by post-editors. The method is improved in (Specia et al., 2009b), which applies Inductive Confidence Machines and a larger set of features to model post-editors' judgement of the translation quality between 'good' and 'bad', or among three levels of post-editing effort.

Our research is more similar in spirit to the third strand. However, we use outputs and features from the TM explicitly; therefore instead of having to solve a regression problem, we only have to solve a much easier binary prediction problem which can be integrated into TMs in a straightforward manner. Because of this, the precision and recall scores reported in this paper are not directly comparable to those in (Specia et al., 2009b) as the latter are computed on a pure SMT system without a TM in the background.

3 Support Vector Machines for Translation Quality Estimation

SVMs (Cortes and Vapnik, 1995) are binary classifiers that classify an input instance based on decision rules which minimize the regularized error function in (1):

$$\begin{array}{ll} \min\limits_{w,b,\xi} & \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum\limits_{i=1}^{l}\xi_i \\ \text{s. t.} & y_i(\mathbf{w}^T\phi(\mathbf{x}_i) + b) \geqslant 1 - \xi_i \\ & \xi_i \geqslant 0 \end{array} \quad (1)$$

where $(\mathbf{x}_i, y_i) \in R^n \times \{+1, -1\}$ are l training instances that are mapped by the function ϕ to a higher dimensional space. $\mathbf{w}$ is the weight vector, ξ is the relaxation variable and $C > 0$ is the penalty parameter.

Solving SVMs is viable using the 'kernel trick': finding a kernel function K in (1) with $K(\mathbf{x}_i, \mathbf{x}_j) = \Phi(\mathbf{x}_i)^T\Phi(\mathbf{x}_j)$. We perform our experiments with the Radial Basis Function (RBF) kernel, as in (2):

$$K(\mathbf{x}_i, \mathbf{x}_j) = exp(-\gamma||\mathbf{x}_i - \mathbf{x}_j||^2), \gamma > 0 \quad (2)$$

When using SVMs with the RBF kernel, we have two free parameters to tune on: the cost parameter C in (1) and the radius parameter γ in (2).

In each of our experimental settings, the parameters C and γ are optimized by a brute-force grid

search. The classification result of each set of parameters is evaluated by cross validation on the training set.

4 Translation Recommendation as Binary Classification

We use an SVM binary classifier to predict the relative quality of the SMT output to make a recommendation. The SVM classifier uses features from the SMT system, the TM and additional linguistic features to estimate whether the SMT output is better than the hit from the TM.

4.1 Problem Formulation

As we treat translation recommendation as a binary classification problem, we have a pair of outputs from TM and MT for each sentence. Ideally the classifier will recommend the output that needs less post-editing effort. As large-scale annotated data is not yet available for this task, we use automatic TER scores (Snover et al., 2006) as the measure for the required post-editing effort. In the future, we hope to train our system on HTER (TER with human targeted references) scores (Snover et al., 2006) once the necessary human annotations are in place. In the meantime we use TER, as TER is shown to have high correlation with HTER.

We label the training examples as in (3):

$$y = \begin{cases} +1 & \text{if } TER(\text{MT}) < TER(\text{TM}) \\ -1 & \text{if } TER(\text{MT}) \geq TER(\text{TM}) \end{cases} \quad (3)$$

Each instance is associated with a set of features from both the MT and TM outputs, which are discussed in more detail in Section 4.3.

4.2 Recommendation Confidence Estimation

In classical settings involving SVMs, confidence levels are represented as margins of binary predictions. However, these margins provide little insight for our application because the numbers are only meaningful when compared to each other. What is more preferable is a probabilistic confidence score (e.g. 90% confidence) which is better understood by post-editors and translators.

We use the techniques proposed by (Platt, 1999) and improved by (Lin et al., 2007) to obtain the posterior probability of a classification, which is used as the confidence score in our system.

Platt's method estimates the posterior probability with a sigmod function, as in (4):

$$Pr(y = 1|\mathbf{x}) \approx P_{A,B}(f) \equiv \frac{1}{1 + exp(Af + B)} \quad (4)$$

where $f = f(\mathbf{x})$ is the decision function of the estimated SVM. A and B are parameters that minimize the cross-entropy error function F on the training data, as in Eq. (5):

$$\min_{z=(A,B)} F(z) = -\sum_{i=1}^{l}(t_i log(p_i) + (1 - t_i) log(1 - p_i)),$$
$$\text{where } p_i = P_{A,B}(f_i), \text{and } t_i = \begin{cases} \frac{N_+ + 1}{N_+ + 2} \text{ if } y_i = +1 \\ \frac{1}{N_- + 2} \text{ if } y_i = -1 \end{cases} \quad (5)$$

where $z = (A, B)$ is a parameter setting, and N_+ and N_- are the numbers of observed positive and negative examples, respectively, for the label y_i. These numbers are obtained using an internal cross-validation on the training set.

4.3 The Feature Set

We use three types of features in classification: the MT system features, the TM feature and system-independent features.

4.3.1 The MT System Features

These features include those typically used in SMT, namely the phrase-translation model scores, the language model probability, the distance-based reordering score, the lexicalized reordering model scores, and the word penalty.

4.3.2 The TM Feature

The TM feature is the fuzzy match (Sikes, 2007) cost of the TM hit. The calculation of fuzzy match score itself is one of the core technologies in TM systems and varies among different vendors. We compute fuzzy match cost as the minimum Edit Distance (Levenshtein, 1966) between the source and TM entry, normalized by the length of the source as in (6), as most of the current implementations are based on edit distance while allowing some additional flexible matching.

$$h_{fm}(t) = \min_{e} \frac{EditDistance(s, e)}{Len(s)} \quad (6)$$

where s is the source side of t, the sentence to translate, and e is the source side of an entry in the TM. For fuzzy match scores F, this fuzzy match cost h_{fm} roughly corresponds to $1-F$. The difference in calculation does not influence classification, and allows direct comparison between a pure TM system and a translation recommendation system in Section 5.4.2.

4.3.3 System-Independent Features

We use several features that are independent of the translation system, which are useful when a third-party translation service is used or the MT system is simply treated as a black-box. These features are source and target side LM scores, pseudo source fuzzy match scores and IBM model 1 scores.

Source-Side Language Model Score and Perplexity. We compute the language model (LM) score and perplexity of the input source sentence on a LM trained on the source-side training data of the SMT system. The inputs that have lower perplexity or higher LM score are more similar to the dataset on which the SMT system is built.

Target-Side Language Model Perplexity. We compute the LM probability and perplexity of the target side as a measure of fluency. Language model perplexity of the MT outputs are calculated, and LM probability is already part of the MT systems scores. LM scores on TM outputs are also computed, though they are not as informative as scores on the MT side, since TM outputs should be grammatically perfect.

The Pseudo-Source Fuzzy Match Score. We translate the output back to obtain a pseudo source sentence. We compute the fuzzy match score between the original source sentence and this pseudo-source. If the MT/TM system performs well enough, these two sentences should be the same or very similar. Therefore, the fuzzy match score here gives an estimation of the confidence level of the output. We compute this score for both the MT output and the TM hit.

The IBM Model 1 Score. The fuzzy match score does not measure whether the hit could be a correct translation, i.e. it does not take into account the correspondence between the source and target, but rather only the source-side information. For the TM hit, the IBM Model 1 score (Brown et al., 1993) serves as a rough estimation of how good a translation it is on the word level; for the MT output, on the other hand, it is a black-box feature to estimate translation quality when the information from the translation model is not available. We compute bidirectional (source-to-target and target-to-source) model 1 scores on both TM and MT outputs.

5 Experiments

5.1 Experimental Settings

Our raw data set is an English–French translation memory with technical translation from Symantec, consisting of 51K sentence pairs. We randomly selected 43K to train an SMT system and translated the English side of the remaining 8K sentence pairs. The average sentence length of the training set is 13.5 words and the size of the training set is comparable to the (larger) TMs used in the industry. Note that we remove the exact matches in the TM from our dataset, because exact matches will be reused and not presented to the post-editor in a typical TM setting.

As for the SMT system, we use a standard log-linear PB-SMT model (Och and Ney, 2002): GIZA++ implementation of IBM word alignment model 4,[1] the refinement and phrase-extraction heuristics described in (Koehn et al., 2003), minimum-error-rate training (Och, 2003), a 5-gram language model with Kneser-Ney smoothing (Kneser and Ney, 1995) trained with SRILM (Stolcke, 2002) on the English side of the training data, and Moses (Koehn et al., 2007) to decode. We train a system in the opposite direction using the same data to produce the pseudo-source sentences.

We train the SVM classifier using the libSVM (Chang and Lin, 2001) toolkit. The SVM-training and testing is performed on the remaining 8K sentences with 4-fold cross validation. We also report 95% confidence intervals.

The SVM hyper-parameters are tuned using the training data of the first fold in the 4-fold cross validation via a brute force grid search. More specifically, for parameter C in (1) we search in the range $[2^{-5}, 2^{15}]$, and for parameter γ (2) we search in the range $[2^{-15}, 2^{3}]$. The step size is 2 on the exponent.

5.2 The Evaluation Metrics

We measure the quality of the classification by precision and recall. Let A be the set of recommended MT outputs, and B be the set of MT outputs that have lower TER than TM hits. We standardly define precision P, recall R and F-value as in (7):

[1] More specifically, we performed 5 iterations of Model 1, 5 iterations of HMM, 3 iterations of Model 3, and 3 iterations of Model 4.

$$P = \frac{|A \bigcap B|}{|A|}, R = \frac{|A \bigcap B|}{|B|} \text{ and } F = \frac{2PR}{P+R} \quad (7)$$

5.3 Recommendation Results

In Table 1, we report recommendation performance using MT and TM system features (SYS), system features plus system-independent features (ALL:SYS+SI), and system-independent features only (SI).

Table 1: Recommendation Results

	Precision	Recall	F-Score
SYS	82.53±1.17	96.44±0.68	88.95±.56
SI	82.56±1.46	95.83±0.52	88.70±.65
ALL	83.45±1.33	95.56±1.33	89.09±.24

From Table 1, we observe that MT and TM system-internal features are very useful for producing a stable (as indicated by the smaller confidence interval) recommendation system (SYS). Interestingly, only using some simple system-external features as described in Section 4.3.3 can also yield a system with reasonably good performance (SI). We expect that the performance can be further boosted by adding more syntactic and semantic features. Combining all the system-internal and -external features leads to limited gains in Precision and F-score compared to using only system-internal features (SYS) only. This indicates that at the default confidence level, current system-external (resp. system-internal) features can only play a limited role in informing the system when current system-internal (resp. system-external) features are available. We show in Section 5.4.2 that combing both system-internal and -external features can yield higher, more stable precision when adjusting the confidence levels of the classifier. Additionally, the performance of system SI is promising given the fact that we are using only a limited number of simple features, which demonstrates a good prospect of applying our recommendation system to MT systems where we do not have access to their internal features.

5.4 Further Improving Recommendation Precision

Table 1 shows that classification recall is very high, which suggests that precision can still be improved, even though the F-score is not low. Considering that TM is the dominant technology used by post-editors, a recommendation to replace the hit from the TM would require more confidence, i.e. higher precision. Ideally our aim is to obtain a level of 0.9 precision at the cost of some recall, if necessary. We propose two methods to achieve this goal.

5.4.1 Classifier Margins

We experiment with different margins on the training data to tune precision and recall in order to obtain a desired balance. In the basic case, the training example would be marked as in (3). If we label both the training and test sets with this rule, the accuracy of the prediction will be maximized.

We try to achieve higher precision by enforcing a larger bias towards negative examples in the training set so that some borderline positive instances would actually be labeled as negative, and the classifier would have higher precision in the prediction stage as in (8).

$$y = \begin{cases} +1 & \text{if } TER(\text{SMT}) + b < TER(\text{TM}) \\ -1 & \text{if } TER(\text{SMT}) + b \geqslant TER(\text{TM}) \end{cases} \quad (8)$$

We experiment with b in [0, 0.25] using MT system features and TM features. Results are reported in Table 2.

Table 2: Classifier margins

	Precision	Recall
TER+0	83.45±1.33	95.56±1.33
TER+0.05	82.41±1.23	94.41±1.01
TER+0.10	84.53±0.98	88.81±0.89
TER+0.15	85.24±0.91	87.08±2.38
TER+0.20	87.59±0.57	75.86±2.70
TER+0.25	89.29±0.93	66.67±2.53

The highest accuracy and F-value is achieved by $TER + 0$, as all other settings are trained on biased margins. Except for a small drop in $TER{+}0.05$, other configurations all obtain higher precision than $TER + 0$. We note that we can obtain 0.85 precision without a big sacrifice in recall with b=0.15, but for larger improvements on precision, recall will drop more rapidly.

When we use b beyond 0.25, the margin becomes less reliable, as the number of positive examples becomes too small. In particular, this causes the SVM parameters we tune on in the first fold to become less applicable to the other folds. This is one limitation of using biased margins to

obtain high precision. The method presented in Section 5.4.2 is less influenced by this limitation.

5.4.2 Adjusting Confidence Levels

An alternative to using a biased margin is to output a confidence score during prediction and to threshold on the confidence score. It is also possible to add this method to the SVM model trained with a biased margin.

We use the SVM confidence estimation techniques in Section 4.2 to obtain the confidence level of the recommendation, and change the confidence threshold for recommendation when necessary. This also allows us to compare directly against a simple baseline inspired by TM users. In a TM environment, some users simply ignore TM hits below a certain fuzzy match score F (usually from 0.7 to 0.8). This fuzzy match score reflects the confidence of recommending the TM hits. To obtain the confidence of recommending an SMT output, our baseline (FM) uses fuzzy match costs $h_{FM} \approx 1-F$ (cf. Section 4.3.2) for the TM hits as the level of confidence. In other words, the higher the fuzzy match cost of the TM hit is (lower fuzzy match score), the higher the confidence of recommending the SMT output. We compare this baseline with the three settings in Section 5.

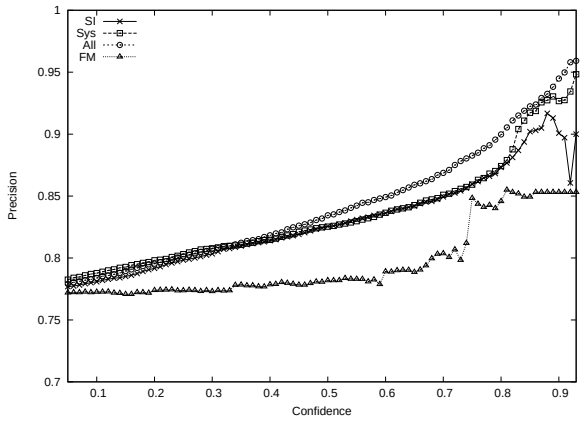

Figure 1: Precision Changes with Confidence Level

Figure 1 shows that the precision curve of FM is low and flat when the fuzzy match costs are low (from 0 to 0.6), indicating that it is unwise to recommend an SMT output when the TM hit has a low fuzzy match cost (corresponding to higher fuzzy match score, from 0.4 to 1). We also observe that the precision of the recommendation receives a boost when the fuzzy match costs for the TM hits are above 0.7 (fuzzy match score lower than 0.3), indicating that SMT output should be recommended when the TM hit has a high fuzzy match cost (low fuzzy match score). With this boost, the precision of the baseline system can reach 0.85, demonstrating that a proper thresholding of fuzzy match scores can be used effectively to discriminate the recommendation of the TM hit from the recommendation of the SMT output.

However, using the TM information only does not always find the easiest-to-edit translation. For example, an excellent SMT output should be recommended even if there exists a good TM hit (e.g. fuzzy match score is 0.7 or more). On the other hand, a misleading SMT output should not be recommended if there exists a poor but useful TM match (e.g. fuzzy match score is 0.2).

Our system is able to tackle these complications as it incorporates features from the MT and the TM systems simultaneously. Figure 1 shows that both the SYS and the ALL setting consistently outperform FM, indicating that our classification scheme can better integrate the MT output into the TM system than this naive baseline.

The SI feature set does not perform well when the confidence level is set above 0.85 (cf. the descending tail of the SI curve in Figure 1). This might indicate that this feature set is not reliable enough to extract the best translations. However, when the requirement on precision is not that high, and the MT-internal features are not available, it would still be desirable to obtain translation recommendations with these black-box features. The difference between SYS and ALL is generally small, but ALL performs steadily better in [0.5, 0,8].

Table 3: Recall at Fixed Precision

	Recall
SYS @85PREC	88.12±1.32
SYS @90PREC	52.73±2.31
SI @85PREC	87.33±1.53
ALL @85PREC	88.57±1.95
ALL @90PREC	51.92±4.28

5.5 Precision Constraints

In Table 3 we also present the recall scores at 0.85 and 0.9 precision for SYS, SI and ALL models to demonstrate our system's performance when there is a hard constraint on precision. Note that our system will return the TM entry when there is an exact match, so the overall precision of the system

is above the precision score we set here in a mature TM environment, as a significant portion of the material to be translated will have a complete match in the TM system.

In Table 3 for MODEL@K, the recall scores are achieved when the prediction precision is better than K with 0.95 confidence. For each model, precision at 0.85 can be obtained without a very big loss on recall. However, if we want to demand further recommendation precision (more conservative in recommending SMT output), the recall level will begin to drop more quickly. If we use only system-independent features (SI), we cannot achieve as high precision as with other models even if we sacrifice more recall.

Based on these results, the users of the TM system can choose between precision and recall according to their own needs. As the threshold does not involve training of the SMT system or the SVM classifier, the user is able to determine this trade-off at runtime.

Table 4: Contribution of Features

	Precision	Recall	F Score
SYS	82.53±1.17	96.44±0.68	88.95±.56
+M1	82.87±1.26	96.23±0.53	89.05±.52
+LM	82.82±1.16	96.20±1.14	89.01±.23
+PS	83.21±1.33	96.61±0.44	89.41±.84

5.6 Contribution of Features

In Section 4.3.3 we suggested three sets of system-independent features: features based on the source- and target-side language model (LM), the IBM Model 1 (M1) and the fuzzy match scores on pseudo-source (PS). We compare the contribution of these features in Table 4.

In sum, all the three sets of system-independent features improve the precision and F-scores of the MT and TM system features. The improvement is not significant, but improvement on every set of system-independent features gives some credit to the capability of SI features, as does the fact that SI features perform close to SYS features in Table 1.

6 Analysis of Post-Editing Effort

A natural question on the integration models is whether the classification reduces the effort of the translators and post-editors: after reading these recommendations, will they translate/edit less than they would otherwise have to? Ideally this question would be answered by human post-editors in a large-scale experimental setting. As we have not yet conducted a manual post-editing experiment, we conduct two sets of analyses, trying to show which type of edits will be required for different recommendation confidence levels. We also present possible methods for human evaluation at the end of this section.

6.1 Edit Statistics

We provide the statistics of the number of edits for each sentence with 0.95 confidence intervals, sorted by TER edit types. Statistics of positive instances in classification (i.e. the instances in which MT output is recommended over the TM hit) are given in Table 5.

When an MT output is recommended, its TM counterpart will require a larger average number of total edits than the MT output, as we expect. If we drill down, however, we also observe that many of the saved edits come from the *Substitution* category, which is the most costly operation from the post-editing perspective. In this case, the recommended MT output actually saves more effort for the editors than what is shown by the TER score. It reflects the fact that TM outputs are not actual translations, and might need heavier editing.

Table 6 shows the statistics of negative instances in classification (i.e. the instances in which MT output is not recommended over the TM hit). In this case, the MT output requires considerably more edits than the TM hits in terms of all four TER edit types, i.e. insertion, substitution, deletion and shift. This reflects the fact that some high quality TM matches can be very useful as a translation.

6.2 Edit Statistics on Recommendations of Higher Confidence

We present the edit statistics of recommendations with higher confidence in Table 7. Comparing Tables 5 and 7, we see that if recommended with higher confidence, the MT output will need substantially less edits than the TM output: e.g. 3.28 fewer substitutions on average.

From the characteristics of the high confidence recommendations, we suspect that these mainly comprise harder to translate (i.e. different from the SMT training set/TM database) sentences, as indicated by the slightly increased edit operations

Table 5: Edit Statistics when Recommending MT Outputs in Classification, confidence=0.5

	Insertion	Substitution	Deletion	Shift
MT	0.9849 ± 0.0408	2.2881 ± 0.0672	0.8686 ± 0.0370	1.2500 ± 0.0598
TM	0.7762 ± 0.0408	4.5841 ± 0.1036	3.1567 ± 0.1120	1.2096 ± 0.0554

Table 6: Edit Statistics when NOT Recommending MT Outputs in Classification, confidence=0.5

	Insertion	Substitution	Deletion	Shift
MT	1.0830 ± 0.1167	2.2885 ± 0.1376	1.0964 ± 0.1137	1.5381 ± 0.1962
TM	0.7554 ± 0.0376	1.5527 ± 0.1584	1.0090 ± 0.1850	0.4731 ± 0.1083

Table 7: Edit Statistics when Recommending MT Outputs in Classification, confidence=0.85

	Insertion	Substitution	Deletion	Shift
MT	1.1665 ± 0.0615	2.7334 ± 0.0969	1.0277 ± 0.0544	1.5549 ± 0.0899
TM	0.8894 ± 0.0594	6.0085 ± 0.1501	4.1770 ± 0.1719	1.6727 ± 0.0846

on the MT side. TM produces much worse edit-candidates for such sentences, as indicated by the numbers in Table 7, since TM does not have the ability to automatically reconstruct an output through the combination of several segments.

6.3 Plan for Human Evaluation

Evaluation with human post-editors is crucial to validate and improve translation recommendation. There are two possible avenues to pursue:

- Test our system on professional post-editors. By providing them with the TM output, the MT output and the one recommended to edit, we can measure the true accuracy of our recommendation, as well as the post-editing time we save for the post-editors;
- Apply the presented method on open domain data and evaluate it using crowdsourcing. It has been shown that crowdsourcing tools, such as the Amazon Mechanical Turk (Callison-Burch, 2009), can help developers to obtain good human judgements on MT output quality both cheaply and quickly. Given that our problem is related to MT quality estimation in nature, it can potentially benefit from such tools as well.

7 Conclusions and Future Work

In this paper we present a classification model to integrate SMT into a TM system, in order to facilitate the work of post-editors. Insodoing we handle the problem of MT quality estimation as binary prediction instead of regression. From the post-editors' perspective, they can continue to work in their familiar TM environment, use the same cost-estimation methods, and at the same time benefit from the power of state-of-the-art MT. We use SVMs to make these predictions, and use grid search to find better RBF kernel parameters.

We explore features from inside the MT system, from the TM, as well as features that make no assumption on the translation model for the binary classification. With these features we make glass-box and black-box predictions. Experiments show that the models can achieve 0.85 precision at a level of 0.89 recall, and even higher precision if we sacrifice more recall. With this guarantee on precision, our method can be used in a TM environment without changing the upper-bound of the related cost estimation.

Finally, we analyze the characteristics of the integrated outputs. We present results to show that, if measured by number, type and content of edits in TER, the recommended sentences produced by the classification model would bring about less post-editing effort than the TM outputs.

This work can be extended in the following ways. Most importantly, it is useful to test the model in user studies, as proposed in Section 6.3. A user study can serve two purposes: 1) it can validate the effectiveness of the method by measuring the amount of edit effort it saves; and 2) the byproduct of the user study – post-edited sentences – can be used to generate HTER scores to train a better recommendation model. Furthermore, we want to experiment and improve on the adaptability of this method, as the current experiment is on a specific domain and language pair.

Abstract

We observe that (1) how a given named entity (NE) is translated (i.e., either semantically or phonetically) depends greatly on its associated entity type, and (2) entities within an aligned pair should share the same type. Also, (3) those initially detected NEs are anchors, whose information should be used to give certainty scores when selecting candidates. From this basis, an integrated model is thus proposed in this paper to jointly identify and align bilingual named entities between Chinese and English. It adopts a new mapping type ratio feature (which is the proportion of NE internal tokens that are semantically translated), enforces an entity type consistency constraint, and utilizes additional monolingual candidate certainty factors (based on those NE anchors). The experiments show that this novel approach has substantially raised the type-sensitive F-score of identified NE-pairs from 68.4% to 81.7% (42.1% F-score imperfection reduction) in our Chinese-English NE alignment task.

1 Introduction

In trans-lingual language processing tasks, such as machine translation and cross-lingual information retrieval, *named entity* (NE) translation is essential. Bilingual NE alignment, which links source NEs and target NEs, is the first step to train the NE translation model.

Since NE alignment can only be conducted after its associated NEs have first been identified, the including-rate of the first recognition stage significantly limits the final alignment performance. To alleviate the above error accumulation problem, two strategies have been proposed in the literature. The first strategy (Al-Onaizan and Knight, 2002; Moore, 2003; Feng et al., 2004; Lee et al., 2006) identifies NEs only on the source side and then finds their corresponding NEs on the target side. In this way, it avoids the NE recognition errors which would otherwise be brought into the alignment stage from the target side; however, the NE errors from the source side still remain.

To further reduce the errors from the source side, the second strategy (Huang et al., 2003) expands the NE candidate-sets in both languages before conducting the alignment, which is done by treating the original results as anchors, and then re-generating further candidates by enlarging or shrinking those anchors' boundaries. Of course, this strategy will be in vain if the NE anchor is missed in the initial detection stage. In our data-set, this strategy significantly raises the NE-pair type-insensitive including-rate [1] from 83.9% to 96.1%, and is thus adopted in this paper.

Although the above expansion strategy has substantially alleviated the error accumulation problem, the final alignment accuracy is still not good (type-sensitive F-score only 68.4%, as indicated in Table 2 in Section 4.2). After having examined the data, we found that: (1) How a given NE is translated, either semantically (called *translation*) or phonetically (called *transliteration*), depends greatly on its associated entity type[2]. The *mapping type ratio*, which is the percentage of NE internal tokens which are translated semantically, can help with the recognition of the associated NE type; (2) Entities within an aligned pair should share the same type, and this restriction should be integrated into NE alignment as a constraint; (3) Those initially identified monolingual NEs can act as anchors to give *monolingual candidate certainty scores*

[1] Which is the percentage of desired NE-pairs that are included in the expanded set, and is the upper bound on NE alignment performance (regardless of NE types).

[2] The proportions of semantic translation, which denote the ratios of semantically translated words among all the associated NE words, for person names (PER), location names (LOC), and organization names (ORG) approximates 0%, 28.6%, and 74.8% respectively in Chinese-English name entity list (2005T34) released by the Linguistic Data Consortium (LDC). Since the title, such as "sir" and "chairman", is not considered as a part of person names in this corpus, PERs are all transliterated there.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 631–639,
Uppsala, Sweden, 11-16 July 2010.

(preference weightings) for the re-generated candidates.

Based on the above observation, a new joint model which adopts the *mapping type ratio*, enforces the *entity type consistency* constraint, and also utilizes the *monolingual candidate certainty factors* is proposed in this paper to jointly identify and align bilingual NEs under an integrated framework. This framework is decomposed into three subtasks: *Initial Detection*, *Expansion*, and *Alignment&Re-identification*. The *Initial Detection* subtask first locates the initial NEs and their associated NE types inside both the Chinese and English sides. Afterwards, the *Expansion* subtask re-generates the candidate-sets in both languages to recover those initial NE recognition errors. Finally, the *Alignment&Re-identification* subtask *jointly* recognizes and aligns bilingual NEs via the proposed joint model presented in Section 3. With this new approach, 41.8% imperfection reduction in type-sensitive F-score, from 68.4% to 81.6%, has been observed in our Chinese-English NE alignment task.

2 Motivation

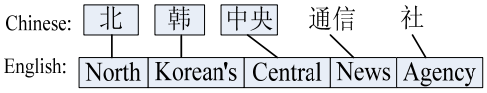
The problem of NE recognition requires both boundary identification and type classification. However, the complexity of these tasks varies with different languages. For example, Chinese NE boundaries are especially difficult to identify because Chinese is not a tokenized language. In contrast, English NE boundaries are easier to identify due to capitalization clues. On the other hand, classification of English NE types can be more challenging (Ji et al., 2006). Since alignment would force the linked NE pair to share the same semantic meaning, the NE that is more reliably identified in one language can be used to ensure its counterpart in another language. This benefits both the NE boundary identification and type classification processes, and it hints that alignment can help to re-identify those initially recognized NEs which had been less reliable.

As shown in the following example, although the desired NE "北韩中央通信社" is recognized partially as "北韩中央" in the initial recognition stage, it would be more preferred if its English counterpart "North Korean's Central News Agency" is given. The reason for this is that "News Agency" would prefer to be linked to "通信社", rather than to be deleted (which would happen if "北韩中央" is chosen as the corresponding Chinese NE).

(I) The initial NE detection in a Chinese sentence:
官方的 <ORG>北韩中央</ORG> 通信社引述海军...

(II) The initial NE detection of its English counterpart:
Official <ORG>North Korean's Central News Agency </ORG> quoted the navy's statement…

(III) The word alignment between two NEs:



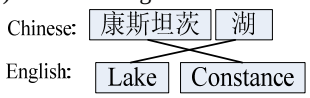
(VI) The re-identified Chinese NE boundary after alignment:
官方的 <ORG>北韩中央通信社</ORG> 引述海军声明...

As another example, the word "lake" in the English NE is linked to the Chinese character "湖" as illustrated below, and this mapping is found to be a translation and not a transliteration. Since translation rarely occurs for personal names (Chen et al., 2003), the desired NE type "LOC" would be preferred to be shared between the English NE "Lake Constance" and its corresponding Chinese NE "康斯坦茨湖". As a result, the original incorrect type "PER" of the given English NE is fixed, and the necessity of using mapping type ratio and NE type consistency constraint becomes evident.

(I) The initial NE detection result in a Chinese sentence:
在 <LOC>康斯坦茨湖</LOC> 工作的一艘渡船船长…

(II) The initial NE detection of its English counterpart:
The captain of a ferry boat who works on <PER>Lake Constance </PER>…

(III) The word alignment between two NEs:



(VI) The re-identified English NE type after alignment:
The captain of a ferry boat who works on <LOC>Lake Constance</LOC>…

3 The Proposed Model

As mentioned in the introduction section, given a Chinese-English sentence-pair (CS, ES), with its initially recognized Chinese NEs $< CNE_i, CType_i >_{i=1}^{S}, S \geq 1$ and English NEs $[ENE_j, EType_j]_{j=1}^{T}, T \geq 1$ ($CType_i$ and $Etype_j$ are original NE types assigned to CNE_i and ENE_j, respectively), we will first re-generate two NE candidate-sets from them by enlarging and shrinking the boundaries of those initially recognized NEs. Let $RCNE_1^{K_C}$ and $RENE_1^{K_E}$ denote these two *re-generated* candidate sets for Chinese and English NEs respectively (K_C and K_E are their set-sizes), and $K = \min(S, T)$, then a total K pairs of final Chinese and English NEs will be picked up from the Cartesian product of

$RCNE_1^{K_C}$ and $RENE_1^{K_E}$, according to their associated *linking score*, which is defined as follows.

Let $Score(RCNE_{<k>}, RENE_{[k]})$ denote the associated *linking score* for a given candidate-pair $RCNE_{<k>}$ and $RENE_{[k]}$, where $<k>$ and $[k]$ are the associated indexes of the re-generated Chinese and English NE candidates, respectively. Furthermore, let $RType_k$ be the NE type to be *re-assigned* and shared by $RCNE_{<k>}$ and $RENE_{[k]}$ (as they possess the same meaning). Assume that $RCNE_{<k>}$ and $RENE_{[k]}$ are derived from initially recognized CNE_i and ENE_j, respectively, and M_{IC} denotes their *internal component mapping*, to be defined in Section 3.1, then $Score(RCNE_{<k>}, RENE_{[k]})$ is defined as follows:

$$Score(RCNE_{<k>}, RENE_{[k]}) = \max_{M_{IC}, RType_k} P\begin{pmatrix} M_{IC}, RType_k, RCNE_{<k>}, RENE_{[k]} \mid \\ <CNE_i, CType_i>, CS, [ENE_j, EType_j], ES \end{pmatrix} \quad (1)$$

Here, the "max" operator varies over each possible internal component mapping M_{IC} and re-assigned type (PER, LOC, and ORG). For brevity, we will drop those associated subscripts from now on, if there is no confusion.

The associated probability factors in the above linking score can be further derived as follows.

$$\begin{aligned} & P\left(M_{IC}, RType, RCNE, RENE \,\middle|\, \begin{matrix} <CNE, CType>, CS, \\ [ENE, EType], ES \end{matrix} \right) \\ & \cong P(M_{IC} \mid RType, RCNE, RENE) \\ & \quad \times P(RCNE \mid CNE, CType, CS, RType) \\ & \quad \times P(RENE \mid ENE, EType, ES, RType) \\ & \quad \times P(RType \mid CNE, ENE, CType, EType) \end{aligned} \quad (2)$$

In the above equation, $P(M_{IC} \mid RType, RCNE, RENE)$ and $P(RType \mid CNE, ENE, CType, EType)$ are the *Bilingual Alignment Factor* and the *Bilingual Type Re-assignment Factor* respectively, to represent the bilingual related scores (Section 3.1). Also, $P(RCNE \mid CNE, CType, CS, RType)$ and $P(RENE \mid ENE, EType, ES, RType)$ are *Monolingual Candidate Certainty Factors* (Section 3.2) used to assign preference to each selected *RCNE* and *RENE*, based on the initially recognized NEs (which act as anchors).

3.1 Bilingual Related Factors

The *bilingual alignment factor* mainly represents the likelihood value of a specific internal component mapping M_{IC}, given a pair of possible NE configurations *RCNE* and *RENE* and their associated *RType*. Since Chinese word segmentation is problematic, especially for transliterated words, the bilingual alignment factor $P(M_{IC} \mid RType, RCNE, RENE)$ in Eq (2) is derived to be conditioned on *RENE* (i.e., starting from the English part).

We define the internal component mapping M_{IC} to be $M_{IC} \equiv <[cpn_{<n>}, ew_{[n]}, Mtype_n]_{n=1}^{N}, \delta>$, where $[cpn_{<n>}, ew_{[n]}, Mtype_n]$ denotes a linked pair consisting of a *Chinese component* $cpn_{<n>}$ (which might contain several Chinese characters) and an *English word* $ew_{[n]}$ within *RCNE* and *RENE* respectively, with their *internal mapping type* $Mtype_n$ to be either *translation* (abbreviated as *TS*) or *transliteration* (abbreviated as *TL*). In total, there are N component mappings, with N_{TS} translation mappings $[cpn_{<n_1>}, ew_{[n_1]}, TS]_{n_1=1}^{N_{TS}}$ and N_{TL} transliteration mappings $[cpn_{<n_2>}, ew_{[n_2]}, TL]_{n_2=1}^{N_{TL}}$, so that $N = N_{TS} + N_{TL}$.

Moreover, since the mapping type distributions of various NE types deviate greatly from one another, as illustrated in the second footnote, the associated *mapping type ratio* $\delta = (N_{TS} / N)$ is thus an important feature, and is included in the internal component mapping configuration specified above. For example, the M_{IC} between "康斯坦茨湖" and "Constance Lake" is [康斯坦茨, *Constance*, *TL*] and [湖, *Lake*, *TS*], so its associated mapping type ratio will be "0.5" (i.e., 1/2). Therefore, the internal mapping $P(M_{IC} \mid RType, RENE)$ is further deduced by introducing the internal mapping type $Mtype_n$ and the mapping type ratio δ as follows:

$$\begin{aligned} & P(M_{IC} \mid RType, RENE) \\ & \equiv P([cpn_{<n>}, ew_{[n]}, Mtype_n]_{n=1}^{N}, \delta \mid RType, RENE) \\ & \approx \prod_{n=1}^{N} \begin{bmatrix} P(cpn_{<n>} \mid Mtype_n, ew_{[n]}, RType) \\ \times P(Mtype_n \mid ew_{[n]}, RType) \end{bmatrix} \\ & \quad \times P(\delta \mid RType) \end{aligned} \quad (3)$$

In the above equation, the mappings between internal components are trained from the syllable/word alignment of NE pairs of different NE types. In more detail, for transliteration, the model adopted in (Huang et al., 2003), which first Romanizes Chinese characters and then transliterates them into English characters, is

used for $P(cpn_{<n>} | TL_n, ew_{[n]}, RType)$. For translation, conditional probability is directly used for $P(cpn_{<n>} | TS_n, ew_{[n]}, RType)$.

Lastly, the *bilingual type re-assignment factor* $P(RType | CNE, ENE, CType, EType)$ proposed in Eq (2) is derived as follows:

$$P(RType | RCNE, RENE, CType, EType) \cong P(RType | CType, EType) \quad (4)$$

As Eq (4) shows, both the Chinese initial NE type and English initial NE type are adopted to jointly identify their shared NE type *RType*.

3.2 Monolingual Candidate Certainty Factors

On the other hand, the *monolingual candidate certainty factors* in Eq (2) indicate the likelihood that a re-generated NE candidate is the true NE given its originally detected NE. For Chinese, it is derived as follows:

$$\begin{aligned} & P(RCNE | CNE, CType, CS, RType) \\ & \cong P(LeftD, RightD, Str[RCNE] | Len_C, CType, RType) \\ & \approx P(LeftD | Len_C, CType, RType) \\ & \times P(RightD | Len_C, CType, RType) \\ & \times \prod_{m=1}^{M} P(cc_m | cc_{m-1}, RType) \end{aligned} \quad (5)$$

Where, the subscript *C* denotes Chinese, and Len_C is the *length* of the originally recognized Chinese NE *CNE*. *LeftD* and *RightD* denote the *left and right distance* (which are the numbers of Chinese characters) that *RCNE* shrinks/enlarges from the left and right boundary of its anchor *CNE*, respectively. As in the above example, assume that *CNE* and *RCNE* are "北韩中央" and "韩中央通信社" respectively, *LeftD* and *RightD* will be "-1" and "+3". Also, *Str*[*RCNE*] stands for the associated Chinese string of *RCNE*, cc_m denotes the *m-th Chinese character* within that string, and *M* denotes the total number of Chinese characters within *RCNE*.

On the English side, following Eq (5), $P(RENE | ENE, EType, ES, RType)$ can be derived similarly, except that *LeftD* and *RightD* will be measured in number of English words. For instance, with *ENE* and *RENE* as "*Lake Constance*" and "*on Lake Constance*" respectively, *LeftD* and *RightD* will be "+1" and "0". Also, the bigram unit cc_m of the Chinese NE string is replaced by the English word unit ew_n.

All the bilingual and monolingual factors mentioned above, which are derived from Eq (1), are weighted differently according to their contributions. The corresponding weighting coefficients are obtained using the well-known *Minimum Error Rate Training* (Och, 2003; commonly abbreviated as MERT) algorithm by minimizing the number of associated errors in the development set.

3.3 Framework for the Proposed Model

The above model is implemented with a three-stage framework: (A) Initial NE Recognition; (B) NE-Candidate-Set Expansion; and (C) NE Alignment&Re-identification. The Following Diagram gives the details of this framework:

For each given bilingual sentence-pair:

(A) Initial NE Recognition: generates the initial NE anchors with off-the-self packages.

(B) NE-Candidate-Set Expansion: For each initially detected NE, several NE candidates will be re-generated from the original NE by allowing its boundaries to be shrunk or enlarged within a pre-specified range.

- (B.1) Create both RCNE and RENE candidate-sets, which are expanded from those initial NEs identified in the previous stage.
- (B.2) Construct an NE-pair candidate-set (named *NE-Pair-Candidate-Set*), which is the Cartesian product of the RCNE and RENE candidate-sets created above.

(C) NE Alignment&Re-identification: Rank each candidate in the NE-Pair-Candidate-Set constructed above with the linking score specified in Eq (1). Afterwards, conduct a beam search process to select the top *K* non-overlapping NE-pairs from this set.

Diagram 1. Steps to Generate the Final NE-Pairs

It is our observation that, four Chinese characters for both shrinking and enlarging, two English words for shrinking and three for enlarging are enough in most cases. Under these conditions, the including-rates for NEs with correct boundaries are raised to 95.8% for Chinese and 97.4% for English; and even the NE-pair including rate is raised to 95.3%. Since the above range limitation setting has an including-rate only 0.8% lower than that can be obtained without any range limitation (which is 96.1%), it is adopted in this paper to greatly reduce the number of NE-pair-candidates.

4 Experiments

To evaluate the proposed joint approach, a prior work (Huang et al., 2003) is re-implemented in our environment as the baseline, in which the translation cost, transliteration cost and tagging cost are used. This model is selected for comparison because it not only adopts the same candidate-set expansion strategy as mentioned above, but also utilizes the monolingual information when selecting NE-pairs (however, only a simple bi-gram model is used as the tagging cost in their paper). Note that it enforces the same NE type only when the tagging cost is evaluated:

$$C_{tag} = \min_{RType}[-\log(\prod_{m=1}^{M} P(cc_m \mid cc_{m-1}, RType)) - \log(\prod_{n=1}^{N} P(ew_n \mid ew_{n-1}, RType))]$$

To give a fairer comparison, the same training-set and testing-set are adopted. The training-set includes two parts. The first part consists of 90,412 aligned sentence-pairs newswire data from the Foreign Broadcast Information Service (FBIS), which is denoted as Training-Set-I. The second Part of the training set is the LDC2005T34 bilingual NE dictionary[3], which is denoted as Training-Set-II. The required feature information is then manually labeled throughout the two training sets.

In our experiments, for the baseline system, the translation cost and the transliteration cost are trained on Training-Set-II, while the tagging cost is trained on Training-Set-I. For the proposed approach, the monolingual candidate certainty factors are trained on Training-Set-I, and Training-Set-II is used to train the parameters relating to bilingual alignment factors.

For the testing-set, 300 sentence pairs are randomly selected from the LDC Chinese-English News Text (LDC2005T06). The average length of the Chinese sentences is 59.4 characters, while the average length of the English sentences is 24.8 words. Afterwards, the answer keys for NE recognition and alignment were annotated manually, and used as the gold standard to calculate metrics of precision (P), recall (R), and F-score (F) for both *NE recognition* (NER) and *NE alignment* (NEA). In Total 765 Chinese NEs and 747 English NEs were manually labeled in the testing-set, within which there are only 718 NE pairs, including 214 PER, 371 LOC and 133 ORG NE-pairs. The number of NE pairs is less than that of NEs, because not all those recognized NEs can be aligned.

Besides, the development-set for MERT weight training is composed of 200 sentence pairs selected from the LDC2005T06 corpus, which includes 482 manually tagged NE pairs. There is no overlap between the training-sets, the development-set and the testing-set.

4.1 Baseline System

Both the baseline and the proposed models share the same initial detection subtask, which adopts the Chinese NE recognizer reported by Wu et al. (2005), which is a hybrid statistical model incorporating multi-knowledge sources, and the English NE recognizer included in the publicly available Mallet toolkit[4] to generate initial NEs. Initial Chinese NEs and English NEs are recognized by these two available packages respectively.

NE-type	P (%): C/E	R (%): C/E	F (%): C/E
PER	80.2 / 79.2	**87.7 / 85.3**	83.8 / 82.1
LOC	**89.8 / 85.9**	87.3 / 81.5	**88.5/ 83.6**
ORG	78.6 / 82.9	82.8 / 79.6	80.6 / 81.2
ALL	83.4 / 82.1	86.0 / 82.6	84.7 / 82.3

Table 1. Initial Chinese/English NER

Table 1 shows the initial NE recognition performances for both Chinese and English (the largest entry in each column is highlighted for visibility). From Table 1, it is observed that the F-score of ORG type is the lowest among all NE types for both English and Chinese. This is because many organization names are partially recognized or missed. Besides, not shown in the table, the location names or abbreviated organization names tend to be incorrectly recognized as person names. In general, the initial Chinese NER outperforms the initial English NER, as the NE type classification turns out to be a more difficult problem for this English NER system.

When those initially identified NEs are directly used for baseline alignment, only 64.1% F score (regard of their name types) is obtained. Such a low performance is mainly due to those NE recognition errors which have been brought into the alignment stage.

To diminish the effect of errors accumulating, which stems from the recognition stage, the baseline system also adopts the same expansion strategy described in Section 3.3 to enlarge the possi-

[3] The LDC2005T34 data-set consists of proofread bilingual entries: 73,352 person names, 76,460 location names and 68,960 organization names.

[4] http://mallet.cs.umass.edu/index.php/Main_Page

ble NE candidate set. However, only a slight improvement (68.4% type-sensitive F-score) is obtained, as shown in Table 2. Therefore, it is conjectured that the baseline alignment model is unable to achieve good performance if those features/factors proposed in this paper are not adopted.

4.2 The Recognition and Alignment Joint Model

To show the individual effect of each factor in the joint model, a series of experiments, from Exp0 to Exp11, are conducted. Exp0 is the *basic system*, which ignores monolingual candidate certainty scores, and also disregards mapping type and NE type consistency constraint by ignoring $P(Mtype_n \mid ew_{[n]}, RType)$ and $P(\delta \mid RType)$, and also replacing $P(cpn_{<n>} \mid Mtype_n, ew_{[n]}, RType)$ with $P(cpn_{<n>} \mid ew_{[n]})$ in Eq (3).

To show the effect of enforcing NE type consistency constraint on internal component mapping, Exp1 (named *Exp0+RType*) replaces $P(cpn_{<n>} \mid ew_{[n]})$ in Exp0 with $P(cpn_{<n>} \mid ew_{[n]}, RType)$; On the other hand, Exp2 (named *Exp0+MappingType*) shows the effect of introducing the component mapping type to Eq (3) by replacing $P(cpn_{<n>} \mid ew_{[n]})$ in Exp0 by $P(cpn_{<n>} \mid Mtype_n, ew_{[n]}) \times P(Mtype_n \mid ew_{[n]})$; Then Exp3 (named *Exp2+MappingTypeRatio*) further adds $P(\delta \mid RType)$ to Exp2, to manifest the contribution from the mapping type ratio. In addition, Exp4 (named *Exp0+RTypeReassignment*) adds the NE type reassignment score, Eq (4), to Exp0 to show the effect of enforcing NE-type consistency. Furthermore, Exp5 (named *All-BiFactors*) shows the full power of the set of proposed bilingual factors by turning on all the options mentioned above. As the bilingual alignment factors would favor the candidates with shorter lengths, $P([cpn_{<n>}, ew_{[n]}, Mtype_n]_{n=1}^{N}, \delta \mid RType, RENE)$, Eq (3), is further *normalized* into the following form:

$$\left[\prod_{n=1}^{N} P(cpn_{<n>} \mid Mtype_n, ew_{[n]}, RType) \times P(Mtype_n \mid ew_{[n]}, RType)\right]^{\frac{1}{N}} \times P(\delta \mid RType),$$

and is shown by Exp6 (named *All-N-BiFactors*).

To show the influence of additional information carried by those initially recognized NEs, Exp7 (named *Exp6+LeftD/RightD*) adds left and right distance information into Exp6, as that specified in Eq (5). To study the monolingual bigram capability, Exp8 (named *Exp6+Bigram*) adds the NEtype dependant bigram model of each language to Exp6. We use SRI Language Modeling Toolkit[5] (SRILM) (Stolcke, 2002) to train various character/word based bi-gram models with different NE types. Similar to what we have done on the bilingual alignment factor above, Exp9 (named *Exp6+N-Bigram*) adds the *normalized* NEtype dependant bigram to Exp6 for removing the bias induced by having different NE lengths. The normalized Chinese NEtype dependant bigram score is defined as $[\prod_{m=1}^{M} P(cc_m \mid cc_{m-1}, RType)]^{\frac{1}{M}}$. A Similar transformation is also applied to the English side.

Lastly, Exp10 (named *Fully-JointModel*) shows the full power of the proposed Recognition and Alignment Joint Model by adopting all the normalized factors mentioned above. The result of a MERT weighted version is further shown by Exp11 (named *Weighted-JointModel*).

Model	P (%)	R (%)	F (%)
Baseline	77.1 (67.1)	79.7 (69.8)	78.4 (68.4)
Exp0 (*Basic System*)	67.9 (62.4)	70.3 (64.8)	69.1 (63.6)
Exp1 (*Exp0 + Rtype*)	69.6 (65.7)	71.9 (68.0)	70.8 (66.8)
Exp2 (*Exp0 + MappingType*)	70.5 (65.3)	73.0 (67.5)	71.7 (66.4)
Exp3 (*Exp2 + MappingTypeRatio*)	72.0 (68.3)	74.5 (70.8)	73.2 (69.5)
Exp4 (*Exp0 + RTypeReassignment*)	70.2 (66.7)	72.7 (69.2)	71.4 (67.9)
Exp5 (*All-BiFactors*)	76.2 (**72.3**)	78.5 (**74.6**)	77.3 (**73.4**)
Exp6 (*All-N-BiFactors*)	**77.7** (**73.5**)	79.9 (**75.7**)	78.8 (**74.6**)
Exp7 (*Exp6 + LeftD/RightD*)	**83.5** (**77.7**)	**85.8** (**80.1**)	**84.6** (**78.9**)
Exp8 (*Exp6 + Bigram*)	**80.4** (**75.5**)	**82.7** (**77.9**)	**81.5** (**76.7**)
Exp9 (*Exp6 + N-Bigram*)	**82.7** (**77.1**)	**85.1** (**79.6**)	**83.9** (**78.3**)
Exp10 (*Fully-JointModel*)	**83.7** (**78.1**)	**86.2** (**80.7**)	**84.9** (**79.4**)
Exp11 (*Weighted-Joint Model*)	**85.9** (**80.5**)	**88.4** (**83.0**)	**87.1** (**81.7**)

Table 2. NEA Type-Insensitive (Type-Sensitive) Performance

Since most papers in the literature are evaluated only based on the boundaries of NEs, two kinds of performance are thus given here. The first one (named type-insensitive) only checks the scope of each NE without taking its associated NE type into consideration, and is reported

[5] http://www.speech.sri.com/projects/srilm/

as the main data at Table 2. The second one (named type-sensitive) would also evaluate the associated NE type of each NE, and is given within parentheses in Table 2. A large degradation is observed when NE type is also taken into account. The highlighted entries are those that are statistically better[6] than that of the baseline system.

4.3 ME Approach with Primitive Features

Although the proposed model has been derived above in a principled way, since all these proposed features can also be directly integrated with the well-known maximum entropy (ME) (Berger et al., 1996) framework without making any assumptions, one might wonder if it is still worth to deriving a model after all the related features have been proposed. To show that not only the features but also the adopted model contribute to the performance improvement, an ME approach is tested as follows for comparison. It directly adopts all those primitive features mentioned above as its inputs (including internal component mapping, initial and final NE type, NE bigram-based string, and left/right distance), without involving any related probability factors derived within the proposed model.

This ME method is implemented with a public package YASMET[7], and is tested under various training-set sizes (400, 4,000, 40,000, and 90,412 sentence-pairs). All those training-sets are extracted from the Training-Set-I mentioned above (a total of 298,302 NE pairs included are manually labeled). Since the ME approach is unable to utilize the bilingual NE dictionary (Training-Set-II), for fair comparison, this dictionary was also not used to train our models here. Table 3 shows the performance (F-score) using the same testing-set. The data within parentheses are relative improvements.

Model	400	4,000	40,000	90,412
ME framework	36.5 (0%)	50.4 (0%)	62.6 (0%)	67.9 (0%)
Un-weighted-JointModel	+4.6 (+12.6%)	+4.5 (+8.9%)	+4.3 (+6.9%)	+4.1 (+6.0%)
Weighted-JointModel	+5.0 (+13.7%)	+4.7 (+9.3%)	+4.6 (+7.3%)	+4.5 (+6.6%)

Table 3. Comparison between ME Framework and Derived Model on the Testing-Set

[6] Statistical significance test is measured on 95% confidence level on 1,000 re-sampling batches (Zhang et al., 2004)
[7] http://www.fjoch.com/YASMET.html

The improvement indicated in Table 3 clearly illustrates the benefit of deriving the model shown in Eq (2). Since a reasonably derived model not only shares the same training-set with the primitive ME version above, but also enjoys the additional knowledge introduced by the human (i.e., the assumptions/constraints implied by the model), it is not surprising to find out that a good model does help, and that it also becomes more noticeable as the training-set gets smaller.

5 Error Analysis and Discussion

Although the proposed model has substantially improved the performance of both NE alignment and recognition, some errors still remain. Having examined those type-insensitive errors, we found that they can be classified into four categories: (A) Original NEs or their components are already not one-to-one mapped (23%). (B) NE components are one-to-one linked, but the associated NE anchors generated from the initial recognition stage are either missing or spurious (24%). Although increasing the number of output candidates generated from the initial recognition stage might cover the missing problem, possible side effects might also be expected (as the complexity of the alignment task would also be increased). (C) Mapping types are not assumed by the model (27%). For example, one NE is abbreviated while its counterpart is not; or some loanwords or out-of-vocabulary terms are translated neither semantically nor phonetically. (D) Wrong NE scopes are selected (26%). Errors of this type are uneasy to resolve, and their possible solutions are beyond the scope of this paper.

Examples of above category (C) are interesting and are further illustrated as follows. As an instance of abbreviation errors, a Chinese NE "葛兰素制药厂 (GlaxoSmithKline Factory)" is tagged as "葛兰素/PRR 制药厂/n", while its counterpart in the English side is simply abbreviated as "GSK" (or replaced by a pronoun "it" sometimes). Linking "葛兰素" to "GSK" (or to the pronoun "it") is thus out of reach of our model. It seems an abbreviation table (or even anaphora analysis) is required to recover these kind of errors.

As an example of errors resulting from loanwords; Japanese kanji "明仁" (the name of a Japanese emperor) is linked to the English word "Akihito". Here the Japanese kanji "明仁" is directly adopted as the corresponding Chinese characters (as those characters were originally borrowed from Chinese), which would be pro-

nounced as “Mingren” in Chinese and thus deviates greatly from the English pronunciation of “Akihito”. Therefore, it is translated neither semantically nor phonetically. Further extending the model to cover this new conversion type seems necessary; however, such a kind of extension is very likely to be language pair dependent.

6 Capability of the Proposed Model

In addition to improving NE alignment, the proposed joint model can also boost the performance of NE recognition in both languages. The corresponding differences in performance (of the weighted version) when compared with the initial NER (ΔP, ΔR and ΔF) are shown in Table 4. Again, those marked entries indicate that they are statistically better than that of the original NER.

NEtype	ΔP (%): C/E	ΔR (%): C/E	ΔF (%): C/E
PER	**+5.4** / **+6.4**	+2.2 / **+2.6**	**+3.9** / **+4.6**
LOC	**+4.0** / **+3.4**	-0.2 / **+2.7**	+1.8 / **+3.0**
ORG	**+7.0** / **+3.9**	**+5.6** / **+9.1**	**+6.2** / **+6.4**
ALL	**+5.3** /**+5.2**	**+2.4** / **+4.0**	**+3.9** / **+4.6**

Table 4. Improvement in Chinese/English NER

The result shows that the proposed joint model has a clear win over the initial NER for either Chinese or English NER. In particular, ORG seems to have yielded the greatest gain amongst NE types, which matches our previous observations that the boundaries of Chinese ORG are difficult to identify with the information only coming from the Chinese sentence, while the type of English ORG is uneasy to classify with the information only coming from the English sentence.

Though not shown in the tables, it is also observed that the proposed approach achieves a 28.9% reduction on the spurious (false positive) and partial tags over the initial Chinese NER, as well as 16.1% relative error reduction compared with the initial English NER. In addition, total 27.2% wrong Chinese NEs and 40.7% wrong English NEs are corrected into right NE types. However, if the mapping type ratio is omitted, only 21.1% wrong Chinese NE types and 34.8% wrong English NE types can be corrected. This clearly indicates that the ratio is essential for identifying NE types.

With the benefits shown above, the alignment model could thus be used to train the monolingual NE recognition model via semi-supervised learning. This advantage is important for updating the NER model from time to time, as various domains frequently have different sets of NEs and new NEs also emerge with time.

Since the Chinese NE recognizer we use is not an open source toolkit, it cannot be used to carry out semi-supervised learning. Therefore, only the English NE recognizer and the alignment model are updated during training iterations. In our experiments, 50,412 sentence pairs are first extracted from Training-Set-I as unlabeled data. Various labeled data-sets are then extracted from the remaining data as different seed corpora (100, 400, 4,000 and 40,000 sentence-pairs). Table 5 shows the results of semi-supervised learning after convergence for adopting only the English NER model (*NER-Only*), the baseline alignment model (*NER+Baseline*), and our un-weighted joint model (*NER+JointModel*) respectively. The *Initial-NER* row indicates the initial performance of the NER model re-trained from different seed corpora. The data within parentheses are relative improvement over *Initial-NER*. Note that the testing set is still the same as before.

As Table 5 shows, with the NER model alone, the performance may even deteriorate after convergence. This is due to the fact that maximizing likelihood does not imply minimizing the error rate. However, with additional mapping constraints from the aligned sentence of another language, the alignment module could guide the searching process to converge to a more desirable point in the parameter space; and these additional constraints become more effective as the seed-corpus gets smaller.

Model	100	400	4,000	40,000
Initial-NER	36.7 (0%)	58.6 (0%)	71.4 (0%)	79.1 (0%)
NER-Only	-2.3 (-6.3%)	-0.5 (-0.8%)	-0.3 (-0.4%)	-0.1 (-0.1%)
NER+Baseline	+4.9 (+13.4%)	+3.4 (5.8%)	+1.7 (2.4%)	+0.7 (0.9%)
NER+Joint Model	+10.7 (+29.2%)	+8.7 (+14.8%)	+4.8 (+6.7%)	+2.3 (+2.9%)

Table 5. Testing-Set Performance for Semi-Supervised Learning of English NE Recognition

7 Conclusion

In summary, our experiments show that the new monolingual candidate certainty factors are more effective than the tagging cost (only bigram model) adopted in the baseline system. Moreover, both the mapping type ratio and the entity type consistency constraint are very helpful in identifying the associated NE boundaries and types. After having adopted the features and enforced

the constraint mentioned above, the proposed framework, which jointly recognizes and aligns bilingual named entities, achieves a remarkable 42.1% imperfection reduction on type-sensitive F-score (from 68.4% to 81.7%) in our Chinese-English NE alignment task.

Although the experiments are conducted on the Chinese-English language pair, it is expected that the proposed approach can also be applied to other language pairs, as no language dependent linguistic feature (or knowledge) is adopted in the model/algorithm used.

Abstract

In this paper, we propose a novel approach to automatic generation of summary templates from given collections of summary articles. This kind of summary templates can be useful in various applications. We first develop an entity-aspect LDA model to simultaneously cluster both sentences and words into aspects. We then apply frequent subtree pattern mining on the dependency parse trees of the clustered and labeled sentences to discover sentence patterns that well represent the aspects. Key features of our method include automatic grouping of semantically related sentence patterns and automatic identification of template slots that need to be filled in. We apply our method on five Wikipedia entity categories and compare our method with two baseline methods. Both quantitative evaluation based on human judgment and qualitative comparison demonstrate the effectiveness and advantages of our method.

1 Introduction

In this paper, we study the task of automatically generating templates for entity summaries. An entity summary is a short document that gives the most important facts about an entity. In Wikipedia, for instance, most articles have an introduction section that summarizes the subject entity before the table of contents and other elaborate sections. These introduction sections are examples of entity summaries we consider. Summaries of entities from the same category usually share some common structure. For example, biographies of physicists usually contain facts about the nationality, educational background, affiliation and major contributions of the physicist, whereas introductions of companies usually list information such as the industry, founder and headquarter of the company. Our goal is to automatically construct a summary template that outlines the most salient types of facts for an entity category, given a collection of entity summaries from this category.

Such kind of summary templates can be very useful in many applications. First of all, they can uncover the underlying structures of summary articles and help better organize the information units, much in the same way as infoboxes do in Wikipedia. In fact, automatic template generation provides a solution to induction of infobox structures, which are still highly incomplete in Wikipedia (Wu and Weld, 2007). A template can also serve as a starting point for human editors to create new summary articles. Furthermore, with summary templates, we can potentially apply information retrieval and extraction techniques to construct summaries for new entities automatically on the fly, improving the user experience for search engine and question answering systems.

Despite its usefulness, the problem has not been well studied. The most relevant work is by Filatova et al. (2006) on automatic creation of domain templates, where the defintion of a domain is similar to our notion of an entity category. Filatova et al. (2006) first identify the important verbs for a domain using corpus statistics, and then find frequent parse tree patterns from sentences containing these verbs to construct a domain template. There are two major limitations of their approach. First, the focus on verbs restricts the template patterns that can be found. Second, redundant or related patterns using different verbs to express the same or similar facts cannot be grouped together. For example, "*won X award*" and "*received X prize*" are considered two different patterns by this approach. We propose a method that can overcome these two limitations. Automatic template generation is also related to a number of other problems that have been studied before, in-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 640–649,
Uppsala, Sweden, 11-16 July 2010.

cluding unsupervised IE pattern discovery (Sudo et al., 2003; Shinyama and Sekine, 2006; Sekine, 2006; Yan et al., 2009) and automatic generation of Wikipedia articles (Sauper and Barzilay, 2009). We discuss the differences of our work from existing related work in Section 6.

In this paper we propose a novel approach to the task of automatically generating entity summary templates. We first develop an entity-aspect model that extends standard LDA to identify clusters of words that can represent different aspects of facts that are salient in a given summary collection (Section 3). For example, the words "received," "award," "won" and "Nobel" may be clustered together from biographies of physicists to represent one aspect, even though they may appear in different sentences from different biographies. Simultaneously, the entity-aspect model separates words in each sentence into background words, document words and aspect words, and sentences likely about the same aspect are naturally clustered together. After this aspect identification step, we mine frequent subtree patterns from the dependency parse trees of the clustered sentences (Section 4). Different from previous work, we leverage the word labels assigned by the entity-aspect model to prune the patterns and to locate template slots to be filled in.

We evaluate our method on five entity categories using Wikipedia articles (Section 5). Because the task is new and thus there is no standard evaluation criteria, we conduct both quantitative evaluation using our own human judgment and qualitative comparison. Our evaluation shows that our method can obtain better sentence patterns in terms of f1 measure compared with two baseline methods, and it can also achieve reasonably good quality of aspect clusters in terms of purity. Compared with standard LDA and K-means sentence clustering, the aspects identified by our method are also more meaningful.

2 The Task

Given a collection of entity summaries from the same entity category, our task is to automatically construct a summary template that outlines the most important information one should include in a summary for this entity category. For example, given a collection of biographies of physicists, ideally the summary template should indicate that important facts about a physicist include his/her educational background, affiliation, major contributions, awards received, etc.

Aspect	Pattern
1	*ENT* received his phd from ? university *ENT* studied ? under ? *ENT* earned his ? in physics from university of ?
2	*ENT* was awarded the medal in ? *ENT* won the ? award *ENT* received the nobel prize in physics in ?
3	*ENT* was ? director *ENT* was the head of ? *ENT* worked for ?
4	*ENT* made contributions to ? *ENT* is best known for work on ? *ENT* is noted for ?

Table 1: Examples of some good template patterns and their aspects generated by our method.

However, it is not clear what is the best representation of such templates. Should a template comprise a list of subtopic labels (e.g. "education" and "affiliation") or a set of explicit questions? Here we define a template format based on the usage of the templates as well as our observations from Wikipedia entity summaries. First, since we expect that the templates can be used by human editors for creating new summaries, we use sentence patterns that are human readable as basic units of the templates. For example, we may have a sentence pattern "*ENT* graduated from ? University" for the entity category "physicist," where *ENT* is a placeholder for the entity that the summary is about, and '?' is a slot to be filled in. Second, we observe that information about entities of the same category can be grouped into subtopics. For example, the sentences "Bohr is a Nobel laureate" and "Einstein received the Nobel Prize" are paraphrases of the same type of facts, while the sentences "Taub earned his doctorate at Princeton University" and "he graduated from MIT" are slightly different but both describe a person's educational background. Therefore, it makes sense to group sentence patterns based on the subtopics they pertain to. Here we call these subtopics the *aspects* of a summary template.

Formally, we define a summary template to be a set of sentence patterns grouped into aspects. Each sentence pattern has a placeholder for the entity to be summarized and possibly one or more template slots to be filled in. Table 1 shows some sentence patterns our method has generated for the "physicist" category.

2.1 Overview of Our Method

Our automatic template generation method consists of two steps:

Aspect Identification: In this step, our goal is to automatically identify the different aspects or subtopics of the given summary collection. We simultaneously cluster sentences and words into aspects, using an entity-aspect model extended from the standard LDA model that is widely used in text mining (Blei et al., 2003). The output of this step are sentences clustered into aspects, with each word labeled as a stop word, a background word, a document word or an aspect word.

Sentence Pattern Generation: In this step, we generate human-readable sentence patterns to represent each aspect. We use frequent subtree pattern mining to find the most representative sentence structures for each aspect. The fixed structure of a sentence pattern consists of aspect words, background words and stop words, while document words become template slots whose values can vary from summary to summary.

3 Aspect Identification

At the aspect identification step, our goal is to discover the most salient aspects or subtopics contained in a summary collection. Here we propose a principled method based on a modified LDA model to simultaneously cluster both sentences and words to discover aspects.

We first make the following observation. In entity summaries such as the introduction sections of Wikipedia articles, most sentences are talking about a single fact of the entity. If we look closely, there are a few different kinds of words in these sentences. First of all, there are stop words that occur frequently in any document collection. Second, for a given entity category, some words are generally used in all aspects of the collection. Third, some words are clearly associated with the aspects of the sentences they occur in. And finally, there are also words that are document or entity specific. For example, in Table 2 we show two sentences related to the "affiliation" aspect from the "physicist" summary collection. Stop words such as "is" and "the" are labeled with "S." The word "physics" can be regarded as a background word for this collection. "Professor" and "university" are clearly related to the "affiliation" aspect. Finally words such as "Modena" and "Chicago" are specifically associated with the subject entities being discussed, that is, they are specific to the summary documents.

To capture background words and document-specific words, Chemudugunta et al. (2007) proposed to introduce a background topic and document-specific topics. Here we borrow their idea and also include a background topic as well as document-specific topics. To discover aspects that are local to one or a few adjacent sentences but may occur in many documents, Titov and McDonald (2008) proposed a multi-grain topic model, which relies on word co-occurrences within short paragraphs rather than documents in order to discover aspects. Inspired by their model, we rely on word co-occurrences within single sentences to identify aspects.

3.1 Entity-Aspect Model

We now formally present our entity-aspect model. First, we assume that stop words can be identified using a standard stop word list. We then assume that for a given entity category there are three kinds of unigram language models (i.e. multinomial word distributions). There is a background model $\phi^{\mathcal{B}}$ that generates words commonly used in all documents and all aspects. There are D document models ψ^d ($1 \leq d \leq D$), where D is the number of documents in the given summary collection, and there are A aspect models ϕ^a ($1 \leq a \leq A$), where A is the number of aspects. We assume that these word distributions have a uniform Dirichlet prior with parameter β.

Since not all aspects are discussed equally frequently, we assume that there is a global aspect distribution θ that controls how often each aspect occurs in the collection. θ is sampled from another Dirichlet prior with parameter α. There is also a multinomial distribution π that controls in each sentence how often we encounter a background word, a document word, or an aspect word. π has a Dirichlet prior with parameter γ.

Let S_d denote the number of sentences in document d, $N_{d,s}$ denote the number of words (after stop word removal) in sentence s of document d, and $w_{d,s,n}$ denote the n'th word in this sentence. We introduce hidden variables $z_{d,s}$ for each sentence to indicate the aspect a sentence belongs to. We also introduce hidden variables $y_{d,s,n}$ for each word to indicate whether a word is generated from the background model, the document model, or the aspect model. Figure 1 shows the process of

generating the whole document collection. The plate notation of the model is shown in Figure 2. Note that the values of α, β and γ are fixed. The number of aspects A is also manually set.

3.2 Inference

Given a summary collection, i.e. the set of all $w_{d,s,n}$, our goal is to find the most likely assignment of $z_{d,s}$ and $y_{d,s,n}$, that is, the assignment that maximizes $p(\boldsymbol{z}, \boldsymbol{y}|\boldsymbol{w}; \alpha, \beta, \gamma)$, where $\boldsymbol{z}$, $\boldsymbol{y}$ and $\boldsymbol{w}$ represent the set of all z, y and w variables, respectively. With the assignment, sentences are naturally clustered into aspects, and words are labeled as either a background word, a document word, or an aspect word.

We approximate $p(\boldsymbol{y}, \boldsymbol{z}|\boldsymbol{w}; \alpha, \beta, \gamma)$ by $p(\boldsymbol{y}, \boldsymbol{z}|\boldsymbol{w}; \hat{\phi}^{\mathcal{B}}, \{\hat{\psi}^d\}_{d=1}^D, \{\hat{\phi}^a\}_{a=1}^A, \hat{\theta}, \hat{\pi})$, where $\hat{\phi}^{\mathcal{B}}$, $\{\hat{\psi}^d\}_{d=1}^D$, $\{\hat{\phi}^a\}_{a=1}^A$, $\hat{\theta}$ and $\hat{\pi}$ are estimated using Gibbs sampling, which is commonly used for inference for LDA models (Griffiths and Steyvers, 2004). Due to space limit, we give the formulas for the Gibbs sampler below without derivation.

First, given sentence s in document d, we sample a value for $z_{d,s}$ given the values of all other z and y variables using the following formula:

$$p(z_{d,s} = a|\boldsymbol{z}_{\neg\{d,s\}}, \boldsymbol{y}, \boldsymbol{w}) \propto \frac{C^{\mathcal{A}}_{(a)} + \alpha}{C^{\mathcal{A}}_{(\cdot)} + A\alpha} \cdot \frac{\prod_{v=1}^{V} \prod_{i=0}^{E_{(v)}} (C^a_{(v)} + i + \beta)}{\prod_{i=0}^{E_{(\cdot)}} (C^a_{(\cdot)} + i + V\beta)}.$$

In the formula above, $\boldsymbol{z}_{\neg\{d,s\}}$ is the current aspect assignment of all sentences excluding the current sentence. $C^{\mathcal{A}}_{(a)}$ is the number of sentences assigned to aspect a, and $C^{\mathcal{A}}_{(\cdot)}$ is the total number of sentences. V is the vocabulary size. $C^a_{(v)}$ is the number of times word v has been assigned to aspect a. $C^a_{(\cdot)}$ is the total number of words assigned to aspect a. All the counts above exclude the current sentence. $E_{(v)}$ is the number of times word v occurs in the current sentence and is assigned to be an aspect word, as indicated by $\boldsymbol{y}$, and $E_{(\cdot)}$ is the total number of words in the current sentence that are assigned to be an aspect word.

We then sample a value for $y_{d,s,n}$ for each word in the current sentence using the following formulas:

$$p(y_{d,s,n} = 1|\boldsymbol{z}, \boldsymbol{y}_{\neg\{d,s,n\}}) \propto \frac{C^{\pi}_{(1)} + \gamma}{C^{\pi}_{(\cdot)} + 3\gamma} \cdot \frac{C^{\mathcal{B}}_{(w_{d,s,n})} + \beta}{C^{\mathcal{B}}_{(\cdot)} + V\beta},$$

$$p(y_{d,s,n} = 2|\boldsymbol{z}, \boldsymbol{y}_{\neg\{d,s,n\}}) \propto \frac{C^{\pi}_{(2)} + \gamma}{C^{\pi}_{(\cdot)} + 3\gamma} \cdot \frac{C^{d}_{(w_{d,s,n})} + \beta}{C^{d}_{(\cdot)} + V\beta},$$

$$p(y_{d,s,n} = 3|\boldsymbol{z}, \boldsymbol{y}_{\neg\{d,s,n\}}) \propto \frac{C^{\pi}_{(3)} + \gamma}{C^{\pi}_{(\cdot)} + 3\gamma} \cdot \frac{C^{a}_{(w_{d,s,n})} + \beta}{C^{a}_{(\cdot)} + V\beta}.$$

In the formulas above, $\boldsymbol{y}_{\neg\{d,s,n\}}$ is the set of all y variables excluding $y_{d,s,n}$. $C^{\pi}_{(1)}$, $C^{\pi}_{(2)}$ and $C^{\pi}_{(3)}$ are the numbers of words assigned to be a background word, a document word, or an aspect word, respectively, and $C^{\pi}_{(\cdot)}$ is the total number of words. $C^{\mathcal{B}}$ and C^d are counters similar to C^a but are for the background model and the document models. In all these counts, the current word is excluded.

With one Gibbs sample, we can make the following estimation:

$$\hat{\phi}_v^B = \frac{C^{\mathcal{B}}_{(v)} + \beta}{C^{\mathcal{B}}_{(\cdot)} + V\beta}, \hat{\psi}_v^d = \frac{C^d_{(v)} + \beta}{C^d_{(\cdot)} + V\beta}, \hat{\phi}_v^a = \frac{C^a_{(v)} + \beta}{C^a_{(\cdot)} + V\beta},$$

$$\hat{\theta}_a = \frac{C^{\mathcal{A}}_{(a)} + \alpha}{C^{\mathcal{A}}_{(\cdot)} + A\alpha}, \hat{\pi}_t = \frac{C^{\pi}_{(t)} + \gamma}{C^{\pi}_{(\cdot)} + 3\gamma} (1 \leq t \leq 3).$$

Here the counts include all sentences and all words.

In our experiments, we set $\alpha = 5$, $\beta = 0.01$ and $\gamma = 20$. We run 100 burn-in iterations through all documents in a collection to stabilize the distribution of $\boldsymbol{z}$ and $\boldsymbol{y}$ before collecting samples. We found that empirically 100 burn-in iterations were sufficient for our data set. We take 10 samples with a gap of 10 iterations between two samples, and average over these 10 samples to get the estimation for the parameters.

After estimating $\hat{\phi}^{\mathcal{B}}$, $\{\hat{\psi}^d\}_{d=1}^D$, $\{\hat{\phi}^a\}_{a=1}^A$, $\hat{\theta}$ and $\hat{\pi}$, we find the values of each $z_{d,s}$ and $y_{d,s,n}$ that maximize $p(\boldsymbol{y}, \boldsymbol{z}|\boldsymbol{w}; \hat{\phi}^{\mathcal{B}}, \{\hat{\psi}^d\}_{d=1}^D, \{\hat{\phi}^a\}_{a=1}^A, \hat{\theta}, \hat{\pi})$. This assignment, together with the standard stop word list we use, gives us sentences clustered into A aspects, where each word is labeled as either a stop word, a background word, a document word or an aspect word.

3.3 Comparison with Other Models

A major difference of our entity-aspect model from standard LDA model is that we assume each sentence belongs to a single aspect while in LDA words in the same sentence can be assigned to different topics. Our one-aspect-per-sentence assumption is important because our goal is to cluster sentences into aspects so that we can mine common sentence patterns for each aspect.

To cluster sentences, we could have used a straightforward solution similar to document clustering, where sentences are represented as feature vectors using the vector space model, and a standard clustering algorithm such as K-means can be applied to group sentences together. However, there are some potential problems with directly applying this typical document clustering method. First, unlike documents, sentences are short, and the number of words in a sentence that imply its aspect is even smaller. Besides, we do not know the aspect-related words in advance. As a result, the cosine similarity between two sentences may not reflect whether they are about the same aspect. We can perform heuristic term weighting, but the method becomes less robust. Second, after sentence clustering, we may still want to identify the the aspect words in each sentence, which are useful in the next pattern mining step. Directly taking the most frequent words from each sentence cluster as aspect words may not work well even after stop word removal, because there can be background words commonly used in all aspects.

4 Sentence Pattern Generation

At the pattern generation step, we want to identify human-readable sentence patterns that best represent each cluster. Following the basic idea from (Filatova et al., 2006), we start with the parse trees of sentences in each cluster, and apply a frequent subtree pattern mining algorithm to find sentence structures that have occurred at least K times in the cluster. Here we use dependency parse trees.

However, different from (Filatova et al., 2006), the word labels (S, B, D and A) assigned by the entity-aspect model give us some advantages. Intuitively, a representative sentence pattern for an aspect should contain at least one aspect word. On the other hand, document words are entity-specific and therefore should not appear in the generic template patterns; instead, they correspond to template slots that need to be filled in. Furthermore, since we work on entity summaries, in each sentence there is usually a word or phrase that refers to the subject entity, and we should have a placeholder for the subject entity in each pattern.

Based on the intuitions above, we have the following sentence pattern generation process.

1. ***Locate subject entities***: In each sentence, we want to locate the word or phrase that refers to the subject entity. For example, in a biography, usually a pronoun "he" or "she" is used to refer to the subject person. We use the following heuristic to locate the subject entities: For each summary document, we first find the top 3 frequent base noun phrases that are subjects of sentences. For example, in a company introduction, the phrase "the company" is probably used frequently as a sentence subject. Then for each sentence, we first look for the title of the Wikipedia article. If it occurs, it is tagged as the subject entity. Otherwise, we check whether one of the top 3 subject base noun phrases occurs, and if so, it is tagged as the subject entity. Otherwise, we tag the subject of the sentence as the subject entity. Finally, for the identified subject entity word or phrase, we replace the label assigned by the entity-aspect model with a

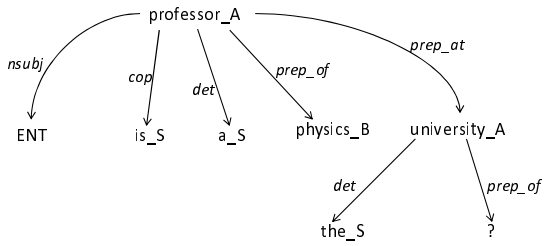

Figure 3: An example labeled dependency parse tree.

new label E.

2. ***Generate labeled parse trees***: We parse each sentence using the Stanford Parser[1]. After parsing, for each sentence we obtain a dependency parse tree where each node is a single word and each edge is labeled with a dependency relation. Each word is also labeled with one of $\{E, S, B, D, A\}$. We replace words labeled with E by a placeholder *ENT*, and replace words labeled with D by a question mark to indicate that these correspond to template slots. For the other words, we attach their labels to the tree nodes. Figure 3 shows an example labeled dependency parse tree.

3. ***Mine frequent subtree patterns***: For the set of parse trees in each cluster, we use FREQT[2], a software that implements the frequent subtree pattern mining algorithm proposed in (Zaki, 2002), to find all subtrees with a minimum support of K.

4. ***Prune patterns***: We remove subtree patterns found by FREQT that do not contain *ENT* or any aspect word. We also remove small patterns that are contained in some other larger pattern in the same cluster.

5. ***Covert subtree patterns to sentence patterns***: The remaining patterns are still represented as subtrees. To covert them back to human-readable sentence patterns, we map each pattern back to one of the sentences that contain the pattern to order the tree nodes according to their original order in the sentence.

In the end, for each summary collection, we obtain A clusters of sentence patterns, where each cluster presumably corresponds to a single aspect or subtopic.

5 Evaluation

Because we study a non-standard task, there is no existing annotated data set. We therefore created a small data set and made our own human judgment for quantitative evaluation purpose.

5.1 Data

We downloaded five collections of Wikipedia articles from different entity categories. We took only the introduction sections of each article (before the tables of contents) as entity summaries. Some statistics of the data set are given in Table 3.

5.2 Quantitative Evaluation

To quantitatively evaluate the summary templates, we want to check (1) whether our sentence patterns are meaningful and can represent the corresponding entity categories well, and (2) whether semantically related sentence patterns are grouped into the same aspect. It is hard to evaluate both together. We therefore separate these two criteria.

5.2.1 Quality of sentence patterns

To judge the quality of sentence patterns without looking at aspect clusters, ideally we want to compute the precision and recall of our patterns, that is, the percentage of our sentence patterns that are meaningful, and the percentage of true meaningful sentence patterns of each category that our method can capture. The former is relatively easy to obtain because we can ask humans to judge the quality of our patterns. The latter is much harder to compute because we need human judges to find the set of true sentence patterns for each entity category, which can be very subjective.

We adopt the following pooling strategy borrowed from information retrieval. Assume we want to compare a number of methods that each can generate a set of sentence patterns from a summary collection. We take the union of these sets

of patterns generated by the different methods and order them randomly. We then ask a human judge to decide whether each sentence pattern is meaningful for the given category. We can then treat the set of meaningful sentence patterns found by the human judge this way as the ground truth, and precision and recall of each method can be computed. If our goal is only to compare the different methods, this pooling strategy should suffice.

We compare our method with the following two baseline methods.

Baseline 1: In this baseline, we use the same subtree pattern mining algorithm to find sentence patterns from each summary collection. We also locate the subject entities and replace them with *ENT*. However, we do not have aspect words or document words in this case. Therefore we do not prune any pattern except to merge small patterns with the large ones that contain them. The patterns generated by this method do not have template slots.

Baseline 2: In the second baseline, we apply a verb-based pruning on the patterns generated by the first baseline, similar to (Filatova et al., 2006). We first find the top-20 verbs using the scoring function below that is taken from (Filatova et al., 2006), and then prune patterns that do not contain any of the top-20 verbs.

$$s(v_i) = \frac{N(v_i)}{\sum_{v_j \in \mathcal{V}} N(v_j)} \cdot \frac{M(v_i)}{D},$$

where $N(v_i)$ is the frequency of verb v_i in the collection, $\mathcal{V}$ is the set of all verbs, D is the total number of documents in the collection, and $M(v_i)$ is the number of documents in the collection that contains v_i.

In Table 4, we show the precision, recall and f1 of the sentence patterns generated by our method and the two baseline methods for the five categories. For our method, we set the support of the subtree patterns K to 2, that is, each pattern has occurred in at least two sentences in the corresponding aspect cluster. For the two baseline methods, because sentences are not clustered, we use a larger support K of 3; otherwise, we find that there can be too many patterns. We can see that overall our method gives better f1 measures than the two baseline methods for most categories. Our method achieves a good balance between precision and recall. For BL-1, the precision is high but recall is low. Intuitively BL-1 should have a higher recall than our method because our method does more pattern pruning than BL-1 using aspect words. Here it is not the case mainly because we used a higher frequency threshold (K = 3) to select frequent patterns in BL-1, giving overall fewer patterns than in our method. For BL-2, the precision is higher than BL-1 but recall is lower. It is expected because the patterns of BL-2 is a subset of that of BL-1.

Category	B	Purity
US Actress	4	0.626
Physicist	6	0.714
US CEO	4	0.674
US Company	4	0.614
Restaurant	3	0.587

Table 5: The true numbers of aspects as judged by the human annotator (B), and the purity of the clusters.

There are some advantages of our method that are not reflected in Table 4. First, many of our patterns contain template slots, which make the pattern more meaningful. In contrast the baseline patterns do not contain template slots. Because the human judge did not give preference over patterns with slots, both "*ENT* won the award" and "*ENT* won the ? award" were judged to be meaningful without any distinction, although the former one generated by our method is more meaningful. Second, compared with BL-2, our method can obtain patterns that do not contain a non-auxiliary verb, such as "*ENT* was ? director."

5.2.2 Quality of aspect clusters

We also want to judge the quality of the aspect clusters. To do so, we ask the human judge to group the ground truth sentence patterns of each category based on semantic relatedness. We then compute the purity of the automatically generated clusters against the human judged clusters using purity. The results are shown in Table 5. In our experiments, we set the number of clusters A used in the entity-aspect model to be 10. We can see from Table 5 that our generated aspect clusters can achieve reasonably good performance.

5.3 Qualitative evaluation

We also conducted qualitative comparison between our entity-aspect model and standard LDA model as well as a K-means sentence clustering method. In Table 6, we show the top 5 frequent words of three sample aspects as found by our method, standard LDA, and K-means. Note that although we try to align the aspects, there is

Method		Category				
		US Actress	Physicist	US CEO	US Company	Restaurant
BL-1	precision	0.714	0.695	0.778	0.622	0.706
	recall	0.545	0.300	0.367	0.425	0.361
	f1	0.618	0.419	0.499	0.505	0.478
BL-2	precision	0.845	0.767	0.829	0.809	1.000
	recall	0.260	0.096	0.127	0.167	0.188
	f1	0.397	0.17	0.220	0.276	0.316
Ours	precision	0.544	0.607	0.586	0.450	0.560
	recall	0.710	0.785	0.712	0.618	0.701
	f1	0.616	0.684	0.643	0.520	0.624

Table 4: Quality of sentence patterns in terms of precision, recall and f1.

Method	Sample Aspects		
	1	2	3
Our entity-aspect model	university received ph.d. college degree	prize nobel physics awarded medal	academy sciences member national society
Standard LDA	physics american professor received university	nobel prize physicist awarded john	physics institute research member sciences
K-means	physics university institute work research	physicist american physics university nobel	physics academy sciences university new

Table 6: Comparison of the top 5 words of three sample aspects using different methods.

no correspondence between clusters numbered the same but generated by different methods.

We can see that our method gives very meaningful aspect clusters. Standard LDA also gives meaningful words, but background words such as "physics" and "physicist" are mixed with aspect words. Entity-specific words such as "john" also appear mixed with aspect words. K-means clusters are much less meaningful, with too many background words mixed with aspect words.

6 Related Work

The most related existing work is on domain template generation by Filatova et al. (2006). There are several differences between our work and theirs. First, their template patterns must contain a non-auxiliary verb whereas ours do not have this restriction. Second, their verb-centered patterns are independent of each other, whereas we group semantically related patterns into aspects, giving more meaningful templates. Third, in their work, named entities, numbers and general nouns are treated as template slots. In our method, we apply the entity-aspect model to automatically identify words that are document-specific, and treat these words as template slots, which can be potentially more robust as we do not rely on the quality of named entity recognition. Last but not least, their documents are event-centered while ours are entity-centered. Therefore we can use heuristics to anchor our patterns on the subject entities.

Sauper and Barzilay (2009) proposed a framework to learn to automatically generate Wikipedia articles. There is a fundamental difference between their task and ours. The articles they generate are long, comprehensive documents consisting of several sections on different subtopics of the subject entity, and they focus on learning the topical structures from complete Wikipedia articles. We focus on learning sentence patterns of the short, concise introduction sections of Wikipedia articles.

Our entity-aspect model is related to a number of previous extensions of LDA models. Chemudugunta et al. (2007) proposed to introduce a background topic and document-specific topics. Our background and document language models are similar to theirs. However, they still treat documents as bags of words rather than sets of sentences as in our model. Titov and McDonald (2008) exploited the idea that a short paragraph within a document is likely to be about the same aspect. Our one-aspect-per-sentence assumption is a stricter than theirs, but it is required in our model for the purpose of mining sentence patterns. The way we separate words into stop words, background words, document words and aspect words bears similarity to that used in (Daumé III and Marcu, 2006; Haghighi and Vanderwende, 2009), but their task is multi-document summarization while ours is to induce summary templates.

7 Conclusions and Future Work

In this paper, we studied the task of automatically generating templates for entity summaries. We proposed an entity-aspect model that can automatically cluster sentences and words into aspects. The model also labels words in sentences as either a stop word, a background word, a document word or an aspect word. We then applied frequent subtree pattern mining to generate sentence patterns that can represent the aspects. We took advantage of the labels generated by the entity-aspect model to prune patterns and to locate template slots. We conducted both quantitative and qualitative evaluation using five collections of Wikipedia entity summaries. We found that our method gave overall better template patterns than two baseline methods, and the aspect clusters generated by our method are reasonably good.

There are a number of directions we plan to pursue in the future in order to improve our method. First, we can possibly apply linguistic knowledge to improve the quality of sentence patterns. Currently the method may generate similar sentence patterns that differ only slightly, e.g. change of a preposition. Also, the sentence patterns may not form complete, meaningful sentences. For example, a sentence pattern may contain an adjective but not the noun it modifies. We plan to study how to use linguistic knowledge to guide the construction of sentence patterns and make them more meaningful. Second, we have not quantitatively evaluated the quality of the template slots, because our judgment is only at the whole sentence pattern level. We plan to get more human judges and more rigorously judge the relevance and usefulness of both the sentence patterns and the template slots. It is also possible to introduce certain rules or constraints to selectively form template slots rather than treating all words labeled with D as template slots.

Abstract

Comparing one thing with another is a typical part of human decision making process. However, it is not always easy to know what to compare and what are the alternatives. To address this difficulty, we present a novel way to automatically mine comparable entities from comparative questions that users posted online. To ensure high precision and high recall, we develop a weakly-supervised bootstrapping method for comparative question identification and comparable entity extraction by leveraging a large online question archive. The experimental results show our method achieves F1-measure of 82.5% in comparative question identification and 83.3% in comparable entity extraction. Both significantly outperform an existing state-of-the-art method.

1 Introduction

Comparing alternative options is one essential step in decision-making that we carry out every day. For example, if someone is interested in certain products such as digital cameras, he or she would want to know what the alternatives are and compare different cameras before making a purchase. This type of comparison activity is very common in our daily life but requires high knowledge skill. Magazines such as *Consumer Reports* and *PC Magazine* and online media such as *CNet.com* strive in providing editorial comparison content and surveys to satisfy this need.

In the World Wide Web era, a comparison activity typically involves: search for relevant web pages containing information about the targeted products, find competing products, read reviews, and identify pros and cons. In this paper, we focus on finding a set of comparable entities given a user's input entity. For example, given an entity, *Nokia N95* (a cellphone), we want to find comparable entities such as *Nokia N82*, *iPhone* and so on.

In general, it is difficult to decide if two entities are comparable or not since people do compare apples and oranges for various reasons. For example, "*Ford*" and "*BMW*" might be comparable as "car manufacturers" or as "market segments that their products are targeting", but we rarely see people comparing "*Ford Focus*" (car model) and "*BMW 328i*". Things also get more complicated when an entity has several functionalities. For example, one might compare "*iPhone*" and "*PSP*" as "portable game player" while compare "*iPhone*" and "*Nokia N95*" as "mobile phone". Fortunately, plenty of comparative questions are posted online, which provide evidences for what people want to compare, e.g. "*Which to buy, iPod or iPhone*?". We call "*iPod*" and "*iPhone*" in this example as *comparators*. In this paper, we define comparative questions and comparators as:

- **Comparative question**: A question that intends to compare two or more entities and it has to mention these entities explicitly in the question.
- **Comparator**: An entity which is a target of comparison in a comparative question.

According to these definitions, Q1 and Q2 below are not comparative questions while Q3 is. "*iPod Touch*" and "*Zune HD*" are comparators.

Q1: "Which one is better?"
Q2: "Is Lumix GH-1 the best camera?"
Q3: "What's the difference between iPod Touch and Zune HD?"

The goal of this work is mining comparators from comparative questions. The results would be very useful in helping users' exploration of

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 650–658,
Uppsala, Sweden, 11-16 July 2010.

alternative choices by suggesting comparable entities based on other users' prior requests.

To mine comparators from comparative questions, we first have to detect whether a question is comparative or not. According to our definition, a comparative question has to be a question with intent to compare at least two entities. Please note that a question containing at least two entities is *not* a comparative question if it does not have comparison intent. However, we observe that a question is very likely to be a comparative question if it contains at least two entities. We leverage this insight and develop a weakly supervised bootstrapping method to identify comparative questions and extract comparators simultaneously.

To our best knowledge, this is the first attempt to specially address the problem on finding good comparators to support users' comparison activity. We are also the first to propose using comparative questions posted online that reflect what users truly care about as the medium from which we mine comparable entities. Our weakly supervised method achieves 82.5% F1-measure in comparative question identification, 83.3% in comparator extraction, and 76.8% in end-to-end comparative question identification and comparator extraction which outperform the most relevant state-of-the-art method by Jindal & Liu (2006b) significantly.

The rest of this paper is organized as follows. The next section discusses previous works. Section 3 presents our weakly-supervised method for comparator mining. Section 4 reports the evaluations of our techniques, and we conclude the paper and discuss future work in Section 5.

2 Related Work

2.1 Overview

In terms of discovering related items for an entity, our work is similar to the research on recommender systems, which recommend items to a user. Recommender systems mainly rely on similarities between items and/or their statistical correlations in user log data (Linden et al., 2003). For example, Amazon recommends products to its customers based on their own purchase histories, similar customers' purchase histories, and similarity between products. However, recommending an item is not equivalent to finding a comparable item. In the case of Amazon, the purpose of recommendation is to entice their customers to add more items to their shopping carts by suggesting similar or related items. While in the case of comparison, we would like to help users explore alternatives, i.e. helping them make a decision among comparable items.

For example, it is reasonable to recommend "*iPod speaker*" or "*iPod batteries*" if a user is interested in "*iPod*", but we would not compare them with "*iPod*". However, items that are comparable with "*iPod*" such as "*iPhone*" or "*PSP*" which were found in comparative questions posted by users are difficult to be predicted simply based on item similarity between them. Although they are all music players, "*iPhone*" is mainly a mobile phone, and "*PSP*" is mainly a portable game device. They are similar but also different therefore beg comparison with each other. It is clear that comparator mining and item recommendation are related but not the same.

Our work on comparator mining is related to the research on entity and relation extraction in information extraction (Cardie, 1997; Califf and Mooney, 1999; Soderland, 1999; Radev et al., 2002; Carreras et al., 2003). Specifically, the most relevant work is by Jindal and Liu (2006a and 2006b) on mining comparative sentences and relations. Their methods applied class sequential rules (CSR) (Chapter 2, Liu 2006) and label sequential rules (LSR) (Chapter 2, Liu 2006) learned from annotated corpora to identify comparative sentences and extract comparative relations respectively in the news and review domains. The same techniques can be applied to comparative question identification and comparator mining from questions. However, their methods typically can achieve high precision but suffer from low recall (Jindal and Liu, 2006b) (J&L). However, ensuring high recall is crucial in our intended application scenario where users can issue arbitrary queries. To address this problem, we develop a weakly-supervised bootstrapping pattern learning method by effectively leveraging unlabeled questions.

Bootstrapping methods have been shown to be very effective in previous information extraction research (Riloff, 1996; Riloff and Jones, 1999; Ravichandran and Hovy, 2002; Mooney and Bunescu, 2005; Kozareva et al., 2008). Our work is similar to them in terms of methodology using bootstrapping technique to extract entities with a specific relation. However, our task is different from theirs in that it requires not only extracting entities (comparator extraction) but also ensuring that the entities are extracted from comparative questions (comparative question identification), which is generally not required in IE task.

2.2 Jindal & Liu 2006

In this subsection, we provide a brief summary of the comparative mining method proposed by Jindal and Liu (2006a and 2006b), which is used as baseline for comparison and represents the state-of-the-art in this area. We first introduce the definition of CSR and LSR rule used in their approach, and then describe their comparative mining method. Readers should refer to J&L's original papers for more details.

CSR and LSR

CSR is a classification rule. It maps a sequence pattern $S(s_1 s_2 \ldots s_n)$ to a class *C*. In our problem, *C* is either *comparative* or *non-comparative*. Given a collection of sequences with class information, every CSR is associated to two parameters: *support* and *confidence*. *Support* is the proportion of sequences in the collection containing *S* as a subsequence. *Confidence* is the proportion of sequences labeled as *C* in the sequences containing the *S*. These parameters are important to evaluate whether a CSR is reliable or not.

LSR is a labeling rule. It maps an input sequence pattern $S(s_1 s_2 \ldots s_i \ldots s_n)$ to a labeled sequence $S'(s_1 s_2 \ldots l_i \ldots s_n)$ by replacing one token (s_i) in the input sequence with a designated label (l_i). This token is referred as the anchor. The anchor in the input sequence could be extracted if its corresponding label in the labeled sequence is what we want (in our case, a comparator). LSRs are also mined from an annotated corpus, therefore each LSR also have two parameters: *support* and *confidence*. They are similarly defined as in CSR.

Supervised Comparative Mining Method

J&L treated comparative sentence identification as a classification problem and comparative relation extraction as an information extraction problem. They first manually created a set of 83 keywords such as *beat*, *exceed*, and *outperform* that are likely indicators of comparative sentences. These keywords were then used as pivots to create part-of-speech (POS) sequence data. A manually annotated corpus with class information, i.e. *comparative* or *non-comparative*, was used to create sequences and CSRs were mined. A Naïve Bayes classifier was trained using the CSRs as features. The classifier was then used to identify comparative sentences.

Given a set of comparative sentences, J&L manually annotated two comparators with labels \$ES1 and \$ES2 and the feature compared with label \$FT for each sentence. J&L's method was only applied to noun and pronoun. To differentiate noun and pronoun that are not comparators or features, they added the fourth label \$NEF, i.e. non-entity-feature. These labels were used as pivots together with special tokens l_i & r_j[1] (token position), #start (beginning of a sentence), and *#end* (end of a sentence) to generate sequence data, sequences with single label only and minimum support greater than 1% are retained, and then LSRs were created. When applying the learned LSRs for extraction, LSRs with higher confidence were applied first.

J&L's method have been proved effective in their experimental setups. However, it has the following weaknesses:

- The performance of J&L's method relies heavily on a set of comparative sentence indicative keywords. These keywords were manually created and they offered no guidelines to select keywords for inclusion. It is also difficult to ensure the completeness of the keyword list.
- Users can express comparative sentences or questions in many different ways. To have high recall, a large annotated training corpus is necessary. This is an expensive process.
- Example CSRs and LSRs given in Jindal & Liu (2006b) are mostly a combination of POS tags and keywords. It is a surprise that their rules achieved high precision but low recall. They attributed most errors to POS tagging errors. However, we suspect that their rules might be too specific and overfit their small training set (about 2,600 sentences). We would like to increase recall, avoid overfitting, and allow rules to include discriminative lexical tokens to retain precision.

In the next section, we introduce our method to address these shortcomings.

3 Weakly Supervised Method for Comparator Mining

Our weakly supervised method is a pattern-based approach similar to J&L's method, but it is different in many aspects: Instead of using separate CSRs and LSRs, our method aims to learn se-

[1] l_i marks a token is at the i^{th} position to the left of the pivot and r_j marks a token is at j^{th} position to the right of the pivot where i and j are between 1 and 4 in J&L (2006b).

quential patterns which can be used to identify

Sequential Patterns
<#start which city is better, $C or $C ? #end>
<, $C or $C ? #end>
<#start $C/NN or $C/NN ? #end>
<which NN is better, $C or $C ?>
<which city is JJR, $C or $C ?>
<which NN is JJR, $C or $C ?>
...

Table 1: Candidate indicative extraction pattern (IEP) examples of the question "*which city is better, NYC or Paris?*"

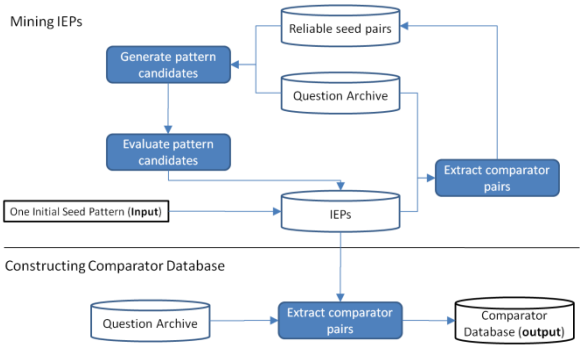

Figure 1: Overview of the bootstrapping alogorithm

comparative question and extract comparators simultaneously.

In our approach, a sequential pattern is defined as a sequence $S(s_1 s_2 \ldots s_i \ldots s_n)$ where s_i can be a word, a POS tag, or a symbol denoting either a comparator ($C), or the beginning (#start) or the end of a question (#end). A sequential pattern is called an *indicative extraction pattern* (IEP) if it can be used to identify comparative questions and extract comparators in them with high reliability. We will formally define the reliability score of a pattern in the next section.

Once a question matches an IEP, it is classified as a comparative question and the token sequences corresponding to the comparator slots in the IEP are extracted as comparators. When a question can match multiple IEPs, the longest IEP is used[2]. Therefore, instead of manually creating a list of indicative keywords, we create a set of IEPs. We will show how to acquire IEPs automatically using a bootstrapping procedure with minimum supervision by taking advantage of a large unlabeled question collection in the following subsections. The evaluations shown in section 4 confirm that our weakly supervised method can achieve high recall while retain high precision.

This pattern definition is inspired by the work of Ravichandran and Hovy (2002). Table 1 shows some examples of such sequential patterns. We also allow POS constraint on comparators as shown in the pattern "<, $C/NN or $C/NN ? #end>". It means that a valid comparator must have a NN POS tag.

3.1 Mining Indicative Extraction Patterns

Our weakly supervised IEP mining approach is based on two key assumptions:

- If a sequential pattern can be used to extract many reliable comparator pairs, it is very likely to be an IEP.
- If a comparator pair can be extracted by an IEP, the pair is *reliable*.

Based on these two assumptions, we design our bootstrapping algorithm as shown in Figure 1. The bootstrapping process starts with a single IEP. From it, we extract a set of initial seed comparator pairs. For each comparator pair, all questions containing the pair are retrieved from a question collection and regarded as comparative questions. From the comparative questions and comparator pairs, all possible sequential patterns are generated and evaluated by measuring their reliability score defined later in the Pattern Evaluation section. Patterns evaluated as reliable ones are IEPs and are added into an IEP repository.

Then, new comparator pairs are extracted from the question collection using the latest IEPs. The new comparators are added to a reliable comparator repository and used as new seeds for pattern learning in the next iteration. All questions from which reliable comparators are extracted are removed from the collection to allow finding new patterns efficiently in later iterations. The process iterates until no more new patterns can be found from the question collection.

There are two key steps in our method: (1) pattern generation and (2) pattern evaluation. In the following subsections, we will explain them in details.

Pattern Generation

To generate sequential patterns, we adapt the surface text pattern mining method introduced in (Ravichandran and Hovy, 2002). For any given comparative question and its comparator pairs, comparators in the question are replaced with symbol $Cs. Two symbols, #start and #end, are attached to the beginning and the end of a sen-

[2] It is because the longest IEP is likely to be the most specific and relevant pattern for the given question.

tence in the question. Then, the following three kinds of sequential patterns are generated from sequences of questions:

- **Lexical patterns:** Lexical patterns indicate sequential patterns consisting of only words and symbols ($C, #start, and #end). They are generated by suffix tree algorithm (Gusfield, 1997) with two constraints: A pattern should contain more than one $C, and its frequency in collection should be more than an empirically determined number β.
- **Generalized patterns:** A lexical pattern can be too specific. Thus, we generalize lexical patterns by replacing one or more words with their POS tags. $2^n - 1$ generalized patterns can be produced from a lexical pattern containing *N* words excluding *$Cs*.
- **Specialized patterns:** In some cases, a pattern can be too general. For example, although a question *"ipod or zune?"* is comparative, the pattern *"*<$C or $C>*"* is too general, and there can be many non-comparative questions matching the pattern, for instance, *"true or false?"*. For this reason, we perform pattern specialization by adding POS tags to all comparator slots. For example, from the lexical pattern "<$C or $C>" and the question "*ipod or zune?*", "<$C/NN or $C/NN?>" will be produced as a specialized pattern.

Note that generalized patterns are generated from lexical patterns and the specialized patterns are generated from the combined set of generalized patterns and lexical patterns. The final set of candidate patterns is a mixture of lexical patterns, generalized patterns and specialized patterns.

Pattern Evaluation

According to our first assumption, a reliability score $R^k(p_i)$ for a candidate pattern p_i at iteration *k* can be defined as follows:

$$R^k(p_i) = \frac{\sum_{\forall cp_j \in CP^{k-1}} N_Q(p_i \rightarrow cp_j)}{N_Q(p_i \rightarrow *)} \quad (1)$$

, where p_i can extract known reliable comparator pairs cp_j. CP^{k-1} indicates the reliable comparator pair repository accumulated until the $(k-1)th$ iteration. $N_Q(x)$ means the number of questions satisfying a condition *x*. The condition $p_i \rightarrow cp_j$ denotes that cp_j can be extracted from a question by applying pattern p_i while the condition $p_i \rightarrow *$ denotes any question containing pattern p_i.

However, Equation (1) can suffer from incomplete knowledge about reliable comparator pairs. For example, very few reliable pairs are generally discovered in early stage of bootstrapping. In this case, the value of Equation (1) might be underestimated which could affect the effectiveness of equation (1) on distinguishing IEPs from non-reliable patterns. We mitigate this problem by a lookahead procedure. Let us denote the set of candidate patterns at the iteration *k* by $\hat{P}^k$. We define the support *S* for comparator pair $\widehat{cp}_i$ which can be extracted by $\hat{P}^k$ and does not exist in the current reliable set:

$$S(\widehat{cp}_i) = N_Q(\hat{P}^k \rightarrow \widehat{cp}_i) \quad (2)$$

where $\hat{P}^k \rightarrow \widehat{cp}_i$ means that one of the patterns in $\hat{P}^k$ can extract $\widehat{cp}_i$ in certain questions. Intuitively, if $\widehat{cp}_i$ can be extracted by many candidate patterns in $\hat{P}^k$, it is likely to be extracted as a reliable one in the next iteration. Based on this intuition, a pair $\widehat{cp}_i$ whose support *S* is more than a threshold α is regarded as a *likely-reliable pair*. Using likely-reliable pairs, lookahead reliability score $\hat{R}(p_i)$ is defined:

$$\hat{R}^k(p_i) = \frac{\sum_{\forall \widehat{cp}_i \in \widehat{CP}^k_{rel}} N_Q(p_i \rightarrow \widehat{cp}_i)}{N_Q(p_i \rightarrow *)} \quad (3)$$

, where $\widehat{CP}^k_{rel}$ indicates a set of likely-reliable pairs based on $\hat{P}^k$.

By interpolating Equation (1) and (3), the final reliability score $R(p_i)^k_{final}$ for a pattern is defined as follows:

$$R(p_i)^k_{final} = \lambda \cdot R^k(p_i) + (1-\lambda) \cdot \hat{R}^k(p_i) \quad (4)$$

Using Equation (4), we evaluate all candidate patterns and select patterns whose score is more than threshold γ as IEPs. All necessary parameter values are empirically determined. We will explain how to determine our parameters in section 4.

4 Experiments

4.1 Experiment Setup

Source Data

All experiments were conducted on about 60M questions mined from Yahoo! Answers' question title field. The reason that we used only a title

field is that they clearly express a main intention of an asker with a form of simple questions in general.

Evaluation Data

Two separate data sets were created for evaluation. First, we collected 5,200 questions by sampling 200 questions from each Yahoo! Answers category[3]. Two annotators were asked to label each question manually as *comparative*, *non-comparative*, or *unknown*. Among them, 139 (2.67%) questions were classified as comparative, 4,934 (94.88%) as non-comparative, and 127 (2.44%) as unknown questions which are difficult to assess. We call this set SET-A.

Because there are only 139 comparative questions in SET-A, we created another set which contains more comparative questions. We manually constructed a keyword set consisting of 53 words such as "*or*" and "*prefer*", which are good indicators of comparative questions. In SET-A, 97.4% of comparative questions contains one or more keywords from the keyword set. We then randomly selected another 100 questions from each Yahoo! Answers category with one extra condition that all questions have to contain at least one keyword. These questions were labeled in the same way as SET-A except that their comparators were also annotated. This second set of questions is referred as SET-B. It contains 853 comparative questions and 1,747 non-comparative questions. For comparative question identification experiments, we used all labeled questions in SET-A and SET-B. For comparator extraction experiments, we used only SET-B. All the remaining unlabeled questions (called as SET-R) were used for training our weakly supervised method.

As a baseline method, we carefully implemented J&L's method. Specifically, CSRs for comparative question identification were learned from the labeled questions, and then a statistical classifier was built by using CSR rules as features. We examined both SVM and Naïve Bayes (NB) models as reported in their experiments. For the comparator extraction, LSRs were learned from SET-B and applied for comparator extraction.

To start the bootstrapping procedure, we applied the IEP *"<#start nn/$c vs/cc nn/$c ?/. #end>"* to all the questions in SET-R and gathered 12,194 comparator pairs as the initial seeds. For our weakly supervised method, there are four parameters, i.e. α, β, γ, and λ, need to be determined empirically. We first mined all possible candidate patterns from the suffix tree using the initial seeds. From these candidate patterns, we applied them to SET-R and got a new set of 59,410 candidate comparator pairs. Among these new candidate comparator pairs, we randomly selected 100 comparator pairs and manually classified them into reliable or non-reliable comparators. Then we found α that maximized precision without hurting recall by investigating frequencies of pairs in the labeled set. By this method, α was set to 3 in our experiments. Similarly, the threshold parameters β and γ for pattern evaluation were set to 10 and 0.8 respectively. For the interpolation parameter λ in Equation (3), we simply set the value to 0.5 by assuming that two reliability scores are equally important.

As evaluation measures for comparative question identification and comparator extraction, we used precision, recall, and F1-measure. All results were obtained from 5-fold cross validation. Note that J&L's method needs a training data but ours use the unlabeled data (SET-R) with weakly supervised method to find parameter setting. This 5-fold evaluation data is not in the unlabeled data. Both methods were tested on the same test split in the 5-fold cross validation. All evaluation scores are averaged across all 5 folds.

For question processing, we used our own statistical POS tagger developed in-house[4].

4.2 Experiment Results

Comparative Question Identification and Comparator Extraction

Table 2 shows our experimental results. In the table, "Identification only" indicates the performances in comparative question identification, "Extraction only" denotes the performances of comparator extraction when only comparative questions are used as input, and "All" indicates the end-to-end performances when question identification results were used in comparator extraction. Note that the results of J&L's method on our collections are very comparable to what is reported in their paper.

In terms of precision, the J&L's method is competitive to our method in comparative ques-

[3] There are 26 top level categories in Yahoo! Answers.

[4] We used NLC-PosTagger which is developed by NLC group of Microsoft Research Asia. It uses the modified Penn Treebank POS set for its output; for example, NNS (plural nouns), NN (nouns), NP (noun phrases), NPS (plural noun phrases), VBZ (verb, present tense, 3rd person singular), JJ (adjective), RB(adverb), and so on.

	Identification only (SET-A+SET-B)			Extraction only (SET-B)		All (SET-B)		
	J&L (CSR)		**Our**	J&L	**Our**	J&L		**Our**
	SVM	NB	**Method**	(LSR)	**Method**	SVM	NB	**Method**
Recall	0.601	0.537	**0.817***	0.621	**0.760***	0.373	0.363	**0.760***
Precision	0.847	**0.851**	0.833	0.861	**0.916***	0.729	0.703	**0.776***
F-score	0.704	0.659	**0.825***	0.722	**0.833***	0.493	0.479	**0.768***

Table 2: Performance comparison between our method and Jindal and Bing's Method (denoted as J&L). The values with * indicate statistically significant improvements over J&L (CSR) SVM or J&L (LSR) according to *t*-test at $p < 0.01$ level.

tion identification. However, the recall is significantly lower than ours. In terms of recall, our method outperforms J&L's method by 35% and 22% in comparative question identification and comparator extraction respectively. In our analysis, the low recall of J&L's method is mainly caused by low coverage of learned CSR patterns over the test set.

In the end-to-end experiments, our weakly supervised method performs significantly better than J&L's method. Our method is about 55% better in F1-measure. This result also highlights another advantage of our method that identifies comparative questions and extracts comparators simultaneously using one single pattern. J&L's method uses two kinds of pattern rules, i.e. CSRs and LSRs. Its performance drops significantly due to error propagations. F1-measure of J&L's method in "All" is about 30% and 32% worse than the scores of "Identification only" and "Extraction" only respectively, our method only shows small amount of performance decrease (approximately 7-8%).

We also analyzed the effect of pattern generalization and specialization. Table 3 shows the results. Despite of the simplicity of our methods, they significantly contribute to performance improvements. This result shows the importance of learning patterns flexibly to capture various comparative question expressions. Among the 6,127 learned IEPs in our database, 5,930 patterns are generalized ones, 171 are specialized ones, and only 26 patterns are non-generalized and specialized ones.

To investigate the robustness of our bootstrapping algorithm for different seed configurations, we compare the performances between two different seed IEPs. The results are shown in Table 4. As shown in the table, the performance of our bootstrapping algorithm is stable regardless of significantly different number of seed pairs generated by the two IEPs. This result implies that our bootstrapping algorithm is not sensitive to the choice of IEP.

Table 5 also shows the robustness of our bootstrapping algorithm. In Table 5, '*All'* indicates the performances that all comparator pairs from a single seed IEP is used for the bootstrapping, and 'Partial' indicate the performances using only 1,000 randomly sampled pairs from '*All'*. As shown in the table, there is no significant performance difference.

In addition, we conducted error analysis for the cases where our method fails to extract correct comparator pairs:

- 23.75% of errors on comparator extraction are due to wrong pattern selection by our simple maximum IEP length strategy.
- The remaining 67.63% of errors come from comparative questions which cannot be covered by the learned IEPs.

	Recall	Precision	F-score

Table 7: Related queries returned by Google related searches for the same target entities in Table 6. The bold ones indicate overlapped queries to the comparators in Table 6.

Examples of Comparator Extraction

By applying our bootstrapping method to the entire source data (60M questions), 328,364 unique comparator pairs were extracted from 679,909 automatically identified comparative questions.

Table 6 lists top 10 frequently compared entities for a target item, such as *Chanel*, *Gap*, in our question archive. As shown in the table, our comparator mining method successfully discovers realistic comparators. For example, for '*Chanel'*, most results are high-end fashion brands such as '*Dior'* or '*Louis Vuitton'*, while the ranking results for '*Gap'* usually contains similar apparel brands for young people, such as '*Old Navy'* or '*Banana Republic'*. For the basketball player '*Kobe*', most of the top ranked comparators are also famous basketball players. Some interesting comparators are shown for '*Canon*' (the company name). It is famous for different kinds of its products, for example, digital cameras and printers, so it can be compared to different kinds of companies. For example, it is compared to '*HP'*, '*Lexmark'*, or '*Xerox',* the printer manufacturers, and also compared to '*Nikon'*, '*Sony'*, or '*Kodak',* the digital camera manufactures. Besides general entities such as a brand or company name, our method also found an interesting comparable entity for a specific item in the experiments. For example, our method recommends '*Nikon d40i*', '*Canon rebel xti*', '*Canon rebel xt*', '*Nikon d3000*', '*Pentax k100d*', '*Canon eos 1000d*' as comparators for the specific camera product '*Nikon 40d*'.

Table 7 can show the difference between our comparator mining and query/item recommendation. As shown in the table, 'Google related searches' generally suggests a mixed set of two kinds of related queries for a target entity: (1) queries specified with subtopics for an original query (e.g., '*Chanel handbag*' for '*Chanel*') and (2) its comparable entities (e.g., '*Dior*' for '*Chanel*'). It confirms one of our claims that comparator mining and query/item recommendation are related but not the same.

5 Conclusion

In this paper, we present a novel weakly supervised method to identify comparative questions and extract comparator pairs simultaneously. We rely on the key insight that a good comparative question identification pattern should extract good comparators, and a good comparator pair should occur in good comparative questions to bootstrap the extraction and identification process. By leveraging large amount of unlabeled data and the bootstrapping process with slight supervision to determine four parameters, we found 328,364 unique comparator pairs and 6,869 extraction patterns without the need of creating a set of comparative question indicator keywords.

The experimental results show that our method is effective in both comparative question identification and comparator extraction. It sig-

nificantly improves recall in both tasks while maintains high precision. Our examples show that these comparator pairs reflect what users are really interested in comparing.

Our comparator mining results can be used for a commerce search or product recommendation system. For example, automatic suggestion of comparable entities can assist users in their comparison activities before making their purchase decisions. Also, our results can provide useful information to companies which want to identify their competitors.

In the future, we would like to improve extraction pattern application and mine rare extraction patterns. How to identify comparator aliases such as '*LV'* and '*Louis Vuitton*' and how to separate ambiguous entities such "*Paris vs. London*" as location and "*Paris vs. Nicole*" as celebrity are all interesting research topics. We also plan to develop methods to summarize answers pooled by a given comparator pair.

Towards robust multi-tool tagging. An OWL/DL-based approach

Christian Chiarcos
University of Potsdam, Germany
chiarcos@uni-potsdam.de

Abstract

This paper describes a series of experiments to test the hypothesis that the parallel application of multiple NLP tools and the integration of their results improves the correctness and robustness of the resulting analysis.

It is shown how annotations created by seven NLP tools are mapped onto tool-independent descriptions that are defined with reference to an ontology of linguistic annotations, and how a majority vote and ontological consistency constraints can be used to integrate multiple alternative analyses of the same token in a consistent way.

For morphosyntactic (parts of speech) and morphological annotations of three German corpora, the resulting merged sets of ontological descriptions are evaluated in comparison to (ontological representation of) existing reference annotations.

1 Motivation and overview

NLP systems for higher-level operations or complex annotations often integrate redundant modules that provide alternative analyses for the same linguistic phenomenon in order to benefit from their respective strengths and to compensate for their respective weaknesses, e.g., in parsing (Crysmann et al., 2002), or in machine translation (Carl et al., 2000). The current trend to parallel and distributed NLP architectures (Aschenbrenner et al., 2006; Gietz et al., 2006; Egner et al., 2007; Luís and de Matos, 2009) opens the possibility of exploring the potential of redundant parallel annotations also for lower levels of linguistic analysis.

This paper evaluates the potential benefits of such an approach with respect to morphosyntax (parts of speech, pos) and morphology in German: In comparison to English, German shows a rich and polysemous morphology, and a considerable number of NLP tools are available, making it a promising candidate for such an experiment.

Previous research indicates that the integration of multiple part of speech taggers leads to more accurate analyses. So far, however, this line of research focused on tools that were trained on the same corpus (Brill and Wu, 1998; Halteren et al., 2001), or that specialize to different subsets of the same tagset (Zavrel and Daelemans, 2000; Tufiş, 2000; Borin, 2000). An even more substantial increase in accuracy and detail can be expected if tools are combined that make use of different annotation schemes.

For this task, ontologies of linguistic annotations are employed to assess the linguistic information conveyed in a particular annotation and to integrate the resulting ontological descriptions in a consistent and tool-independent way. The merged set of ontological descriptions is then evaluated with reference to morphosyntactic and morphological annotations of three corpora of German newspaper articles, the NEGRA corpus (Skut et al., 1998), the TIGER corpus (Brants et al., 2002) and the Potsdam Commentary Corpus (Stede, 2004, PCC).

2 Ontologies and annotations

Various repositories of linguistic annotation terminology have been developed in the last decades, ranging from early texts on annotation standards (Bakker et al., 1993; Leech and Wilson, 1996) over relational data base models (Bickel and Nichols, 2000; Bickel and Nichols, 2002) to more recent formalizations in OWL/RDF (or with OWL/RDF export), e.g., the General Ontology of Linguistic Description (Farrar and Langendoen, 2003, GOLD), the ISO TC37/SC4 Data Category Registry (Ide and Romary, 2004; Kemps-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 659–670,
Uppsala, Sweden, 11-16 July 2010.

Snijders et al., 2009, DCR), the OntoTag ontology (Aguado de Cea et al., 2002), or the Typological Database System ontology (Saulwick et al., 2005, TDS). Despite their common level of representation, however, these efforts have not yet converged into a unified and generally accepted ontology of linguistic annotation terminology, but rather, different resources are maintained by different communities, so that a considerable amount of disagreement between them and their respective definitions can be observed.[1]

Such conceptual mismatches and incompatibilities between existing terminological repositories have been the motivation to develop the OLiA architecture (Chiarcos, 2008) that employs a shallow Reference Model to mediate between (ontological models of) annotation schemes and several existing terminology repositories, incl. GOLD, the DCR, and OntoTag. When an annotation receives a representation in the OLiA Reference Model, it is thus also interpretable with respect to other linguistic ontologies. Therefore, the findings for the OLiA Reference Model in the experiments described below entail similar results for an application of GOLD or the DCR to the same task.

2.1 The OLiA ontologies

The Ontologies of Linguistic Annotations – briefly, OLiA ontologies (Chiarcos, 2008) – represent an architecture of modular OWL/DL ontologies that formalize several intermediate steps of the mapping between concrete annotations, a Reference Model and existing terminology repositories ('External Reference Models' in OLiA terminology) such as the DCR.[2]

The OLiA ontologies were originally developed as part of an infrastructure for the sustainable maintenance of linguistic resources (Schmidt et al., 2006) where they were originally applied to the formal representation and documentation of annotation schemes, and for concept-based annotation queries over to multiple, heterogeneous corpora annotated with different annotation schemes (Rehm et al., 2007; Chiarcos et al., 2008). NLP applications of the OLiA ontologies include a proposal to integrate them with the OntoTag ontologies and to use them for interface specifications between modules in NLP pipeline architectures (Buyko et al., 2008). Further, Hellmann (2010) described the application of the OLiA ontologies within NLP2RDF, an OWL-based blackboard approach to assess the meaning of text from grammatical analyses and subsequent enrichment with ontological knowledge sources.

OLiA distinguishes three different classes of ontologies:

- The OLiA REFERENCE MODEL specifies the common terminology that different annotation schemes can refer to. It is primarily based on a blend of concepts of EAGLES and GOLD, and further extended in accordance with different annotation schemes, with the TDS ontology and with the DCR (Chiarcos, 2010).
- Multiple OLiA ANNOTATION MODELs formalize annotation schemes and tag sets. Annotation Models are based on the original documentation and data samples, so that they provide an authentic representation of the annotation not biased with respect to any particular interpretation.
- For every Annotation Model, a LINKING MODEL defines `subClassOf` ($\sqsubseteq$) relationships between concepts/properties in the respective Annotation Model and the Reference Model. Linking Models are interpretations of Annotation Model concepts and properties in terms of the Reference Model, and thus multiple alternative Linking Models for the same Annotation Model are possible. Other Linking Models specify $\sqsubseteq$ relationships between Reference Model concepts/properties and concepts/properties of an External Reference Model such as GOLD or the DCR.

The OLiA Reference Model (namespace `olia`) specifies concepts that describe linguistic categories (e.g., `olia:Determiner`) and grammatical features (e.g., `olia:Accusative`), as well

[1] As one example, a GOLD Numeral is a Determiner (Numeral $\sqsubseteq$ Quantifier $\sqsubseteq$ Determiner, `http://linguistics-ontology.org/gold/2008/Numeral`), whereas a DCR Numeral is defined on the basis of its semantic function, without any references to syntactic categories (`http://www.isocat.org/datcat/DC-1334`). Thus, *two* in *two of them* is a DCR Numeral but not a GOLD Numeral.

[2] The OLiA Reference Model is accessible via `http://nachhalt.sfb632.uni-potsdam.de/owl/olia.owl`. Several annotation models, e.g., `stts.owl`, `tiger.owl`, `connexor.owl`, `morphisto.owl` can be found in the same directory together with the corresponding linking files `stts-link.rdf`, `tiger-link.rdf`, `connexor-link.rdf` and `morphisto-link.rdf`.

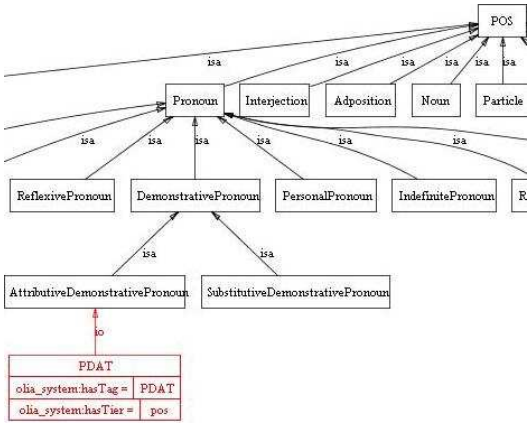

Figure 1: Attributive demonstrative pronouns (`PDAT`) in the STTS Annotation Model

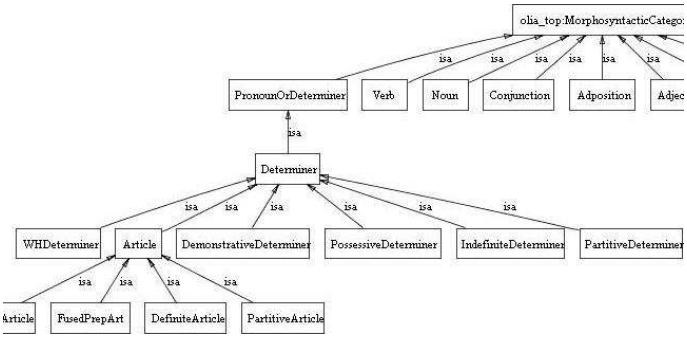

Figure 2: Selected morphosyntactic categories in the OLiA Reference Model

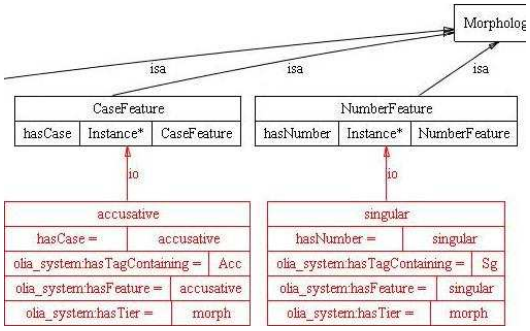

Figure 3: Individuals for accusative and singular in the TIGER Annotation Model

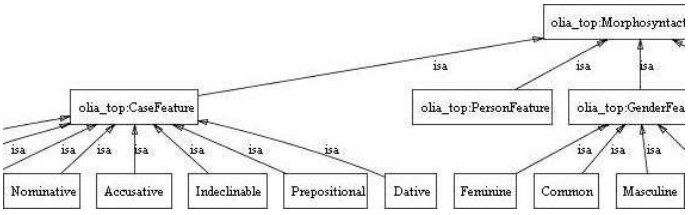

Figure 4: Selected morphological features in the OLiA Reference Model

as properties that define possible relations between those (e.g., `olia:hasCase`). More general concepts that represent organizational information rather than possible annotations (e.g., `MorphosyntacticCategory` and `CaseFeature`) are stored in a separate ontology (namespace `olia_top`).

The Reference Model is a shallow ontology: It does not specify disjointness conditions of concepts and cardinality or domain restrictions of properties. Instead, it assumes that such constraints are inherited by means of $\sqsubseteq$ relationships from an External Reference Model. Different External Reference Models may take different positions on the issue – as languages do[3] –, so that this aspect is left underspecified in the Reference Model.

Figs. 2 and 4 show excerpts of category and feature hierarchies in the Reference Model.

With respect to morphosyntactic annotations (parts of speech, `pos`) and morphological annotations (`morph`), five Annotation Models for German are currently available: STTS (Schiller et al., 1999, `pos`), TIGER (Brants and Hansen, 2002, `morph`), Morphisto (Zielinski and Simon, 2008, `pos, morph`), RFTagger (Schmid and Laws, 2008, `pos, morph`), Connexor (Tapanainen and Järvinen, 1997, `pos, morph`). Further Annotation Models for `pos` and `morph` cover five different annotation schemes for English (Marcus et al., 1994; Sampson, 1995; Mandel, 2006; Kim et al., 2003, Connexor), two annotation schemes for Russian (Meyer, 2003; Sharoff et al., 2008), an annotation scheme designed for typological research and currently applied to approx. 30 different languages (Dipper et al., 2007), an annotation scheme for Old High German (Petrova et al., 2009), and an annotation scheme for Tibetan (Wagner and Zeisler, 2004).

[3]Based on primary experience with Western European languages, for example, one might assume that a `hasGender` property applies to nouns, adjectives, pronouns and determiners only. Yet, this is language-specific restriction: Russian finite verbs, for example, show gender congruency in past tense.

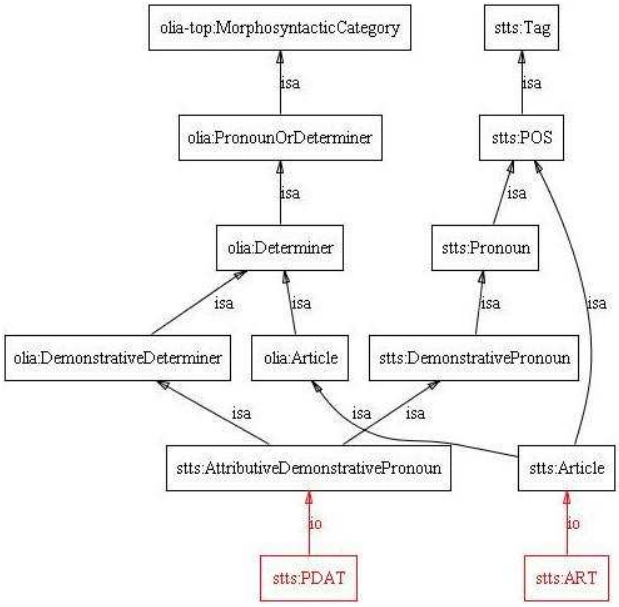

Figure 5: The STTS tags `PDAT` and `ART`, their representation in the Annotation Model and linking with the Reference Model.

Annotation Models differ from the Reference Model mostly in that they include not only concepts and properties, but also individuals: Annotation Model concepts reflect an abstract conceptual categorization, whereas individuals represent concrete values used to annotate the corresponding phenomenon. An individual is applicable to all annotations that match the string value specified by this individual's `hasTag`, `hasTagContaining`, `hasTagStartingWith`, or `hasTagEndingWith` properties. Fig. 1 illustrates the structure of the STTS Annotation Model (namespace `stts`) for the individual `stts:PDAT` that represents the tag used for attributive demonstrative pronouns (demonstrative determiners). Fig. 3 illustrates the individuals `tiger:accusative` and `tiger:singular` from the hierarchy of morphological features in the TIGER Annotation Model (namespace `tiger`).

Fig. 5 illustrates the linking between the STTS Annotation Model and the OLiA Reference Model for the individuals `stts:PDAT` and `stts:ART`.

2.2 Integrating different morphosyntactic and morphological analyses

With the OLiA ontologies as described above, annotations from different annotation schemes can now be interpreted in terms of the OLiA Reference Model (or External Reference Models like GOLD or the DCR).

As an example, consider the attributive demonstrative pronoun *diese* in (1).

(1)

Diese	nicht	neue	Erkenntnis	konnte
this	not	new	insight	could
der	Markt	der	Möglichkeiten	am
the	market	of.the	possibilities	on.the
Sonnabend	in	Treuenbrietzen	bestens	
Saturday	in	Treuenbrietzen	in.the.best.way	
unterstreichen	.			
underline				

'The 'Market of Possibilities', held this Saturday in Treuenbrietzen, provided best evidence for this well-known (lit. 'not new') insight.' (PCC, #4794)

The phrase *diese nicht neue Erkenntnis* poses two challenges. First, it has to be recognized that the demonstrative pronoun is attributive, although it is separated from adjective and noun by *nicht* 'not'. Second, the phrase is in accusative case, although the morphology is ambiguous between accusative and nominative, and nominative case would be expected for a sentence-initial NP.

The Connexor analysis (Tapanainen and Järvinen, 1997) actually fails in both aspects (2).

(2) `PRON Dem FEM SG NOM` (Connexor)

The ontological analysis of this annotation begins by identifying the set of individuals from the Connexor Annotation Model that match it according to their `hasTag` (etc.) properties. The RDF triplet `connexor:NOM connexor:hasTagContaining 'NOM'`[4] indicates that the tag is an application of the individual `connexor:NOM`, an instance of `connexor:Case`. Further, the annotation matches `connexor:PRON` (an instance of `connexor:Pronoun`), etc. The result is a set of individuals that express different aspects of the meaning of the annotation.

For these individuals, the Annotation Model specifies superclasses (`rdf:type`) and other properties, i.e., `connexor:NOM connexor:hasCase connexor:NOM`, etc. The linguistic unit represented by the actual token can now be characterized by these properties: Every property applicable to a member in the individual set is assumed to be applicable to the linguistic unit as well. In order to save space, we use a notation closer to predicate logic (with the token as implicit subject). In terms of the Annotation Model, the token *diese* is thus described by the following descriptions:

[4]RDF triplets are quoted in simplified form, with XML namespaces replacing the actual URIs.

(3) `rdf:type(connexor:Pronoun)`
`connexor:hasCase(connexor:NOM) ...`

The Linking Model `connexor-link.rdf` provides us with the information that (i) `connexor:Pronoun` is a subclass of the Reference Model concept `olia:Pronoun`, (ii) `connexor:NOM` is an instance of the Reference Model concept `olia:Nominative`, and (iii) `olia:hasCase` is a subproperty of `olia:hasCase`.

Accordingly, the predicates that describe the token *diese* can be reformulated in terms of the Reference Model. `rdf:type(connexor:Pronoun)` entails `rdf:type(olia:Pronoun)`, etc. Similarly, we know that for some i:`olia:Nominative` it is true that `olia:hasCase(`i`)`, abbreviated here as `olia:hasCase(some olia:Nominative)`.

In this way, the grammatical information conveyed in the original Connexor annotation can be represented in an annotation-independent and tagset-neutral way as shown for the Connexor analysis in (4).

(4) `rdf:type(olia:PronounOrDeterminer)`
`rdf:type(olia:Pronoun)`
`olia:hasNumber(some olia:Singular)`
`olia:hasGender(some olia:Feminine)`
`rdf:type(olia:DemonstrativePronoun)`
`olia:hasCase(some olia:Nominative)`

Analogously, the corresponding RFTagger analysis (Schmid and Laws, 2008) given in (5) can be transformed into a description in terms of the OLiA Reference Model such as in (6).

(5) `PRO.Dem.Attr.-3.Acc.Sg.Fem` (RFTagger)

(6) `rdf:type(olia:PronounOrDeterminer)`
`olia:hasNumber(some olia:Singular)`
`olia:hasGender(some olia:Feminine)`
`olia:hasCase(some olia:Accusative)`
`rdf:type(olia:DemonstrativeDeterminer)`
`rdf:type(olia:Determiner)`

For every description obtained from these (and further) analyses, an integrated and consistent generalization can be established as described in the following section.

3 Processing linguistic annotations

3.1 Evaluation setup

Fig. 6 sketches the architecture of the evaluation environment set up for this study.[5] The input to the system is a set of documents with

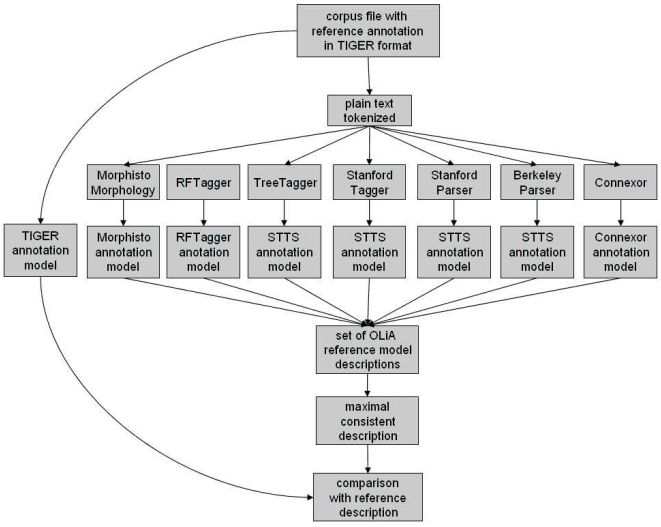

Figure 6: Evaluation setup

TIGER/NEGRA-style morphosyntactic or morphological annotation (Skut et al., 1998; Brants and Hansen, 2002) whose annotations are used as gold standard.

From the annotated document, the plain tokenized text is extracted and analyzed by one or more of the following NLP tools:

(i) Morphisto, a morphological analyzer without contextual disambiguation (Zielinski and Simon, 2008),

(ii) two part of speech taggers: the TreeTagger (Schmid, 1994) and the Stanford Tagger (Toutanova et al., 2003),

(iii) the RFTagger that performs part of speech and morphological analysis (Schmid and Laws, 2008),

(iv) two PCFG parsers: the StanfordParser (Klein and Manning, 2003) and the BerkeleyParser (Petrov and Klein, 2007), and

(v) the Connexor dependency parser (Tapanainen and Järvinen, 1997).

These tools annotate parts of speech, and those in (i), (iii) and (v) also provide morphological features. All components ran in parallel threads on the same machine, with the exception of Morphisto that was addressed as a web service. The set of matching Annotation Model individuals for every annotation and the respective set of Reference Model descriptions are determined by means of

[5] The code used for the evaluation setup is available under `http://multiparse.sourceforge.net`.

OLiA description	$\sum$	Morphisto	Connexor	RF Tagger	Tree Tagger	Stanford Tagger	Stanford Parser	Berkeley Parser
word class `type(...)`								
`PronounOrDeterminer`	7	1(4/4)*	1	1	1	1	1	1
`Determiner`	5.5	0.5**	0	1	1	1	1	1
`DemonstrativeDeterminer`	5.5	0.5**	0	1	1	1	1	1
`Pronoun`	1.5	0.5**	1	0	0	0	0	0
`DemonstrativePronoun`	1.5	0.5**	1	0	0	0	0	0
morphology `hasXY(...)`					n/a	n/a	n/a	n/a
`hasNumber(some Singular)`	2.5	0.5 (2/4)	1	1				
`hasGender(some Feminine)`	2.5	0.5 (2/4)	1	1				
`hasCase(some Accusative)`	1.5	0.5 (2/4)	0	1				
`hasCase(some Nominative)`	1.5	0.5 (2/4)	1	0				
`hasNumber(some Plural)`	0.5	0.5 (2/4)	0	0				

* Morphisto produces four alternative candidate analyses for this example, so every alternative analysis receives the confidence score 0.25

** Morphisto does not distinguish attributive and substitutive pronouns, it predicts `type(Determiner ⊔ Pronoun)`

Table 1: Confidence scores for *diese* in ex. (1)

the Pellet reasoner (Sirin et al., 2007) as described above.

A disambiguation routine (see below) then determines the maximal consistent set of ontological descriptions. Finally, the outcome of this process is compared to the set of descriptions corresponding to the original annotation in the corpus.

3.2 Disambiguation

Returning to examples (4) and (6) above, we see that the resulting set of descriptions conveys properties that are obviously contradicting, e.g., `hasCase(some Nominative)` besides `hasCase(some Accusative)`.

Our approach to disambiguation combines ontological consistency criteria with a confidence ranking. As we simulate an uninformed approach, the confidence ranking follows a majority vote.

For *diese* in (1), the consultation of all seven tools results a confidence ranking as shown in Tab. 1: If a tool supports a description with its analysis, the confidence score is increased by 1 (or by $1/n$ if the tool proposes n alternative annotations). A maximal consistent set of descriptions is then established as follows:

(i) Given a confidence-ranked list of available descriptions $S = (s_1, ..., s_n)$ and a result set $T = \emptyset$.

(ii) Let s_1 be the first element of $S = (s_1, ..., s_n)$.

(iii) If s_1 is consistent with every description $t \in T$, then add s_1 to T: $T := T \cup \{s_1\}$

(iv) Remove s_1 from S and iterate in (ii) until S is empty.

The consistency of ontological descriptions is defined here as follows:[6]

- Two concepts A and B are consistent iff

  $$A \equiv B \text{ or } A \sqsubseteq B \text{ or } B \sqsubseteq A$$

  Otherwise, A and B are disjoint.

- Two descriptions $pred_1(A)$ and $pred_2(B)$ are consistent iff

  A and B are consistent or
  $pred_1$ is neither a subproperty
  nor a superproperty of $pred_2$

This heuristic formalizes an implicit disjointness assumption for all concepts in the ontology (all concepts are disjoint unless one is a subconcept of the other). Further, it imposes an implicit cardinality constraint on properties (e.g., `hasCase(some Accusative)` and `hasCase(some Nominative)` are inconsistent because `Accusative` and `Nominative` are sibling concepts and thus disjoint).

For the example *diese*, the descriptions `type(Pronoun)` and `type(DemonstrativePronoun)` are inconsistent with `type(Determiner)`, and `hasNumber(some Plural)` is inconsistent with `hasNumber(some Singular)` (Figs. 2 and 4); these descriptions are thus ruled out. The `hasCase` descriptions have identical confidence scores, so that the first `hasCase` description that the algorithm encounters is chosen for the set of resulting descriptions, the other one is ruled out because of their inconsistency.

[6]The OLiA Reference Model does not specify disjointness constraints, and neither do GOLD or the DCR as External Reference Models. The axioms of the OntoTag ontologies, however, are specific to Spanish and cannot be directly applied to German.

	PCC	TIGER	NEGRA
best-performing tool (StanfordTagger)

M+R	.769	.737
C+R	.773	.753
all tools	.791	.770

Table 3: Recall for morphological `hasXY()` descriptions

The resulting, maximal consistent set of descriptions is then compared with the ontological descriptions that correspond to the original annotation in the corpus.

4 Evaluation

Six experiments were conducted with the goal to evaluate the prediction of word classes and morphological features on parts of three corpora of German newspaper articles: NEGRA (Skut et al., 1998), TIGER (Brants et al., 2002), and the Potsdam Commentary Corpus (Stede, 2004, PCC). From every corpus 10,000 tokens were considered for the analysis.

TIGER and NEGRA are well-known resources that also influenced the design of several of the tools considered. For this reason, the PCC was consulted, a small collection of newspaper commentaries, 30,000 tokens in total, annotated with TIGER-style parts of speech and syntax (by members of the TIGER project). None of the tools considered here were trained on this data, so that it provides independent test data.

The ontological descriptions were evaluated for recall:[7]

$$(7)\quad recall(T) = \frac{\sum_{i=1}^{n} |D_{predicted}(t_i) \cap D_{target}(t_i)|}{\sum_{i=1}^{n} |D_{target}(t_i)|}$$

In (7), T is a text (a list of tokens) with $T = (t_1, ..., t_n)$, $D_{predicted}(t)$ are descriptions retrieved from the NLP analyses of the token t, and $D_{target}(t)$ is the set of descriptions that correspond to the original annotation of t in the corpus.

[7] Precision and accuracy may not be appropriate measurements in this case: Annotation schemes differ in their expressiveness, so that a description predicted by an NLP tool but not found in the reference annotation may nevertheless be correct. The RFTagger, for example, assigns demonstrative pronouns the feature '3rd person', that is not found in TIGER/NEGRA-style annotation because of its redundancy.

4.1 Word classes

Table 2 shows that the recall of `rdf:type` descriptions (for word classes) increases continuously with the number of NLP tools applied. The combination of all seven tools actually shows a better recall than the best-performing single NLP tool. (The NEGRA corpus is an apparent exception only; the exceptionally high recall of the Stanford Tagger reflects the fact that it was trained on NEGRA.)

A particularly high increase in recall occurs when tools are combined that compensate for their respective deficits. Morphisto, for example, generates alternative morphological analyses, so that the disambiguation algorithm performs a random choice between these. Morphisto has thus the worst recall among all tools considered (PCC .69, TIGER .65, NEGRA .70 for word classes). As compared to this, Connexor performs a contextual disambiguation; its recall is, however, limited by its coarse-grained word classes (PCC .73, TIGER .72, NEGRA .73). The combination of both tools yields a more detailed and context-sensitive analysis and thus results in a boost in recall by more than 13% (PCC .87, TIGER .86, NEGRA .86).

4.2 Morphological features

For morphological features, Tab. 3 shows the same tendencies that were also observed for word classes: The more tools are combined, the greater the recall of the generated descriptions, and the recall of combined tools often outperforms the recall of individual tools.

The three tools that provide morphological annotations (Morphisto, Connexor, RFTagger) were evaluated against 10,000 tokens from TIGER and NEGRA respectively. The best-performing tool was the RFTagger, which possibly reflects the fact

that it was trained on TIGER-style annotations, whereas Morphisto and Connexor were developed on the basis of independent resources and thus differ from the reference annotation in their respective degree of granularity.

5 Summary and Discussion

With the ontology-based approach described in this paper, the performance of annotation tools can be evaluated on a conceptual basis rather than by means of a string comparison with target annotations. A formal model of linguistic concepts is extensible, finer-grained and, thus, potentially more adequate for the integration of linguistic annotations than string-based representations, especially for heterogeneous annotations, if the tagsets involved are structured according to different design principles (e.g., due to different terminological traditions, different communities involved, etc.).

It has been shown that by **abstracting from tool-specific representations** of linguistic annotations, annotations from different tagsets can be represented with reference to the OLiA ontologies (and/or with other OWL/RDF-based terminology repositories linked as External Reference Models). In particular, it is possible to compare an existing reference annotation with annotations produced by NLP tools that use independently developed and differently structured annotation schemes (such as Connexor vs. RFTagger vs. Morphisto).

Further, an algorithm for the **integration of different annotations** has been proposed that makes use of a majority-based confidence ranking and ontological consistency conditions. As consistency conditions are not formally defined in the OLiA Reference Model (which is expected to inherit such constraints from External Reference Models), a heuristic, structure-based definition of consistency was applied.

This heuristic consistency definition is overly rigid and rules out a number of consistent alternative analyses, as it is the case for overlapping categories.[8] Despite this rigidity, we witness an **increase of recall** when multiple alternative analyses are integrated. This increase of recall may result from a compensation of tool-specific deficits, e.g., with respect to annotation granularity. Also, the improved recall can be explained by a compensation of overfitting, or deficits that are inherent to a particular approach (e.g., differences in the coverage of the linguistic context).

It can thus be stated that the integration of multiple alternative analyses has the potential to produce linguistic analyses that are both more robust and more detailed than those of the original tools.

The primary field of application of this approach is most likely to be seen in a context where applications are designed that make direct use of OWL/RDF representations as described, for example, by Hellmann (2010). It is, however, also possible to use ontological representations to bootstrap novel and more detailed annotation schemes, cf. Zavrel and Daelemans (2000). Further, the conversion from string-based representations to ontological descriptions is reversible, so that results of ontology-based disambiguation and validation can also be reintegrated with the original annotation scheme. The idea of such a reversion algorithm was sketched by Buyko et al. (2008) where the OLiA ontologies were suggested as a means to translate between different annotation schemes.[9]

6 Extensions and Related Research

Natural extensions of the approach described in this paper include:

(i) Experiments with formally defined consistency conditions (e.g., with respect to restrictions on the domain of properties).

(ii) Context-sensitive disambiguation of morphological features (e.g., by combination with a chunker and adjustment of confidence scores for morphological features over all tokens in the current chunk, cf. Kermes and Evert, 2002).

(iii) Replacement of majority vote by more elaborate strategies to merge grammatical analyses.

[8] Preposition-determiner compounds like German *am* 'on the', for example, are both prepositions and determiners.

[9] The mapping from ontological descriptions to tags of a particular scheme is possible, but neither trivial nor necessarily lossless: Information of ontological descriptions that cannot be expressed in the annotation scheme under consideration (e.g., the distinction between attributive and substitutive pronouns in the Morphisto scheme) will be missing in the resulting string representation. For complex annotations, where ontological descriptions correspond to different substrings, an additional 'tag grammar' may be necessary to determine the appropriate ordering of substrings according to the annotation scheme (e.g., in the Connexor analysis).

(iv) Application of the algorithm for the ontological processing of node labels and edge labels in syntax annotations.

(v) Integration with other ontological knowledge sources in order to improve the recall of morphosyntactic and morphological analyses (e.g., for disambiguating grammatical case).

Extensions (iii) and (iv) are currently pursued in an ongoing research effort described by Chiarcos et al. (2010). Like morphosyntactic and morphological features, node and edge labels of syntactic trees are ontologically represented in several Annotation Models, the OLiA Reference Model, and External Reference Models, the merging algorithm as described above can thus be applied for syntax, as well. Syntactic annotations, however, involve the additional challenge to align different structures before node and edge labels can be addressed, an issue not further discussed here for reasons of space limitations.

Alternative strategies to merge grammatical analyses may include alternative voting strategies as discussed in literature on classifier combination, e.g., weighted majority vote, pairwise voting (Halteren et al., 1998), credibility profiles (Tufiş, 2000), or hand-crafted rules (Borin, 2000). A novel feature of our approach as compared to existing applications of these methods is that confidence scores are not attached to plain strings, but to ontological descriptions: Tufiş, for example, assigned confidence scores not to tools (as in a weighted majority vote), but rather, assessed the 'credibility' of a tool *with respect to the predicted tag*. If this approach is applied to ontological descriptions in place of tags, it allows us to consider the credibility of pieces of information regardless of the actual string representation of tags. For example, the credibility of `hasCase` descriptions can be assessed independently from the credibility of `hasGender` descriptions even if the original annotation merged both aspects in one single tag (as the RFTagger does, for example, cf. ex. 5).

Extension (v) has been addressed in previous research, although mostly with the opposite perspective: Already Cimiano and Reyle (2003) noted that the integration of grammatical and semantic analyses may be used to resolve ambiguity and underspecifications, and this insight has also motivated the ontological representation of linguistic resources such as WordNet (Gangemi et al., 2003), FrameNet (Scheffczyk et al., 2006), the linking of corpora with such ontologies (Hovy et al., 2006), the modelling of entire corpora in OWL/DL (Burchardt et al., 2008), and the extension of existing ontologies with ontological representations of selected linguistic features (Buitelaar et al., 2006; Davis et al., 2008).

Aguado de Cea et al. (2004) sketched an architecture for the closer ontology-based integration of grammatical and semantic information using OntoTag and several NLP tools for Spanish. Aguado de Cea et al. (2008) evaluate the benefits of this approach for the Spanish particle *se*, and conclude for this example that the combination of multiple tools yields more detailed and more accurate linguistic analyses of particularly problematic, polysemous function words. A similar increase in accuracy has also been repeatedly reported for ensemble combination approaches, that are, however, limited to tools that produce annotations according to the *same* tagset (Brill and Wu, 1998; Halteren et al., 2001).

These observations provide further support for our conclusion that the ontology-based integration of morphosyntactic analyses enhances both the robustness and the level of detail of morphosyntactic and morphological analyses. Our approach extends the philosophy of ensemble combination approaches to NLP tools that do not only employ different strategies and philosophies, but also different annotation schemes.

Acknowledgements

From 2005 to 2008, the research on linguistic ontologies described in this paper was funded by the German Research Foundation (DFG) in the context of the Collaborative Research Center (SFB) 441 "Linguistic Data Structures", Project C2 "Sustainability of Linguistic Resources" (University of Tübingen), and since 2007 in the context of the SFB 632 "Information Structure", Project D1 "Linguistic Database" (University of Potsdam). The author would also like to thank Julia Ritz, Angela Lahee, Olga Chiarcos and three anonymous reviewers for helpful hints and comments.

Temporal information processing of a new language: fast porting with minimal resources

Francisco Costa and **António Branco**
Universidade de Lisboa

Abstract

We describe the semi-automatic adaptation of a TimeML annotated corpus from English to Portuguese, a language for which TimeML annotated data was not available yet. In order to validate this adaptation, we use the obtained data to replicate some results in the literature that used the original English data. The fact that comparable results are obtained indicates that our approach can be used successfully to rapidly create semantically annotated resources for new languages.

1 Introduction

Temporal information processing is a topic of natural language processing boosted by recent evaluation campaigns like TERN2004,[1] TempEval-1 (Verhagen et al., 2007) and the forthcoming TempEval-2[2] (Pustejovsky and Verhagen, 2009). For instance, in the TempEval-1 competition, three tasks were proposed: a) identifying the temporal relation (such as *overlap*, *before* or *after*) holding between events and temporal entities such as dates, times and temporal durations denoted by expressions (i.e. temporal expressions) occurring in the same sentence; b) identifying the temporal relation holding between events expressed in a document and its creation time; c) identifying the temporal relation between the main events expressed by two adjacent sentences.

Supervised machine learning approaches are pervasive in the tasks of temporal information processing. Even when the best performing systems in these competitions are symbolic, there are machine learning solutions with results close to their performance. In TempEval-1, where there were statistical and rule-based systems, almost all systems achieved quite similar results. In the TERN2004 competition (aimed at identifying and normalizing temporal expressions), a symbolic system performed best, but since then machine learning solutions, such as (Ahn et al., 2007), have appeared that obtain similar results.

These evaluations made available sets of annotated data for English and other languages, used for training and evaluation. One natural question to ask is whether it is feasible to adapt the training and test data made available in these competitions to other languages, for which no such data still exist. Since the annotations are largely of a semantic nature, not many changes need to be done in the annotations once the textual material is translated. In essence, this would be a fast way to create temporal information processing systems for languages for which there are no annotated data yet.

In this paper, we report on an experiment that consisted in adapting the English data of TempEval-1 to Portuguese. The results of machine learning algorithms over the data thus obtained are compared to those reported for the English TempEval-1 competition. Since the results are quite similar, this permits to conclude that such an approach can rapidly generate relevant and comparable data and is useful when porting temporal information processing solutions to new languages.

The advantages of adapting an existing corpus instead of annotating text from scratch are: i) potentially less time consuming, if it is faster to translate the original text than it is to annotate new text (this can be the case if the annotations are semantic and complex); b) the annotations can be transposed without substantial modifications, which is the case if they are semantic in nature; c) less man power required: text annotation requires multiple annotators in order to guarantee the quality of the annotation tags, translation of the markables and transposition of the annotations

in principle do not; d) the data obtained are comparable to the original data in all respects except for language: genre, domain, size, style, annotation decisions, etc., which allows for research to be conducted with a derived corpus that is comparable to research using the original corpus. There is of course the caveat that the adaptation process can introduce errors.

This paper proceeds as follows. In Section 2, we provide a quick overview of the TimeML annotations in the TempEval-1 data. In Section 3, it is described how the data were adapted to Portuguese. Section 4 contains a brief quantitative comparison of the two corpora. In Section 5, the results of replicating one of the approaches present in the TempEval-1 challenge with the Portuguese data are presented. We conclude this paper in Section 6.

2 Brief Description of the Annotations

Figure 1 contains an example of a document from the TempEval-1 corpus, which is similar to the TimeBank corpus (Pustejovsky et al., 2003).

In this corpus, event terms are tagged with `<EVENT>`. The relevant attributes are `tense`, `aspect`, `class`, `polarity`, `pos`, `stem`. The `stem` is the term's lemma, and `pos` is its part-of-speech. Grammatical tense and aspect are encoded in the features `tense` and `aspect`. The attribute `polarity` takes the value `NEG` if the event term is in a negative syntactic context, and `POS` otherwise. The attribute `class` contains several levels of information. It makes a distinction between terms that denote actions of speaking, which take the value `REPORTING` and those that do not. For these, it distinguishes between states (value `STATE`) and non-states (value `OCCURRENCE`), and it also encodes whether they create an intensional context (value `I_STATE` for states and value `I_ACTION` for non-states).

Temporal expressions (timexes) are inside `<TIMEX3>` elements. The most important features for these elements are `value`, `type` and `mod`. The timex's `value` encodes a normalized representation of this temporal entity, its `type` can be e.g. `DATE`, `TIME` or `DURATION`. The `mod` attribute is optional. It is used for expressions like *early this year*, which are annotated with `mod="START"`. As can be seen in Figure 1 there are other attributes for timexes that encode whether it is the document's creation time (`functionInDocument`) and whether its value can be determined from the expression alone or requires other sources of information (`temporalFunction` and `anchorTimeID`).

The `<TLINK>` elements encode temporal relations. The attribute `relType` represents the type of relation, the feature `eventID` is a reference to the first argument of the relation. The second argument is given by the attribute `relatedToTime` (if it is a time interval or duration) or `relatedToEvent` (if it is another event; this is for task C). The `task` feature is the name of the TempEval-1 task to which this temporal relation pertains.

3 Data Adaptation

We cleaned all TimeML markup in the TempEval-1 data and the result was fed to the Google Translator Toolkit.[3] This tool combines machine translation with a translation memory. A human translator corrected the proposed translations manually.

After that, we had the three collections of documents (the TimeML data, the English unannotated data and the Portuguese unannotated data) aligned by paragraphs (we just kept the line breaks from the original collection in the other collections). In this way, for each paragraph in the Portuguese data we know all the corresponding TimeML tags in the original English paragraph.

We tried using machine translation software (we used GIZA++ (Och and Ney, 2003)) to perform word alignment on the unannotated texts, which would have enabled us to transpose the TimeML annotations automatically. However, word alignment algorithms have suboptimal accuracy, so the results would have to be checked manually. Therefore we abandoned this idea, and instead we simply placed the different TimeML markup in the correct positions manually. This is possible since the TempEval-1 corpus is not very large. A small script was developed to place all relevant TimeML markup at the end of each paragraph in the Portuguese text, and then each tag was manually repositioned. Note that the `<TLINK>` elements always occur at the end of each document, each in a separate line: therefore they do not need to be repositioned.

During this manual repositioning of the annotations, some attributes were also changed man-

```

Figure 1: Extract of a document contained in the training data of the first TempEval-1

ually. In particular, the attributes `stem`, `tense` and `aspect` of `<EVENT>` elements are language specific and needed to be adapted. Sometimes, the `pos` attribute also needs to be changed, since e.g. a verb in English can be translated as a noun in Portuguese. The attribute `class` of the same kind of elements can be different, too, because natural sounding translations are sometimes not literal.

3.1 Annotation Decisions

When porting the TimeML annotations from English to Portuguese, a few decisions had to be made. For illustration purposes, Figure 2 contains the Portuguese equivalent of the extract presented in Figure 1.

For `<TIMEX3>` elements, the issue is that if the temporal expression to be annotated is a prepositional phrase, the preposition should not be inside the `<TIMEX3>` tags according to the TimeML specification. In the case of Portuguese, this raises the question of whether to leave contractions of prepositions with determiners outside these tags (in the English data the preposition is outside and the determiner is inside).[4] We chose to leave them outside, as can be seen in that Figure. In this example the prepositional phrase *from the night*/*da noite* is annotated with the English noun phrase *the night* inside the `<TIMEX3>` element, but the Portuguese version only contains the noun *noite* inside those tags.

For `<EVENT>` elements, some of the attributes are adapted. The value of the attribute `stem` is obviously different in Portuguese. The attributes `aspect` and `tense` have a different set of possible values in the Portuguese data, simply because the morphology of the two languages is different. In the example in Figure 1 the value `PPI` for the attribute `tense` stands for *pretérito perfeito do indicativo*. We chose to include mood information in the `tense` attribute because the different tenses of the indicative and the subjunctive moods do not line up perfectly as there are more tenses for the indicative than for the subjunctive. For the `aspect` attribute, which encodes grammatical aspect, we only use the values `NONE` and `PROGRESSIVE`, leaving out the values `PERFECTIVE` and `PERFECTIVE_PROGRESSIVE`, as in Portuguese there is no easy match between perfective aspect and grammatical categories.

The attributes of `<TIMEX3>` elements carry over to the Portuguese corpus unchanged, and the `<TLINK>` elements are taken verbatim from the original documents.

4 Data Description

The original English data for TempEval-1 are based on the TimeBank data, and they are split into one dataset for training and development and another dataset for evaluation. The full data are organized in 182 documents (162 documents in the training data and another 20 in the test data). Each document is a news report from television broadcasts or newspapers. A large amount of the documents (123 in the training set and 12 in the test data) are taken from a 1989 issue of the Wall Street Journal.

The training data comprise 162 documents with

[4] The fact that prepositions are placed outside of temporal expressions seems odd at first, but this is because in the original TimeBank, from which the TempEval data were derived, they are tagged as `<SIGNAL>`s. The TempEval-1 data does not contain `<SIGNAL>` elements, however.

Figure 2: Extract of a document contained in the Portuguese data

2,236 sentences (i.e. 2236 <s> elements) and 52,740 words. It contains 6799 <EVENT> elements, 1,244 <TIMEX3> elements and 5,790 <TLINK> elements. Note that not all the events are included here: the ones expressed by words that occur less than 20 times in TimeBank were removed from the TempEval-1 data.

The test dataset contains 376 sentences and 8,107 words. The number of <EVENT> elements is 1,103; there are 165 <TIMEX3>s and 758 <TLINK>s.

The Portuguese data of course contain the same (translated) documents. The training dataset has 2,280 sentences and 60,781 words. The test data contains 351 sentences and 8,920 words.

5 Comparing the two Datasets

One of the systems participating in the TempEval-1 competition, the USFD system (Hepple et al., 2007), implemented a very straightforward solution: it simply trained classifiers with Weka (Witten and Frank, 2005), using as attributes information that was readily available in the data and did not require any extra natural language processing (for all tasks, the attribute relType of <TLINK> elements is unknown and must be discovered, but all the other information is given).

The authors' objectives were to see "whether a 'lite' approach of this kind could yield reasonable performance, before pursuing possibilities that relied on 'deeper' NLP analysis methods", "which of the features would contribute positively to system performance" and "if any [machine learning] approach was better suited to the TempEval tasks than any other". In spite of its simplicity, they obtained results quite close to the best systems.

For us, the results of (Hepple et al., 2007) are interesting as they allow for a straightforward evaluation of our adaptation efforts, since the same machine learning implementations can be used with the Portuguese data, and then compared to their results.

The differences in the data are mostly due to language. Since the languages are different, the distribution of the values of several attributes are different. For instance, we included both tense and mood information in the tense attribute of <EVENT>s, as mentioned in Section 3.1, so instead of seven possible values for this attribute, the Portuguese data contains more values, which can cause more data sparseness. Other attributes affected by language differences are aspect, pos, and class, which were also possibly changed during the adaptation process.

One important difference between the English and the Portuguese data originates from the fact that events with a frequency lower than 20 were removed from the English TempEval-1 data. Since there is not a 1 to 1 relation between English event terms and Portuguese event terms, we do not have the guarantee that all event terms in the Portuguese data have a frequency of at least 20 occurrences in the entire corpus.[5]

The work of (Hepple et al., 2007) reports on both cross-validation results for various classifiers over the training data and evaluation results on the training data, for the English dataset. We we will

[5] In fact, out of 1,649 different stems for event terms in the Portuguese training data, only 45 occur at least 20 times.

Table 1: Features used for the English TempEval-1 tasks. N/A means the feature was not applicable to the task, ✓ means the feature was used by the best performing classifier for the task, and × means it was not used by that classifier. From (Hepple et al., 2007).

be comparing their results to ours.

Our purpose with this comparison is to validate the corpus adaptation. Similar results would not necessarily indicate the quality of the adapted corpus. After all, a word-by-word translation would produce data that would yield similar results, but it would also be a very poor translation, and therefore the resulting corpus would not be very interesting. The quality of the translation is not at stake here, since it was manually revised. But similar results would indicate that the obtained data are comparable to the original data, and that they are similarly useful to tackle the problem for which the original data were collected. This would confirm our hypothesis that adapting an existing corpus can be an effective way to obtain new data for a different language.

5.1 Results for English

The attributes employed for English by (Hepple et al., 2007) are summarized in Table 1. The class is the attribute `relType` of `<TLINK>` elements.

The EVENT features are taken from `<EVENT>` elements. The EVENT-`string` attribute is the character data inside the element. The other attributes correspond to the feature of `<EVENT>` with the same name. The TIMEX3 features also correspond to attributes of the relevant `<TIMEX3>` element. The ORDER features are boolean and computed as follows:

- ORDER-`event-first` is whether the `<EVENT>` element occurs in the text before the `<TIMEX3>` element;
- ORDER-`event-between` is whether an `<EVENT>` element occurs in the text between the two temporal entities being ordered;
- ORDER-`timex-between` is the same, but for temporal expressions;
- ORDER-`adjacent` is whether both ORDER-`event-between` and ORDER-`timex-between` are false (but other textual data may occur between the two entities).

	Task		
Algorithm	A	B	C
baseline	49.8	62.1	42.0
`lazy.KStar`	**58.2**	76.7	54.0
`rules.DecisionTable`	53.3	**79.0**	52.9
`functions.SMO`	55.1	78.1	**55.5**
`rules.JRip`	50.7	78.6	53.4
`bayes.NaiveBayes`	56.3	76.2	50.7

Table 2: Performance of several machine learning algorithms on the English TempEval-1 training data, with cross-validation. The best result for each task is in boldface. From (Hepple et al., 2007).

Cross-validation over the training data produced the results in Table 2. The baseline used is the majority class baseline, as given by Weka's `rules.ZeroR` implementation. The `lazy.KStar` algorithm is a nearest-neighbor classifier that uses an entropy-based measure to compute instance similarity. Weka's `rules.DecisionTable` algorithm assigns to an unknown instance the majority class of the training examples that have the same attribute values as that instance that is being classified. `functions.SMO` is an implementation of Support Vector Machines (SVM), `rules.JRip` is the RIPPER algorithm, and `bayes.NaiveBayes` is a Naive Bayes classifier.

Algorithm	Task A	B	C
baseline	49.8	62.1	42.0
`lazy.KStar`	**57.4**	77.7	53.3
`rules.DecisionTable`	54.2	78.1	51.6
`functions.SMO`	55.5	**79.3**	56.8
`rules.JRip`	52.1	77.6	52.1
`bayes.NaiveBayes`	56.0	78.2	53.5
`trees.J48`	55.6	79.0	**59.3**

Table 3: Performance of several machine learning algorithms on the Portuguese data for the TempEval-1 tasks. The best result for each task is in boldface.

5.2 Attributes

We created a small script to convert the XML annotated files into CSV files, that can be read by Weka. In this process, we included the same attributes as the USFD authors used for English.

For task C, (Hepple et al., 2007) are not very clear whether the EVENT attributes used were related to just one of the two events being temporally related. In any case, we used two of each of the EVENT attributes, one for each event in the temporal relation to be determined. So, for instance, an extra attribute EVENT2-`tense` is where the tense of the second event in the temporal relation is kept.

5.3 Results

The majority class baselines produce the same results as for English. This was expected: the class distribution is the same in the two datasets, since the `<TLINK>` elements were copied to the adapted corpus without any changes.

For the sake of comparison, we used the same classifiers as (Hepple et al., 2007), and we used the attributes that they found to work best for English (presented above in Table 1). The results for the Portuguese dataset are in Table 3, using 10-fold cross-validation on the training data.

We also present the results for Weka's implementation of the C4.5 algorithm, to induce decision trees. The motivation to run this algorithm over these data is that decision trees are human readable and make it easy to inspect what decisions the classifier is making. This is also true of `rules.JRip`. The results for the decision trees are in this table, too.

The results obtained are almost identical to the results for the original dataset in English. The best performing classifier for task A is the same as for English. For task B, Weka's `functions.SMO` produced better results with the Portuguese data than `rules.DecisionTable`, the best performing classifier with the English data for this task. In task C, the SVM algorithm was also the best performing algorithm among those that were also tried on the English data, but decision trees produced even better results here.

For English, the best performing classifier for each task on the training data, according to Table 2, was used for evaluation on the test data: the results showed a 59% F-measure for task A, 73% for task B, and 54% for task C.

Similarly, we also evaluated the best algorithm for each task (according to Table 3) with the Portuguese test data, after training it on the entire training dataset. The results are: in task A the `lazy.KStar` classifier scored 58.6%, and the SVM classifier scored 75.5% in task B and 59.4% in task C, with `trees.J48` scoring 61% in this task.

The results on the test data are also fairly similar for the two languages/datasets.

We inspected the decision trees and rule sets produced by `trees.J48` and `rules.JRip`, in order to see what the classifiers are doing.

Task B is probably the easiest task to check this way, because we expect grammatical tense to be highly predictive of the temporal order between an event and the document's creation time.

And, indeed, the top of the tree induced by `trees.J48` is quite interesting:

```
eTense =  PI:  OVERLAP (388.0/95.0)
eTense =  PPI:  BEFORE (1051.0/41.0)
```

Here, `eTense` is the EVENT-`tense` attribute of `<EVENT>` elements, `PI` stands for present indicative, and `PPI` is past indicative (*pretérito perfeito do indicativo*). In general, one sees past tenses associated with the `BEFORE` class and future tenses associated with the `AFTER` class (including the conditional forms of verbs). Infinitives are mostly associated with the `AFTER` class, and present subjunctive forms with `AFTER` and `OVERLAP`. Figure 3 shows the rule set induced by the RIPPER algorithm.

The classifiers for the other tasks are more difficult to inspect. For instance, in task A, the event term and the temporal expression that denote the entities that are to be ordered may not even be directly syntactically related. Therefore, it is hard to

```
(eClass = OCCURRENCE) and ( eTense =  INF) and ( ePolarity =  POS) =>  lRelType= AFTER
                                                                          (183.0/77.0)
( eTense =  FI) =>  lRelType= AFTER (55.0/10.0)
(eClass = OCCURRENCE) and ( eTense =  IR-PI+INF) =>  lRelType= AFTER (26.0/4.0)
(eClass = OCCURRENCE) and ( eTense =  PC) =>  lRelType= AFTER (15.0/3.0)
(eClass = OCCURRENCE) and ( eTense =  C) =>  lRelType= AFTER (17.0/2.0)
( eTense =  PI) =>  lRelType= OVERLAP (388.0/95.0)
(eClass = ASPECTUAL) and ( eTense =  PC) =>  lRelType= OVERLAP (9.0/2.0)
 =>  lRelType= BEFORE (1863.0/373.0)
```

Figure 3: `rules.JRip` classifier induced for task B. `INF` stands for infinitive, `FI` is future indicative, `IR-PI+INF` is an infinitive form following a present indicative form of the verb *ir* (*to go*), `PC` is present subjunctive, `C` is conditional, `PI` is present indicative.

see how interesting the inferred rules are, because we do not know what would be interesting in this scenario. In any case, the top of the induced tree for task A is:

```
oAdjacent =  True: OVERLAP (554.0/128.0)
```

Here, `oAdjacent` is the ORDER-`adjacent` attribute. Assuming this attribute is an indication that the event term and the temporal expression are related syntactically, it is interesting to see that the typical temporal relation between the two entities in this case is an `OVERLAP` relation. The rest of the tree is much more *ad-hoc*, making frequent use of the `stem` attribute of `<EVENT>` elements, suggesting the classifier is memorizing the data.

Task C, where two events are to be ordered, produced more complicated classifiers. Generally the induced rules and the tree paths compare the tense and the class of the two event terms, showing some expected heuristics (such as, if the tense of the first event is future and the tense of the second event is past, assign `AFTER`). But there are also many several rules for which we do not have clear intuitions.

6 Discussion

In this paper, we described the semi-automatic adaptation of a TimeML annotated corpus from English to Portuguese, a language for which TimeML annotated data was not available yet.

Because most of the TimeML annotations are semantic in nature, they can be transposed to a translation of the original corpus, with few adaptations being required.

In order to validate this adaptation, we used the obtained data to replicate some results in the literature that used the original English data.

The results for the Portuguese data are very similar to the ones for English. This indicates that our approach to adapt existing annotated data to a different language is fruitful.

A Taxonomy, Dataset, and Classifier for Automatic Noun Compound Interpretation

Stephen Tratz and **Eduard Hovy**
Information Sciences Institute
University of Southern California

{stratz,hovy}@isi.edu

Abstract

The automatic interpretation of noun-noun compounds is an important subproblem within many natural language processing applications and is an area of increasing interest. The problem is difficult, with disagreement regarding the number and nature of the relations, low inter-annotator agreement, and limited annotated data. In this paper, we present a novel taxonomy of relations that integrates previous relations, the largest publicly-available annotated dataset, and a supervised classification method for automatic noun compound interpretation.

1 Introduction

Noun compounds (e.g., 'maple leaf') occur very frequently in text, and their interpretation—determining the relationships between adjacent nouns as well as the hierarchical dependency structure of the NP in which they occur—is an important problem within a wide variety of natural language processing (NLP) applications, including machine translation (Baldwin and Tanaka, 2004) and question answering (Ahn et al., 2005). The interpretation of noun compounds is a difficult problem for various reasons (Spärck Jones, 1983). Among them is the fact that no set of relations proposed to date has been accepted as complete and appropriate for general-purpose text. Regardless, automatic noun compound interpretation is the focus of an upcoming SEMEVAL task (Butnariu et al., 2009).

Leaving aside the problem of determining the dependency structure among strings of three or more nouns—a problem we do not address in this paper—automatic noun compound interpretation requires a taxonomy of noun-noun relations, an automatic method for accurately assigning the relations to noun compounds, and, in the case of supervised classification, a sufficiently large dataset for training.

Earlier work has often suffered from using taxonomies with coarse-grained, highly ambiguous predicates, such as prepositions, as various labels (Lauer, 1995) and/or unimpressive inter-annotator agreement among human judges (Kim and Baldwin, 2005). In addition, the datasets annotated according to these various schemes have often been too small to provide wide coverage of the noun compounds likely to occur in general text.

In this paper, we present a large, fine-grained taxonomy of 43 noun compound relations, a dataset annotated according to this taxonomy, and a supervised, automatic classification method for determining the relation between the head and modifier words in a noun compound. We compare and map our relations to those in other taxonomies and report the promising results of an inter-annotator agreement study as well as an automatic classification experiment. We examine the various features used for classification and identify one very useful, novel family of features. Our dataset is, to the best of our knowledge, the largest noun compound dataset yet produced. We will make it available via http://www.isi.edu.

2 Related Work

2.1 Taxonomies

The relations between the component nouns in noun compounds have been the subject of various linguistic studies performed throughout the years, including early work by Jespersen (1949). The taxonomies they created are varied. Lees created an early taxonomy based primarily upon grammar (Lees, 1960). Levi's influential work postulated that *complex nominals* (Levi's name for noun compounds that also permits certain adjectival modifiers) are all derived either via nominalization or

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 678–687,
Uppsala, Sweden, 11-16 July 2010.

by deleting one of nine predicates (i.e., CAUSE, HAVE, MAKE, USE, BE, IN, FOR, FROM, ABOUT) from an underlying sentence construction (Levi, 1978). Of the taxonomies presented by purely linguistic studies, our categories are most similar to those proposed by Warren (1978), whose categories (e.g., MATERIAL+ARTEFACT, OBJ+PART) are generally less ambiguous than Levi's.

In contrast to studies that claim the existence of a relatively small number of semantic relations, Downing (1977) presents a strong case for the existence of an unbounded number of relations. While we agree with Downing's belief that the number of relations is unbounded, we contend that the vast majority of noun compounds fits within a relatively small set of categories.

The relations used in computational linguistics vary much along the same lines as those proposed earlier by linguists. Several lines of work (Finin, 1980; Butnariu and Veale, 2008; Nakov, 2008) assume the existence of an unbounded number of relations. Others use categories similar to Levi's, such as Lauer's (1995) set of prepositional paraphrases (i.e., OF, FOR, IN, ON, AT, FROM, WITH, ABOUT) to analyze noun compounds. Some work (e.g., Barker and Szpakowicz, 1998; Nastase and Szpakowicz, 2003; Girju et al., 2005; Kim and Baldwin, 2005) use sets of categories that are somewhat more similar to those proposed by Warren (1978). While most of the noun compound research to date is not domain specific, Rosario and Hearst (2001) create and experiment with a taxonomy tailored to biomedical text.

2.2 Classification

The approaches used for automatic classification are also varied. Vanderwende (1994) presents one of the first systems for automatic classification, which extracted information from online sources and used a series of rules to rank a set of most likely interpretations. Lauer (1995) uses corpus statistics to select a prepositional paraphrase. Several lines of work, including that of Barker and Szpakowicz (1998), use memory-based methods. Kim and Baldwin (2005) and Turney (2006) use nearest neighbor approaches based upon WordNet (Fellbaum, 1998) and Turney's Latent Relational Analysis, respectively. Rosario and Hearst (2001) utilize neural networks to classify compounds according to their domain-specific relation taxonomy. Moldovan et al. (2004) use SVMs as well as a novel algorithm (i.e., semantic scattering). Nastase et al. (2006) experiment with a variety of classification methods including memory-based methods, SVMs, and decision trees. Ó Séaghdha and Copestake (2009) use SVMs and experiment with kernel methods on a dataset labeled using a relatively small taxonomy. Girju (2009) uses cross-linguistic information from parallel corpora to aid classification.

3 Taxonomy

3.1 Creation

Given the heterogeneity of past work, we decided to start fresh and build a new taxonomy of relations using naturally occurring noun pairs, and then compare the result to earlier relation sets. We collected 17509 noun pairs and over a period of 10 months assigned one or more relations to each, gradually building and refining our taxonomy. More details regarding the dataset are provided in Section 4.

The relations we produced were then compared to those present in other taxonomies (e.g., Levi, 1978; Warren, 1978; Barker and Szpakowicz, 1998; Girju et al., 2005), and they were found to be fairly similar. We present a detailed comparison in Section 3.4.

We tested the relation set with an initial inter-annotator agreement study (our latest inter-annotator agreement study results are presented in Section 6). However, the mediocre results indicated that the categories and/or their definitions needed refinement. We then embarked on a series of changes, testing each generation by annotation using Amazon's Mechanical Turk service, a relatively quick and inexpensive online platform where requesters may publish tasks for anonymous online workers (Turkers) to perform. Mechanical Turk has been previously used in a variety of NLP research, including recent work on noun compounds by Nakov (2008) to collect short phrases for linking the nouns within noun compounds.

For the Mechanical Turk annotation tests, we created five sets of 100 noun compounds from noun compounds automatically extracted from a random subset of New York Times articles written between 1987 and 2007 (Sandhaus, 2008). Each of these sets was used in a separate annotation round. For each round, a set of 100 noun compounds was uploaded along with category defini-

Table 1: The semantic relations, their frequency in the dataset, examples, and *approximate* relation mappings to previous relation sets. $\approx$-approximately equivalent; $\supset$/$\subset$-super/sub set; ∞-some overlap; $\cup$-union; initials BGLNVW refer respectively to the works of (Barker and Szpakowicz, 1998; Girju et al., 2005; Girju, 2007; Levi, 1978; Nastase and Szpakowicz, 2003; Vanderwende, 1994; Warren, 1978).

tions and examples. Turkers were asked to select one or, if they deemed it appropriate, two categories for each noun pair. After all annotations for the round were completed, they were examined, and any taxonomic changes deemed appropriate (e.g., the creation, deletion, and/or modification of categories) were incorporated into the taxonomy before the next set of 100 was uploaded. The categories were substantially modified during this process. They are shown in Table 1 along with examples and an approximate mapping to several other taxonomies.

3.2 Category Descriptions

Our categories are defined with sentences. For example, the SUBSTANCE category has the definition *n_1 is one of the primary physical substances/materials/ingredients that n_2 is made/composed out of/from*. Our LOCATION category's definition reads *n_1 is the location / geographic scope where n_2 is at, near, from, generally found, or occurs*. Defining the categories with sentences is advantageous because it is possible to create straightforward, explicit defintions that humans can easily test examples against.

3.3 Taxonomy Groupings

In addition to influencing the category definitions, some taxonomy groupings were altered with the hope that this would improve inter-annotator agreement for cases where Turker disagreement was systematic. For example, LOCATION and WHOLE + PART/MEMBER OF were commonly disagreed upon by Turkers so they were placed within their own taxonomic subgroup. The ambiguity between these categories has previously been observed by Girju (2009).

Turkers also tended to disagree between the categories related to composition and containment. Due this apparent similarity they were also grouped together in the taxonomy.

The ATTRIBUTE categories are positioned near the TOPIC group because some Turkers chose a TOPIC category when an ATTRIBUTE category was deemed more appropriate. This may be because attributes are relatively abstract concepts that are often somewhat *descriptive* of whatever possesses them. A prime example of this is *street name*.

3.4 Contrast with other Taxonomies

In order to ensure completeness, we mapped into our taxonomy the relations proposed in most previous work including those of Barker and Szpakowicz (1998) and Girju et al. (2005). The results, shown in Table 1, demonstrate that our taxonomy is similar to several taxonomies used in other work. However, there are three main differences and several less important ones. The first major difference is the absence of a significant THEME or OBJECT category. The second main difference is that our taxonomy does not include a PURPOSE category and, instead, has several smaller categories. Finally, instead of possessing a single TOPIC category, our taxonomy has several, finer-grained TOPIC categories. These differences are significant because THEME/OBJECT, PURPOSE, and TOPIC are typically among the most frequent categories.

THEME/OBJECT is typically the category to which other researchers assign noun compounds whose head noun is a nominalized verb and whose modifier noun is the THEME/OBJECT of the verb. This is typically done with the justification that the relation/predicate (the root verb of the nominalization) is overtly expressed.

While including a THEME/OBJECT category has the advantage of simplicity, its disadvantages are significant. This category leads to a significant ambiguity in examples because many compounds fitting the THEME/OBJECT category also match some other category as well. Warren (1978) gives the examples of *soup pot* and *soup container* to illustrate this issue, and Girju (2009) notes a substantial overlap between THEME and MAKE-PRODUCE. Our results from Mechanical Turk showed significant overlap between PURPOSE and OBJECT categories (present in an earlier version of the taxonomy). For this reason, we do not include a separate THEME/OBJECT category. If it is important to know whether the modifier also holds a THEME/OBJECT relationship, we suggest treating this as a separate classification task.

The absence of a single PURPOSE category is another distinguishing characteristic of our taxonomy. Instead, the taxonomy includes a number of finer-grained categories (e.g., PERFORM/ENGAGE_IN), which can be conflated to create a PURPOSE category if necessary. During our Mechanical Turk-based refinement process, our now-defunct PURPOSE category was found to be ambiguous with many other categories as well as difficult to define. This problem has been noted by others. For example, Warren (1978)

points out that *tea* in *tea cup* qualifies as both the *content* and the *purpose* of the *cup*. Similarly, while WHOLE+PART/MEMBER was selected by most Turkers for *bike tire*, one individual chose PURPOSE. Our investigation identified five main purpose-like relations that most of our PURPOSE examples can be divided into, including activity performance (PERFORM/ENGAGE_IN), creation/provision (CREATE/PROVIDE/CAUSE OF), obtainment/access (OBTAIN/ACCESS/SEEK), supervision/management (ORGANIZE/SUPERVISE/AUTHORITY), and opposition (MITIGATE/OPPOSE/DESTROY).

The third major distinguishing different between our taxonomy and others is the absence of a single TOPIC/ABOUT relation. Instead, our taxonomy has several finer-grained categories that can be conflated into a TOPIC category. Unlike the previous two distinguishing characteristics, which were motivated primarily by Turker annotations, this separation was largely motivated by author dissatisfaction with a single TOPIC category.

Two differentiating characteristics of less importance are the absence of BENEFICIARY or SOURCE categories (Barker and Szpakowicz, 1998; Nastase and Szpakowicz, 2003; Girju et al., 2005). Our EMPLOYER, CONSUMER, and USER/RECIPIENT categories combined more or less cover BENEFICIARY. Since SOURCE is ambiguous in multiple ways including causation (*tsunami injury*), provision (*government grant*), ingredients (*rice wine*), and locations (*north wind*), we chose to exclude it.

4 Dataset

Our noun compound dataset was created from two principal sources: an in-house collection of terms extracted from a large corpus using part-of-speech tagging and mutual information and the Wall Street Journal section of the Penn Treebank. Compounds including one or more proper nouns were ignored. In total, the dataset contains 17509 unique, out-of-context examples, making it by far the largest hand-annotated compound noun dataset in existence that we are aware of. Proper nouns were not included.

The next largest available datasets have a variety of drawbacks for noun compound interpretation in general text. Kim and Baldwin's (2005) dataset is the second largest available dataset, but inter-annotator agreement was only 52.3%, and the annotations had an usually lopsided distribution; 42% of the data has TOPIC labels. Most (73.23%) of Girju's (2007) dataset consists of noun-preposition-noun constructions. Rosario and Heart's (2001) dataset is specific to the biomedical domain, while Ó Séaghdha and Copestake's (2009) data is labeled with only 5 extremely coarse-grained categories. The remaining datasets are too small to provide wide coverage. See Table 2 below for size comparison with other publicly available, semantically annotated datasets.

Size	Work
17509	Tratz and Hovy, 2010
2169	Kim and Baldwin, 2005
2031	*Girju, 2007*
1660	Rosario and Hearst, 2001
1443	Ó Séaghdha and Copestake, 2007
505	*Barker and Szpakowicz, 1998*
600	*Nastase and Szpakowicz, 2003*
395	Vanderwende, 1994
385	Lauer, 1995

Table 2: Size of various available noun compound datasets labeled with relation annotations. Italics indicate that the dataset contains n-prep-n constructions and/or non-nouns.

5 Automated Classification

We use a Maximum Entropy (Berger et al., 1996) classifier with a large number of boolean features, some of which are novel (e.g., the inclusion of words from WordNet definitions). Maximum Entropy classifiers have been effective on a variety of NLP problems including preposition sense disambiguation (Ye and Baldwin, 2007), which is somewhat similar to noun compound interpretation. We use the implementation provided in the MALLET machine learning toolkit (McCallum, 2002).

5.1 Features Used

WordNet-based Features

- {Synonyms, Hypernyms} for all NN and VB entries for each word
- Intersection of the words' hypernyms
- All terms from the 'gloss' for each word
- Intersection of the words' 'gloss' terms
- Lexicographer file names for each word's NN and VB entries (e.g., n_1:substance)

- Logical AND of lexicographer file names for the two words (e.g., n_1:substance $\wedge$ n_2:artifact)
- Lists of all link types (e.g., meronym links) associated with each word
- Logical AND of the link types (e.g., n_1:hasMeronym(s) $\wedge$ n_2:hasHolonym(s))
- Part-of-speech (POS) indicators for the existence of VB, ADJ, and ADV entries for each of the nouns
- Logical AND of the POS indicators for the two words
- 'Lexicalized' indicator for the existence of an entry for the compound as a single term
- Indicators if either word is a part of the other word according to Part-Of links
- Indicators if either word is a hypernym of the other
- Indicators if either word is in the definition of the other

Roget's Thesaurus-based Features

- Roget's divisions for all noun (and verb) entries for each word
- Roget's divisions shared by the two words

Surface-level Features

- Indicators for the suffix types (e.g., de-adjectival, de-nominal [non]agentive, de-verbal [non]agentive)
- Indicators for degree, number, order, or locative prefixes (e.g., ultra-, poly-, post-, and inter-, respectively)
- Indicators for whether or not a preposition occurs within either term (e.g., 'down' in 'breakdown')
- The last {two, three} letters of each word

Web 1T N-gram Features

To provide information related to term usage to the classifier, we extracted trigram and 4-gram features from the Web 1T Corpus (Brants and Franz, 2006), a large collection of n-grams and their counts created from approximately one trillion words of Web text. Only n-grams containing lowercase words were used. 5-grams were not used due to memory limitations. Only n-grams containing both terms (including plural forms) were extracted. Table 3 describes the extracted n-gram features.

5.2 Cross Validation Experiments

We performed 10-fold cross validation on our dataset, and, for the purpose of comparison, we also performed 5-fold cross validation on Ó Séaghdha's (2007) dataset using his folds. Our classification accuracy results are 79.3% on our data and 63.6% on the Ó Séaghdha data. We used the χ^2 measure to limit our experiments to the most useful 35000 features, which is the point where we obtain the highest results on Ó Séaghdha's data. The 63.6% figure is similar to the best previously reported accuracy for this dataset of 63.1%, which was obtained by Ó Séaghdha and Copestake (2009) using kernel methods.

For comparison with SVMs, we used Thorsten Joachims' $SVM^{multiclass}$, which implements an optimization solution to Cramer and Singer's (2001) multiclass SVM formulation. The best results were similar, with 79.4% on our dataset and 63.1% on Ó Séaghdha's. $SVM^{multiclass}$ was, however, observed to be very sensitive to the tuning of the C parameter, which determines the tradeoff between training error and margin width. The best results for the datasets were produced with C set to 5000 and 375 respectively.

Table 3: Patterns for extracting trigram and 4-Gram features from the Web 1T Corpus for a given noun compound (n_1 n_2).

To assess the impact of the various features, we ran the cross validation experiments for each feature type, alternating between including *only* one

feature type and including all feature types *except* that one. The results for these runs using the Maximum Entropy classifier are presented in Table 4.

There are several points of interest in these results. The WordNet gloss terms had a surprisingly strong influence. In fact, by themselves they proved roughly as useful as the hypernym features, and their removal had the single strongest negative impact on accuracy for our dataset. As far as we know, this is the first time that WordNet definition words have been used as features for noun compound interpretation. In the future, it may be valuable to add definition words from other machine-readable dictionaries. The influence of the Web 1T n-gram features was somewhat mixed. They had a positive impact on the Ó Séaghdha data, but their affect upon our dataset was limited and mixed, with the removal of the 4-gram features actually improving performance slightly.

	Our Data		Ó Séaghdha Data

6 Evaluation

6.1 Evaluation Data

To assess the quality of our taxonomy and classification method, we performed an inter-annotator agreement study using 150 noun compounds extracted from a random subset of articles taken from New York Times articles dating back to 1987 (Sandhaus, 2008). The terms were selected based upon their frequency (i.e., a compound occurring twice as often as another is twice as likely to be selected) to label for testing purposes. Using a heuristic similar to that used by Lauer (1995), we only extracted binary noun compounds not part of a larger sequence. Before reaching the 150 mark, we discarded 94 of the drawn examples because they were included in the training set. Thus, our training set covers roughly 38.5% of the binary noun compound *instances* in recent New York Times articles.

6.2 Annotators

Due to the relatively high speed and low cost of Amazon's Mechanical Turk service, we chose to use Mechanical Turkers as our annotators.

Using Mechanical Turk to obtain inter-annotator agreement figures has several drawbacks. The first and most significant drawback is that it is impossible to force each Turker to label every data point without putting all the terms onto a single web page, which is highly impractical for a large taxonomy. Some Turkers may label every compound, but most do not. Second, while we requested that Turkers only work on our task if English was their first language, we had no method of enforcing this. Third, Turker annotation quality varies considerably.

6.3 Combining Annotators

To overcome the shortfalls of using Turkers for an inter-annotator agreement study, we chose to request ten annotations per noun compound and then combine the annotations into a single set of selections using a weighted voting scheme. To combine the results, we calculated a "quality" score for each Turker based upon how often he/she agreed with the others. This score was computed as the average percentage of other Turkers who agreed with his/her annotations. The score for each label for a particular compound was then computed as the sum of the Turker quality scores of the Turkers

who annotated the compound. Finally, the label with the highest rating was selected.

6.4 Inter-annotator Agreement Results

The raw agreement scores along with Cohen's κ (Cohen, 1960), a measure of inter-annotator agreement that discounts random chance, were calculated against the authors' labeling of the data for each Turker, the weighted-voting annotation set, and the automatic classification output. These statistics are reported in Table 5 along with the individual Turker "quality" scores. The 54 Turkers who made fewer than 3 annotations were excluded from the calculations under the assumption that they were not dedicated to the task, leaving a total of 49 Turkers. Due to space limitations, only results for Turkers who annotated 15 or more instances are included in Table 5.

We recomputed the κ statistics after conflating the category groups in two different ways. The first variation involved conflating all the TOPIC categories into a single topic category, resulting in a total of 37 categories (denoted by κ* in Table 5). For the second variation, in addition to conflating the TOPIC categories, we conflated the ATTRIBUTE categories into a single category and the PURPOSE/ACTIVITY categories into a single category, for a total of 27 categories (denoted by κ** in Table 5).

Id	N	Weight	Agree	κ	κ*	κ**
1	23	0.45	0.70	0.67	0.67	0.74
2	34	0.46	0.68	0.65	0.65	0.72
3	35	0.34	0.63	0.60	0.61	0.61
4	24	0.46	0.63	0.59	0.68	0.76
5	16	0.58	0.63	0.59	0.59	0.54
Voted	150	NA	0.59	0.57	0.61	0.67
6	52	0.45	0.58	0.54	0.60	0.60
7	38	0.35	0.55	0.52	0.54	0.56
8	149	0.36	0.52	0.49	0.53	0.58
Auto	150	NA	0.51	0.47	0.47	0.45
9	88	0.38	0.48	0.45	0.49	0.59
10	36	0.42	0.47	0.43	0.48	0.52
11	104	0.29	0.46	0.43	0.48	0.52
12	38	0.33	0.45	0.40	0.46	0.47
13	66	0.31	0.42	0.39	0.39	0.49
14	15	0.27	0.40	0.34	0.31	0.29
15	62	0.23	0.34	0.29	0.35	0.38
16	150	0.23	0.30	0.26	0.26	0.30
17	19	0.24	0.26	0.21	0.17	0.14
18	144	0.21	0.25	0.20	0.22	0.22
19	29	0.18	0.21	0.14	0.17	0.31
20	22	0.18	0.18	0.12	0.10	0.16
21	51	0.19	0.18	0.13	0.20	0.26
22	41	0.02	0.02	0.00	0.00	0.01

Table 5: Annotation results. Id – annotator id; N – number of annotations; Weight – voting weight; Agree – raw agreement versus the author's annotations; κ – Cohen's κ agreement; κ* and κ** – Cohen's κ results after conflating certain categories. Voted – combined annotation set using weighted voting; Auto – automatic classification output.

6.5 Results Discussion

The .57-.67 κ figures achieved by the Voted annotations compare well with previously reported inter-annotator agreement figures for noun compounds using fine-grained taxonomies. Kim and Baldwin (2005) report an agreement of 52.31% (not κ) for their dataset using Barker and Szpakowicz's (1998) 20 semantic relations. Girju et al. (2005) report .58 κ using a set of 35 semantic relations, only 21 of which were used, and a .80 κ score using Lauer's 8 prepositional paraphrases. Girju (2007) reports .61 κ agreement using a similar set of 22 semantic relations for noun compound annotation in which the annotators are shown translations of the compound in foreign languages. Ó Séaghdha (2007) reports a .68 κ for a relatively small set of relations (BE, HAVE, IN, INST, ACTOR, ABOUT) after removing compounds with non-specific associations or high lexicalization. The correlation between our automatic "quality" scores for the Turkers who performed at least three annotations and their simple agreement with our annotations was very strong at 0.88.

The .51 automatic classification figure is respectable given the larger number of categories in the taxonomy. It is also important to remember that the training set covers a large portion of the two-word noun compound instances in recent New York Times articles, so substantially higher accuracy can be expected on many texts. Interestingly, conflating categories only improved the κ statistics for the Turkers, not the automatic classifier.

7 Conclusion

In this paper, we present a novel, fine-grained taxonomy of 43 noun-noun semantic relations, the largest annotated noun compound dataset yet created, and a supervised classification method for automatic noun compound interpretation.

We describe our taxonomy and provide mappings to taxonomies used by others. Our inter-annotator agreement study, which utilized non-experts, shows good inter-annotator agreement

given the difficulty of the task, indicating that our category definitions are relatively straightforward. Our taxonomy provides wide coverage, with only 2.32% of our dataset marked as other/lexicalized and 2.67% of our 150 inter-annotator agreement data marked as such by the combined Turker (Voted) annotation set.

We demonstrated the effectiveness of a straightforward, supervised classification approach to noun compound interpretation that uses a large variety of boolean features. We also examined the importance of the different features, noting a novel and very useful set of features—the words comprising the definitions of the individual words.

8 Future Work

In the future, we plan to focus on the interpretation of noun compounds with 3 or more nouns, a problem that includes bracketing noun compounds into their dependency structures in addition to noun-noun semantic relation interpretation. Furthermore, we would like to build a system that can handle longer noun phrases, including prepositions and possessives.

We would like to experiment with including features from various other lexical resources to determine their usefulness for this problem.

Eventually, we would like to expand our data set and relations to cover proper nouns as well. We are hopeful that our current dataset and relation definitions, which will be made available via http://www.isi.edu will be helpful to other researchers doing work regarding text semantics.

Ekaterina.Shutova@cl.cam.ac.uk

Abstract

Automatic processing of metaphor can be clearly divided into two subtasks: *metaphor recognition* (distinguishing between literal and metaphorical language in a text) and *metaphor interpretation* (identifying the intended literal meaning of a metaphorical expression). Both of them have been repeatedly addressed in NLP. This paper is the first comprehensive and systematic review of the existing computational models of metaphor, the issues of metaphor annotation in corpora and the available resources.

1 Introduction

Our production and comprehension of language is a multi-layered computational process. Humans carry out high-level semantic tasks effortlessly by subconsciously employing a vast inventory of complex linguistic devices, while simultaneously integrating their background knowledge, to reason about reality. An ideal model of language understanding would also be capable of performing such high-level semantic tasks.

However, a great deal of NLP research to date focuses on processing lower-level linguistic information, such as e.g. part-of-speech tagging, discovering syntactic structure of a sentence (parsing), coreference resolution, named entity recognition and many others. Another cohort of researchers set the goal of improving application-based statistical inference (e.g. for recognizing textual entailment or automatic summarization). In contrast, there have been fewer attempts to bring the state-of-the-art NLP technologies together to model the way humans use language to frame high-level reasoning processes, such as for example, creative thought.

The majority of computational approaches to figurative language still exploit the ideas articulated three decades ago (Wilks, 1978; Lakoff and Johnson, 1980; Fass, 1991) and often rely on task-specific hand-coded knowledge. However, recent work on lexical semantics and lexical acquisition techniques opens many new avenues for creation of fully automated models for recognition and interpretation of figurative language. In this paper I will focus on the phenomenon of metaphor and describe the most prominent computational approaches to metaphor, as well the issues of resource creation and metaphor annotation.

Metaphors arise when one concept is viewed in terms of the properties of the other. In other words it is based on *similarity* between the concepts. Similarity is a kind of association implying the presence of characteristics in common. Here are some examples of metaphor.

(1) Hillary *brushed aside* the accusations.

(2) How can I *kill* a process? (Martin, 1988)

(3) I *invested* myself fully in this relationship.

(4) And then my heart with pleasure *fills*,
And *dances* with the daffodils.[1]

In metaphorical expressions seemingly unrelated features of one concept are associated with another concept. In the example (2) the *computational process* is viewed as something *alive* and, therefore, its forced termination is associated with the act of killing.

Metaphorical expressions represent a great variety, ranging from conventional metaphors, which we reproduce and comprehend every day, e.g. those in (2) and (3), to poetic and largely novel ones, such as (4). The use of metaphor is ubiquitous in natural language text and it is a serious bottleneck in automatic text understanding.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 688–697,
Uppsala, Sweden, 11-16 July 2010.

In order to estimate the frequency of the phenomenon, Shutova (2010) conducted a corpus study on a subset of the British National Corpus (BNC) (Burnard, 2007) representing various genres. They manually annotated metaphorical expressions in this data and found that 241 out of 761 sentences contained a metaphor. Due to such a high frequency of their use, a system capable of recognizing and interpreting metaphorical expressions in unrestricted text would become an invaluable component of any semantics-oriented NLP application.

Automatic processing of metaphor can be clearly divided into two subtasks: *metaphor recognition* (distinguishing between literal and metaphorical language in text) and *metaphor interpretation* (identifying the intended literal meaning of a metaphorical expression). Both of them have been repeatedly addressed in NLP.

2 Theoretical Background

Four different views on metaphor have been broadly discussed in linguistics and philosophy: the comparison view (Gentner, 1983), the interaction view (Black, 1962), (Hesse, 1966), the selectional restrictions violation view (Wilks, 1975; Wilks, 1978) and the conceptual metaphor view (Lakoff and Johnson, 1980)[2]. All of these approaches share the idea of an interconceptual mapping that underlies the production of metaphorical expressions. In other words, metaphor always involves two concepts or conceptual domains: the *target* (also called *topic* or *tenor* in the linguistics literature) and the *source* (or *vehicle*). Consider the examples in (5) and (6).

(5) He *shot down* all of my arguments. (Lakoff and Johnson, 1980)

(6) He *attacked* every weak point in my argument. (Lakoff and Johnson, 1980)

According to Lakoff and Johnson (1980), a mapping of a concept of *argument* to that of *war* is employed here. The *argument*, which is the target concept, is viewed in terms of a *battle* (or a *war*), the source concept. The existence of such a link allows us to talk about arguments using the war terminology, thus giving rise to a number of metaphors.

[2] A detailed overview and criticism of these four views can be found in (Tourangeau and Sternberg, 1982).

However, Lakoff and Johnson do not discuss how metaphors can be recognized in the linguistic data, which is the primary task in the automatic processing of metaphor. Although humans are highly capable of producing and comprehending metaphorical expressions, the task of distinguishing between literal and non-literal meanings and, therefore, identifying metaphor in text appears to be challenging. This is due to the variation in its use and external form, as well as a not clear-cut semantic distinction. Gibbs (1984) suggests that literal and figurative meanings are situated at the ends of a single continuum, along which metaphoricity and idiomaticity are spread. This makes demarcation of metaphorical and literal language fuzzy.

So far, the most influential account of metaphor recognition is that of Wilks (1978). According to Wilks, metaphors represent a violation of *selectional restrictions* in a given context. Selectional restrictions are the semantic constraints that a verb places onto its arguments. Consider the following example.

(7) My car *drinks* gasoline. (Wilks, 1978)

The verb *drink* normally takes an *animate* subject and a *liquid* object. Therefore, *drink* taking a *car* as a subject is an anomaly, which may in turn indicate the metaphorical use of *drink*.

3 Automatic Metaphor Recognition

One of the first attempts to identify and interpret metaphorical expressions in text automatically is the approach of Fass (1991). It originates in the work of Wilks (1978) and utilizes hand-coded knowledge. Fass (1991) developed a system called met*, capable of discriminating between literalness, metonymy, metaphor and anomaly. It does this in three stages. First, literalness is distinguished from non-literalness using selectional preference violation as an indicator. In the case that non-literalness is detected, the respective phrase is tested for being a metonymic relation using hand-coded patterns (such as CONTAINER-for-CONTENT). If the system fails to recognize metonymy, it proceeds to search the knowledge base for a *relevant analogy* in order to discriminate metaphorical relations from anomalous ones. E.g., the sentence in (7) would be represented in this framework as (*car,drink,gasoline*), which does not satisfy the preference (*animal,drink,liquid*), as *car*

is not a hyponym of *animal*. met* then searches its knowledge base for a triple containing a hypernym of both the actual argument and the desired argument and finds (*thing,use,energy_source*), which represents the metaphorical interpretation.

However, Fass himself indicated a problem with the selectional preference violation approach applied to metaphor recognition. The approach detects any kind of non-literalness or anomaly in language (metaphors, metonymies and others), and not only metaphors, i.e., it overgenerates. The methods met* uses to differentiate between those are mainly based on hand-coded knowledge, which implies a number of limitations.

Another problem with this approach arises from the high conventionality of metaphor in language. This means that some metaphorical senses are very common. As a result the system would extract selectional preference distributions skewed towards such conventional metaphorical senses of the verb or one of its arguments. Therefore, although some expressions may be fully metaphorical in nature, no selectional preference violation can be detected in their use. Another counterargument is bound to the fact that interpretation is always context dependent, e.g. the phrase *all men are animals* can be used metaphorically, however, without any violation of selectional restrictions.

Goatly (1997) addresses the phenomenon of metaphor by identifying a set of linguistic cues indicating it. He gives examples of lexical patterns indicating the presence of a metaphorical expression, such as *metaphorically speaking, utterly, completely, so to speak* and, surprisingly, *literally*. Such cues would probably not be enough for metaphor extraction on their own, but could contribute to a more complex system.

The work of Peters and Peters (2000) concentrates on detecting figurative language in lexical resources. They mine WordNet (Fellbaum, 1998) for the examples of systematic polysemy, which allows to capture metonymic and metaphorical relations. The authors search for nodes that are relatively high up in the WordNet hierarchy and that share a set of common word forms among their descendants. Peters and Peters found that such nodes often happen to be in metonymic (e.g. *publication – publisher*) or metaphorical (e.g. *supporting structure – theory*) relation.

The CorMet system discussed in (Mason, 2004) is the first attempt to discover source-target domain mappings automatically. This is done by "finding systematic variations in domain-specific selectional preferences, which are inferred from large, dynamically mined Internet corpora". For example, Mason collects texts from the LAB domain and the FINANCE domain, in both of which *pour* would be a characteristic verb. In the LAB domain *pour* has a strong selectional preference for objects of type *liquid*, whereas in the FINANCE domain it selects for *money*. From this Mason's system infers the domain mapping FINANCE – LAB and the concept mapping *money – liquid*. He compares the output of his system against the Master Metaphor List (Lakoff et al., 1991) containing hand-crafted metaphorical mappings between concepts. Mason reports an accuracy of 77%, although it should be noted that as any evaluation that is done by hand it contains an element of subjectivity.

Birke and Sarkar (2006) present a sentence clustering approach for non-literal language recognition implemented in the TroFi system (Trope Finder). This idea originates from a similarity-based word sense disambiguation method developed by Karov and Edelman (1998). The method employs a set of seed sentences, where the senses are annotated; computes similarity between the sentence containing the word to be disambiguated and all of the seed sentences and selects the sense corresponding to the annotation in the most similar seed sentences. Birke and Sarkar (2006) adapt this algorithm to perform a two-way classification: literal vs. non-literal, and they do not clearly define the kinds of tropes they aim to discover. They attain a performance of 53.8% in terms of f-score.

The method of Gedigan et al. (2006) discriminates between literal and metaphorical use. They trained a maximum entropy classifier for this purpose. They obtained their data by extracting the lexical items whose frames are related to MOTION and CURE from FrameNet (Fillmore et al., 2003). Then they searched the PropBank Wall Street Journal corpus (Kingsbury and Palmer, 2002) for sentences containing such lexical items and annotated them with respect to metaphoricity. They used PropBank annotation (arguments and their semantic types) as features to train the classifier and report an accuracy of 95.12%. This result is, however, only a little higher than the performance of the naive baseline assigning majority class to all instances (92.90%). These numbers

can be explained by the fact that 92.00% of the verbs of MOTION and CURE in the Wall Street Journal corpus are used metaphorically, thus making the dataset unbalanced with respect to the target categories and the task notably easier.

Both Birke and Sarkar (2006) and Gedigan et al. (2006) focus only on metaphors expressed by a verb. As opposed to that the approach of Krishnakumaran and Zhu (2007) deals with verbs, nouns and adjectives as parts of speech. They use hyponymy relation in WordNet and word bigram counts to predict metaphors at a sentence level. Given an IS-A metaphor (e.g. *The world is a stage*[3]) they verify if the two nouns involved are in hyponymy relation in WordNet, and if they are not then this sentence is tagged as containing a metaphor. Along with this they consider expressions containing a verb or an adjective used metaphorically (e.g. *He planted good ideas in their minds* or *He has a fertile imagination*). Hereby they calculate bigram probabilities of verb-noun and adjective-noun pairs (including the hyponyms/hypernyms of the noun in question). If the combination is not observed in the data with sufficient frequency, the system tags the sentence containing it as metaphorical. This idea is a modification of the selectional preference view of Wilks. However, by using bigram counts over verb-noun pairs Krishnakumaran and Zhu (2007) loose a great deal of information compared to a system extracting verb-object relations from parsed text. The authors evaluated their system on a set of example sentences compiled from the Master Metaphor List (Lakoff et al., 1991), whereby highly conventionalized metaphors (they call them *dead metaphors*) are taken to be negative examples. Thus they do not deal with literal examples as such: essentially, the distinction they are making is between the senses included in WordNet, even if they are conventional metaphors, and those not included in WordNet.

4 Automatic Metaphor Interpretation

Almost simultaneously with the work of Fass (1991), Martin (1990) presents a Metaphor Interpretation, Denotation and Acquisition System (MIDAS). In this work Martin captures hierarchical organisation of conventional metaphors. The idea behind this is that the more specific conventional metaphors descend from the general ones. Given an example of a metaphorical expression, MIDAS searches its database for a corresponding metaphor that would explain the anomaly. If it does not find any, it abstracts from the example to more general concepts and repeats the search. If it finds a suitable general metaphor, it creates a mapping for its descendant, a more specific metaphor, based on this example. This is also how novel metaphors are acquired. MIDAS has been integrated with the Unix Consultant (UC), the system that answers users questions about Unix. The UC first tries to find a literal answer to the question. If it is not able to, it calls MIDAS which detects metaphorical expressions via selectional preference violation and searches its database for a metaphor explaining the anomaly in the question.

Another cohort of approaches relies on performing inferences about entities and events in the source and target domains for metaphor interpretation. These include the KARMA system (Narayanan, 1997; Narayanan, 1999; Feldman and Narayanan, 2004) and the ATT-Meta project (Barnden and Lee, 2002; Agerri et al., 2007). Within both systems the authors developed a metaphor-based reasoning framework in accordance with the theory of conceptual metaphor. The reasoning process relies on manually coded knowledge about the world and operates mainly in the source domain. The results are then projected onto the target domain using the conceptual mapping representation. The ATT-Meta project concerns metaphorical and metonymic description of mental states and reasoning about mental states using first order logic. Their system, however, does not take natural language sentences as input, but logical expressions that are representations of small discourse fragments. KARMA in turn deals with a broad range of abstract actions and events and takes parsed text as input.

Veale and Hao (2008) derive a "fluid knowledge representation for metaphor interpretation and generation", called Talking Points. Talking Points are a set of characteristics of concepts belonging to source and target domains and related facts about the world which the authors acquire automatically from WordNet and from the web. Talking Points are then organized in *Slipnet*, a framework that allows for a number of insertions, deletions and substitutions in definitions of such characteristics in order to establish a connection between the target and the source

[3] William Shakespeare

concepts. This work builds on the idea of *slippage* in knowledge representation for understanding analogies in abstract domains (Hofstadter and Mitchell, 1994; Hofstadter, 1995). Below is an example demonstrating how slippage operates to explain the metaphor *Make-up is a Western burqa*.

Make-up =>
≡ typically worn by women
≈ expected to be worn by women
≈ must be worn by women
≈ must be worn by Muslim women
Burqa <=

By doing insertions and substitutions the system arrives from the definition *typically worn by women* to that of *must be worn by Muslim women*, and thus establishes a link between the concepts of *make-up* and *burqa*. Veale and Hao (2008), however, did not evaluate to which extent their knowledge base of Talking Points and the associated reasoning framework are useful to interpret metaphorical expressions occurring in text.

Shutova (2010) defines metaphor interpretation as a paraphrasing task and presents a method for deriving literal paraphrases for metaphorical expressions from the BNC. For example, for the metaphors in "All of this *stirred* an unfathomable excitement in her" or "a carelessly *leaked* report" their system produces interpretations "All of this provoked an unfathomable excitement in her" and "a carelessly disclosed report" respectively. They first apply a probabilistic model to rank all possible paraphrases for the metaphorical expression given the context; and then use automatically induced selectional preferences to discriminate between figurative and literal paraphrases. The selectional preference distribution is defined in terms of selectional association measure introduced by Resnik (1993) over the noun classes automatically produced by Sun and Korhonen (2009). Shutova (2010) tested their system only on metaphors expressed by a verb and report a paraphrasing accuracy of 0.81.

5 Metaphor Resources

Metaphor is a knowledge-hungry phenomenon. Hence there is a need for either an extensive manually-created knowledge-base or a robust knowledge acquisition system for interpretation of metaphorical expressions. The latter being a hard task, a great deal of metaphor research resorted to the first option. Although hand-coded knowledge proved useful for metaphor interpretation (Fass, 1991; Martin, 1990), it should be noted that the systems utilizing it have a very limited coverage.

One of the first attempts to create a multi-purpose knowledge base of source–target domain mappings is the Master Metaphor List (Lakoff et al., 1991). It includes a classification of metaphorical mappings (mainly those related to mind, feelings and emotions) with the corresponding examples of language use. This resource has been criticized for the lack of clear structuring principles of the mapping ontology (Lönneker-Rodman, 2008). The taxonomical levels are often confused, and the same classes are referred to by different class labels. This fact and the chosen data representation in the Master Metaphor List make it not suitable for computational use. However, both the idea of the list and its actual mappings ontology inspired the creation of other metaphor resources.

The most prominent of them are MetaBank (Martin, 1994) and the Mental Metaphor Databank[4] created in the framework of the ATT-meta project (Barnden and Lee, 2002; Agerri et al., 2007). The MetaBank is a knowledge-base of English metaphorical conventions, represented in the form of *metaphor maps* (Martin, 1988) containing detailed information about source-target concept mappings backed by empirical evidence. The ATT-meta project databank contains a large number of examples of metaphors of mind classified by source–target domain mappings taken from the Master Metaphor List.

Along with this it is worth mentioning metaphor resources in languages other than English. There has been a wealth of research on metaphor in Spanish, Chinese, Russian, German, French and Italian. The Hamburg Metaphor Database (Lönneker, 2004; Reining and Lönneker-Rodman, 2007) contains examples of metaphorical expressions in German and French, which are mapped to senses from EuroWordNet[5] and annotated with source–target domain mappings taken from the Master Metaphor List.

Alonge and Castelli (2003) discuss how metaphors can be represented in ItalWordNet for

[4] http://www.cs.bham.ac.uk/∼jab/ATT-Meta/Databank/

[5] EuroWordNet is a multilingual database with wordnets for several European languages (Dutch, Italian, Spanish, German, French, Czech and Estonian). The wordnets are structured in the same way as the Princeton WordNet for English. URL: http://www.illc.uva.nl/EuroWordNet/

Italian and motivate this by linguistic evidence. Encoding metaphorical information in general-domain lexical resources for English, e.g. WordNet (Lönneker and Eilts, 2004), would undoubtedly provide a new platform for experiments and enable researchers to directly compare their results.

6 Metaphor Annotation in Corpora

To reflect two distinct aspects of the phenomenon, metaphor annotation can be split into two stages: identifying metaphorical senses in text (akin word sense disambiguation) and annotating source – target domain mappings underlying the production of metaphorical expressions. Traditional approaches to metaphor annotation include manual search for lexical items used metaphorically (Pragglejaz Group, 2007), for source and target domain vocabulary (Deignan, 2006; Koivisto-Alanko and Tissari, 2006; Martin, 2006) or for linguistic markers of metaphor (Goatly, 1997). Although there is a consensus in the research community that the phenomenon of metaphor is not restricted to similarity-based extensions of meanings of isolated words, but rather involves reconceptualization of a whole area of experience in terms of another, there still has been surprisingly little interest in annotation of cross-domain mappings. However, a corpus annotated for conceptual mappings could provide a new starting point for both linguistic and cognitive experiments.

6.1 Metaphor and Polysemy

The theorists of metaphor distinguish between two kinds of metaphorical language: *novel* (or *poetic*) metaphors, that surprise our imagination, and *conventionalized* metaphors, that become a part of an ordinary discourse. "Metaphors begin their lives as novel poetic creations with marked rhetorical effects, whose comprehension requires a special imaginative leap. As time goes by, they become a part of general usage, their comprehension becomes more automatic, and their rhetorical effect is dulled" (Nunberg, 1987). Following Orwell (1946) Nunberg calls such metaphors "dead" and claims that they are not psychologically distinct from literally-used terms.

This scheme demonstrates how metaphorical associations capture some generalisations governing polysemy: over time some of the aspects of the target domain are added to the meaning of a term in a source domain, resulting in a (metaphorical) sense extension of this term. Copestake and Briscoe (1995) discuss sense extension mainly based on metonymic examples and model the phenomenon using lexical rules encoding metonymic patterns. Along with this they suggest that similar mechanisms can be used to account for metaphoric processes, and the conceptual mappings encoded in the sense extension rules would define the limits to the possible shifts in meaning.

However, it is often unclear if a metaphorical instance is a case of broadening of the sense in context due to general vagueness in language, or it manifests a formation of a new distinct metaphorical sense. Consider the following examples.

(8) a. As soon as I *entered* the room I noticed the difference.

b. How can I *enter* Emacs?

(9) a. My tea is *cold*.

b. He is such a *cold* person.

Enter in (8a) is defined as "to go or come into a place, building, room, etc.; to pass within the boundaries of a country, region, portion of space, medium, etc."[6] In (8b) this sense stretches to describe dealing with *software*, whereby COMPUTER PROGRAMS are viewed as PHYSICAL SPACES. However, this extended sense of *enter* does not appear to be sufficiently distinct or conventional to be included into the dictionary, although this could happen over time.

The sentence (9a) exemplifies the basic sense of *cold* – "of a temperature sensibly lower than that of the living human body", whereas *cold* in (9b) should be interpreted metaphorically as "void of ardour, warmth, or intensity of feeling; lacking enthusiasm, heartiness, or zeal; indifferent, apathetic". These two senses are clearly linked via the metaphoric mapping between EMOTIONAL STATES and TEMPERATURES.

A number of metaphorical senses are included in WordNet, however without any accompanying semantic annotation.

6.2 Metaphor Identification

6.2.1 Pragglejaz Procedure

Pragglejaz Group (2007) proposes a metaphor identification procedure (MIP) within the frame-

[6] Sense definitions are taken from the Oxford English Dictionary.

work of the Metaphor in Discourse project (Steen, 2007). The procedure involves metaphor annotation at the word level as opposed to identifying metaphorical relations (between words) or source–target domain mappings (between concepts or domains). In order to discriminate between the verbs used metaphorically and literally the annotators are asked to follow the guidelines:

1. For each verb establish its meaning in context and try to imagine a more basic meaning of this verb on other contexts. Basic meanings normally are: (1) more concrete; (2) related to bodily action; (3) more precise (as opposed to vague); (4) historically older.

2. If you can establish the basic meaning that is distinct from the meaning of the verb in this context, the verb is likely to be used metaphorically.

Such annotation can be viewed as a form of word sense disambiguation with an emphasis on metaphoricity.

6.2.2 Source – Target Domain Vocabulary

Another popular method that has been used to extract metaphors is searching for sentences containing lexical items from the source domain, the target domain, or both (Stefanowitsch, 2006). This method requires exhaustive lists of source and target domain vocabulary.

Martin (2006) conducted a corpus study in order to confirm that metaphorical expressions occur in text in contexts containing such lexical items. He performed his analysis on the data from the Wall Street Journal (WSJ) corpus and focused on four conceptual metaphors that occur with considerable regularity in the corpus. These include NUMERICAL VALUE AS LOCATION, COMMERCIAL ACTIVITY AS CONTAINER, COMMERCIAL ACTIVITY AS PATH FOLLOWING and COMMERCIAL ACTIVITY AS WAR. Martin manually compiled the lists of terms characteristic for each domain by examining sampled metaphors of these types and then augmented them through the use of thesaurus. He then searched the WSJ for sentences containing vocabulary from these lists and checked whether they contain metaphors of the above types. The goal of this study was to evaluate predictive ability of contexts containing vocabulary from (1) source domain and (2) target domain, as well as (3) estimating the likelihood of a metaphorical expression following another metaphorical expression described by the same mapping. He obtained the most positive results for metaphors of the type NUMERICAL-VALUE-AS-LOCATION ($P(Metaphor|Source) = 0.069$, $P(Metaphor|Target) = 0.677$, $P(Metaphor|Metaphor) = 0.703$).

6.3 Annotating Source and Target Domains

Wallington et al. (2003) carried out a metaphor annotation experiment in the framework of the ATT-Meta project. They employed two teams of annotators. Team A was asked to annotate "interesting stretches", whereby a phrase was considered interesting if (1) its significance in the document was non-physical, (2) it could have a physical significance in another context with a similar syntactic frame, (3) this physical significance was related to the abstract one. Team B had to annotate phrases according to their own intuitive definition of metaphor. Besides metaphorical expressions Wallington et al. (2003) attempted to annotate the involved source – target domain mappings. The annotators were given a set of mappings from the Master Metaphor List and were asked to assign the most suitable ones to the examples. However, the authors do not report the level of interannotator agreement nor the coverage of the mappings in the Master Metaphor List on their data.

Shutova and Teufel (2010) adopt a different approach to the annotation of source – target domain mappings. They do not rely on predefined mappings, but instead derive independent sets of most common source and target categories. They propose a two stage procedure, whereby the metaphorical expressions are first identified using MIP, and then the source domain (where the basic sense comes from) and the target domain (the given context) are selected from the lists of categories. Shutova and Teufel (2010) report interannotator agreement of 0.61 (κ).

7 Conclusion and Future Directions

The eighties and nineties provided us with a wealth of ideas on the structure and mechanisms of the phenomenon of metaphor. The approaches formulated back then are still highly influential, although their use of hand-coded knowledge is becoming increasingly less convincing. The last decade witnessed a high technological leap in

natural language computation, whereby manually crafted rules gradually give way to more robust corpus-based statistical methods. This is also the case for metaphor research. The latest developments in the lexical acquisition technology will in the near future enable fully automated corpus-based processing of metaphor.

However, there is still a clear need in a unified metaphor annotation procedure and creation of a large publicly available metaphor corpus. Given such a resource the computational work on metaphor is likely to proceed along the following lines: (1) automatic acquisition of an extensive set of valid metaphorical associations from linguistic data via statistical pattern matching; (2) using the knowledge of these associations for metaphor recognition in the unseen unrestricted text and, finally, (3) interpretation of the identified metaphorical expressions by deriving the closest literal paraphrase (a representation that can be directly embedded in other NLP applications to enhance their performance).

Besides making our thoughts more vivid and filling our communication with richer imagery, metaphors also play an important structural role in our cognition. Thus, one of the long term goals of metaphor research in NLP and AI would be to build a computational intelligence model accounting for the way metaphors organize our conceptual system, in terms of which we think and act.

Acknowledgments

I would like to thank Anna Korhonen and my reviewers for their most helpful feedback on this paper. The support of Cambridge Overseas Trust, who fully funds my studies, is gratefully acknowledged.

Abstract

We present a game-theoretic model of bargaining over a metaphor in the context of political communication, find its equilibrium, and use it to rationalize observed linguistic behavior. We argue that game theory is well suited for modeling discourse as a dynamic resulting from a number of conflicting pressures, and suggest applications of interest to computational linguists.

1 Introduction

A 13 Dec 1992 article in *The Times* starts thus:

> The European train chugged out of the station last night; for most of the day it looked as if it might be stalled there for some time. It managed to pull away at around 10:30 pm only after the Spanish prime minister, Felipe Gonzalez, forced the passengers in the first class carriages into a last minute whip round to sweeten the trip for the European Community's poor four: Spain, Portugal, Greece and Ireland.
>
> The fat controller, Helmut Kohl, beamed with satisfaction as the deal was done. The elegantly-suited Francois Mitterrand was equally satisfied. But nobody was as pleased as John Major, stationmaster for the UK presidency, for whom the agreement marked a scarce high point in a battered premiership.
>
> The departure had actually been delayed by seven months by Danes on the line. Just when that problem was solved, there was the voluble outbreak, orchestrated by Spain, from the poor four passengers demanding that they should travel free and be given spending money, too.
>
> The coupling of the carriages may not be reliably secure but the pan-European express is in motion. That few seem to agree the destination suggests that future arguments are inevitable at every set of points. Next stop: Copenhagen.

Apart from an entertaining read, the extended metaphor provides an elaborate conceptual correspondence between a familiar domain of train journeys and the unfolding process of European integration. Carriages are likened to nation states; passengers to their peoples; treaties to stations; politicians to responsible rail company employees.

In a compact form, the metaphor gives expression to both the small and the large scale of the process. It provides for the recent history: Denmark's failure to ratify the 1992 Maastricht treaty until opt-outs were negotiated later that year is compared to dissenters sabotaging the journey by laying on the tracks (*Danes on the line*); negotiations over the Cohesion Fund that would provide less developed regions with financial aid to help them comply with convergence criteria are likened to second class carriages with poor passengers for whom the journey had to be subsidized. At a more general level, the European integration is a purposeful movement towards some destination according to a worked out plan, getting safely through negotiation and implementation from one treaty to another, as a train moving on its rails through subsequent stations, with each nation being separate yet tied with everyone else. Numerous inferences regarding speed, timetables, stations, passengers, different classes of tickets, temporary obstacles on the tracks, and so on can be made by the reader based on the knowledge of train journeys, giving him or her a feeling of an enhanced understanding[1] of the highly complex process of European integration.

So apt was the metaphor that political fights were waged over its details (Musolff, 2000). Worries about destination were given an eloquent expression by Margaret Thatcher (*Sunday Times*, 20 Sept 1992):

> She warned EC leaders to stop their endless round of summits and take notice of their own people. "There is a fear that the European train will thunder forward, laden with its customary cargo of gravy, towards a destination neither wished for nor understood by electorates. But the train can be stopped," she said.

[1] More on enhanced understanding in sections 3.2 and 4.2.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 698–709,
Uppsala, Sweden, 11-16 July 2010.

The metaphor proved flexible enough for further elaboration. John Major, a Conservative PM of Britain, spoke on June 1st, 1994 about his vision of the decision making at the EU level, saying that he had never believed that Europe must act as one on every issue, and advocating "a sensible new approach, varying when it needs to, multi-track, multi-speed, multi-layered." He attempted to turn a largely negative Conservative take on the European train (see Thatcher above) into a tenable positive vision — each nation-carriage is now presumably a rather autonomous entity, waiting on a side track for the right locomotive, in a huge yet smoothly operating railroad system.

Major's political opponents offered their counter-frames. In both cases, the imagery of a large transportation system was taken up, yet turned around to suggest that "multi, for everyone" amounts to Britain being in "the slow lane," and a different image was suggested that makes the negative evaluation of Britain's opt-outs more poignant — a football metaphor, where relegation to the second division is a sign of a weak performance, and a school metaphor, where Britain is portrayed as an under-achiever:

John Cunningham, Labour He has admitted that his Government would let Britain fall behind in Europe. He is apparently willing to offer voluntary relegation to the second division in Europe, and he isn't even prepared to put up a fight. I believe that in any two-speed Europe, Britain must be up with those in the fast lane. Clearly Mr Major does not.

Paddy Ashdown, Liberal Democrat Are you really saying that the best that Britain can hope for under your leadership is ... the slow lane of a two-speed Europe? Most people in this country will want to aim higher, and will reject your view of a 'drop-out' Britain.

The pro-European camp rallied around the "Britain in the slow lane" version as a critical stance towards the government's European policy. Of the alternative metaphors, the school metaphor has some traction in the Euro discourse, where the European (mainly German) financial officers are compared to school authorities, and governments struggling to meet the strict convergence criteria to enter the Euro are compared to pupils that barely make the grade with Britain as a 'drop-out' who gave up even trying (Musolff, 2000).

The fact that European policy is being communicated and negotiated via a metaphor is not surprising; after all, "there is always someone willing to help us think by providing us with a metaphor that accords with HIS views."[2] From the point of view of the dynamics of political discourse, the puzzle is rather the apparent tendency of politicians to be compelled by the *rival's* metaphorical framework. Thatcher tries to turn the train metaphor used by the pro-EU camp around. Yet, assuming metaphors are matters of choice, why should Thatcher feel constrained by her rival's choice, why doesn't she ignore it and merely suggest a new metaphor of her own design? As the evidence above suggests, this is not Thatcher's idiosyncrasy, as Major and his rivals acted similarly. Can this dynamic be explained?

In this article, we use the explanatory framework of game theory, seeking to rationalize the observed behavior by designing a game that would produce, at equilibrium, the observed dynamics. Specifically, we formalize the notion that the price of "locking" the public into a metaphorical frame of reference is that a politician is coerced into staying within the metaphor as well, even if he or she is at the receiving end of a rival's rhetorical move.

Since the use of game theory is not common in computational linguistics, we first explain its main attributes, justify our decision to make use of it, and draw connections to research questions that can benefit from its application (section 2). Next, we design the game of bargaining over a metaphor, and find its equilibrium (section 3), followed by a discussion (section 4).

2 Game-Theoretic models

The basic construct is that of a game, that is, a model of participants in an interaction (called "players"), their goals (or "utilities") and allowable moves. Different moves yield different utilities for a player; it is assumed that each player would pick a strategy that maximizes her utility. The observable is the actual sequence of moves; importantly, these are assumed to be the optimal outcome (an equilibrium) of the relevant game. A popular notion of equilibrium is Nash equilibrium (Nash, 1950). For extensive form games (the type employed in this paper), the notion of *subgame perfect equilibirum* is typically used, denoting a Nash equilibrium that would remain such if the players start from any stage of the evolving game (Selten (1975; 1965)).

The task of a game theorist is to reverse-engineer the model for which the observed se-

[2] Capitalization in the original, Bolinger (1980, p. 146).

quence of actions is an equilibrium. The resulting model is thereby able to rationalize the observed behavior as a naturally emerging dynamics between agents maximizing certain utility functions. In economics, game-theoretic models are used to explain price change, organization of production, and market failures (Mas-Colell et al., 1995; von Neumann and Morgenstern, 1944); in biology — the operation of natural selection processes (Axelrod and Hamilton, 1981; Maynard Smith and Price, 1973); in social sciences — political institutions, collective action, and conflict (Greif, 2006; Schelling, 1997; North, 1990). In recent applications in linguistics, pragmatic phenoma such as implicatures are rendered as an equilibrium outcome of a communication game (Jäger and Ebert, 2008; van Rooij, 2008; Ross, 2007; van Rooij and Schulz, 2004; Parikh, 2001; Glazer and Rubinstein, 2001; Dekker and van Rooy, 2000).

Computing equilibria is simple for some games and quite evolved for others. For example, computing the equilibrium of a zero-sum game is equivalent to LP optimization (Luce and Raiffa, 1957); an equilibrium of general bimatrix games can be found using a pivoting algorithm (von Stengel, 2007; Lemke and Howson, 1964). Interesting connections have been pointed out between game theory and machine learning: Freund and Schapire (1996) present both online learning and boosting as a repeated zero-sum game; Shalev-Shwartz and Singer (2006) show similarly that loss minimization in online learning is akin to an equilibrium path in a repeated game.

While game theoretic models are not much utilized in computational linguistics, they are quite attractive to tackle some of the problems computational linguists are interested in. For example, generation of referring expressions (Paraboni et al., 2007; Gardent et al., 2004; Siddharthan and Copestake, 2004; Dale and Reiter, 1995) can be rendered as a communication game with utility functions that reflect pressures to use shorter expressions while avoiding excessive ambiguity (Clark and Parikh, 2007), with corpora annotated for entity mentions informing the design of a model. Generally, computational linguistics research produces algorithms to detect entities of various kinds, be it topics, named entities, metaphors, moves in a multi-party conversations, or syntactic constructions in large corpora; such primary data can be used to trace developments not only in chronological terms (Gruhl et al., 2004; Allan, 2002), but in strategic terms, i.e. in terms that reflect agendas of the actors, such as political agendas in legislatures (Quinn et al., 2006) or activist forums (Greene and Resnik, 2009), research agendas in group meetings (Morgan et al., 2001), or social agendas in speed-dates (Jurafsky et al., 2009). Game theoretical models are well suited for modeling dynamics that emerge under multiple, possibly conflicting constraints, as we exemplify in this article.

3 The model

We extend Rubinstein (1982) model of negotiation through offers and counter-offers between two players with a public benefit constraint.

The model consists of (1) two players representing the opposing sides, (2) a set of **frames** $X \subset \mathbb{R}^n$ compact and convex, (3) preference relations described by continuous utility functions $U_1, U_2 : X \to \mathbb{R}^+$, (4) a sequence of frames $\mathcal{X}_0 \subset \mathcal{X}_1 \ldots \subset 2^X$ that can be suggested to the public, and (5) a sequence of public preferences over frames in $\mathcal{X}_t$ for $t=0, 1, 2, \ldots$ described by a public utility function U_t^p.

The game proceeds as follows. Initially the frame is $F_0=X$. In odd rounds player 1 appeals to the public with a frame $A_t^1 \in \mathcal{X}_{t|_{F_t}}$, $\mathcal{X}_{t|_{F_t}} = \{A \in \mathcal{X}_t : A \subset F_t\}$, player 2 counters with a frame $A_t^2 \in \mathcal{X}_{t|_{F_t}}$. The public chooses one of the frames based on $U_t^p(A_t^i)$ with ties broken in 1's favor. The accepted frame becomes the current frame for the next round F_{t+1}. In even rounds the parts of players 1 and 2 are reversed.

A finite sequence $F_0, \ldots, F_{t-1}$ gives the *history* of the bargaining process up to t. A *strategy* σ_i of player i is a function specifying for any history $h=\{F_0, \ldots, F_{t-1}\}$ the move player i makes at time t, namely the frame A_t^i she chooses to address the public. A sequence $F_0, F_1, F_2, F_3, \ldots$ describes a path the bargaining process can take, leading to an *outcome* $\cap_{t=0}^{\infty} F_t$. The players' utility for an outcome is given by $U_i = \lim_{t\to\infty} \int_{F_t} U_i(x) d\chi_{F_t}$ for $i=1, 2$ where χ_{F_t} is a probability measure on F_t. If $\cap_{t=0}^{\infty} F_t = \{x\}$ the utility is the point utility of x otherwise it is the expected utility on the intersection set.

3.1 Player utility

For a given issue under discussion, such as European integration process, we order the possible

states of the world along a single dimension that spans the policy variations proposed by the different players (politicians). Politics of a single issue are routinely modeled as lying on a single dimension.[3] In the British context, various configurations of the unfolding European reality are situated along the line between high degree of integration and complete separatism; Liberal Democrats are the most pro-European party, while United Kingdom Independence Party are at the far-right end of the scale, preferring British withdrawal from the EU. The two major parties, Labour and Conservatives (Tories), prefer intermediate left-leaning and right-leaning positions, respectively. A schematic description is shown in figure 1.

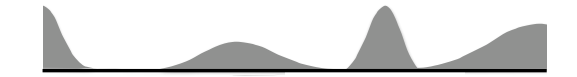

Figure 1: Preferences on pro-anti Europe axis.

The utilities of the different players can in this case be described as continuous single-peaked functions over an interval.[4] Thus X=$[0,1]$, and the utility functions $U_i(x)$=$\phi(||x-v_i||)$ for $v_i \in X$ where ϕ is a monotonically strictly decreasing function and $||\ ||$ is Euclidean distance.

3.2 Public utility

We note the difference between two types of utilities: The utility of the players is over outcomes, the utility of the public is over sets of outcomes (frames). The latter does not represent a utility the public has for one outcome or another, but rather a utility it has for an enhanced understanding. Thus, the public's utility from a frame is a function of the information content of the proposed frame relative to the current frame, i.e. the relative entropy of the two sets.[5] Formally, if the accepted frame at time t is F_t then for any Borel set $A \subset F_t$ the public utility for A is $U^p_t(A)$=$\Pi(\mathrm{Ent}_t(A))$ where $\mathrm{Ent}_t(A)$=$-\mu_t(A)\log\mu_t(A)$ for a continuous probability measure μ_t on F_t and Π is a continuous, monotone ascending function; for $A \not\subset F_t$, $U^p_t(A)$=0. We take μ_t to be the relative length of the segment $\mu_t(A)$=$\frac{|A|}{|F_t|}$, hence the entropy maximizing subsegments are of length $\frac{|F_t|}{2}$.

3.3 Game dynamics

At every point in the game, a certain set of the states-of-affairs is being deemed sufficiently probable by the public to require consideration. Suppose that initially any state of affairs within the interval $[0,1]$ is assigned a uniform probability and thus merits public attention. Each in her turn, the players propose to the public to concentrate on a subset of the currently considered states of affairs, arguing that those are the likelier ones to obtain, hence merit further attention. The metaphor used to deliver the proposal describes the newly proposed subset in a way that makes those states-of-affairs that are in it aligned with the metaphor, whereas all other states are left out of the proposed metaphorical frame. As the game proceeds, the public attention is concentrated on successively smaller sets of eventualities, and these are given a more and more detailed metaphoric description, providing the educational gratification of increasingly knowing better and better what is going on. At each step, each player strives to provide maximum public gratification while leading the public to focus on the frame (i.e. subset of states of affairs) that best meets the player's preferences.[6]

Figure 2 sketches the frame negotiation through train metaphor, from some point in time when the general train metaphor got established, through Thatcher's flashing out the issue of excessive speed and unclear direction, Major's multi-track corrective, and reply of his opponents on the left. The final frame has all those states of affairs that fit the extended metaphor – everyone is acting within the same broad system of rules, with Britain and perhaps others sometimes wanting to negotiate special, more gradual procedures, which would leave Britain less tightly integrated into the com-

[3] Indeed, Poole and Rosenthal (1997) argue that no more than two dimensions are needed to account for voting patterns on *all* issues in the US Congress.

[4] Single-peakedness is a common assumption in position modeling in political science (Downs, 1957).

[5] The notion that new beliefs are refinements of existing ones is current in contemporary theorizing about formation and change of beliefs, evaluations, and preferences. An update based on the latest available information is consistent with memory-based theories; in our model, in the equilibrium, the current frame contains information about the path-so-far, thus early stages of the bargaining processes are in some sense integrated into the current frame, compatible with the rival, online model of belief formation. See Druckman and Luria (2000) for a review of the relevant literature.

[6] We note that in our model every utterance has an impact on the public for which the player bears the consequences and is therefore a (costly) strategic move in the game. This is different from models of cheap talk such as Aumann (1990), Lewis (1969) where communication is devoid of strategic moves and is used primarily as a coordination device.

munity than some other European partners.

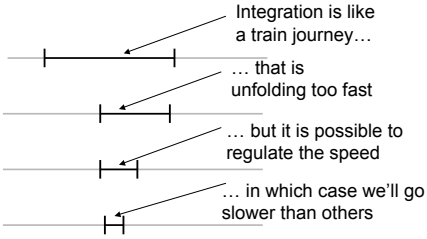

Figure 2: Bargaining over train metaphor.

3.4 The equilibrium

A pair of strategies (σ_1, σ_2) is a *Nash equilibrium* if there is no deviation strategy σ such that (σ, σ_2) leads to an outcome with higher utility for player 1 than outcome of (σ_1, σ_2) and the same for player 2. A *subgame* are all the possible moves following a history h=$\{F_0, \ldots, F_t\}$, in our case it is equivalent to a game with an initial frame F_t and the corresponding utilities. A *sub-strategy* is that part of the original strategy that is a strategy on the subgame. A pair of strategies is a *subgame perfect equilibrium* if, for any subgame, their sub-strategies are a Nash equilibrium.

Theorem 1 *In the frame bargaining game with single-peaked preferences*

1. *There exists a canonical subgame perfect equilibrium path* $F_0, F_1, F_2, \ldots$ *such that* $\cap_{t=0}^{\infty} F_t$=$\{x\}$.

2. *For any subgame perfect equilibrium path* $F'_0, F'_1, F'_2, \ldots$ *there exists* T *such that* $\cap_{t=0}^{\infty} F'_t$=$\cap_{t=0}^{T} F_t$.

The theorem states that the outcome of the bargaining will always be a frame on the canonical path. The rivals would suggest more specific frames either until convergence or until a situation where any further specification would produce a frame that "misses their point," so-to-speak, by removing too much of the favorable outcome space for both players. Figure 3 shows a situation where parties could decide to stall on the current frame: If player 1 has to choose between retaining F_0, or playing F_1 which would result in the rival's playing F_2, player 1 might choose to remain in F_0 if the utility of any outcome of the subgame starting from F_2 is lower than that of F_0, as long as player 1 believes that player 2 would reason similarly.

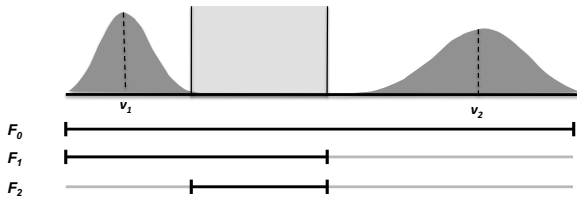

Figure 3: Stalled bargaining.

The idea of the proof is to construct a pair of strategies where each side attempts to pull the publicly accepted frame in the direction of its peak utility point. We show, assuming the peak of the first mover is to the left of peak of the second, that any deviation of the first mover would enable the second to shift the public frame more to the right, to an outcome of lower utility to the first mover. The full details of the proof of part 1 are given in the appendix; part 2 is proved in an accompanying technical report.

The equilibrium exhibits the following properties: (a) a first mover's advantage — for any player, the outcome would be closer to her peak point if she moves first than if she moves second; (b) a centrist's advantage — if a player moves first and her peak is closer to the middle of the initial frame, she can derive a higher utility from the outcome than if her peak were further from the middle. Please see appendix for justifications.

4 Discussion

4.1 Political communication

This article studies some properties of frame bargaining through metaphor in political communication, where rival politicians choose how to elaborate the current metaphor to educate the public about the ongoing situation in a way most consistent with their political preferences. Modeling the public preferences as highest relative entropy subset of possible states-of-affairs, we show that strategic choices by the politicians lead to a subgame perfect equilibrium where the less politically extreme player who moves first is at an advantage.

In a democracy, such player would typically be the government, as the bulk of voters do not by definition vote for extreme views, and since the government is the agent that brings about changes in the current states of affairs, and is thus the first and most prepared to explain them to the public. Indeed, Entman's model of frame activation in political discourse is hierarchical, with the govern-

ment (administration) being the topmost frame-activator, and opposition and media elites typically reacting to the administration's frame (Entman, 2003).

4.2 Metaphor in political communication

The role of metaphor in communication has long been a subject of interest, with views ranging from an ornament that beautifies the argument in the ancient rhetorical traditions, to the contemporary views of conceptual metaphor as permeating every aspect of life (Lakoff and Johnson, 1980).

In political communication specifically, metaphor has long been known as a framing device. Framing can be defined as "selecting and highlighting some facets of events or issues, and making connections among them in order to promote a particular interpretation, evaluation, or solution" (Entman, 2003). Metaphors are notorious for allowing subliminal framing, where the metaphor seems so natural that the aspects of the phenomenon in question that do *not* align with the metaphor are seamlessly concealed. For example, WAR AS A COMPETITIVE GAME metaphor emphasizes the glory of winning and the shame of defeat, but hides the death-and-suffering aspect of the war, which makes sports metaphors a strategic choice when wishing to arouse a pro-war sentiment in the audience (Lakoff, 1991). Such subliminal framing can often be effectively contested by merely exposing the frame.

Our examples show a different use of metaphor. Far from being subliminal or covert, the details of the metaphor, its implications, and the evaluation promoted by any given version are an important tool in the public discussion of a complex political issue. The function of metaphorical framing here resembles a pedagogical one, where rendering an abstract theory in physics (such as electricity) in concrete commonsensical terms (such as water flow) is an effective strategy to enhance the students' understanding of the former (Gentner and Gentner, 1983). The measure of success for a given version of the frame is its ability to sway the public in the evaluative direction envisioned by the author by providing sufficient *educational benefit*, so-to-speak, that is, convincingly rendering a good portion of a complex reality in accessible terms.

Once a frame is found that provides extensive education benefit, such as the EUROPEAN INTEGRATION AS TRAIN JOURNEY above, a politician's attempt to debunk a metaphor as inappropriate risk public antagonism, as this would be akin to taking the benefit of enhanced understanding away. Thus, rather than contesting the validity of the metaphoric frame, politicians strive to find a way to turn the metaphor around, i.e. accept the general framework, but focus on a previously unexplored aspect that would lead to a different evaluative tilt. Our results show that being the first to use an effective metaphor that manages to lock the public in its framework is a strategic advantage as the need to communicate with the same public would compel the rival to take up the metaphor of your choice. To our knowledge, this is the first explanation of the use of extended metaphor in political communication on a complex issue in terms of the agendas of the rival parties and the changing disposition of the public being addressed. It is an open question whether similar "locking in" of the public can be attained by non-metaphorical means, and whether the ensuing dynamics would be similar.

4.3 Social dynamics

This article contributes to the growing literature on modeling social linguistic behavior, like debates (Somasundaran and Wiebe, 2009), dating (Jurafsky et al., 2009; Ranganath et al., 2009), collaborative authoring and editing in wikis (Leuf and Cunningham, 2001) such as Wikipedia (Vuong et al., 2008; Kittur et al., 2007; Viégas et al., 2004). The latter literature in particular sees the social activity as an unfolding process, for example, detecting the onset and resolution of a controversy over the content of a Wikipedia article through tracking article talk[7] and deletion-and-reversion patterns. Somewhat similarly to the metaphor debate discussed in this article, Viégas et al. (2004) note first-mover advantage in Wikipedia authoring, that is, the first version gives the tone for the subsequent edits and has its parts survive for relatively many editing cycles. Finding out how the initial contribution constrains and guides subsequent edits of the content of a Wikipedia article and what kind of argumentative strategies are employed in persuading others to retain one's contribution is an interesting direction for future research.

A number of recent studies of the linguistic aspects of social processes are construed as if the

[7] a page separate from the main article that is devoted to the discussion of the edits

events are taking place all-at-once — there is no differentiation between early and later stages of a debate in Somasundaran and Wiebe (2009) or initial and subsequent speed-dates for the same subject in Jurafsky et al. (2009). Yet adopting a dynamic perspective stands to reason in such cases.

For example, Somasundaran and Wiebe (2009) built a system for recognizing stance in an online debate (such as pro-iPhone or pro-Blackberry on http://www.covinceme.net). They noticed that the task was complicated by concessions — acknowledgments of some virtues of the competitor before stating own preference. This is quite possibly an instance of debate dynamics whereby as the debate evolves certain common ground emerges between the sides and the focus of the debate changes from the initial stage of elucidating which features are better in which product to a stage where the "facts" are settled and acknowledged by both sides and the debate moves to evaluation of the relative importance of those features.

As another example, consider the construction of statistical models of various emotional and personality traits based on a corpus of speed dates such as Jurafsky et al. (2009). Take the trait of intelligence. In their experiment with speed-dates, Fisman et al. (2006) found that males tend to disprefer females they perceive as more intelligent or ambitious than themselves. Consequently, an intelligent female might choose to act less intelligent in later rounds of speed dating if she has not so far met a sufficiently intelligent male, assuming she prefers a less-intelligent male to no match at all.

Better sensitivity to the dynamics of social processes underlying the observed linguistic communication will we believe result in increased interest in game-theoretic models, as these are especially well suited to handle cases where the sides have certain goals and adapt their moves based on the current situations, the other side's move, and possibly other considerations, such as the need to address effectively a wider audience, beyond the specific interlocutors. A game theoretic explanation advances the understanding of the process being modeled, and hence of the applicability, and the potential adaptation, of statistical models developed on a certain dataset to situations that differ somewhat from the original data: For example, a corpus with more rounds of speed-dates per participant might suddenly make females seem smarter, or a debate with a longer history would feature more, and perhaps more elaborate, concessions.

5 Empirical challenges

We suggested that models of dynamics such as the one presented in this article be built over data where entities of interest are clearly identified. This article is based on chapters 1 and 2 of the book by Musolff (2000) which itself is informed by a corpus-linguistic analysis of metaphor in media discourse in Britain and Germany. We now discuss the state of affairs in empirical approaches to detecting metaphors.

5.1 Metaphors in NLP

Metaphors received increasing attention from computational linguistics community in the last two decades. The tasks that have been addressed are explication of the reasoning behind the metaphor (Barnden et al., 2002; Narayanan, 1999; Hobbs, 1992); detection of conventional metaphors between two specific domains (Mason, 2004); classification of words, phrases or sentences as metaphoric or non-metaphoric (Krishnakumaran and Zhu, 2007; Birke and Sarkar, 2006; Gedigian et al., 2006; Fass, 1991).

We are not aware of research on automatic methods specifically geared to recognition of extended metaphors. Indeed, most computational work cited above concentrates on the detection of a local incongruity due to a violation of selectional restrictions when the verb or one of its arguments is used metaphorically (as in *Protesters derailed the conference*). Extended metaphors are expected to be difficult for such approaches, since many of the clauses are completely situated in the source domain and hence no local incongruities exist (see examples on the first page of this article).

5.2 Data collection

Supervised approaches to metaphor detection need to rely on annotated data. While metaphors are ubiquitous in language, an annotation project that seeks to narrow the scope of relevant metaphors down to metaphors from a particular source domain (such as train journeys) that describe a particular target domain (such as European integration) and are uttered by certain entities (such as senior UK politicians) face the problem of sparsity of the relevant data in the larger discourse: A random sample of the size amenable to human an-

notation is unlikely to capture in sufficient detail material pertaining to the one metaphor of interest.

To increase the likelihood of finding mentions of the source domain, a lexicon of words from the source domain can be used to select documents (Hardie et al., 2007; Gedigian et al., 2006). Another approach is metaphor "harvesting" – hypothesizing that metaphors of interest would occur in close proximity to lexical items representing the target domain of the metaphor, such as the 4 word window around the lemma *Europe* used in Reining and Lönneker-Rodman (2007).

5.3 Data annotation

A further challenge is producing reliable annotations. Pragglejaz (2007) propose a methodology for testing metaphoricity of a word in discourse and report κ=0.56-0.70 agreement for a group of six highly expert annotators. Beigman Klebanov et al. (2008) report κ=0.66 for detecting paragraphs containing metaphors from the source domains LOVE and VEHICLE with multiple non-expert annotators, though other source domains that often feature highly conventionalized metaphors (like *structure* or *foundation* from BUILDLING domain) or are more abstract and difficult to delimit (such as AUTHORITY) present a more challenging annotation task.

5.4 Measuring metaphors

A fully empirical basis for the kind of model presented in this paper would also involve defining a metric on metaphors that would allow measuring the frame chosen by the given version of the metaphor relatively to other such frames – that is, quantifying which part of the "integration is a train journey" metaphor is covered by those states of affairs that also fit Thatcher's critical rendition.

6 Conclusion

This article addressed a specific communicative setting (rival politicians trying to "sell" to the public their versions of the unfolding realities and necessary policies) and a specific linguistic tool (an extended metaphor), showing that the particular use made of metaphor in such setting can be rationalized based on the characteristics of the setting.

Various questions now arise. Given the central role played by the public gratification constraint in our model, would conversational situations without the need to persuade the public, such as meetings of small groups of peers or phone conversations between friends, tend less to the use of extended metaphor? Conversely, does the use of extended metaphor in other settings testify to the existence of presumed onlookers who need to be "captured" in a particular version of reality — as in pedagogic or poetic context?

Considerations of the participants' agendas and their impact on the ensuing dynamics of the exchange would we believe lead to further interest in game theoretic models when addressing complex social dynamics in situations like collaborative authoring, debates, or dating, and will augment the existing mostly statistical approaches with a broader picture of the relevant communication.

A Proof of Existence of a Subgame Perfect Equilibrium

For a segment $[a, b]$ and $a \leq v_1 < v_2 \leq b$ let $U_1(x)=\phi(||x - v_1||)$ and $U_2(x)=\phi(||x - v_2||)$ be utility functions with peaks v_1 and v_2, respectively. For a history $h=\{F_0, \ldots, F_t\}$ where $F_t=[l_t, r_t]$, let $\sigma_1^*(h)$, player 1's move, be defined as choosing $F_{t+1}=[l_{t+1}, r_{t+1}]$ such that $|F_{t+1}|=\frac{|F_t|}{2}$, and r_{t+1} is as close as possible to v_1. σ_2^* sets l_{t+1} with respect to v_2 in a symmetric fashion. Since F_t shrinks by half every round, $\lim_{t\to\infty} l_t = \lim_{t\to\infty} r_t = x^*$, converging to a point. We now show (σ_1^*, σ_2^*) is an equilibrium by showing that neither player has a profitable deviation.

Notice that after the first round the subgame is identical to the initial game with F_1 replacing F_0, and the roles of players reversed. Player 2 had no influence on the choice of F_1, hence she has a profitable deviation iff she has a profitable deviation on the continuation subgame where she is the first mover. It thus suffices to show that the first mover (player 1) has no profitable deviations to establish that (σ_1^*, σ_2^*) is an equilibrium.

Since by definition σ_2^* always chooses an entropy maximizing segment, for player 1 to choose a non-entropy maximizing segment (more or less than half the length) amounts to yielding the round to player 2, which is equivalent in terms of the resulting accepted frame to a situation where player 1 chooses an entropy maximizing segment – the same one chosen by player 2. Thus we need to consider only deviations with entropy maximizing frames.

Step 1: Suppose σ_1' is a strategy of player 1 and let $F_0', F_1', F_2', \ldots$ be the sequence of frames on

the path corresponding to the pair (σ_1', σ_2^*). Let t_0 be the first move deviating from the equilibrium path, namely $F_{t_0} \neq F'_{t_0}$. We first show that F_{t_0-1} could not be (a) completely to the left of v_1 or (b) completely to the right of v_2. Suppose (a) holds. Then by definition $r_{t_0-2}=r_{t_0-1}<v_1$, and, inductively, $r_0=r_{t_0-1}<v_1$; this contradicts $r_0=1$ that follows from $F_0=[0,1]$. Possibility (b) is similarly refuted. Therefore, the only two cases for F_{t_0-1} with respect to v_1 are depicted in figure 4. Note that this implies $v_1 \leq x^* \leq v_2$.

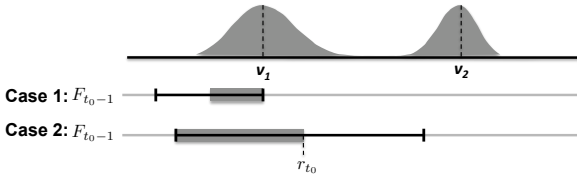

Figure 4: Two cases of current frame location.

Step 2: In case 1, σ_1^* will choose frames of type $[l_t, v_1]$ for any $t \geq t_0$, and σ_2^* will do the same on any history in the continuation game, hence the outcome will eventually be v_1. As this is player 1's peak utility point, she has no profitable deviation.

Step 3: In case 2, F_{t_0} is the leftmost entropy maximizing subsegment of F_{t_0-1} and the deviation F'_{t_0} can only be a shift to the right namely $r'_{t_0} \geq r_{t_0}$. If player 2 could choose $[v_2, r_{t_0+1}]$ given r_{t_0}, she can still choose the same frame given r'_{t_0}, so the outcome would be v_2 and F'_{t_0} was not profitable. If player 2 could not choose $[v_2, r_{t_0+1}]$ given r_{t_0}, implying that $x^* < v_2$, but as a result of the deviation can now choose $[v_2, r'_{t_0+1}]$, implying that the outcome would be v_2, clearly player 1 has not benefited from the deviation since U_1 is descending right of v_1. If player 2 still cannot choose $[v_2, r'_{t_0+1}]$ after the deviation, she would choose the rightmost entropy maximizing segment with $l'_{t_0+1} \geq l_{t_0+1}$. If this still allows player 1 to do $[l'_{t_0+2}, v_1]$ and hence to lead to v_1 as the outcome, it was possible in $[l_{t_0+2}, v_1]$ as well, so no profit is gained by having deviated. Otherwise, $r'_{t_0+2} \geq r_{t_0+2}$.

Step 3 can be repeated ad infinitum to show that $r'_t \geq r_t$ unless for some history h the deviation enables $\sigma_2(h)=[v_2, r'_t]$. In the former case we get $\lim_{t\to\infty} r'_t = x' \geq x^* = \lim_{t\to\infty} r_t$ where $\cap_{t=1}^{\infty} F'_t = \{x'\}$. Since r'_t and r_t are to the right of v_1 and U_1 is descending right of v_1 it follows that $U_1(x^*) \geq U_1(x')$. In the latter case $x' \geq v_2$. Since F_t is never strictly to the right of v_2, $x^* = \lim_{t\to\infty} l_t \leq v_2 \leq x'$, therefore $U_1(x^*) \geq U_1(x')$. In either case the deviation σ'_1 cannot result in a better outcome for player 1. This finishes the proof that (σ_1^*, σ_2^*) is a Nash equilibrium.

Notice that (σ_1^*, σ_2^*) prescribe sub-strategies on any subgame that are themselves Nash equilibria for the subgames, hence (σ_1^*, σ_2^*) is a subgame perfect equilibrium □

First Mover's Advantage: The proof of step 3 shows that having the left boundary of the current frame further to the right cannot yield a better outcome for player 1. Yet, if player 1's first turn comes after that of player 2, she will start with a current frame with the left boundary further to the right than the initial frame before player 2 moved, since moving the left boundary is player 2's equilibrium strategy. Hence a player would never achieve a better outcome starting second if both players are playing the canonical strategy.

Centrist's Advantage: Let M be the middle of F_0. Consider a more extreme version of player 1 — player $1^\#$. Suppose w.l.g. $v_1^\# < v_1 \leq M$. In case $v_1^\# < v_1 < v_2$, for all utilities u of the outcome of dynamics vs player 2, if player $1^\#$ could attain u, player 1 could attain u or more; the reverse is not true, for example when $|v_1^\# - l_t| < \frac{|F_t|}{2} \leq |v_1 - l_t|$ and player 1 (or $1^\#$) is moving first. In case $v_2 < v_1^\# < v_1$, if player 1 (or $1^\#$) moves first, she is able to force her peak point as the outcome. If $v_1^\# < v_2 < v_1$, player 1 can force v_1 as the outcome, whereas player $1^\#$ would not necessarily be able to force $v_1^\#$, as player 2 would pull the outcome towards v_2. Hence a first moving centrist is never worse off, and often better off, than a first moving extremist.

Abstract

Syntactic knowledge is important for discourse relation recognition. Yet only heuristically selected flat paths and 2-level production rules have been used to incorporate such information so far. In this paper we propose using tree kernel based approach to automatically mine the syntactic information from the parse trees for discourse analysis, applying kernel function to the tree structures directly. These structural syntactic features, together with other normal flat features are incorporated into our composite kernel to capture diverse knowledge for simultaneous discourse identification and classification for both explicit and implicit relations. The experiment shows tree kernel approach is able to give statistical significant improvements over flat syntactic path feature. We also illustrate that tree kernel approach covers more structure information than the production rules, which allows tree kernel to further incorporate information from a higher dimension space for possible better discrimination. Besides, we further propose to leverage on temporal ordering information to constrain the interpretation of discourse relation, which also demonstrate statistical significant improvements for discourse relation recognition on PDTB 2.0 for both explicit and implicit as well.

1 Introduction

Discourse relations capture the internal structure and logical relationship of coherent text, including *Temporal*, *Causal* and *Contrastive* relations etc. The ability of recognizing such relations between text units including identifying and classifying provides important information to other natural language processing systems, such as language generation, document summarization, and question answering. For example, *Causal* relation can be used to answer more sophisticated, non-factoid *'Why'* questions.

Lee et al. (2006) demonstrates that modeling discourse structure requires prior linguistic analysis on syntax. This shows the importance of syntactic knowledge to discourse analysis. However, most of previous work only deploys lexical and semantic features (Marcu and Echihabi, 2002; Pettibone and PonBarry, 2003; Saito et al., 2006; Ben and James, 2007; Lin et al., 2009; Pitler et al., 2009) with only two exceptions (Ben and James, 2007; Lin et al., 2009). Nevertheless, Ben and James (2007) only uses flat syntactic path connecting connective and arguments in the parse tree. The hierarchical structured information in the trees is not well preserved in their flat syntactic path features. Besides, such a syntactic feature selected and defined according to linguistic intuition has its limitation, as it remains unclear what kinds of syntactic heuristics are effective for discourse analysis.

The more recent work from Lin et al. (2009) uses 2-level production rules to represent parse tree information. Yet it doesn't cover all the other sub-trees structural information which can be also useful for the recognition.

In this paper we propose using tree kernel based method to automatically mine the syntactic

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 710–719,
Uppsala, Sweden, 11-16 July 2010.

information from the parse trees for discourse analysis, applying kernel function to the parse tree structures directly. These structural syntactic features, together with other flat features are then incorporated into our composite kernel to capture diverse knowledge for simultaneous discourse identification and classification. The experiment shows that tree kernel is able to effectively incorporate syntactic structural information and produce statistical significant improvements over flat syntactic path feature for the recognition of both explicit and implicit relation in Penn Discourse Treebank (PDTB; Prasad et al., 2008). We also illustrate that tree kernel approach covers more structure information than the production rules, which allows tree kernel to further work on a higher dimensional space for possible better discrimination.

Besides, inspired by the linguistic study on tense and discourse anaphor (Webber, 1988), we further propose to incorporate temporal ordering information to constrain the interpretation of discourse relation, which also demonstrates statistical significant improvements for discourse relation recognition on PDTB v2.0 for both explicit and implicit relations.

The organization of the rest of the paper is as follows. We briefly introduce PDTB in Section 2. Section 3 gives the related work on tree kernel approach in NLP and its difference with production rules, and also linguistic study on tense and discourse anaphor. Section 4 introduces the frame work for discourse recognition, as well as the baseline feature space and the SVM classifier. We present our kernel-based method in Section 5, and the usage of temporal ordering feature in Section 6. Section 7 shows the experiments and discussions. We conclude our works in Section 8.

2 Penn Discourse Tree Bank

The Penn Discourse Treebank (PDTB) is the largest available annotated corpora of discourse relations (Prasad et al., 2008) over 2,312 Wall Street Journal articles. The PDTB models discourse relation in the predicate-argument view, where a discourse connective (e.g., *but*) is treated as a predicate taking two text spans as its arguments. The argument that the discourse connective syntactically bounds to is called Arg2, and the other argument is called Arg1.

The PDTB provides annotations for both explicit and implicit discourse relations. An *explicit* relation is triggered by an explicit connective. Example (1) shows an explicit *Contrast* relation signaled by the discourse connective *'but'*.

(1). Arg1. *Yesterday, the retailing and financial services giant reported a 16% drop in third-quarter earnings to $257.5 million, or 75 cents a share, from a restated $305 million, or 80 cents a share, a year earlier.*
Arg2. <u>But</u> the news was even worse for Sears's core U.S. retailing operation, the largest in the nation.

In the PDTB, *local* implicit relations are also annotated. The annotators insert a connective expression that best conveys the inferred *implicit* relation between adjacent sentences within the same paragraph. In Example (2), the annotators select *'because'* as the most appropriate connective to express the inferred *Causal* relation between the sentences. There is one special label *AltLex* pre-defined for cases where the insertion of an *Implicit* connective to express an inferred relation led to a *redundancy* in the expression of the relation. In Example (3), the *Causal* relation derived between sentences is *alternatively lexicalized* by some *non-connective expression* shown in square brackets, so no *implicit* connective is inserted. In our experiments, we treat *AltLex* Relations the same way as normal *Implicit* relations.

(2). Arg1. *Some have raised their cash positions to record levels.*
Arg2. <u>Implicit = Because</u> High cash positions help buffer a fund when the market falls.

(3). Arg1. *Ms. Bartlett's previous work, which earned her an international reputation in the non-horticultural art world, often took gardens as its nominal subject.*
Arg2. [Mayhap this metaphorical connection made] the BPC Fine Arts Committee think she had a literal green thumb.

The PDTB also captures two non-implicit cases: (a) *Entity* relation where the relation between adjacent sentences is based on entity coherence (Knott et al., 2001) as in Example (4); and (b) *No* relation where no discourse or entity-based coherence relation can be inferred between adjacent sentences.

(4). But for South Garden, the grid was to be a 3-D network of masonry or hedge walls with real plants inside them.

In a Letter to the BPCA, kelly/varnell called *this* "arbitrary and amateurish."

Each *Explicit*, *Implicit* and *AltLex* relation is annotated with a sense. The *senses* in PDTB are arranged in a three-level hierarchy. The top level has four tags representing four major semantic classes: *Temporal*, *Contingency*, *Comparison* and *Expansion*. For each class, a second level of *types* is defined to further refine the semantic of the class levels. For example, *Contingency* has two types *Cause* and *Condition*. A third level of *subtype* specifies the semantic contribution of each argument. In our experiments, we use only the top level of the sense annotations.

3 Related Work

Tree Kernel based Approach in NLP. While the feature based approach may not be able to fully utilize the syntactic information in a parse tree, an alternative to the feature-based methods, tree kernel methods (Haussler, 1999) have been proposed to implicitly explore features in a high dimensional space by employing a kernel function to calculate the similarity between two objects directly. In particular, the kernel methods could be very effective at reducing the burden of feature engineering for structured objects in NLP research (Culotta and Sorensen, 2004). This is because a kernel can measure the similarity between two discrete structured objects by directly using the original representation of the objects instead of explicitly enumerating their features.

Indeed, using kernel methods to mine structural knowledge has shown success in some NLP applications like parsing (Collins and Duffy, 2001; Moschitti, 2004) and relation extraction (Zelenko et al., 2003; Zhang et al., 2006). However, to our knowledge, the application of such a technique to discourse relation recognition still remains unexplored.

Lin et al. (2009) has explored the 2-level production rules for discourse analysis. However, Figure 1 shows that only 2-level sub-tree structures (e.g. T_a - T_e) are covered in production rules. Other sub-trees beyond 2-level (e.g. T_f - T_j) are only captured in the tree kernel, which allows tree kernel to further leverage on information from higher dimension space for possible better discrimination. Especially, when there are enough training data, this is similar to the study

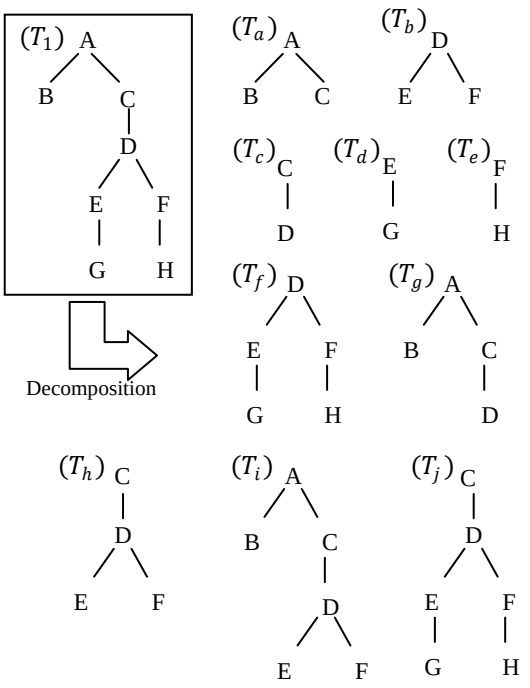

Figure 1. Different sub-tree sets for T_1 used by 2-level production rules and convolution tree kernel approaches. T_a-T_j and T_1 itself are covered by tree kernel, while only T_a-T_e are covered by production rules.

on language modeling that N-gram beyond unigram and bigram further improves the performance in large corpus.

Tense and Temporal Ordering Information. Linguistic studies (Webber, 1988) show that a tensed clause C_b provides two pieces of semantic information: (a) a description of an event (or situation) E_b; and (b) a particular configuration of the *point of event* (ET), the *point of reference* (RT) and the *point of speech* (ST). Both the characteristics of E_b and the configuration of ET, RT and ST are critical to interpret the relationship of event E_b with other events in the discourse model. Our observation on temporal ordering information is in line with the above, which is also incorporated in our discourse analyzer.

4 The Recognition Framework

In the learning framework, a training or testing instance is formed by a non-overlapping clause(s)/sentence(s) pair. Specifically, since *implicit* relations in PDTB are defined to be *local*, only clauses from adjacent sentences are paired for implicit cases. During training, for each discourse relation encountered, a positive instance is created by pairing the two arguments. Also a

set of negative instances is formed by paring each argument with neighboring non-argument clauses or sentences. Based on the training instances, a binary classifier is generated for each type using a particular learning algorithm. During resolution, (a) clauses within same sentence and sentences within three-sentence spans are paired to form an explicit testing instance; and (b) neighboring sentences within three-sentence spans are paired to form an implicit testing instance. The instance is presented to each explicit or implicit relation classifier which then returns a class label with a confidence value indicating the likelihood that the candidate pair holds a particular discourse relation. The relation with the highest confidence value will be assigned to the pair.

4.1 Base Features

In our system, the base features adopted include lexical pair, distance and attribution etc. as listed in Table 1. All these base features have been proved effective for discourse analysis in previous work.

Feature Names	Description
(F1)	cue phrase
(F2)	neighboring punctuation
(F3)	position of connective if presents
(F4)	extents of arguments
(F5)	relative order of arguments
(F6)	distance between arguments
(F7)	grammatical role of arguments
(F8)	lexical pairs
(F9)	attribution

Table 1. Base Feature Set

4.2 Support Vector Machine

In theory, any discriminative learning algorithm is applicable to learn the classifier for discourse analysis. In our study, we use Support Vector Machine (Vapnik, 1995) to allow the use of kernels to incorporate the structure feature.

Suppose the training set S consists of labeled vectors $\{(x_i, y_i)\}$, where x_i is the feature vector of a training instance and y_i is its class label. The classifier learned by SVM is:

$$f(x) = sgn\left(\sum_{i=1} y_i a_i x * x_i + b\right)$$

where a_i is the learned parameter for a feature vector x_i, and b is another parameter which can be derived from a_i . A testing instance x is classified as positive if $f(x) > 0$[1].

One advantage of SVM is that we can use tree kernel approach to capture syntactic parse tree information in a particular high-dimension space.

In the next section, we will discuss how to use kernel to incorporate the more complex structure feature.

5 Incorporating Structural Syntactic Information

A parse tree that covers both discourse arguments could provide us much syntactic information related to the pair. Both the syntactic flat path connecting connective and arguments and the 2-level production rules in the parse tree used in previous study can be directly described by the tree structure. Other syntactic knowledge that may be helpful for discourse resolution could also be implicitly represented in the tree. Therefore, by comparing the common sub-structures between two trees we can find out to which level two trees contain similar syntactic information, which can be done using a convolution tree kernel.

The value returned from the tree kernel reflects the similarity between two instances in syntax. Such syntactic similarity can be further combined with other flat linguistic features to compute the overall similarity between two instances through a composite kernel. And thus an SVM classifier can be learned and then used for recognition.

5.1 Structural Syntactic Feature

Parsing is a sentence level processing. However, in many cases two discourse arguments do not occur in the same sentence. To present their syntactic properties and relations in a single tree structure, we construct a syntax tree for each paragraph by attaching the parsing trees of all its sentences to an upper paragraph node. In this paper, we only consider discourse relations within 3 sentences, which only occur within each pa-

[1] In our task, the result of $f(x)$ is used as the confidence value of the candidate argument pair x to hold a particular discourse relation.

ragraph, thus paragraph parse trees are sufficient. Our 3-sentence spans cover 95% discourse relation cases in PDTB v2.0.

Having obtained the parse tree of a paragraph, we shall consider how to select the appropriate portion of the tree as the structured feature for a given instance. As each instance is related to two arguments, the structured feature at least should be able to cover both of these two arguments. Generally, the more substructure of the tree is included, the more syntactic information would be provided, but at the same time the more noisy information would likely be introduced. In our study, we examine three structured features that contain different substructures of the paragraph parse tree:

Min-Expansion This feature records the minimal structure covering both arguments and connective word in the parse tree. It only includes the nodes occurring in the shortest path connecting Arg1, Arg2 and connective, via the nearest commonly commanding node. For example, considering Example (5), Figure 2 illustrates the representation of the structured feature for this relation instance. Note that the two clauses underlined with dashed lines are *attributions* which are not part of the relation.

(5). Arg1. *Suppression of the book,* Judge Oakes observed, *would operate as a prior restraint and thus involve the First Amendment.*

Arg2. Moreover, and here Judge Oakes went to the heart of the question, "Responsible biographers and historians constantly use primary sources, letters, diaries and memoranda."

Simple-Expansion *Min-Expansion* could, to some degree, describe the syntactic relationships between the connective and arguments. However, the syntactic properties of the argument pair might not be captured, because the tree structure surrounding the argument is not taken into consideration. To incorporate such information, *Simple-Expansion* not only contains all the nodes in *Min-Expansion*, but also includes the first-level children of these nodes[2]. Figure 3 illustrates such a feature for Example (5). We can see that the nodes "PRN" in both sentences are included in the feature.

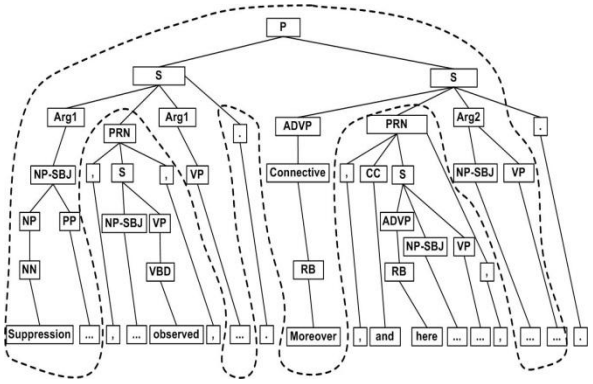

Figure 2. Min-Expansion tree built from golden standard parse tree for the explicit discourse relation in Example (5). Note that to distinguish from other words, we explicitly mark up in the structured feature the arguments and connective, by appending a string tag "Arg1", "Arg2" and "Connective" respectively.

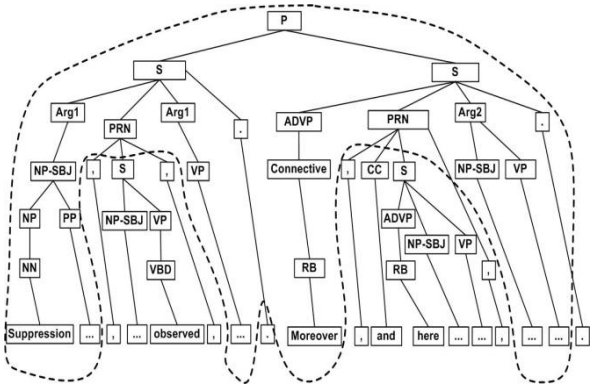

Figure 3. Simple-Expansion tree for the explicit discourse relation in Example (5).

Full-Expansion This feature focuses on the tree structure between two arguments. It not only includes all the nodes in *Simple-Expansion*, but also the nodes (beneath the nearest commanding parent) that cover the words between the two arguments. Such a feature keeps the most information related to the argument pair. Figure 4

[2] We will not expand the nodes denoting the sentences other than where the arguments occur.

shows the structure for feature *Full-Expansion* of Example (5). As illustrated, different from in *Simple-Expansion*, each sub-tree of "PRN" in each sentence is fully expanded and all its children nodes are included in *Full-Expansion*.

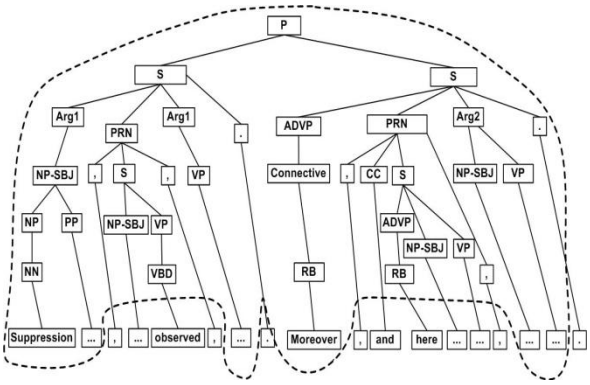

Figure 4. Full-Expansion tree for the explicit discourse relation in Example (5).

5.2 Convolution Parse Tree Kernel

Given the parse tree defined above, we use the same convolution tree kernel as described in (Collins and Duffy, 2002) and (Moschitti, 2004). In general, we can represent a parse tree T by a vector of integer counts of each sub-tree type (regardless of its ancestors):

$$\emptyset(T) = (\#of\ subtrees\ of\ type\ 1, \dots, \#\ of\ subtrees\ of type\ I, \dots, \#\ of\ subtrees\ of\ type\ n).$$

This results in a very high dimensionality since the number of different sub-trees is exponential in its size. Thus, it is computational infeasible to directly use the feature vector $\emptyset(T)$. To solve the computational issue, a tree kernel function is introduced to calculate the dot product between the above high dimensional vectors efficiently.

Given two tree segments T_1 and T_2, the tree kernel function is defined:

$$\begin{aligned} K(T_1, T_2) &= < \emptyset(T_1), \emptyset(T_2) > \\ &= \sum_i \emptyset(T_1)[i], \emptyset(T_2)[i] \\ &= \sum_{n_1 \in N_1} \sum_{n_2 \in N_2} \sum_i I_i(n_1) * I_i(n_2) \end{aligned}$$

where N_1 and N_2 are the sets of all nodes in trees T_1 and T_2, respectively; and $I_i(n)$ is the indicator function that is 1 iff a subtree of type i occurs with root at node n or zero otherwise. (Collins and Duffy, 2002) shows that $K(T_1, T_2)$ is an instance of convolution kernels over tree structures, and can be computed in $O(|N_1|, |N_2|)$ by the following recursive definitions:

$$\Delta(n_1, n_2) = \sum_i I_i(n_1) * I_i(n_2)$$

(1) $\Delta(n_1, n_2) = 0$ if n_1 and n_2 do not have the same syntactic tag or their children are different;

(2) else if both n_1 and n_2 are pre-terminals (i.e. POS tags), $\Delta(n_1, n_2) = 1 \times \lambda$;

(3) else, $\Delta(n_1, n_2) =$

$$\lambda \prod_{j=1}^{nc(n_1)} (1 + \Delta(ch(n_1, j), ch(n_2, j))),$$

where $nc(n_1)$ is the number of the children of n_1, $ch(n, j)$ is the j^{th} child of node n and λ ($0 < \lambda < 1$) is the decay factor in order to make the kernel value less variable with respect to the sub-tree sizes. In addition, the recursive rule (3) holds because given two nodes with the same children, one can construct common sub-trees using these children and common sub-trees of further offspring.

The parse tree kernel counts the number of common sub-trees as the syntactic similarity measure between two instances. The time complexity for computing this kernel is $O(|N_1| \cdot |N_2|)$.

5.3 Composite Tree Kernel

Besides the above convolution parse tree kernel $\widehat{K}_{tree}(x_1, x_2) = K(T_1, T_2)$ defined to capture the syntactic information between two instances x_1 and x_2, we also use another kernel $\widehat{K}_{flat}$ to capture other flat features, such as base features (described in Table 1) and temporal ordering information (described in Section 6). In our study, the composite kernel is defined in the following way:

$$\begin{aligned} \widehat{K}_1(x_1, x_2) = \alpha \cdot \widehat{K}_{flat}(x_1, x_2) + \\ (1 - \alpha) \cdot \widehat{K}_{tree}(x_1, x_2). \end{aligned}$$

Here, $\widehat{K}(\cdot, \cdot)$ can be normalized by $\widehat{K}(y, z) = K(y, z)/\sqrt{K(y, y) \cdot K(z, z)}$ and α is the coefficient.

6 Using Temporal Ordering Information

In our discourse analyzer, we also add in temporal information to be used as features to predict discourse relations. This is because both our observations and some linguistic studies (Webber, 1988) show that temporal ordering information including tense, aspectual and event orders between two arguments may constrain the discourse relation type. For example, the connective

word is the same in both Example (6) and (7), but the tense shift from progressive form in clause 6.a to simple past form in clause 6.b, indicating that the *twisting* occurred during the state of *running the marathon*, usually signals a *temporal* discourse relation; while in Example (7), both clauses are in past tense and it is marked as a *Causal* relation.

(6). a. Yesterday Holly was running a marathon
b. ***when*** she twisted her ankle.

(7). a. Use of dispersants was approved
b. ***when*** a test on the third day showed some positive results.

Inspired by the linguistic model from Webber (1988) as described in Section 3, we explore the temporal order of events in two adjacent sentences for discourse relation interpretation. Here event is represented by the *head of verb*, and the temporal order refers to the *logical* occurrence (i.e. before/at/after) between events. For instance, the event ordering in Example (8) can be interpreted as:

$$Event(broken) \prec_{before} Event(went) .$$

8. a. John went to the hospital.
b. He had broken his ankle on a patch of ice.

We notice that the feasible temporal order of events differs for different discourse relations. For example, in *causal* relations, *cause* event usually happens before *effect* event, i.e.

$$Event(cause) \prec_{before} Event(effect).$$

So it is possible to infer a *causal* relation in Example (8) if and only if 8.b is taken to be the *cause* event and 8.a is taken to be the effect event. That is, 8.b is taken as happening prior to *his going into hospital*.

In our experiments, we use the TARSQI[3] system to identify event, analyze tense and aspectual information, and label the temporal order of events. Then the tense and temporal ordering information is extracted as features for discourse relation recognition.

7 Experiments and Results

In this section we provide the results of a set of experiments focused on the task of simultaneous discourse identification and classification.

7.1 Experimental Settings

We experiment on PDTB v2.0 corpus. Besides four top-level discourse relations, we also consider *Entity* and *No* relations described in Section 2. We directly use the golden standard parse trees in Penn TreeBank. We employ an SVM coreference resolver trained and tested on ACE 2005 with 79.5% Precision, 66.7% Recall and 72.5% F_1 to label coreference mentions of the same named entity in an article. For learning, we use the binary SVMLight developed by (Joachims, 1998) and Tree Kernel Toolkits developed by (Moschitti, 2004). All classifiers are trained with default learning parameters.

The performance is evaluated using *Accuracy* which is calculated as follow:

$$Accuracy = \frac{TruePositive + TrueNegative}{All}$$

Sections 2-22 are used for training and Sections 23-24 for testing. In this paper, we only consider any non-overlapping clauses/sentences pair in 3-sentence spans. For training, there were 14812, 12843 and 4410 instances for *Explicit*, *Implicit* and *Entity+No* relations respectively; while for testing, the number was 1489, 1167 and 380.

7.2 System with Structural Kernel

Table 2 lists the performance of simultaneous identification and classification on level-1 discourse senses. In the first row, only base features described in Section 4 are used. In the second row, we test Ben and James (2007)'s algorithm which uses heuristically defined syntactic paths and acts as a good baseline to compare with our learned-based approach using the structured information. The last three rows of Table 2 reports the results combining base features with three syntactic structured features (i.e. *Min-Expansion*, *Simple-Expansion* and *Full-Expansion*) described in Section 5.

We can see that all our tree kernels outperform the manually constructed flat path feature in all three groups including *Explicit* only, *Implicit* only and *All* relations, with the accuracy increasing by 1.8%, 6.7% and 3.1% respectively. Especially, it shows that structural syntactic information is more helpful for *Implicit* cases which is generally much harder than *Explicit* cases. We

Features	Accuracy		
	Explicit	Implicit	All
Base Features	67.1	29	48.6
Base + Manually selected flat path features	70.3	32	52.6
Base + Tree kernel (Min-Expansion)	71.9	38.6	55.6
Base + Tree kernel (Simple-Expansion)	**72.1**	**38.7**	**55.7**
Base + Tree kernel (Full-Expansion)	71.8	38.4	55.4

Table 2. Results of the syntactic structured kernels on level-1 discourse relation recognition.

conduct chi square statistical significance test on *All* relations between flat path approach and *Simple-Expansion* approach, which shows the performance improvements are statistical significant ($\rho < 0.05$) through incorporating tree kernel. This proves that structural syntactic information has good predication power for discourse analysis in both explicit and implicit relations. We also observe that among the three syntactic structured features, *Min-Expansion* and *Simple-Expansion* achieve similar performances which are better than the result for *Full-Expansion*. This may be due to that most significant information is with the arguments and the shortest path connecting connectives and arguments. However, *Full-Expansion* that includes more information in other branches may introduce too many details which are rather tangential to discourse recognition. Our subsequent reports will focus on *Simple-Expansion*, unless otherwise specified.

As described in Section 5, to compute the structural information, parse trees for different sentences are connected to form a large tree for a paragraph. It would be interesting to find how the structured information works for discourse relations whose arguments reside in different sentences. For this purpose, we test the accuracy for discourse relations with the two arguments occurring in the same sentence, one-sentence apart, and two-sentence apart. Table 3 compares the learning systems with/without the structured feature present. From the table, for all three cases, the accuracies drop with the increase of the distances between the two arguments. However, adding the structured information would bring consistent improvement against the baselines regardless of the number of sentence distance. This observation suggests that the structured syntactic information is more helpful for inter-sentential discourse analysis.

We also concern about how the structured information works for identification and classification respectively. Table 4 lists the results for the two sub-tasks. As shown, with the structured information incorporated, the system (Base + Tree Kernel) can boost the performance of the two baselines (Base Features in the first row andBase + Manually selected paths in the second row), for both identification and classification respectively. We also observe that the structural syntactic information is more helpful for classification task which is generally harder than identification. This is in line with the intuition that classification is generally a much harder task. We find that due to the weak modeling of *Entity* relations, many *Entity* relations which are non-discourse relation instances are mis-identified as implicit *Expansion* relations. Nevertheless, it clearly directs our future work.

Sentence Distance	0 (959)	1 (1746)	2 (331)
Base Features	52	49.2	35.5
Base + Manually selected flat path features	56.7	52	43.8
Base + Tree Kernel	58.3	55.6	49.7

Table 3. Results of the syntactic structured kernel for discourse relations recognition with arguments in different sentences apart.

Tasks	Identification	Classification
Base Features	58.6	50.5
Base + Manually selected flat path features	59.7	52.6
Base + Tree Kernel	63.3	59.3

Table 4. Results of the syntactic structured kernel for simultaneous discourse identification and classification subtasks.

7.3 System with Temporal Ordering Information

To examine the effectiveness of our temporal ordering information, we perform experiments

on simultaneous identification and classification of level-1 discourse relations to compare with using only base feature set as baseline. The results are shown in Table 5. We observe that the use of temporal ordering information increases the accuracy by 3%, 3.6% and 3.2% for *Explicit*, *Implicit* and *All* groups respectively. We conduct chi square statistical significant test on *All* relations, which shows the performance improvement is statistical significant ($\rho < 0.05$). It indicates that temporal ordering information can constrain the discourse relation types inferred within a clause(s)/sentence(s) pair for both explicit and implicit relations.

Features	Accuracy		
	Explicit	Implicit	All
Base Features	67.1	29	48.6
Base + Temporal Ordering Information	70.1	32.6	51.8

Table 5. Results of tense and temporal order information on level-1 discourse relations.

We observe that although temporal ordering information is useful in both explicit and implicit relation recognition, the contributions of the specific information are quite different for the two cases. In our experiments, we use tense and aspectual information for explicit relations, while event ordering information is used for implicit relations. The reason is explicit connective itself provides a strong hint for explicit relation, so tense and aspectual analysis which yields a reliable result can provide additional constraints, thus can help explicit relation recognition. However, event ordering which would inevitably involve more noises will adversely affect the explicit relation recognition performance. On the other hand, for implicit relations with no explicit connective words, tense and aspectual information alone is not enough for discourse analysis. Event ordering can provide more necessary information to further constrain the inferred relations.

7.4 Overall Results

We also evaluate our model which combines base features, tree kernel and tense/temporal ordering information together on *Explicit*, *Implicit* and *All* Relations respectively. The overall results are shown in Table 6.

Relations	Accuracy
Explicit	74.2
Implicit	40.0
All	57.3

Table 6. Overall results for combined model (Base + Tree Kernel + Tense/Temporal).

8 Conclusions and Future Works

The purpose of this paper is to explore how to make use of the structural syntactic knowledge to do discourse relation recognition. In previous work, syntactic information from parse trees is represented as a set of heuristically selected flat paths or 2-level production rules. However, the features defined this way may not necessarily capture all useful syntactic information provided by the parse trees for discourse analysis. In the paper, we propose a kernel-based method to incorporate the structural information embedded in parse trees. Specifically, we directly utilize the syntactic parse tree as a structure feature, and then apply kernels to such a feature, together with other normal features. The experimental results on PDTB v2.0 show that our kernel-based approach is able to give statistical significant improvement over flat syntactic path method. In addition, we also propose to incorporate temporal ordering information to constrain the interpretation of discourse relations, which also demonstrate statistical significant improvements for discourse relation recognition, both explicit and implicit.

In future, we plan to model *Entity* relations which constitute 24% of *Implicit+Entity+No* relation cases, thus to improve the accuracy of relation detection.

Hierarchical Joint Learning: Improving Joint Parsing and Named Entity Recognition with Non-Jointly Labeled Data

Jenny Rose Finkel and Christopher D. Manning
Computer Science Department
Stanford University
Stanford, CA 94305
{jrfinkel|manning}@cs.stanford.edu

Abstract

One of the main obstacles to producing high quality joint models is the lack of jointly annotated data. Joint modeling of multiple natural language processing tasks outperforms single-task models learned from the same data, but still underperforms compared to single-task models learned on the more abundant quantities of available single-task annotated data. In this paper we present a novel model which makes use of additional single-task annotated data to improve the performance of a joint model. Our model utilizes a hierarchical prior to link the feature weights for shared features in several single-task models and the joint model. Experiments on joint parsing and named entity recognition, using the OntoNotes corpus, show that our hierarchical joint model can produce substantial gains over a joint model trained on only the jointly annotated data.

1 Introduction

Joint learning of multiple types of linguistic structure results in models which produce more consistent outputs, and for which performance improves across all aspects of the joint structure. Joint models can be particularly useful for producing analyses of sentences which are used as input for higher-level, more semantically-oriented systems, such as question answering and machine translation. These high-level systems typically combine the outputs from many low-level systems, such as parsing, named entity recognition (NER) and coreference resolution. When trained separately, these single-task models can produce outputs which are inconsistent with one another, such as named entities which do not correspond to any nodes in the parse tree (see Figure 1 for an example). Moreover, one expects that the different types of annotations should provide useful information to one another, and that modeling them jointly should improve performance. Because a named entity should correspond to a node in the parse tree, strong evidence about either aspect of the model should positively impact the other aspect.

However, designing joint models which actually improve performance has proven challenging. The CoNLL 2008 shared task (Surdeanu et al., 2008) was on joint parsing and semantic role labeling, but the best systems (Johansson and Nugues, 2008) were the ones which completely decoupled the tasks. While negative results are rarely published, this was not the first failed attempt at joint parsing and semantic role labeling (Sutton and McCallum, 2005). There have been some recent successes with joint modeling. Zhang and Clark (2008) built a perceptron-based joint segmenter and part-of-speech (POS) tagger for Chinese, and Toutanova and Cherry (2009) learned a joint model of lemmatization and POS tagging which outperformed a pipelined model. Adler and Elhadad (2006) presented an HMM-based approach for unsupervised joint morphological segmentation and tagging of Hebrew, and Goldberg and Tsarfaty (2008) developed a joint model of segmentation, tagging and parsing of Hebrew, based on lattice parsing. No discussion of joint modeling would be complete without mention of (Miller et al., 2000), who trained a Collins-style generative parser (Collins, 1997) over a syntactic structure augmented with the *template entity* and *template relations* annotations for the MUC-7 shared task.

One significant limitation for many joint models is the lack of jointly annotated data. We built a joint model of parsing and named entity recognition (Finkel and Manning, 2009b), which had small gains on parse performance and moderate gains on named entity performance, when compared with single-task models trained on the same data. However, the performance of our model, trained using the OntoNotes corpus (Hovy et al., 2006), fell short of separate parsing and named

entity models trained on larger corpora, annotated with only one type of information.

This paper addresses the problem of how to learn high-quality joint models with smaller quantities of jointly-annotated data that has been augmented with larger amounts of single-task annotated data. To our knowledge this work is the first attempt at such a task. We use a hierarchical prior to link a joint model trained on jointly-annotated data with other single-task models trained on single-task annotated data. The key to making this work is for the joint model to share some features with each of the single-task models. Then, the singly-annotated data can be used to influence the feature weights for the shared features in the joint model. This is an important contribution, because it provides all the benefits of joint modeling, but without the high cost of jointly annotating large corpora. We applied our hierarchical joint model to parsing and named entity recognition, and it reduced errors by over 20% on both tasks when compared to a joint model trained on only the jointly annotated data.

2 Related Work

Our task can be viewed as an instance of *multi-task learning*, a machine learning paradigm in which the objective is to simultaneously solve multiple, related tasks for which you have separate labeled training data. Many schemes for multitask learning, including the one we use here, are instances of hierarchical models. There has not been much work on multi-task learning in the NLP community; Daumé III (2007) and Finkel and Manning (2009a) both build models for multi-domain learning, a variant on domain adaptation where there exists labeled training data for all domains and the goal is to improve performance on all of them. Ando and Zhang (2005) utilized a multi-task learner within their semi-supervised algorithm to learn feature representations which were useful across a large number of related tasks. Outside of the NLP community, Elidan et al. (2008) used an undirected Bayesian transfer hierarchy to jointly model the shapes of multiple mammal species. Evgeniou et al. (2005) applied a hierarchical prior to modeling exam scores of students. Other instances of multi-task learning include (Baxter, 1997; Caruana, 1997; Yu et al., 2005; Xue et al., 2007). For a more general discussion of hierarchical models, we direct the reader to Chapter 5 of (Gelman et al., 2003) and Chapter 12 of (Gelman and Hill, 2006).

3 Hierarchical Joint Learning

In this section we will discuss the main contribution of this paper, our hierarchical joint model which improves joint modeling performance through the use of *single-task models* which can be trained on *singly-annotated data*. Our experiments are on a joint parsing and named entity task, but the technique is more general and only requires that the *base models* (the joint model and single-task models) share some features. This section covers the general technique, and we will cover the details of the parsing, named entity, and joint models that we use in Section 4.

3.1 Intuitive Overview

As discussed, we have a joint model which requires jointly-annotated data, and several single-task models which only require singly-annotated data. The key to our hierarchical model is that the joint model must have features in common with each of the single models, though it can also have features which are only present in the joint model.

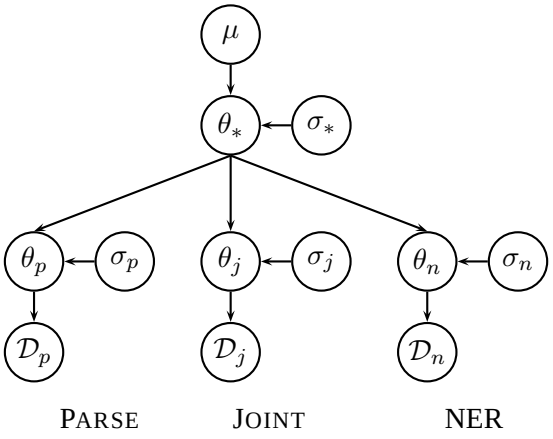

Figure 2: A graphical representation of our hierarchical joint model. There are separate base models for just parsing, just NER, and joint parsing and NER. The parameters for these models are linked via a hierarchical prior.

Each model has its own set of parameters (feature weights). However, parameters for the features which are shared between the single-task models and the joint model are able to influence one another via a hierarchical prior. This prior encourages the learned weights for the different models to be similar to one another. After training has been completed, we retain only the joint model's parameters. Our resulting joint model is of higher quality than a comparable joint model trained on only the jointly-annotated data, due to all of the evidence provided by the additional single-task data.

3.2 Formal Model

We have a set $\mathcal{M}$ of three base models: a parse-only model, an NER-only model and a joint model. These have corresponding log-likelihood functions $\mathcal{L}_p(\mathcal{D}_p;\theta_p)$, $\mathcal{L}_n(\mathcal{D}_n;\theta_n)$, and $\mathcal{L}_j(\mathcal{D}_j;\theta_j)$, where the $\mathcal{D}$s are the training data for each model, and the θs are the model-specific parameter (feature weight) vectors. These likelihood functions do *not* include priors over the θs. For representational simplicity, we assume that each of these vectors is the same size and corresponds to the same ordering of features. Features which don't apply to a particular model type (e.g., parse features in the named entity model) will always be zero, so their weights have no impact on that model's likelihood function. Conversely, allowing the presence of those features in models for which they do not apply will not influence their weights in the other models because there will be no evidence about them in the data. These three models are linked by a hierarchical prior, and their feature weight vectors are all drawn from this prior. The parameters θ_* for this prior have the same dimensionality as the model-specific parameters θ_m and are drawn from another, top-level prior. In our case, this top-level prior is a zero-mean Gaussian.[1]

The graphical representation of our hierarchical model is shown in Figure 2. The log-likelihood of this model is

$$\mathcal{L}_{\textit{hier-joint}}(\mathcal{D};\theta) = \sum_{m\in\mathcal{M}} \left(\mathcal{L}_m(\mathcal{D}_m;\theta_m) - \sum_i \frac{(\theta_{m,i}-\theta_{*,i})^2}{2\sigma_m^2} \right) - \sum_i \frac{(\theta_{*,i}-\mu_i)^2}{2\sigma_*^2} \quad (1)$$

The first summation in this equation computes the log-likelihood of each model, using the data and parameters which correspond to that model, and the prior likelihood of that model's parameters, based on a Gaussian prior centered around the top-level, non-model-specific parameters θ_*, and with model-specific variance σ_m. The final summation in the equation computes the prior likelihood of the top-level parameters θ_* according to a Gaussian prior with variance σ_* and mean μ (typically zero). This formulation encourages each base model to have feature weights similar to the top-level parameters (and hence one another).

The effects of the variances σ_m and σ_* warrant some discussion. σ_* has the familiar interpretation of dictating how much the model "cares" about feature weights diverging from zero (or μ). The model-specific variances, σ_m, have an entirely different interpretation. They dictate how how strong the penalty is for the domain-specific parameters to diverge from one another (via their similarity to θ_*). When σ_m are very low, then they are encouraged to be very similar, and taken to the extreme this is equivalent to completely tying the parameters between the tasks. When σ_m are very high, then there is less encouragement for the parameters to be similar, and taken to the extreme this is equivalent to completely decoupling the tasks.

We need to compute partial derivatives in order to optimize the model parameters. The partial derivatives for the parameters for each base model m are given by:

$$\frac{\partial \mathcal{L}_{\textit{hier}}(\mathcal{D};\theta)}{\partial \theta_{m,i}} = \frac{\partial \mathcal{L}_m(\mathcal{D}_m,\theta_m)}{\partial \theta_{m,i}} - \frac{\theta_{m,i}-\theta_{*,i}}{\sigma_d^2} \quad (2)$$

where the first term is the partial derivative according to the base model, and the second term is

[1] Though we use a zero-mean Gaussian prior, this top-level prior could take many forms, including an L_1 prior, or another hierarchical prior.

the prior centered around the top-level parameters. The partial derivatives for the top level parameters θ_* are:

$$\frac{\partial \mathcal{L}_{\textit{hier}}(\mathcal{D};\theta)}{\partial \theta_{*,i}} = \left(\sum_{m \in \mathcal{M}} \frac{\theta_{*,i} - \theta_{m,i}}{\sigma_m^2} \right) - \frac{\theta_{*,i} - \mu_i}{\sigma_*^2} \tag{3}$$

where the first term relates to how far each model-specific weight vector is from the top-level parameter values, and the second term relates how far each top-level parameter is from zero.

When a model has strong evidence for a feature, effectively what happens is that it pulls the value of the top-level parameter for that feature closer to the model-specific value for it. When it has little or no evidence for a feature then it will be pulled in the direction of the top-level parameter for that feature, whose value was influenced by the models which have evidence for that feature.

3.3 Optimization with Stochastic Gradient Descent

Inference in joint models tends to be slow, and often requires the use of stochastic optimization in order for the optimization to be tractable. L-BFGS and gradient descent, two frequently used numerical optimization algorithms, require computing the value and partial derivatives of the objective function using the entire training set. Instead, we use stochastic gradient descent. It requires a stochastic objective function, which is meant to be a low computational cost estimate of the real objective function. In most NLP models, such as logistic regression with a Gaussian prior, computing the stochastic objective function is fairly straightforward: you compute the model likelihood and partial derivatives for a randomly sampled subset of the training data. When computing the term for the prior, it must be rescaled by multiplying its value and derivatives by the proportion of the training data used. The stochastic objective function, where $\widehat{\mathcal{D}} \subseteq \mathcal{D}$ is a randomly drawn subset of the full training set, is given by

$$\mathcal{L}_{stoch}(\mathcal{D};\theta) = \mathcal{L}_{orig}(\widehat{\mathcal{D}};\theta) - \frac{|\widehat{\mathcal{D}}|}{|\mathcal{D}|} \sum_i \frac{(\theta_{*,i})^2}{2\sigma_*^2} \tag{4}$$

This is a *stochastic* function, and multiple calls to it with the same $\mathcal{D}$ and θ will produce different values because $\widehat{\mathcal{D}}$ is resampled each time. When designing a stochastic objective function, the critical fact to keep in mind is that the summed values and partial derivatives for any split of the data need to be equal to that of the full dataset. In practice, stochastic gradient descent only makes use of the partial derivatives and not the function value, so we will focus the remainder of the discussion on how to rescale the partial derivatives.

We now describe the more complicated case of stochastic optimization with a hierarchical objective function. For the sake of simplicity, let us assume that we are using a batch size of one, meaning $|\widehat{\mathcal{D}}| = 1$ in the above equation. Note that in the hierarchical model, each datum (sentence) in each base model should be weighted equally, so whichever dataset is the largest should be proportionally more likely to have one of its data sampled. For the sampled datum d, we then compute the function value and partial derivatives with respect to the correct base model for that datum. When we rescale the model-specific prior, we rescale based on the number of data in that model's training set, *not* the total number of data in all the models combined. Having uniformly randomly drawn datum $d \in \bigcup_{m \in \mathcal{M}} \mathcal{D}_m$, let $m(d) \in \mathcal{M}$ tell us to which model's training data the datum belongs. The stochastic partial derivatives will equal zero for all model parameters θ_m such that $m \neq m(d)$, and for $\theta_{m(d)}$ it becomes:

$$\frac{\partial \mathcal{L}_{\textit{hier-stoch}}(\mathcal{D};\theta)}{\partial \theta_{m(d),i}} = \tag{5}$$
$$\frac{\partial \mathcal{L}_{m(d)}(\{d\};\theta_{m(d)})}{\partial \theta_{m(d),i}} - \frac{1}{|\mathcal{D}_{m(d)}|} \left(\frac{\theta_{m(d),i} - \theta_{*,i}}{\sigma_d^2} \right)$$

Now we will discuss the stochastic partial derivatives with respect to the top-level parameters θ_*, which requires modifying Equation 3. The first term in that equation is a summation over all the models. In the stochastic derivative we only perform this computation for the datum's model $m(d)$, and then we rescale that value based on the number of data in that datum's model $|\mathcal{D}_{m(d)}|$. The second term in that equation is rescaled by the *total* number of data in all models combined. The stochastic partial derivatives with respect to θ_* become:

$$\frac{\partial \mathcal{L}_{\textit{hier-stoch}}(\mathcal{D};\theta)}{\partial \theta_{*,i}} = \tag{6}$$
$$\frac{1}{|\mathcal{D}_{m(d)}|} \left(\frac{\theta_{*,i} - \theta_{m(d),i}}{\sigma_m^2} \right) - \frac{1}{\sum_{m \in \mathcal{M}} |\mathcal{D}_m|} \left(\frac{\theta_{*,i}}{\sigma_*^2} \right)$$

where for conciseness we omit μ under the assumption that it equals zero.

An equally correct formulation for the partial derivative of θ_* is to simply rescale Equation 3 by the *total* number of data in all models. Early experiments found that both versions gave similar performance, but the latter was significantly

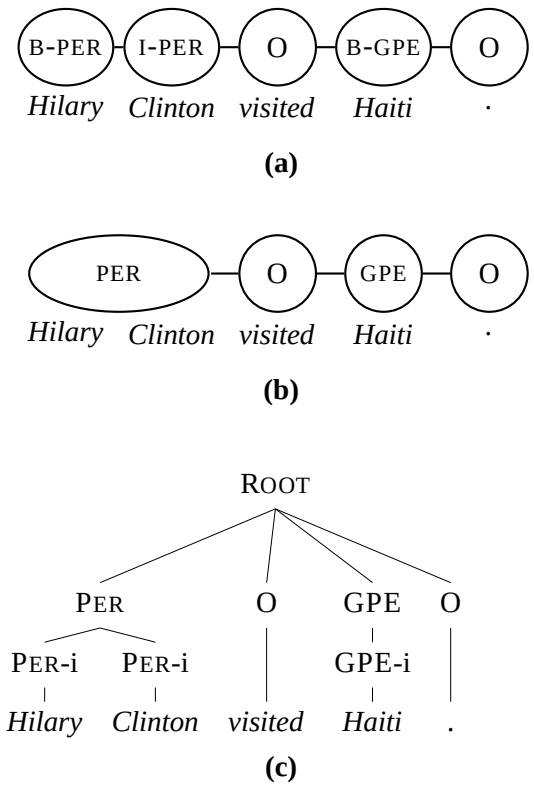

Figure 3: A linear-chain CRF **(a)** labels each word, whereas a semi-CRF **(b)** labels entire entities. A semi-CRF can be represented as a tree **(c)**, where **i** indicates an internal node for an entity.

slower to compute because it required summing over the parameter vectors for all base models instead of just the vector for the datum's model.

When using a batch size larger than one, you compute the given functions for each datum in the batch and then add them together.

4 Base Models

Our hierarchical joint model is composed of three separate models, one for just named entity recognition, one for just parsing, and one for joint parsing and named entity recognition. In this section we will review each of these models individually.

4.1 Semi-CRF for Named Entity Recognition

For our named entity recognition model we use a semi-CRF (Sarawagi and Cohen, 2004; Andrew, 2006). Semi-CRFs are very similar to the more popular linear-chain CRFs, but with several key advantages. Semi-CRFs *segment and label* the text simultaneously, whereas a linear-chain CRF will *only label* each word, and segmentation is implied by the labels assigned to the words. When doing named entity recognition, a semi-CRF will have one node for each entity, unlike a regular CRF which will have one node for each word.[2] See Figure 3a-b for an example of a semi-CRF and a linear-chain CRF over the same sentence. Note that the entity *Hilary Clinton* has one node in the semi-CRF representation, but two nodes in the linear-chain CRF. Because different segmentations have different model structures in a semi-CRF, one has to consider all possible structures (segmentations) as well as all possible labelings. It is common practice to limit segment length in order to speed up inference, as this allows for the use of a modified version of the forward-backward algorithm. When segment length is not restricted, the inference procedure is the same as that used in parsing (Finkel and Manning, 2009c).[3] In this work we do not enforce a length restriction, and directly utilize the fact that the model can be transformed into a parsing model. Figure 3c shows a parse tree representation of a semi-CRF.

While a linear-chain CRF allows features over adjacent words, a semi-CRF allows them over adjacent segments. This means that a semi-CRF can utilize all features used by a linear-chain CRF, and can also utilize features over entire segments, such as *First National Bank of New York City*, instead of just adjacent words like *First National* and *Bank of*. Let $\mathbf{y}$ be a vector representing the labeling for an entire sentence. y_i encodes the label of the ith segment, along with the span of words the segment encompasses. Let θ be the feature weights, and $\mathbf{f}(s, y_i, y_{i-1})$ the feature function over adjacent segments y_i and y_{i-1} in sentence s.[4] The log likelihood of a semi-CRF for a single sentence s is given by:

$$\mathcal{L}(\mathbf{y}|s;\theta) = \frac{1}{Z_s} \sum_{i=1}^{|\mathbf{y}|} \exp\{\theta \cdot \mathbf{f}(s, y_i, y_{i-1})\} \quad (7)$$

The partition function Z_s serves as a normalizer. It requires summing over the set $\mathbf{y}_s$ of all possible segmentations and labelings for the sentence s:

$$Z_s = \sum_{\mathbf{y} \in \mathbf{y}_s} \sum_{i=1}^{|\mathbf{y}|} \exp\{\theta \cdot \mathbf{f}(s, y_i, y_{i-1})\} \quad (8)$$

[2] Both models will have one node per word for non-entity words.

[3] While converting a semi-CRF into a parser results in much slower inference than a linear-chain CRF, it is still significantly faster than a treebank parser due to the reduced number of labels.

[4] There can also be features over single entities, but these can be encoded in the feature function over adjacent entities, so for notational simplicity we do not include an additional term for them.

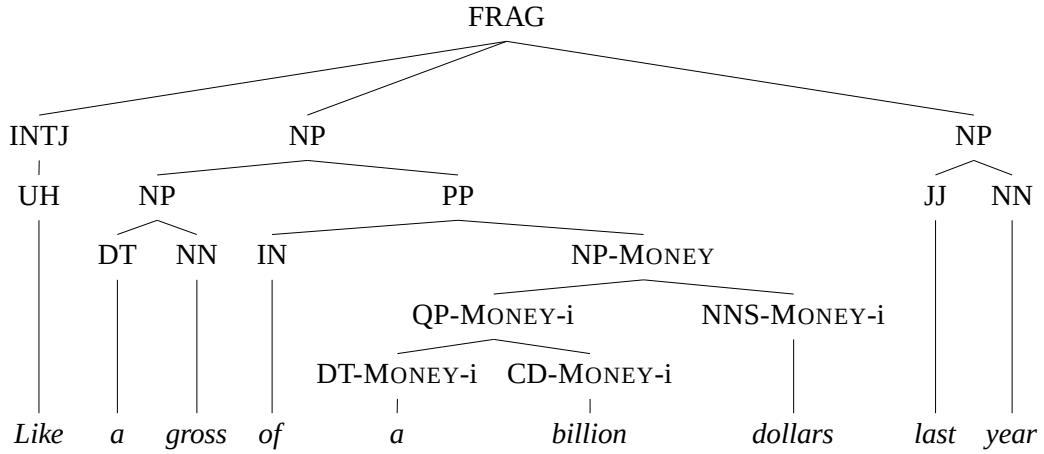

Figure 4: An example of a sentence jointly annotated with parse and named entity information. Named entities correspond to nodes in the tree, and the parse label is augmented with the named entity information.

Because we use a tree representation, it is easy to ensure that the features used in the NER model are identical to those in the joint parsing and named entity model, because the joint model (which we will discuss in Section 4.3) is also based on a tree representation where each entity corresponds to a single node in the tree.

4.2 CRF-CFG for Parsing

Our parsing model is the discriminatively trained, conditional random field-based context-free grammar parser (CRF-CFG) of (Finkel et al., 2008). The relationship between a CRF-CFG and a PCFG is analogous to the relationship between a linear-chain CRF and a hidden Markov model (HMM) for modeling sequence data. Let t be a complete parse tree for sentence s, and each local subtree $r \in t$ encodes both the rule from the grammar, and the span and split information (e.g $\text{NP}_{(7,9)} \rightarrow \text{JJ}_{(7,8)}\text{NN}_{(8,9)}$ which covers the last two words in Figure 1). The feature function $\mathbf{f}(r, s)$ computes the features, which are defined over a local subtree r and the words of the sentence. Let θ be the vector of feature weights. The log-likelihood of tree t over sentence s is:

$$\mathcal{L}(t|s;\theta) = \frac{1}{Z_s} \sum_{r \in t} \exp\{\theta \cdot \mathbf{f}(r, s)\} \quad (9)$$

To compute the partition function Z_s, which serves to normalize the function, we must sum over $\tau(s)$, the set of all possible parse trees for sentence s. The partition function is given by:

$$Z_s = \sum_{t' \in \tau(s)} \sum_{r \in t'} \exp\{\theta \cdot \mathbf{f}(r, s)\}$$

We also need to compute the partial derivatives which are used during optimization. Let $f_i(r, s)$ be the value of feature i for subtree r over sentence s, and let $E_\theta[f_i|s]$ be the expected value of feature i in sentence s, based on the current model parameters θ. The partial derivatives of θ are then given by

$$\frac{\partial \mathcal{L}}{\partial \theta_i} = \sum_{(t,s) \in \mathcal{D}} \left(\left(\sum_{r \in t} f_i(r, s) \right) - E_\theta[f_i|s] \right) \quad (10)$$

Just like with a linear-chain CRF, this equation will be zero when the feature expectations in the model equal the feature values in the training data.

A variant of the inside-outside algorithm is used to efficiently compute the likelihood and partial derivatives. See (Finkel et al., 2008) for details.

4.3 Joint Model of Parsing and Named Entity Recognition

Our base joint model for parsing and named entity recognition is the same as (Finkel and Manning, 2009b), which is also based on the discriminative parser discussed in the previous section. The parse tree structure is augmented with named entity information; see Figure 4 for an example. The features in the joint model are designed in a manner that fits well with the hierarchical joint model: some are over just the parse structure, some are over just the named entities, and some are over the joint structure. The joint model shares the NER and parse features with the respective single-task models. Features over the joint structure only appear in the joint model, and their weights are only indirectly influenced by the singly-annotated data.

In the parsing model, the grammar consists of only the rules observed in the training data. In the joint model, the grammar is augmented with ad-

Table 1: Training and test set sizes for the five datasets in sentences. The file ranges refer to the numbers within the names of the original OntoNotes files.

ditional joint rules which are composed by adding named entity information to existing parse rules. Because the grammars are based on the observed data, and the two models have different data, they will have somewhat different grammars. In our hierarchical joint model, we added all observed rules from the joint data (stripped of named entity information) to the parse-only grammar, and we added all observed rules from the parse-only data to the grammar for the joint model, and augmented them with named entity information in the same manner as the rules observed in the joint data.

Earlier we said that the NER-only model uses identical named entity features as the joint model (and similarly for the parse-only model), but this is not quite true. They use identical *feature templates*, such as *word*, but different realizations of those features will occur with the different datasets. For instance, the NER-only model may have *word=Nigel* as a feature, but because *Nigel* never occurs in the joint data, that feature is never manifested and no weight is learned for it. We deal with this similarly to how we dealt with the grammar: if a named entity feature occurs in either the joint data or the NER-only data, then both models will learn a weight for that feature. We do the same thing for the parse features. This modeling decision gives the joint model access to potentially useful features to which it would not have had access if it were not part of the hierarchical model.[5]

5 Experiments and Discussion

We compared our hierarchical joint model to a regular (non-hierarchical) joint model, and to parse-only and NER-only models. Our baseline experiments were modeled after those in (Finkel and Manning, 2009b), and while our results were not identical (we updated to a newer release of the data), we had similar results and found the same general trends with respect to how the joint model improved on the single models. We used OntoNotes 3.0 (Hovy et al., 2006), and made the same data modifications as (Finkel and Manning, 2009b) to ensure consistency between the parsing and named entity annotations. Table 2 has our complete set of results, and Table 1 gives the number of training and test sentences. For each section of the data (ABC, MNB, NBC, PRI, VOA) we ran experiments training a linear-chain CRF on only the named entity information, a CRF-CFG parser on only the parse information, a joint parser and named entity recognizer, and our hierarchical model. For the hierarchical model, we used the CNN portion of the data (5093 sentences) for the extra named entity data (and ignored the parse trees) and the remaining portions combined for the extra parse data (and ignored the named entity annotations). We used $\sigma_* = 1.0$ and $\sigma_m = 0.1$, which were chosen based on early experiments on development data. Small changes to σ_m do not appear to have much influence, but larger changes do. We similarly decided how many iterations to run stochastic gradient descent for (20) based on early development data experiments. We did not run this experiment on the CNN portion of the data, because the CNN data was already being used as the extra NER data.

As Table 2 shows, the hierarchical model did substantially better than the joint model overall, which is not surprising given the extra data to which it had access. Looking at the smaller corpora (NBC and MNB) we see the largest gains, with both parse and NER performance improving by about 8% F1. ABC saw about a 6% gain on both tasks, and VOA saw a 1% gain on both. Our one negative result is in the PRI portion: parsing improves slightly, but NER performance decreases by almost 2%. The same experiment on development data resulted in a performance increase, so we are not sure why we saw a decrease here. One general trend, which is not surprising, is that the hierarchical model helps the smaller datasets more than the large ones. The source of this is twofold: lower baselines are generally easier to improve upon, and the larger corpora had less singly-annotated data to provide improvements, because it was composed of the remaining, smaller, sections of OntoNotes. We found it interesting that the gains tended to be similar on both tasks for all datasets, and believe this fact is due to our use of roughly the same amount of singly-annotated data for both parsing and NER.

One possible conflating factor in these experiments is that of domain drift. While we tried to

[5] In the non-hierarchical setting, you could include those features in the optimization, but, because there would be no evidence about them, their weights would be zero due to regularization.

		Parse Labeled Bracketing			Named Entities

get the most similar annotated data available – data which was annotated by the same annotators, and all of which is broadcast news – these are still different domains. While this is likely to have a negative effect on results, we also believe this scenario to be a more realistic than if it were to also be data drawn from the exact same distribution.

6 Conclusion

In this paper we presented a novel method for improving joint modeling using additional data which has not been labeled with the entire joint structure. While conventional wisdom says that adding more training data should always improve performance, this work is the first to our knowledge to incorporate singly-annotated data into a joint model, thereby providing a method for this additional data, which cannot be directly used by the non-hierarchical joint model, to help improve joint modeling performance. We built single-task models for the non-jointly labeled data, designing those single-task models so that they have features in common with the joint model, and then linked all of the different single-task and joint models via a hierarchical prior. We performed experiments on joint parsing and named entity recognition, and found that our hierarchical joint model substantially outperformed a joint model which was trained on only the jointly annotated data.

Future directions for this work include automatically learning the variances, σ_m and σ_* in the hierarchical model, so that the degree of information sharing between the models is optimized based on the training data available. We are also interested in ways to modify the objective function to place more emphasis on learning a good joint model, instead of equally weighting the learning of the joint and single-task models.

Detecting Errors in Automatically-Parsed Dependency Relations

Markus Dickinson
Indiana University
md7@indiana.edu

Abstract

We outline different methods to detect errors in automatically-parsed dependency corpora, by comparing so-called dependency rules to their representation in the training data and flagging anomalous ones. By comparing each new rule to every relevant rule from training, we can identify parts of parse trees which are likely erroneous. Even the relatively simple methods of comparison we propose show promise for speeding up the annotation process.

1 Introduction and Motivation

Given the need for high-quality dependency parses in applications such as statistical machine translation (Xu et al., 2009), natural language generation (Wan et al., 2009), and text summarization evaluation (Owczarzak, 2009), there is a corresponding need for high-quality dependency annotation, for the training and evaluation of dependency parsers (Buchholz and Marsi, 2006). Furthermore, parsing accuracy degrades unless sufficient amounts of labeled training data from the same domain are available (e.g., Gildea, 2001; Sekine, 1997), and thus we need larger and more varied annotated treebanks, covering a wide range of domains. However, there is a bottleneck in obtaining annotation, due to the need for manual intervention in annotating a treebank. One approach is to develop automatically-parsed corpora (van Noord and Bouma, 2009), but a natural disadvantage with such data is that it contains parsing errors. Identifying the most problematic parses for human post-processing could combine the benefits of automatic and manual annotation, by allowing a human annotator to efficiently correct automatic errors. We thus set out in this paper to detect errors in automatically-parsed data.

If annotated corpora are to grow in scale and retain a high quality, annotation errors which arise from automatic processing must be minimized, as errors have a negative impact on training and evaluation of NLP technology (see discussion and references in Boyd et al., 2008, sec. 1). There is work on detecting errors in dependency corpus annotation (Boyd et al., 2008), but this is based on finding inconsistencies in annotation for identical recurring strings. This emphasis on identical strings can result in high precision, but many strings do not recur, negatively impacting the recall of error detection. Furthermore, since the same strings often receive the same automatic parse, the types of inconsistencies detected are likely to have resulted from manual annotation. While we can build from the insight that simple methods can provide reliable annotation checks, we need an approach which relies on more general properties of the dependency structures, in order to develop techniques which work for automatically-parsed corpora.

Developing techniques to detect errors in parses in a way which is independent of corpus and parser has fairly broad implications. By using only the information available in a training corpus, the methods we explore are applicable to annotation error detection for either hand-annotated or automatically-parsed corpora and can also provide insights for parse reranking (e.g., Hall and Novák, 2005) or parse revision (Attardi and Ciaramita, 2007). Although we focus only on detecting errors in automatically-parsed data, similar techniques have been applied for hand-annotated data (Dickinson, 2008; Dickinson and Foster, 2009).

Our general approach is based on extracting a grammar from an annotated corpus and comparing *dependency rules* in a new (automatically-annotated) corpus to the grammar. Roughly speaking, if a dependency rule—which represents all the dependents of a head together (see section 3.1)—does not fit well with the grammar, it is flagged as potentially erroneous. The methods do not have to be retrained for a given parser's output (e.g.,

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 729–738,
Uppsala, Sweden, 11-16 July 2010.

Campbell and Johnson, 2002), but work by comparing any tree to what is in the training grammar (cf. also approaches stacking hand-written rules on top of other parsers (Bick, 2007)).

We propose to flag erroneous parse rules, using information which reflects different grammatical properties: POS lookup, bigram information, and full rule comparisons. We build on a method to detect so-called ad hoc rules, as described in section 2, and then turn to the main approaches in section 3. After a discussion of a simple way to flag POS anomalies in section 4, we evaluate the different methods in section 5, using the outputs from two different parsers. The methodology proposed in this paper is easy to implement and independent of corpus, language, or parser.

2 Approach

We take as a starting point two methods for detecting *ad hoc* rules in constituency annotation (Dickinson, 2008). Ad hoc rules are CFG productions extracted from a treebank which are "used for specific constructions and unlikely to be used again," indicating annotation errors and rules for ungrammaticalities (see also Dickinson and Foster, 2009).

Each method compares a given CFG rule to all the rules in a treebank grammar. Based on the number of similar rules, a score is assigned, and rules with the lowest scores are flagged as potentially ad hoc. This procedure is applicable whether the rules in question are from a new data set—as in this paper, where parses are compared to a training data grammar—or drawn from the treebank grammar itself (i.e., an internal consistency check).

The two methods differ in how the comparisons are done. First, the *bigram method* abstracts a rule to its bigrams. Thus, a rule such as NP → JJ NN provides support for NP → DT JJ JJ NN, in that it shares the JJ NN sequence. By contrast, in the other method, which we call the *whole rule method*,[1] a rule is compared in its totality to the grammar rules, using Levenshtein distance. There is no abstraction, meaning all elements are present—e.g., NP → DT JJ JJ NN is very similar to NP → DT JJ NN because the sequences differ by only one category.

While previously used for constituencies, what is at issue is simply the *valency* of a rule, where by valency we refer to a head and its entire set of arguments and adjuncts (cf. Przepiórkowski, 2006)—that is, a head and all its dependents. The methods work because we expect there to be regularities in valency structure in a treebank grammar; non-conformity to such regularities indicates a potential problem.

3 Ad hoc rule detection

3.1 An appropriate representation

To capture valency, consider the dependency tree from the Talbanken05 corpus (Nilsson and Hall, 2005) in figure 1, for the Swedish sentence in (1), which has four dependency pairs.[2]

(1) Det går bara inte ihop .
it goes just not together
'It just doesn't add up.'

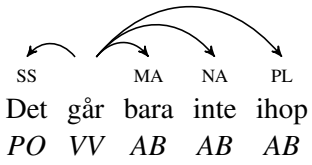

Figure 1: Dependency graph example

On a par with constituency rules, we define a grammar *rule* as a dependency relation rewriting as a head with its sequence of POS/dependent pairs (cf. Kuhlmann and Satta, 2009), as in figure 2. This representation supports the detection of idiosyncracies in valency.[3]

1. TOP → root ROOT:VV
2. ROOT → SS:PO VV MA:AB NA:AB PL:AB
3. SS → PO
4. MA → AB
5. NA → AB
6. PL → AB

Figure 2: Rule representation for (1)

For example, for the ROOT category, the head is a verb (VV), and it has 4 dependents. The extent to which this rule is odd depends upon whether comparable rules—i.e., other ROOT rules or other VV rules (see section 3.2)—have a similar set of dependents. While many of the other rules seem rather spare, they provide useful information, showing categories which have no dependents. With a TOP rule, we have a rule for every

[1] This is referred to *whole daughters* in Dickinson (2008), but the meaning of "daughters" is less clear for dependencies.

[2] Category definitions are in appendix A.

[3] Valency is difficult to define for coordination and is specific to an annotation scheme. We leave this for the future.

head, including the virtual root. Thus, we can find anomalous rules such as TOP → root ROOT:AV ROOT:NN, where multiple categories have been parsed as ROOT.

3.2 Making appropriate comparisons

In comparing rules, we are trying to find evidence that a particular (parsed) rule is valid by examining the evidence from the (training) grammar.

Units of comparison To determine similarity, one can compare dependency relations, POS tags, or both. Valency refers to both properties, e.g., verbs which allow verbal (POS) subjects (dependency). Thus, we use the pairs of dependency relations and POS tags as the units of comparison.

Flagging individual elements Previous work scored only entire rules, but some dependencies are problematic and others are not. Thus, our methods score individual elements of a rule.

Comparable rules We do not want to compare a rule to all grammar rules, only to those which *should* have the same valents. Comparability could be defined in terms of a rule's dependency relation (LHS) or in terms of its head. Consider the four different object (OO) rules in (2). These vary a great deal, and much of the variability comes from the fact that they are headed by different POS categories, which tend to have different selectional properties. The head POS thus seems to be predictive of a rule's valency.

(2) a. OO → **PO**
b. OO → DT:EN AT:AJ **NN** ET:VV
c. OO → SS:PO **QV** VG:VV
d. OO → DT:PO AT:AJ **VN**

But we might lose information by ignoring rules with the same left-hand side (LHS). Our approach is thus to take the greater value of scores when comparing to rules *either* with the same dependency relation or with the same head. A rule has multiple chances to prove its value, and low scores will only be for rules without any type of support.

Taking these points together, for a given rule of interest r, we assign a score (S) to each element e_i in r, where $r = e_1...e_m$ by taking the maximum of scores for rules with the same head (h) or same LHS (lhs), as in (3). For the first element in (2b), for example, S(DT:EN) = max{s(DT:EN, NN), s(DT:EN, OO)}. The question is now how we define $s(e_i, c)$ for the comparable element c.

(3) $S(e_i) = \max\{s(e_i, h), s(e_i, lhs)\}$

3.3 Whole rule anomalies

3.3.1 Motivation

The whole rule method compares a list of a rule's dependents to rules in a database, and then flags rule elements without much support. By using all dependents as a basis for comparison, this method detects improper dependencies (e.g., an adverb modifying a noun), dependencies in the wrong overall location of a rule (e.g., an adverb before an object), and rules with unnecessarily long argument structures. For example, in (4), we have an improper relation between *skall* ('shall') and *sambeskattas* ('be taxed together'), as in figure 3. It is parsed as an adverb (AA), whereas it should be a verb group (VG). The rule for this part of the tree is +F → ++:++ SV AA:VV, and the AA:VV position will be low-scoring because the ++:++ SV context does not support it.

(4) Makars övriga inkomster är B-inkomster
spouses' other incomes are B-incomes
och *skall* som tidigare *sambeskattas* .
and shall as previously be taxed togeher .
'The other incomes of spouses are B-incomes and shall, as previously, be taxed together.'

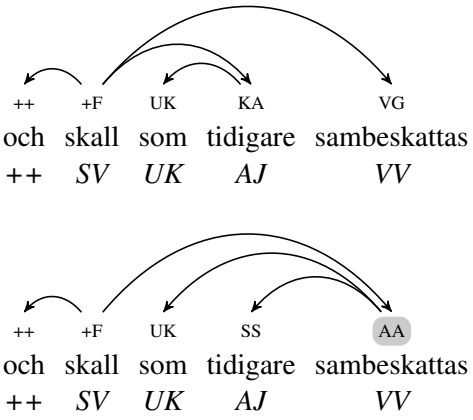

Figure 3: Wrong label (top=gold, bottom=parsed)

3.3.2 Implementation

The method we use to determine similarity arises from considering what a rule is like without a problematic element. Consider +F → ++:++ SV AA:VV from figure 3, where AA should be a different category (VG). The rule without this error, +F → ++:++ SV, starts several rules in the

training data, including some with VG:VV as the next item. The subrule ++:++ SV seems to be reliable, whereas the subrules containing AA:VV (++:++ AA:VV and SV AA:VV) are less reliable. We thus determine reliability by seeing how often each subsequence occurs in the training rule set.

Throughout this paper, we use the term *subrule* to refer to a rule subsequence which is exactly one element shorter than the rule it is a component of. We examine subrules, counting their frequency *as subrules*, not as complete rules. For example, TOP rules with more than one dependent are problematic, e.g., TOP → root ROOT:AV ROOT:NN. Correspondingly, there are no rules with *three* elements containing the subrule root ROOT:AV.

We formalize this by setting the score $s(e_i, c)$ equal to the summation of the frequencies of all comparable subrules containing e_i from the training data, as in (5), where B is the set of subrules of r with length one less.

(5) $s(e_i, c) = \sum_{sub \in B : e_i \in sub} C(sub, c)$

For example, with c = +F, the frequency of +F → ++:++ SV as a subrule is added to the scores for ++:++ and SV. In this case, +F → ++:++ SV **VG:BV**, +F → ++:++ SV **VG:AV**, and +F → ++:++ SV **VG:VV** all add support for +F → ++:++ SV being a legitimate subrule. Thus, ++:++ and SV are less likely to be the sources of any problems. Since +F → SV AA:VV and +F → ++:++ AA:VV have very little support in the training data, AA:VV receives a low score.

Note that the subrule count $C(sub, c)$ is different than counting the number of rules containing a subrule, as can be seen with identical elements. For example, for SS → VN ET:PR ET:PR, C(VN ET:PR, SS) = 2, in keeping with the fact that there are 2 pieces of evidence for its legitimacy.

3.4 Bigram anomalies

3.4.1 Motivation

The bigram method examines relationships between adjacent sisters, complementing the whole rule method by focusing on local properties. For (6), for example, we find the gold and parsed trees in figure 4. For the long parsed rule TA → PR HD:ID HD:ID **IR:IR AN:RO JR:IR**, all elements get low whole rule scores, i.e., are flagged as potentially erroneous. But only the final elements have anomalous bigrams: HD:ID IR:IR, IR:IR AN:RO, and AN:RO JR:IR all never occur.

(6) När det gäller inkomståret 1971 (
when it concerns the income year 1971 (
taxeringsåret 1972) skall barnet ...
assessment year 1972) shall the child ...
'Concerning the income year of 1971 (assessment year 1972), the child ...'

3.4.2 Implementation

To obtain a bigram score for an element, we simply add together the bigrams which contain the element in question, as in (7).

(7) $s(e_i, c) = C(e_{i-1}\mathbf{e_i}, c) + C(\mathbf{e_i}e_{i+1}, c)$

Consider the rule from figure 4. With $c = TA$, the bigram HD:ID IR:IR never occurs, so both HD:ID and IR:IR get 0 added to their score. HD:ID **HD:ID**, however, is a frequent bigram, so it adds weight to HD:ID, i.e., positive evidence comes from the bigram on the left. If we look at IR:IR, on the other hand, **IR:IR** AN:RO occurs 0 times, and so IR:IR gets a total score of 0.

Both scoring methods treat each element independently. Every single element could be given a low score, even though once one is corrected, another would have a higher score. Future work can examine factoring in all elements at once.

4 Additional information

The methods presented so far have limited definitions of comparability. As using complementary information has been useful in, e.g., POS error detection (Loftsson, 2009), we explore other simple comparable properties of a dependency grammar. Namely, we include: a) frequency information of an overall dependency rule and b) information on how likely each dependent is to be in a relation with its head, described next.

4.1 Including POS information

Consider PA → SS:NN XX:XX HV OO:VN, as illustrated in figure 5 for the sentence in (8). This rule is entirely correct, yet the XX:XX position has low whole rule and bigram scores.

(8) Uppgift om vilka orter som
information of which neighborhood who
har utkörning finner Ni också i ...
has delivery find you also in ...
'You can also find information about which neighborhoods have delivery services in ...'

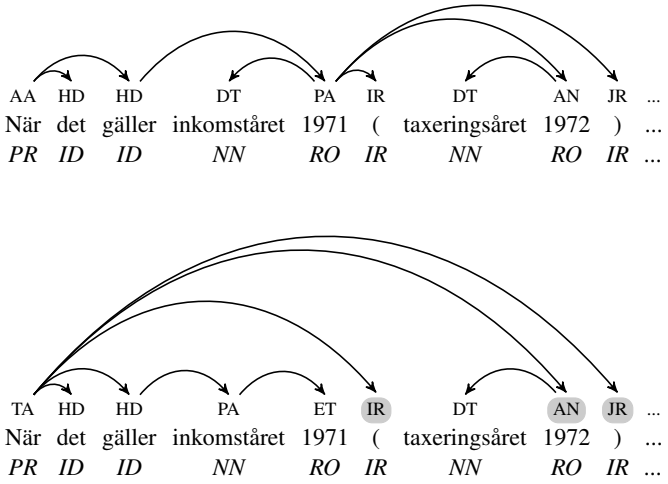

Figure 4: A rule with extra dependents (top=gold, bottom=parsed)

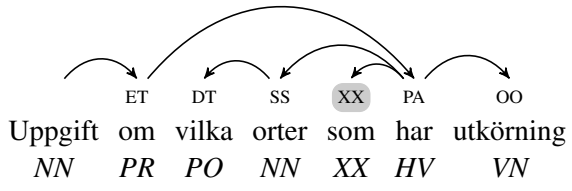

Figure 5: Overflagging (gold=parsed)

One method which does not have this problem of overflagging uses a "lexicon" of POS tag pairs, examining relations between POS, irrespective of position. We extract POS pairs, note their dependency relation, and add a L/R to the label to indicate which is the head (Boyd et al., 2008). Additionally, we note how often two POS categories occur as a non-depenency, using the label NIL, to help determine whether there should be any attachment. We generate NILs by enumerating all POS pairs in a sentence. For example, from figure 5, the parsed POS pairs include NN PR $\mapsto$ ET-L, NN PO $\mapsto$ NIL, etc.

We convert the frequencies to probabilities. For example, of 4 total occurrences of XX HV in the training data, 2 are XX-R (cf. figure 5). A probability of 0.5 is quite high, given that NILs are often the most frequent label for POS pairs.

5 Evaluation

In evaluating the methods, our main question is: how accurate are the dependencies, in terms of both attachment and labeling? We therefore currently examine the scores for elements functioning as dependents in a rule. In figure 5, for example, for *har* ('has'), we look at its score within ET $\rightarrow$ PR **PA:HV** and not when it functions as a head, as in PA $\rightarrow$ SS:NN XX:XX **HV** OO:VN.

Relatedly, for each method, we are interested in whether elements with scores below a threshold have worse attachment accuracy than scores above, as we predict they do. We can measure this by scoring each testing data position below the threshold as a 1 if it has the correct head and dependency relation and a 0 otherwise. These are simply labeled attachment scores (LAS). Scoring separately for positions above and below a threshold views the task as one of sorting parser output into two bins, those more or less likely to be correctly parsed. For development, we also report unlabeled attachement scores (UAS).

Since the goal is to speed up the post-editing of corpus data by flagging erroneous rules, we also report the precision and recall for error detection. We count either attachment or labeling errors as an error, and precision and recall are measured with respect to how many errors are found below the threshold. For development, we use two F-scores to provide a measure of the settings to examine across language, corpus, and parser conditions: the balanced F_1 measure and the $F_{0.5}$ measure, weighing precision twice as much. Precision is likely more important in this context, so as to prevent annotators from sorting through too many false positives. In practice, one way to use these methods is to start with the lowest thresholds and work upwards until there are too many non-errors.

To establish a basis for comparison, we compare

method performance to a parser on its own.[4] By examining the parser output without any automatic assistance, how often does a correction need to be made?

5.1 The data

All our data comes from the CoNLL-X Shared Task (Buchholz and Marsi, 2006), specifically the 4 data sets freely available online. We use the Swedish Talbanken data (Nilsson and Hall, 2005) and the transition-based dependency parser MaltParser (Nivre et al., 2007), with the default settings, for developing the method. To test across languages and corpora, we use MaltParser on the other 3 corpora: the Danish DDT (Kromann, 2003), Dutch Alpino (van der Beek et al., 2002), and Portuguese Bosque data (Afonso et al., 2002). Then, we present results using the graph-based parser MSTParser (McDonald and Pereira, 2006), again with default settings, to test the methods across parsers. We use the gold standard POS tags for all experiments.

5.2 Development data

In the first line of table 1, we report the baseline MaltParser accuracies on the Swedish test data, including baseline error detection precision (=1-LAS_b), recall, and (the best) F-scores. In the rest of table 1, we report the best-performing results for each of the methods,[5] providing the number of rules below and above a particular threshold, along with corresponding UAS and LAS values. To get the raw number of identified rules, multiply the number of corpus position below a threshold (b) times the error detection precision (P). For example, the bigram method with a threshold of 39 leads to finding 283 errors ($455 \times .622$).

Dependency elements with frequency below the lowest threshold have lower attachment scores (66.6% vs. 90.1% LAS), showing that simply using a complete rule helps sort dependencies. However, frequency thresholds have fairly low precision, i.e., 33.4% at their best. The whole rule and bigram methods reveal greater precision in identifying problematic dependencies, isolating elements with lower UAS and LAS scores than with frequency, along with corresponding greater precision and F-scores. The bigram method is more fine-grained, identifying small numbers of rule elements at each threshold, resulting in high error detection precision. With a threshold of 39, for example, we find over a quarter of the parser errors with 62% precision, from this one piece of information. For POS information, we flag 23.6% of the cases with over 60% precision (at 81.6).

Taking all these results together, we can begin to sort more reliable from less reliable dependency tree elements, using very simple information. Additionally, these methods naturally group cases together by linguistic properties (e.g., adverbial-verb dependencies within a particualr context), allowing a human to uncover the principle behind parse failure and ajudicate similar cases at the same time (cf. Wallis, 2003).

5.3 Discussion

Examining some of the output from the Talbanken test data by hand, we find that a prominent cause of false positives, i.e., correctly-parsed cases with low scores, stems from low-frequency dependency-POS label pairs. If the dependency rarely occurs in the training data with the particular POS, then it receives a low score, regardless of its context. For example, the parsed rule TA $\rightarrow$ **IG:IG** RO has a correct dependency relation (IG) between the POS tags IG and its head RO, yet is assigned a whole rule score of 2 and a bigram score of 20. It turns out that IG:IG only occurs 144 times in the training data, and in 11 of those cases (7.6%) it appears immediately before RO. One might consider normalizing the scores based on overall frequency or adjusting the scores to account for other dependency rules in the sentence: in this case, there may be no better attachment.

Other false positives are correctly-parsed elements that are a part of erroneous rules. For instance, in AA $\rightarrow$ UK:UK SS:PO TA:AJ AV SP:AJ OA:PR **+F:HV** +F:HV, the first +F:HV is correct, yet given a low score (0 whole rule, 1 bigram). The following and erroneous +F:HV is similarly given a low score. As above, such cases might be handled by looking for attachments in other rules (cf. Attardi and Ciaramita, 2007), but these cases should be relatively unproblematic for hand-correction, given the neighboring error.

We also examined false negatives, i.e., errors with high scores. There are many examples of PR PA:NN rules, for instance, with the NN improp-

[4] One may also use parser confidence or parser revision methods as a basis of comparison, but we are aware of no systematic evaluation of these approaches for detecting errors.

Table 1: MaltParser results for Talbanken, for select values (b = below, a = above threshold (Thr.))

erly attached, but there are also many correct instances of PR PA:NN. To sort out the errors, one needs to look at lexical knowledge and/or other dependencies in the tree. With so little context, frequent rules with only one dependent are not prime candidates for our methods of error detection.

5.4 Other corpora

We now turn to the parsed data from three other corpora. The Alpino and Bosque corpora are approximately the same size as Talbanken, so we use the same thresholds for them. The DDT data is approximately half the size; to adjust, we simply halve the scores. In tables 2, 3, and 4, we present the results, using the best $F_{0.5}$ and F_1 settings from development. At a glance, we observe that the best method differs for each corpus and depending on an emphasis of precision or recall, with the bigram method generally having high precision.

Score	Thr.	b	LAS_b	LAS_a	P	R

	763	1767	53.5%	83.2%	46.5%	56.1%

Table 2: MaltParser results for Alpino

For Alpino, error detection is better with frequency than, for example, bigram scores. This is likely due to the fact that Alpino has the smallest label set of any of the corpora, with only 24 dependency labels and 12 POS tags (cf. 64 and 41 in Talbanken, respectively). With a smaller label set, there are less possible bigrams that could be anomalous, but more reliable statistics about a whole rule. Likewise, with fewer possible POS tag pairs, Alpino has lower precision for the low-threshold POS scores than the other corpora.

	381.5	1214	62.5%	85.9%	37.5%	41.0%

Table 4: MaltParser results for DDT

For the whole rule scores, the DDT data is worse (compare its 46.1% precision with Bosque's 45.6%, with vastly different recall values), which could be due to the smaller training data. One might also consider the qualitative differences in the dependency inventory of DDT compared to the others—e.g., appositions, distinctions in names, and more types of modifiers.

5.5 MSTParser

Turning to the results of running the methods on the output of MSTParser, we find similar but slightly worse values for the whole rule and bigram methods, as shown in tables 5-8. What is

most striking are the differences in the POS-based method for Bosque and DDT (tables 7 and 8), where a large percentage of the test corpus is underneath the threshold. MSTParser is apparently positing fewer distinct head-dependent pairs, as most of them fall under the given thresholds. With the exception of the POS-based method for DDT (where LAS_b is actually higher than LAS_a) the different methods seem to be accurate enough to be used as part of corpus post-editing.

6 Summary and Outlook

We have proposed different methods for flagging the errors in automatically-parsed corpora, by treating the problem as one of looking for anomalous rules with respect to a treebank grammar. The different methods incorporate differing types and amounts of information, notably comparisons among dependency rules and bigrams within such rules. Using these methods, we demonstrated success in sorting well-formed output from erroneous output across language, corpora, and parsers.

Given that the rule representations and comparison methods use both POS and dependency information, a next step in evaluating and improving the methods is to examine automatically POS-tagged data. Our methods should be able to find POS errors in addition to dependency errors. Furthermore, although we have indicated that differences in accuracy can be linked to differences in the granularity and particular distinctions of the annotation scheme, it is still an open question as to which methods work best for which schemes and for which constructions (e.g., coordination).

Abstract

In this paper, we present a simple and effective method to address the issue of how to generate diversified translation systems from a single Statistical Machine Translation (SMT) engine for system combination. Our method is based on the framework of boosting. First, a sequence of *weak* translation systems is generated from a baseline system in an iterative manner. Then, a *strong* translation system is built from the ensemble of these weak translation systems. To adapt boosting to SMT system combination, several key components of the original boosting algorithms are redesigned in this work. We evaluate our method on Chinese-to-English Machine Translation (MT) tasks in three baseline systems, including a phrase-based system, a hierarchical phrase-based system and a syntax-based system. The experimental results on three NIST evaluation test sets show that our method leads to significant improvements in translation accuracy over the baseline systems.

1 Introduction

Recent research on Statistical Machine Translation (SMT) has achieved substantial progress. Many SMT frameworks have been developed, including phrase-based SMT (Koehn et al., 2003), hierarchical phrase-based SMT (Chiang, 2005), syntax-based SMT (Eisner, 2003; Ding and Palmer, 2005; Liu et al., 2006; Galley et al., 2006; Cowan et al., 2006), etc. With the emergence of various structurally different SMT systems, more and more studies are focused on combining multiple SMT systems for achieving higher translation accuracy rather than using a single translation system.

The basic idea of system combination is to extract or generate a translation by voting from an ensemble of translation outputs. Depending on how the translation is combined and what voting strategy is adopted, several methods can be used for system combination, e.g. sentence-level combination (Hildebrand and Vogel, 2008) simply selects one from original translations, while some more sophisticated methods, such as word-level and phrase-level combination (Matusov et al., 2006; Rosti et al., 2007), can generate new translations differing from any of the original translations.

One of the key factors in SMT system combination is the diversity in the ensemble of translation outputs (Macherey and Och, 2007). To obtain diversified translation outputs, most of the current system combination methods require multiple translation engines based on different models. However, this requirement cannot be met in many cases, since we do not always have the access to multiple SMT engines due to the high cost of developing and tuning SMT systems. To reduce the burden of system development, it might be a nice way to combine a set of translation systems built from a single translation engine. A key issue here is how to generate an ensemble of diversified translation systems from a single translation engine in a principled way.

Addressing this issue, we propose a boosting-based system combination method to learn a combined translation system from a single SMT engine. In this method, a sequence of *weak* translation systems is generated from a baseline system in an iterative manner. In each iteration, a new weak translation system is learned, focusing more on the sentences that are relatively poorly translated by the previous weak translation system. Finally, a *strong* translation system is built from the ensemble of the weak translation systems.

Our experiments are conducted on Chinese-to-English translation in three state-of-the-art SMT systems, including a phrase-based system, a hierarchical phrase-based system and a syntax-based

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 739–748,
Uppsala, Sweden, 11-16 July 2010.

Input: a model u, a sequence of (training) samples $\{(f_1, \mathbf{r}_1), ..., (f_m, \mathbf{r}_m)\}$ where f_i is the i-th source sentence, and $\mathbf{r}_i$ is the set of reference translations for f_i.
Output: a new translation system

Initialize: $D_1(i) = 1 / m$ for all $i = 1, ..., m$
For $t = 1, ..., T$

1. Train a translation system $u(\boldsymbol{\lambda}^*_t)$ on $\{(f_i, \mathbf{r}_i)\}$ using distribution D_t
2. Calculate the error rate ε_t of $u(\boldsymbol{\lambda}^*_t)$ on $\{(f_i, \mathbf{r}_i)\}$
3. Set

$$\alpha_t = \frac{1}{2}\ln(\frac{1+\varepsilon_t}{\varepsilon_t}) \quad (3)$$

4. Update weights

$$D_{t+1}(i) = \frac{D_t(i)e^{\alpha_t \cdot l_i}}{Z_t} \quad (4)$$

where l_i is the loss on the i-th training sample, and Z_t is the normalization factor.

Output the final system:

$$v(u(\boldsymbol{\lambda}^*_1), ..., u(\boldsymbol{\lambda}^*_T))$$

Figure 1: Boosting-based System Combination

system. All the systems are evaluated on three NIST MT evaluation test sets. Experimental results show that our method leads to significant improvements in translation accuracy over the baseline systems.

2 Background

Given a source string f, the goal of SMT is to find a target string e^* by the following equation.

$$e^* = \arg\max_e(\Pr(e \mid f)) \quad (1)$$

where $\Pr(e \mid f)$ is the probability that e is the translation of the given source string f. To model the posterior probability $\Pr(e \mid f)$, most of the state-of-the-art SMT systems utilize the log-linear model proposed by Och and Ney (2002), as follows,

$$\Pr(e \mid f) = \frac{\exp(\sum_{m=1}^{M}\lambda_m \cdot h_m(f,e))}{\sum_{e'}\exp(\sum_{m=1}^{M}\lambda_m \cdot h_m(f,e'))} \quad (2)$$

where $\{h_m(f, e) \mid m = 1, ..., M\}$ is a set of *features*, and λ_m is the *feature weight* corresponding to the m-th feature. $h_m(f, e)$ can be regarded as a function that maps every pair of source string f and target string e into a non-negative value, and λ_m can be viewed as the contribution of $h_m(f, e)$ to the overall score $\Pr(e \mid f)$.

In this paper, u denotes a log-linear model that has M fixed features $\{h_1(f,e), ..., h_M(f,e)\}$, $\boldsymbol{\lambda} = \{\lambda_1, ..., \lambda_M\}$ denotes the M parameters of u, and $u(\boldsymbol{\lambda})$ denotes a SMT system based on u with parameters $\boldsymbol{\lambda}$. Generally, $\boldsymbol{\lambda}$ is trained on a training data set[1] to obtain an optimized weight vector $\boldsymbol{\lambda}^*$ and consequently an optimized system $u(\boldsymbol{\lambda}^*)$.

3 Boosting-based System Combination for Single Translation Engine

Suppose that there are T available SMT systems $\{u_1(\boldsymbol{\lambda}^*_1), ..., u_T(\boldsymbol{\lambda}^*_T)\}$, the task of system combination is to build a new translation system $v(u_1(\boldsymbol{\lambda}^*_1), ..., u_T(\boldsymbol{\lambda}^*_T))$ from $\{u_1(\boldsymbol{\lambda}^*_1), ..., u_T(\boldsymbol{\lambda}^*_T)\}$. Here $v(u_1(\boldsymbol{\lambda}^*_1), ..., u_T(\boldsymbol{\lambda}^*_T))$ denotes the *combination system* which combines translations from the ensemble of the output of each $u_i(\boldsymbol{\lambda}^*_i)$. We call $u_i(\boldsymbol{\lambda}^*_i)$ a *member system* of $v(u_1(\boldsymbol{\lambda}^*_1), ..., u_T(\boldsymbol{\lambda}^*_T))$. As discussed in Section 1, the diversity among the outputs of member systems is an important factor to the success of system combination. To obtain diversified member systems, traditional methods concentrate more on using structurally different member systems, that is $u_1 \neq u_2 \neq ... \neq u_T$. However, this constraint condition cannot be satisfied when multiple translation engines are not available.

In this paper, we argue that the diversified member systems can also be generated from a single engine $u(\boldsymbol{\lambda}^*)$ by adjusting the weight vector $\boldsymbol{\lambda}^*$ in a principled way. In this work, we assume that $u_1 = u_2 = ... = u_T = u$. Our goal is to find a series of $\boldsymbol{\lambda}^*_i$ and build a combined system from $\{u(\boldsymbol{\lambda}^*_i)\}$. To achieve this goal, we propose a

[1] The data set used for weight training is generally called *development set* or *tuning set* in the SMT field. In this paper, we use the term *training set* to emphasize the training of log-linear model.

boosting-based system combination method (Figure 1).

Like other boosting algorithms, such as AdaBoost (Freund and Schapire, 1997; Schapire, 2001), the basic idea of this method is to use weak systems (*member systems*) to form a strong system (*combined system*) by repeatedly calling weak system trainer on different distributions over the training samples. However, since most of the boosting algorithms are designed for the classification problem that is very different from the translation problem in natural language processing, several key components have to be redesigned when boosting is adapted to SMT system combination.

3.1 Training

In this work, Minimum Error Rate Training (MERT) proposed by Och (2003) is used to estimate feature weights $\boldsymbol{\lambda}$ over a series of training samples. As in other state-of-the-art SMT systems, BLEU is selected as the accuracy measure to define the error function used in MERT. Since the weights of training samples are not taken into account in BLEU[2], we modify the original definition of BLEU to make it sensitive to the distribution $D_t(i)$ over the training samples. The modified version of BLEU is called *weighted BLEU* (WBLEU) in this paper.

Let $E = e_1 \ldots e_m$ be the translations produced by the system, $R = \boldsymbol{r}_1 \ldots \boldsymbol{r}_m$ be the reference translations where $\boldsymbol{r}_i = \{r_{i1}, \ldots, r_{iN}\}$, and $D_t(i)$ be the weight of the i-th training sample $(f_i, \boldsymbol{r}_i)$. The weighted BLEU metric has the following form:

$$\begin{aligned}&\mathrm{WBLEU}(E,R)\\ &= \exp\left(1-\max\left\{1,\frac{\sum_{i=1}^{m} D_t(i)\min_{1\le j\le N}\{|\,g_1(r_{ij})\,|\}}{\sum_{i=1}^{m} D_t(i)\,|\,g_1(e_i)\,|}\right\}\right)\times\\ &\prod_{n=1}^{4}\left(\frac{\sum_{i=1}^{\mathrm{m}} D_t(i)\left|g_n(e_i)\bigcap\left(\bigcup_{j=1}^{N} g_n(r_{ij})\right)\right|}{\sum_{i=1}^{\mathrm{m}} D_t(i)\left|g_n(e_i)\right|}\right)^{1/4}\end{aligned} \quad (5)$$

where $g_n(s)$ is the multi-set of all n-grams in a string s. In this definition, n-grams in e_i and $\{r_{ij}\}$ are weighted by $D_t(i)$. If the i-th training sample has a larger weight, the corresponding n-grams will have more contributions to the overall score $\mathrm{WBLEU}(E,R)$. As a result, the i-th training sample gains more importance in MERT. Obviously the original BLEU is just a special case of WBLEU when all the training samples are equally weighted.

As the weighted BLEU is used to measure the translation accuracy on the training set, the error rate is defined to be:

$$\varepsilon_t = 1 - \mathrm{WBLEU}(E,R) \quad (6)$$

3.2 Re-weighting

Another key point is the maintaining of the distribution $D_t(i)$ over the training set. Initially all the weights of training samples are set equally. On each round, we increase the weights of the samples that are relatively poorly translated by the current weak system so that the MERT-based trainer can focus on the hard samples in next round. The update rule is given in Equation 4 with two parameters α_t and l_i in it.

α_t can be regarded as a measure of the importance that the t-th weak system gains in boosting. The definition of α_t guarantees that α_t always has a positive value[3]. A main effect of α_t is to scale the weight updating (e.g. a larger α_t means a greater update).

l_i is the loss on the i-th sample. For each i, let $\{e_{i1}, \ldots, e_{in}\}$ be the n-best translation candidates produced by the system. The loss function is defined to be:

$$l_i = \mathrm{BLEU}(e_i^*, \boldsymbol{r}_i) - \frac{1}{k}\sum_{j=1}^{k}\mathrm{BLEU}(e_{ij}, \boldsymbol{r}_i) \quad (7)$$

where $\mathrm{BLEU}(e_{ij}, \boldsymbol{r}_i)$ is the smoothed sentence-level BLEU score (Liang et al., 2006) of the translation e with respect to the reference translations $\boldsymbol{r}_i$, and e_i^* is the oracle translation which is selected from $\{e_{i1}, \ldots, e_{in}\}$ in terms of $\mathrm{BLEU}(e_{ij}, \boldsymbol{r}_i)$. l_i can be viewed as a measure of the average cost that we guess the top-k translation candidates instead of the oracle translation. The value of l_i counts for the magnitude of weight update, that is, a larger l_i means a larger weight update on $D_t(i)$. The definition of the loss function here is similar to the one used in (Chiang et al., 2008) where only the top-1 translation candidate (i.e. $k = 1$) is taken into account.

3.3 System Combination Scheme

In the last step of our method, a strong translation system $v(u(\boldsymbol{\lambda}^*_1), \ldots, u(\boldsymbol{\lambda}^*_T))$ is built from the

[2] In this paper, we use the NIST definition of BLEU where the *effective reference length* is the length of the shortest reference translation.

[3] Note that the definition of α_t here is different from that in the original AdaBoost algorithm (Freund and Schapire, 1997; Schapire, 2001) where α_t is a negative number when $\varepsilon_t > 0.5$.

ensemble of member systems $\{u(\boldsymbol{\lambda}^*_1), ..., u(\boldsymbol{\lambda}^*_T)\}$. In this work, a sentence-level combination method is used to select the best translation from the pool of the *n*-best outputs of all the member systems.

Let $H(u(\boldsymbol{\lambda}^*_t))$ (or H_t for short) be the set of the *n*-best translation candidates produced by the *t*-th member system $u(\boldsymbol{\lambda}^*_t)$, and $H(v)$ be the union set of all H_t (i.e. $H(v) = \bigcup H_t$). The final translation is generated from $H(v)$ based on the following scoring function:

$$e^* = \arg\max_{e \in H(v)} \sum_{t=1}^{T} \beta_t \cdot \phi_t(e) + \psi(e, H(v)) \quad (8)$$

where $\phi_t(e)$ is the log-scaled model score of *e* in the *t*-th member system, and β_t is the corresponding feature weight. It should be noted that $e \in H_i$ may not exist in any $H_{i' \neq i}$. In this case, we can still calculate the model score of *e* in any other member systems, since all the member systems are based on the same model and share the same feature space. $\psi(e, H(v))$ is a consensus-based scoring function which has been successfully adopted in SMT system combination (Duan et al., 2009; Hildebrand and Vogel, 2008; Li et al., 2009). The computation of $\psi(e, H(v))$ is based on a linear combination of a set of *n*-gram consensuses-based features.

$$\psi(e, H(v)) = \sum_n \theta_n^+ \cdot h_n^+(e, H(v)) + \sum_n \theta_n^- \cdot h_n^-(e, H(v)) \quad (9)$$

For each order of *n*-gram, $h_n^+(e, H(v))$ and $h_n^-(e, H(v))$ are defined to measure the *n*-gram agreement and disagreement between *e* and other translation candidates in $H(v)$, respectively. θ_n^+ and θ_n^- are the feature weights corresponding to $h_n^+(e, H(v))$ and $h_n^-(e, H(v))$. As $h_n^+(e, H(v))$ and $h_n^-(e, H(v))$ used in our work are exactly the same as the features used in (Duan et al., 2009) and similar to the features used in (Hildebrand and Vogel, 2008; Li et al., 2009), we do not present the detailed description of them in this paper.

If *p* orders of *n*-gram are used in computing $\psi(e, H(v))$, the total number of features in the system combination will be $T + 2 \times p$ (*T* model-score-based features defined in Equation 8 and $2 \times p$ consensus-based features defined in Equation 9). Since all these features are combined linearly, we use MERT to optimize them for the combination model.

4 Optimization

If implemented naively, the translation speed of the final translation system will be very slow. For a given input sentence, each member system has to encode it individually, and the translation speed is inversely proportional to the number of member systems generated by our method. Fortunately, with the thought of computation, there are a number of optimizations that can make the system much more efficient in practice.

A simple solution is to run member systems in parallel when translating a new sentence. Since all the member systems share the same data resources, such as language model and translation table, we only need to keep one copy of the required resources in memory. The translation speed just depends on the computing power of parallel computation environment, such as the number of CPUs.

Furthermore, we can use joint decoding techniques to save the computation of the equivalent translation hypotheses among member systems. In joint decoding of member systems, the search space is structured as a translation hypergraph where the member systems can share their translation hypotheses. If more than one member systems share the same translation hypothesis, we just need to compute the corresponding feature values only once, instead of repeating the computation in individual decoders. In our experiments, we find that over 60% translation hypotheses can be shared among member systems when the number of member systems is over 4. This result indicates that promising speed improvement can be achieved by using the joint decoding and hypothesis sharing techniques.

Another method to speed up the system is to accelerate *n*-gram language model with *n*-gram caching techniques. In this method, a *n*-gram cache is used to store the most frequently and recently accessed *n*-grams. When a new *n*-gram is accessed during decoding, the cache is checked first. If the required *n*-gram hits the cache, the corresponding *n*-gram probability is returned by the cached copy rather than refetching the original data in language model. As the translation speed of SMT system depends heavily on the computation of *n*-gram language model, the acceleration of *n*-gram language model generally leads to substantial speed-up of SMT system. In our implementation, the *n*-gram caching in general brings us over 30% speed improvement of the system.

5 Experiments

Our experiments are conducted on Chinese-to-English translation in three SMT systems.

5.1 Baseline Systems

The first SMT system is a phrase-based system with two reordering models including the maximum entropy-based lexicalized reordering model proposed by Xiong et al. (2006) and the hierarchical phrase reordering model proposed by Galley and Manning (2008). In this system all phrase pairs are limited to have source length of at most 3, and the reordering limit is set to 8 by default[4].

The second SMT system is an in-house reimplementation of the Hiero system which is based on the hierarchical phrase-based model proposed by Chiang (2005).

The third SMT system is a syntax-based system based on the string-to-tree model (Galley et al., 2006; Marcu et al., 2006), where both the minimal GHKM and SPMT rules are extracted from the bilingual text, and the composed rules are generated by combining two or three minimal GHKM and SPMT rules. Synchronous binarization (Zhang et al., 2006; Xiao et al., 2009) is performed on each translation rule for the CKY-style decoding.

In this work, baseline system refers to the system produced by the boosting-based system combination when the number of iterations (i.e. T) is set to 1. To obtain satisfactory baseline performance, we train each SMT system for 5 times using MERT with different initial values of feature weights to generate a group of *baseline candidates*, and then select the best-performing one from this group as the final baseline system (i.e. the starting point in the boosting process) for the following experiments.

5.2 Experimental Setup

Our bilingual data consists of 140K sentence pairs in the FBIS data set[5]. GIZA++ is employed to perform the bi-directional word alignment between the source and target sentences, and the final word alignment is generated using the intersect-diag-grow method. All the word-aligned bilingual sentence pairs are used to extract phrases and rules for the baseline systems. A 5-gram language model is trained on the target-side of the bilingual data and the Xinhua portion of English Gigaword corpus. Berkeley Parser is used to generate the English parse trees for the rule extraction of the syntax-based system. The data set used for weight training in boosting-based system combination comes from NIST MT03 evaluation set. To speed up MERT, all the sentences with more than 20 Chinese words are removed. The test sets are the NIST evaluation sets of MT04, MT05 and MT06. The translation quality is evaluated in terms of case-insensitive NIST version BLEU metric. Statistical significant test is conducted using the bootstrap re-sampling method proposed by Koehn (2004).

Beam search and cube pruning (Huang and Chiang, 2007) are used to prune the search space in all the three baseline systems. By default, both of the beam size and the size of n-best list are set to 20.

In the settings of boosting-based system combination, the maximum number of iterations is set to 30, and k (in Equation 7) is set to 5. The n-gram consensuses-based features (in Equation 9) used in system combination ranges from unigram to 4-gram.

5.3 Evaluation of Translations

First we investigate the effectiveness of the boosting-based system combination on the three systems.

Figures 2-5 show the BLEU curves on the development and test sets, where the X-axis is the iteration number, and the Y-axis is the BLEU score of the system generated by the boosting-based system combination. The points at iteration 1 stand for the performance of the baseline systems. We see, first of all, that all the three systems are improved during iterations on the development set. This trend also holds on the test sets. After 5, 7 and 8 iterations, relatively stable improvements are achieved by the phrase-based system, the Hiero system and the syntax-based system, respectively. The BLEU scores tend to converge to the stable values after 20 iterations for all the systems. Figures 2-5 also show that the boosting-based system combination seems to be more helpful to the phrase-based system than to the Hiero system and the syntax-based system. For the phrase-based system, it yields over 0.6 BLEU point gains just after the 3rd iteration on all the data sets.

Table 1 summarizes the evaluation results, where the BLEU scores at iteration 5, 10, 15, 20 and 30 are reported for the comparison. We see that the boosting-based system method stably ac-

[4] Our in-house experimental results show that this system performs slightly better than Moses on Chinese-to-English translation tasks.

	Phrase-based				Hiero				Syntax-based			
	Dev.	MT04	MT05	MT06	Dev.	MT04	MT05	MT06	Dev.	MT04	MT05	MT06
Baseline	33.21	33.68	32.68	30.59	33.42	34.30	33.24	30.62	35.84	35.71	35.11	32.43
Baseline+600best	33.32	33.93	32.84	30.76	33.48	34.46	33.39	30.75	35.95	35.88	35.23	32.58
Boosting-5Iterations	33.95*	34.32*	33.33*	31.33*	33.73	34.48	33.44	30.83	36.03	35.92	35.27	33.09
Boosting-10Iterations	34.14*	34.68*	33.42*	31.35*	33.75	34.65	33.75*	31.02	36.14	36.39*	35.47	33.15*
Boosting-15Iterations	33.99*	34.78*	33.46*	31.45*	34.03*	34.88*	33.98*	31.20*	36.36*	36.46*	35.53*	33.43*
Boosting-20Iterations	34.09*	35.11*	33.56*	31.45*	34.17*	35.00*	34.04*	31.29*	36.44*	36.79*	35.77*	33.36*
Boosting-30Iterations	34.12*	35.16*	33.76*	31.59*	34.05*	34.99*	34.05*	31.30*	36.52*	36.81*	35.71*	33.46*

Table 1: Summary of the results (BLEU4[%]) on the development and test sets. * = significantly better than baseline ($p < 0.05$).

hieves significant BLEU improvements after 15 iterations, and the highest BLEU scores are generally yielded after 20 iterations.

Also as shown in Table 1, over 0.7 BLEU point gains are obtained on the phrase-based system after 10 iterations. The largest BLEU improvement on the phrase-based system is over 1 BLEU point in most cases. These results reflect that our method is relatively more effective for the phrase-based system than for the other two systems, and thus confirms the fact we observed in Figures 2-5.

We also investigate the impact of *n*-best list size on the performance of baseline systems. For the comparison, we show the performance of the baseline systems with the *n*-best list size of 600 (*Baseline+600best* in Table 1) which equals to the maximum number of translation candidates accessed in the final combination system (combine 30 member systems, i.e. *Boosing-30Iterations*).

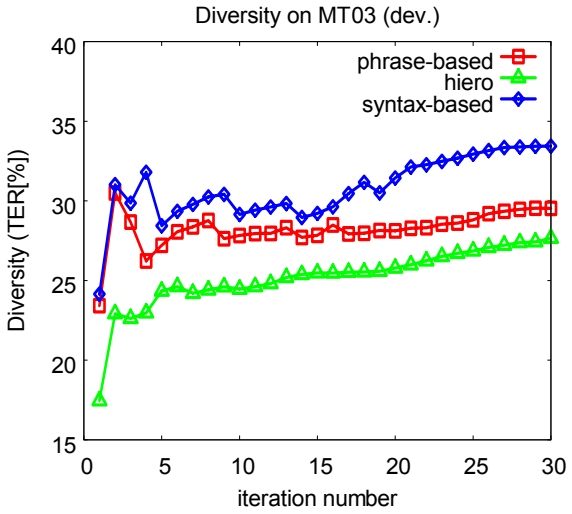

Figure 6: Diversity on the development set

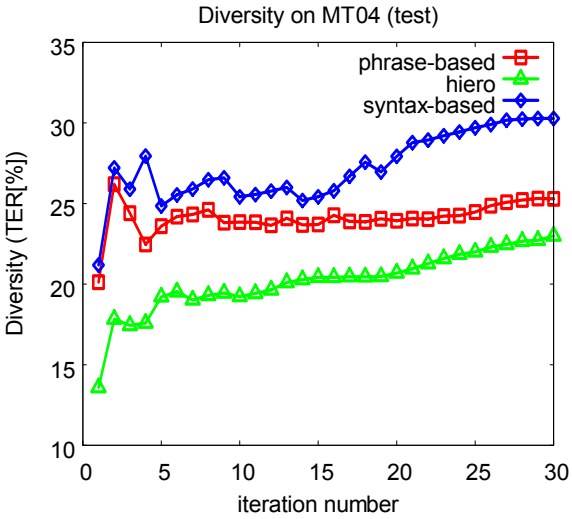

Figure 7: Diversity on the test set of MT04

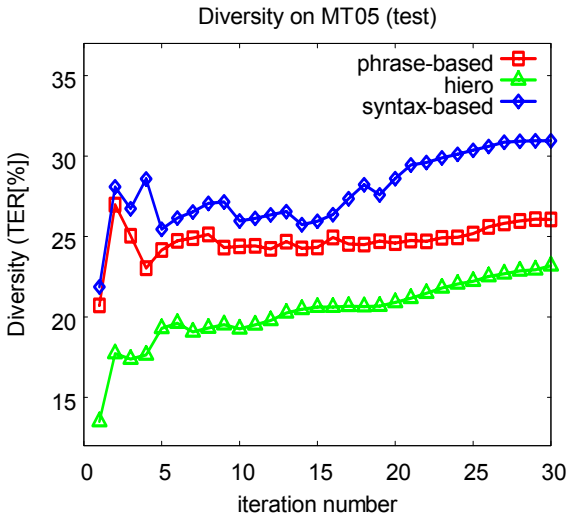

Figure 8: Diversity on the test set of MT05

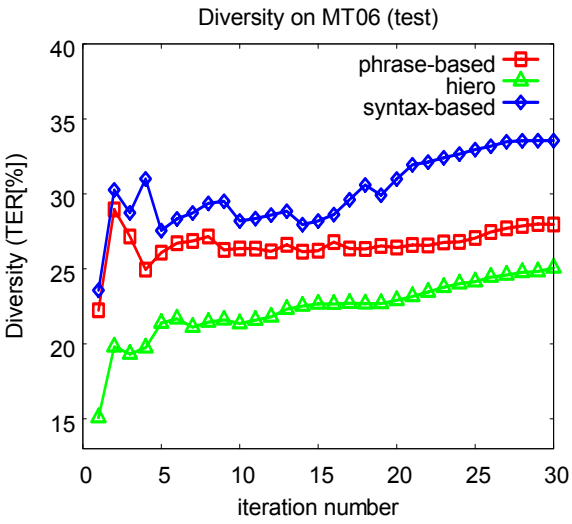

Figure 9: Diversity on the test set of MT06

As shown in Table 1, *Baseline+600best* obtains stable improvements over *Baseline*. It indicates that the access to larger *n*-best lists is helpful to improve the performance of baseline systems. However, the improvements achieved by *Baseline+600best* are modest compared to the improvements achieved by *Boosting-30Iterations*. These results indicate that the SMT systems can benefit more from the diversified outputs of member systems rather than from larger *n*-best lists produced by a single system.

5.4 Diversity among Member Systems

We also study the change of diversity among the outputs of member systems during iterations. The diversity is measured in terms of the Translation Error Rate (TER) metric proposed in (Snover et al., 2006). A higher TER score means that more edit operations are performed if we transform one translation output into another translation output, and thus reflects a larger diversity between the two outputs. In this work, the TER score for a given group of member systems is calculated by averaging the TER scores between the outputs of each pair of member systems in this group.

Figures 6-9 show the curves of diversity on the development and test sets, where the X-axis is the iteration number, and the Y-axis is the diversity. The points at iteration 1 stand for the diversities of baseline systems. In this work, the baseline's diversity is the TER score of the group of baseline candidates that are generated in advance (Section 5.1).

We see that the diversities of all the systems increase during iterations in most cases, though a few drops occur at a few points. It indicates that our method is very effective to generate diversified member systems. In addition, the diversities of baseline systems (iteration 1) are much lower

than those of the systems generated by boosting (iterations 2-30). Together with the results shown in Figures 2-5, it confirms our motivation that the diversified translation outputs can lead to performance improvements over the baseline systems.

Also as shown in Figures 6-9, the diversity of the Hiero system is much lower than that of the phrase-based and syntax-based systems at each individual setting of iteration number. This interesting finding supports the observation that the performance of the Hiero system is relatively more stable than the other two systems as shown in Figures 2-5. The relative lack of diversity in the Hiero system might be due to the *spurious ambiguity* in Hiero derivations which generally results in very few different translations in translation outputs (Chiang, 2007).

5.5 Evaluation of Oracle Translations

In this set of experiments, we evaluate the oracle performance on the *n*-best lists of the baseline systems and the combined systems generated by boosting-based system combination. Our primary goal here is to study the impact of our method on the upper-bound performance.

Table 2 shows the results, where *Baseline+600best* stands for the top-600 translation candidates generated by the baseline systems, and *Boosting-30iterations* stands for the ensemble of 30 member systems' top-20 translation candidates. As expected, the oracle performance of *Boosting-30Iterations* is significantly higher than that of *Baseline+600best*. This result indicates that our method can provide much "better" translation candidates for system combination than enlarging the size of *n*-best list naively. It also gives us a rational explanation for the significant improvements achieved by our method as shown in Section 5.3.

Data Set	Method	Phrase-based	Hiero	Syntax-based
Dev.	Baseline+600best	46.36	46.51	46.92
	Boosting-30Iterations	47.78*	47.44*	48.70*
MT04	Baseline+600best	43.94	44.52	46.88
	Boosting-30Iterations	45.97*	45.47*	49.40*
MT05	Baseline+600best	42.32	42.47	45.21
	Boosting-30Iterations	44.82*	43.44*	47.02*
MT06	Baseline+600best	39.47	39.39	40.52
	Boosting-30Iterations	41.51*	40.10*	41.88*

Table 2: Oracle performance of various systems. * = significantly better than baseline ($p < 0.05$).

6 Related Work

Boosting is a machine learning (ML) method that has been well studied in the ML community (Freund, 1995; Freund and Schapire, 1997; Collins et al., 2002; Rudin et al., 2007), and has been successfully adopted in natural language processing (NLP) applications, such as document classification (Schapire and Singer, 2000) and named entity classification (Collins and Singer, 1999). However, most of the previous work did not study the issue of how to improve a single SMT engine using boosting algorithms. To our knowledge, the only work addressing this issue is (Lagarda and Casacuberta, 2008) in which the boosting algorithm was adopted in phrase-based SMT. However, Lagarda and Casacuberta (2008)'s method calculated errors over the phrases that were chosen by phrase-based systems, and could not be applied to many other SMT systems, such as hierarchical phrase-based systems and syntax-based systems. Differing from Lagarda and Casacuberta's work, we are concerned more with proposing a general framework which can work with most of the current SMT models and empirically demonstrating its effectiveness on various SMT systems.

There are also some other studies on building diverse translation systems from a single translation engine for system combination. The first attempt is (Macherey and Och, 2007). They empirically showed that diverse translation systems could be generated by changing parameters at early-stages of the training procedure. Following Macherey and Och (2007)'s work, Duan et al. (2009) proposed a feature subspace method to build a group of translation systems from various different sub-models of an existing SMT system. However, Duan et al. (2009)'s method relied on the heuristics used in feature sub-space selection. For example, they used the remove-one-feature strategy and varied the order of *n*-gram language model to obtain a satisfactory group of diverse systems. Compared to Duan et al. (2009)'s method, a main advantage of our method is that it can be applied to most of the SMT systems without designing any heuristics to adapt it to the specified systems.

7 Discussion and Future Work

Actually the method presented in this paper is doing something rather similar to Minimum Bayes Risk (MBR) methods. A main difference lies in that the consensus-based combination method here does not model the posterior probability of each hypothesis (i.e. all the hypotheses are assigned an equal posterior probability when we calculate the consensus-based features).

Greater improvements are expected if MBR methods are used and consensus-based combination techniques smooth over noise in the MERT pipeline.

In this work, we use a sentence-level system combination method to generate final translations. It is worth studying other more sophisticated alternatives, such as word-level and phrase-level system combination, to further improve the system performance.

Another issue is how to determine an appropriate number of iterations for boosting-based system combination. It is especially important when our method is applied in the real-world applications. Our empirical study shows that the stable and satisfactory improvements can be achieved after 6-8 iterations, while the largest improvements can be achieved after 20 iterations. In our future work, we will study in-depth principled ways to determine the appropriate number of iterations for boosting-based system combination.

8 Conclusions

We have proposed a boosting-based system combination method to address the issue of building a strong translation system from a group of weak translation systems generated from a single SMT engine. We apply our method to three state-of-the-art SMT systems, and conduct experiments on three NIST Chinese-to-English MT evaluations test sets. The experimental results show that our method is very effective to improve the translation accuracy of the SMT systems.

Abstract

Prior use of machine learning in genre classification used a list of labels as classification categories. However, genre classes are often organised into hierarchies, e.g., covering the subgenres of fiction. In this paper we present a method of using the hierarchy of labels to improve the classification accuracy. As a testbed for this approach we use the Brown Corpus as well as a range of other corpora, including the BNC, HGC and Syracuse. The results are not encouraging: apart from the Brown corpus, the improvements of our structural classifier over the flat one are not statistically significant. We discuss the relation between structural learning performance and the visual and distributional balance of the label hierarchy, suggesting that only balanced hierarchies might profit from structural learning.

1 Introduction

Automatic genre identification (AGI) can be traced to the mid-1990s (Karlgren and Cutting, 1994; Kessler et al., 1997), but this research became much more active in recent years, partly because of the explosive growth of the Web, and partly because of the importance of making genre distinctions in NLP applications. In Information Retrieval, given the large number of web pages on any given topic, it is often difficult for the users to find relevant pages that are in the right genre (Vidulin et al., 2007). As for other applications, the accuracy of many tasks, such as machine translation, POS tagging (Giesbrecht and Evert, 2009) or identification of discourse relations (Webber, 2009) relies of defining the language model suitable for the genre of a given text. For example, the accuracy of POS tagging reaching 96.9% on newspaper texts drops down to 85.7% on forums (Giesbrecht and Evert, 2009), i.e., every seventh word in forums is tagged incorrectly.

This interest in genres resulted in a proliferation of studies on corpus development of web genres and comparison of methods for AGI. The two corpora commonly used for this task are KI-04 (Meyer zu Eissen and Stein, 2004) and Santinis (Santini, 2007). The best results reported for these corpora (with 10-fold cross-validation) reach 84.1% on KI-04 and 96.5% accuracy on Santinis (Kanaris and Stamatatos, 2009). In our research (Sharoff et al., 2010) we produced even better results on these two benchmarks (85.8% and 97.1%, respectively). However, this impressive accuracy is not realistic *in vivo*, i.e., in classifying web pages retrieved as a result of actual queries. One reason comes from the limited number of genres present in these two collections (eight genres in KI-04 and seven in Santinis). As an example, only front pages of online newspapers are listed in Santinis, but not actual newspaper articles, so once an article is retrieved, it cannot be assigned to any class at all. Another reason why the high accuracy is not useful concerns the limited number of sources in each collection, e.g., all FAQs in Santinis come from either a website with FAQs on hurricanes or another one with tax advice. In the end, a classifier built for FAQs on this training data relies on a high topic-genre correlation in this particular collection and fails to spot any other FAQs.

There are other corpora, which are more diverse in the range of their genres, such as the fifteen genres of the Brown Corpus (Kučera and Francis, 1967) or the seventy genres of the BNC (Lee, 2001), but because of the number of genres in them and the diversity of documents within each genre, the accuracy of prior work on these collections is much less impressive. For example, Karlgren and Cutting (1994) using linear discriminant analysis achieve an accuracy of 52% without us-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 749–759,
Uppsala, Sweden, 11-16 July 2010.

ing cross-validation (the entire Brown Corpus was used as both the test set and training set), with the accuracy improving to 65% when the 15 genres are collapsed into 10, and to 73% with only 4 genres (Figure 1). This result suggests the importance of the hierarchy of genres. Firstly, making a decision on higher levels might be easier than on lower levels (fiction or non-fiction rather than science fiction or mystery). Secondly, we might be able to improve the accuracy on lower levels, by taking into account the relevant position of each node in the hierarchy (distinguishing between `reportage` or `editorial` becomes easier when we know they are safely under the category of `press`).

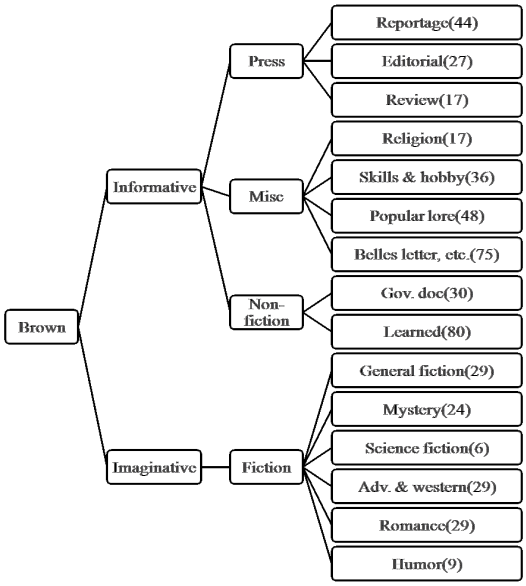

Figure 1: Hierarchy of Brown corpus.

This paper explores a way of using information on the hierarchy of labels for improving fine-grained genre classification. To the best of our knowledge, this is the first work presenting structural genre classification and distance measures for genres. In Section 2 we present a structural reformulation of Support Vector Machines (SVMs) that can take similarities between different genres into account. This formulation necessitates the development of distance measures between different genres in a hierarchy, of which we present three different types in Section 3, along with possible estimation procedures for these distances. We present experiments with these novel structural SVMs and distance measures on three different corpora in Section 4. Our experiments show that structural SVMs can outperform the non-structural standard. However, the improvement is only statistically significant on the Brown corpus. In Section 5 we investigate potential reasons for this, including the (im)balance of different genre hierarchies and problems with our distance measures.

2 Structural SVMs

Discriminative methods are often used for classification, with SVMs being a well-performing method in many tasks (Boser et al., 1992; Joachims, 1999). Linear SVMs on a flat list of labels achieve high efficiency and accuracy in text classification when compared to nonlinear SVMs or other state-of-the-art methods. As for structural output learning, a few SVM-based objective functions have been proposed, including margin formulation for hierarchical learning (Dekel et al., 2004) or general structural learning (Joachims et al., 2009; Tsochantaridis et al., 2005). But many implementations are not publicly available, and their scalability to real-life text classification tasks is unknown. Also they have not been applied to genre classification.

Our formulation can be taken as a special instance of the structural learning framework in (Tsochantaridis et al., 2005). However, they concentrate on more complicated label structures as for sequence alignment or parsing. They proposed two formulations, slack-rescaling and margin-rescaling, claiming that margin-rescaling has two disadvantages. First, it potentially gives significant weight to output values that might not be easily confused with the target values, because every increase in the loss increases the required margin. However, they did not provide empirical evidence for this claim. Second, margin rescaling is not necessarily invariant to the scaling of the distance matrix. We still used margin-rescaling because it allows us to use the sequential dual method for large-scale implementation (Keerthi et al., 2008), which is not applicable to the slack-rescaling formulation. For web page classification we will need fast processing. In addition, we performed model calibration to address the second disadvantage (distance matrix invariance).

Let $\mathbf{x}$ be a document and $\mathbf{w}_m$ a weight vector associated with the genre class m in a corpus with k genres at the most fine-grained level. The predicted class is the class achieving the maximum inner product between $\mathbf{x}$ and the weight vector for the class, denoted as,

$$\arg\max_m \ \mathbf{w}_m^T \mathbf{x}, \forall m. \qquad (1)$$

Accurate prediction requires that when a document vector is multiplied with the weight vector associated with its own class, the resulting inner product should be larger than its inner products with a weight vector for any other genre class m. This helps us to define criteria for weight vectors. Let $\mathbf{x}_i$ be the $i-$th training document, and y_i its genre label. For its weight vector $\mathbf{w}_{y_i}$, the inner product $\mathbf{w}_{y_i}^T \mathbf{x}_i$ should be larger than all other products $\mathbf{w}_m^T \mathbf{x}_i$, that is,

$$\mathbf{w}_{y_i}^T \mathbf{x}_i - \mathbf{w}_m^T \mathbf{x}_i \geq 0, \forall m. \quad (2)$$

To strengthen the constraints, the zero value on the right hand side of the inequality for the flat SVM can be replaced by a positive value, corresponding to a distance measure $h(y_i, m)$ between two genre classes, leading to the following constraint:

$$\mathbf{w}_{y_i}^T \mathbf{x}_i - \mathbf{w}_m^T \mathbf{x}_i \geq h(y_i, m), \forall m. \quad (3)$$

To allow feasible models, in real scenarios such constraints can be violated, but the degree of violation is expected to be small. For each document, the maximum violation in the k constraints is of interest, as given by the following loss term:

$$Loss_i = \max_m \{h(y_i, m) - \mathbf{w}_{y_i}^T \mathbf{x}_i + \mathbf{w}_m^T \mathbf{x}_i\}. \quad (4)$$

Adding up all loss terms over all training documents, and further introducing a term to penalize large values in the weight vectors, we have the following objective function (C is a user-specified nonnegative parameter).

$$\min_{m,i} : \frac{1}{2} \sum_{m=1}^{k} \mathbf{w}_m^T \mathbf{w}_m + C \sum_{i=1}^{p} Loss_i. \quad (5)$$

Efficient methods can be derived by borrowing the sequential dual methods in (Keerthi et al., 2008) or other optimization techniques (Crammer and Singer, 2002).

3 Genre Distance Measures

The structural SVM (Section 2) requires a distance measure h between two genres. We can derive such distance measures from the genre hierarchy in a way similar to word similarity measures that were invented for lexical hierarchies such as WordNet (see (Pedersen et al., 2007) for an overview). In the following, we will first shortly summarise path-based and information-based measures for similarity. However, information-based measures are based on the information content of a node in a hierarchy. Whereas the information content of a word or concept in a lexical hierarchy has been well-defined (Resnik, 1995), it is less clear how to estimate the information content of a genre label. We will therefore discuss several different ways of estimating information content of nodes in a genre hierarchy.

3.1 Distance Measures based on Path Length

If genre labels are organised into a tree (Figure 1), one of the simplest ways to measure distance between two genre labels (= tree nodes) is ***path length*** ($h(a,b)_{plen}$):

$$f(a, LCS(a,b)) + f(b, LCS(a,b)), \quad (6)$$

where a and b are two nodes in the tree, $LCS(a,b)$ is their Least Common Subsumer, and $f(a, LCS(a,b))$ is the number of levels passed through when traversing from a to the ancestral node $LCS(a,b)$. In other words, the distance counts the number of edges traversed from nodes a to b in the tree. For example, the distance between `Learned` and `Misc` in Figure 1 would be 3.

As an alternative, the ***maximum path length*** $h(a,b)_{pmax}$ to their least common subsumer can be used to reduce the range of possible values:

$$\max\{f(a, LCS(a,b)), f(b, LCS(a,b))\}. \quad (7)$$

The ***Leacock & Chodorow*** similarity measure (Leacock and Chodorow, 1998) normalizes the path length measure (6) by the maximum number of nodes D when traversing down from the root.

$$s(a,b)_{plsk} = -log((h(a,b)_{plen} + 1)/2D). \quad (8)$$

To convert it into a distance measure, we can invert it $h(a,b)_{plsk} = 1/s(a,b)_{plsk}$.

Other path-length based measures include the ***Wu & Palmer*** Similarity (Wu and Palmer, 1994).

$$s(a,b)_{pwupal} = \frac{2f(R, LCS(a,b))}{(f(R,a) + f(R,b))}, \quad (9)$$

where R describes the hierarchy's root node. Here similarity is proportional to the shared path from the root to the least common subsumer of two nodes. Since the Wu & Palmer similarity is always between [0 1), we can convert it into a distance measure by $h(a,b)_{pwupal} = 1 - s(a,b)_{pwupal}$.

3.2 Distance Measures based on Information Content

Path-based distance measures work relatively well on balanced hierarchies such as the one in Figure 1 but fail to treat hierarchies with different levels of granularity well. For lexical hierarchies, as a result, several distance measures based on *information content* have been suggested where the information content of a concept c in a hierarchy is measured by (Resnik, 1995)

$$IC(c) = -log(\frac{freq(c)}{freq(root)}). \quad (10)$$

The frequency $freq$ of a concept c is the sum of the frequency of the node c itself and the frequencies of all its subnodes. Since the root may be a dummy concept, its frequency is simply the sum of the frequencies of all its subnodes. The similarity between two nodes can then be defined as the information content of their least common subsumer:

$$s(a,b)_{resk} = IC(LCS(a,b)). \quad (11)$$

If two nodes just share the root as their subsumer, their similarity will be zero. To convert 11 into a distance measure, it is possible to add a constant 1 to it before inverting it, as given by

$$h(a,b)_{resk} = 1/(s(a,b)_{resk} + 1). \quad (12)$$

Several other similarity measures have been proposed based on the Resnik similarity such as the one by (Lin, 1998):

$$s(a,b)_{lin} = \frac{2IC(LCS(a,b))}{IC(a) + IC(b)}. \quad (13)$$

Again to avoid the effect of zero similarity when defining the ***Lin's distance*** we use:

$$h(a,b)_{lin} = 1/(s(a,b)_{lin} + 1). \quad (14)$$

(Jiang and Conrath, 1997) directly define ***Jiang's distance*** ($h(a,b)_{jng}$):

$$IC(a) + IC(b) - 2IC(LCS(a,b)). \quad (15)$$

3.2.1 Information Content of Genre Labels

The notion of information content of a genre is not straightforward. We use two ways of measuring the frequency $freq$ of a genre, depending on its interpretation.

Genre Frequency based on Document Occurrence. We can interpret the "frequency" of a genre node simply as the number of all documents belonging to that genre (including any of its subgenres). Unfortunately, there are no estimates for genre frequencies on, for example, a representative sample of web documents. Therefore, we approximate genre frequencies from the document frequencies (*dfs*) in the training sets used in classification. Note that (i) for balanced class distributions this information will not be helpful and (ii) that this is a relatively poor substitute for an estimation on an independent, representative corpus.

Genre Frequency based on Genre Labels. We can also use the labels/names of the genre nodes as the unit of frequency estimation. Then, the frequency of a genre node is the occurrence frequency of its label in a corpus plus the occurrence frequencies of the labels of all its subnodes. Note that there is no direct correspondence between this measure and the document frequency of a genre: measuring the number of times the potential genre label *poem* occurs in a corpus is not in any way equivalent to the number of poems in that corpus. However, the measure is still structurally aware as frequencies of labels of subnodes are included, i.e. a higher level genre label will have higher frequency (and lower information content) than a lower level genre label.[1]

For label frequency estimation, we manually expand any label abbreviations (such as "newsp" for BNC genre labels), delete stop words and function words and then use two search methods. For the search method $word$ we simply search the frequency of the genre label in a corpus, using three different corpora (the BNC, Brown and Google web search). As for the BNC and Brown corpus some labels are very rarely mentioned, we for these two corpora use also a search method $gram$ where all character 5-grams within the genre label are searched for and their frequencies aggregated.

3.3 Terminology

Algorithms are prefixed by the kind of distance measure they employ — IC for Information content and p for path-based). If the measure is infor-

[1] Obviously when using this measure we rely on genre labels which are meaningful in the sense that lower level labels were chosen to be more specific and therefore probably rarer terms in a corpus. The measure could not possibly be useful on a genre hierarchy that would give random names to its genres such as *genre 1*.

mation content based the specific measure is mentioned next, such as lin. The way for measuring genre frequency is indicated last with df for measuring via document frequency and $word/gram$ when measured via frequency of genre labels. If frequencies of genre labels are used, the corpus for counting the occurrence of genre labels is also indicated via *brown*, *bnc* or the Web as estimated by Google hit counts gg. Standard non-structural SVMs are indicated by $flat$.

4 Experiments

4.1 Datasets

We use four genre-annotated corpora for genre classification: the Brown Corpus (Kučera and Francis, 1967), BNC (Lee, 2001), HGC (Stubbe and Ringlstetter, 2007) and Syracuse (Crowston et al., 2009). They have a wide variety of genre labels (from 15 in the Brown corpus to 32 genres in HGC to 70 in the BNC to 292 in Syracuse), and different types of hierarchies.

4.2 Evaluation Measures

We use standard classification accuracy (Acc) on the most fine-grained level of target categories in the genre hierarchy.

In addition, given a structural distance H, misclassifications can be weighted based on the distance measure. This allows us to penalize incorrect predictions which are further away in the hierarchy (such as between government documents and westerns) more than "close" mismatches (such as between science fiction and westerns). Formally, given the classification confusion matrix M then each M_{ab} for $a \neq b$ contains the number of class a documents that are misclassified into class b. To achieve proper normalization in giving weights to misclassified entries, we can redistribute a total weight $k-1$ to each row of H proportionally to its values, where k is the number of genres. That is, given g the row summation of H, we define a weight matrix Q by normalizing the rows of H in a way given by $Q_{ab} = (k-1)h_{ab}/g_a,\ a \neq b$. We further assign a unit value to the diagonal of Q. Then it is possible to construct a structurally-aware measure (S-Acc):

$$\text{S-Acc} = \sum_a M_{aa} / \sum_{a,b} M_{ab} Q_{ab}. \qquad (16)$$

4.3 Experimental Setup

We compare structural SVMs using all path-based and information-content based measures (see also Section 3.3). As a baseline we use the accuracy achieved by a standard "flat" SVM.

We use 10-fold (randomised) cross validation throughout. In each fold, for each genre class 10% of documents are used for testing. For the remaining 90%, a portion of 10% are sampled for parameter tuning, leaving 80% for training. In each round the validation set is used to help determine the best C associated with Equation (5) based on the validation accuracy from the candidate list 0.0001, 0.0005, 0.001, 0.005, 0.01, 0.05, 0.1, 0.5, 1. Note via this experiment setup, all methods are tuned to their best performance.

For any algorithm comparison, we use a McNemar test with the significance level of 5% as recommended by (Dietterich, 1998).

4.4 Features

The features used for genre classification are character 4-grams for all algorithms, i.e. each document is represented by a binary vector indicating the existence of each character 4-gram. We used character n-grams because they are very easy to extract, language-independent (no need to rely on parsing or even stemming), and they are known to have the best performance in genre classification tasks (Kanaris and Stamatatos, 2009; Sharoff et al., 2010).

4.5 Brown Corpus Results

The Brown Corpus has 500 documents and is organized in a hierarchy with a depth of 3. It contains 15 end-level genres. In one experiment in (Karlgren and Cutting, 1994) the subgenres under *fiction* are grouped together, leading to 10 genres to classify.

Results on 10-genre Brown Corpus. A standard flat SVM achieves an accuracy of 64.4% whereas the best structural SVM based on Lin's information content distance measure (IC-lin-word-bnc) achieves 68.8% accuracy, significantly better at the 1% level. The result is also significantly better than prior work on the Brown corpus in (Karlgren and Cutting, 1994) (who use the whole corpus as test as well as training data). Table 1 summarizes the best performing measures that all outperform the flat SVM at the 1% level.

Table 1: Brown 10-genre Classification Results.

Method	Accuracy
Karlgren and Cutting, 1994	65 (Training)
Flat SVM	64.40
SSVM(IC-lin-word-bnc)	68.80
SSVM(IC-lin-word-br)	68.60
SSVM(IC-lin-gram-br)	67.80

Figure 2 provides the box plots of accuracy scores. The dashed boxes indicate that the distance measures perform significantly worse than the best performing *IC-lin-word-bnc* at the bottom. The solid boxes indicate the corresponding measures are statistically comparable to the *IC-lin-word-bnc* in terms of the mean accuracy they can achieve.

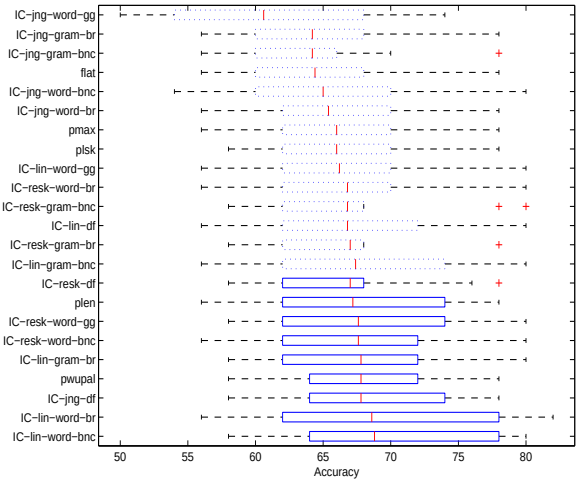

Figure 2: Accuracy on Brown Corpus (10 genres).

Results on 15-genre Brown Corpus. We perform experiments on all 15 genres on the end level of the Brown corpus. The increase of genre classes leads to reduced classification performance. In our experiment, the flat SVM achieves an accuracy of 52.40%, and the structural SVM using path length measure achieves 55.40%, a difference significant at the 5% level. The structural SVMs using information content measures *IC-lin-gram-bnc and IC-resk-word-br* also perform equally well. In addition, we improve on the training accuracy of 52% reported in (Karlgren and Cutting, 1994).

We are also interested in structural accuracy (S-Acc) to see whether the structural SVMs make fewer "big" mistakes. Table 2 shows a cross comparison of structural accuracy. Each row shows how accurate the corresponding method is under the structural accuracy criteria given in the column. The 'no-struct' column corresponds to vanilla accuracy. It is natural to expect each diagonal entry of the numeric table to be the highest, since the respective method is optimised for its own structural distance. However, in our case, Lin's information content measure and the plen measure perform well under any structural accuracy evaluation measure and outperform flat SVMs.

4.6 Other Corpora

In spite of the promising results on the Brown Corpus, structural SVMs on other corpora (BNC, HGC, Syracuse) did not show considerable improvement.

HGC contains 1330 documents divided into 32 approximately equally frequent classes. Its hierarchy has just two levels. Standard accuracy for the best performing structural methods on HGC is just the same as for flat SVM (69.1%), with marginally better structural accuracy (for example, 71.39 vs. 71.04%, using a path-length based structural accuracy). The BNC corpus contains 70 genres and 4053 documents. The number of documents per class ranges from 2 to 501. The accuracy of SSVM is also just comparable to flat SVM (73.6%). The Syracuse corpus is a recently developed large collection of 3027 annotated webpages divided into 292 genres (Crowston et al., 2009). Focusing only on genres containing 15 or more examples, we arrived at a corpus of 2293 samples and 52 genres. Accuracy for flat (53.3%) and structural SVMs (53.7%) are again comparable.

5 Discussion

Given that structural learning can help in topical classification tasks (Tsochantaridis et al., 2005; Dekel et al., 2004), the lack of success on genres is surprising. We now discuss potential reasons for this lack of success.

5.1 Tree Depth and Balance

Our best results were achieved on the Brown corpus, whose genre tree has at least three attractive properties. Firstly, it has a depth greater than 2, i.e. several levels are distinguished. Secondly, it seems visually balanced: branches from root to leaves (or terminals) are of pretty much equal length; branching factors are similar, for example ranging between 2 and 6 for the last level of branching. Thirdly, the number of examples at

Table 2: Structural Accuracy on Brown 15-genre Classification.

Method	no-struct (=typical accuracy)	IC-lin-gram-bnc	plen	IC-resk-word-br	IC-jng-word-gg
flat	52.40	55.34	60.60	58.91	52.19
IC-lin-gram-bnc	55.00	58.15	63.59	61.83	53.85
plen	**55.40**	**58.74**	**64.51**	**62.61**	**54.27**
IC-resk-word-br	55.00	58.24	63.96	62.08	54.08
IC-jng-word-gg	46.00	49.00	54.89	53.01	52.58

each leaf node is roughly comparable (distributional balance).

The other hierarchies violate these properties to a large extent. Thus, the genres in HGC are almost represented by a flat list with just one extra level over 32 categories. Similarly, the vast majority of genres in the Syracuse corpus are also organised in two levels only. Such flat hierarchies do not offer much scope to improve over a completely flat list. There are considerably more levels in the BNC for some branches, e.g., *written/national/broadsheet/arts*, but many other genres are still only specified to the second level of its hierarchy, e.g., *written/adverts*. In addition, the BNC is also distributionally imbalanced, i.e. the number of documents per class varies from 2 to 501 documents.

To test our hypothesis, we tried to skew the Brown genre tree in two ways. First, we kept the tree relatively balanced visually and distributionally but flattened it by removing the second layer *Press, Misc, Non-Fiction, Fiction* from the hierarchy, leaving a tree with only two layers. Second, we skewed the visual and distributional balance of the tree by collapsing its three leaf-level genres under *Press*, and the two under *non-fiction*, leading to 12 genres to classify (cf. Figure 1).

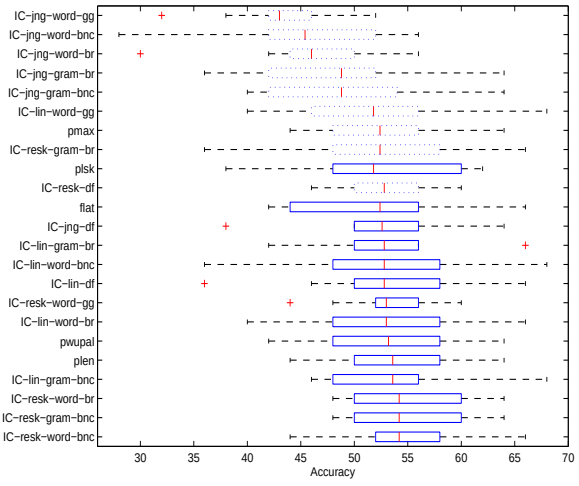

Figure 3: Accuracy on flattened Brown Corpus (15 genres).

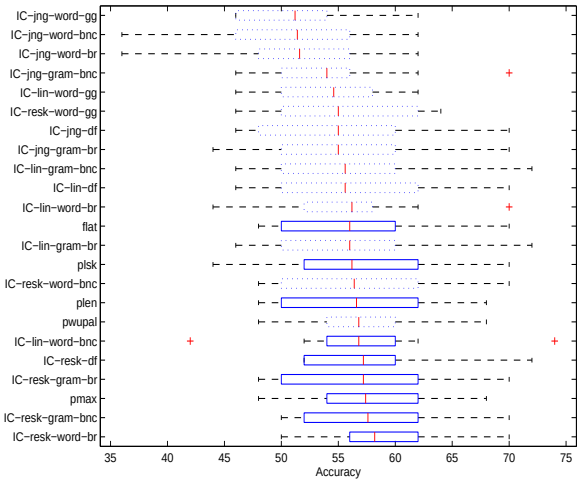

Figure 4: Accuracy on skewed Brown Corpus (12 genres).

As expected, the structural methods on either skewed or flattened hierarchies are not significantly better than the flat SVM. For the flattened hierarchy of 15 leaf genres the maximal accuracy is 54.2% vs. 52.4% for the flat SVM (Figure 3), a non-significant improvement. Similarly, the maximal accuracy on the skewed 12-genre hierarchy is 58.2% vs. 56% (see also Figure 4), again a not significant improvement.

To measure the degree of balance of a tree, we introduce two tree balance scores based on entropy. First, for both measures we extend all branches to the maximum depth of the tree. Then level by level we calculate an entropy score, either according to how many tree nodes at the next level belong to a node at this level (denoted as **vb: visual balance**), or according to how many end level documents belong to a node at this level (denoted as **db: distribution balance**). To make trees with different numbers of internal nodes and leaves more comparable, the entropy score at each level is normalized by the maximal entropy achieved by a tree with uniform distribution of nodes/documents, which is simply $-log(1/N)$, where N denotes the number of nodes at the corre-

sponding level. Finally, the entropy scores for all levels are averaged. It can be shown that any perfect N-ary tree will have the largest visual balance score of 1. If in addition its nodes at each level contain the same number of documents, the distribution balance score will reach the maximum, too.

Table 3 shows the balance scores for all the corpora we use. The first two rows for the Brown corpus have both large visual balance and distribution balance scores. As shown earlier, for those two setups the structural SVMs perform better than the flat approach. In contrast, for the tree hierarchies of Brown that we deformed or flattened, and also BNC and Syracuse, either or both of the two balance scores tend to be lower, and no improvement has been obtained over the flat approach. This may indicate that a further exploration of the relation between tree balance and the performance of structural SVMs is warranted. However, high visual balance and distribution scores do not necessarily imply high performance of structural SVMs, as very flat trees are also visually very balanced. As an example, HGC has a high visual balance score due to a shallow hierarchy and a high distributional balance score due to a roughly equal number of documents contained in each genre. However, HGC did not benefit from structural learning as it is also a very shallow hierarchy; therefore we think that a third variable depth also needs to be taken into account.

A similar observation on the importance of well-balanced hierarchies comes from a recent Pascal challenge on large scale hierarchical text classification,[2] which shows that some flat approaches perform competitively in topic classification with imbalanced hierarchies. However, the participants do not explore explicitly the relation between tree balance and performance.

Other methods for measuring tree balance (some of which are related to ours) are used in the field of phylogenetic research (Shao and Sokal, 1990) but they are only applicable to visual balance. In addition, the methods they used often provide conflicting results on which trees are considered as balanced (Shao and Sokal, 1990).

Table 3: Tree Balance Scores

Corpus	depth	vb	db
Brown (10 genres)	3	**0.9115**	**0.9024**
Brown (15 genres)	3	**0.9186**	**0.9083**
Brown (15, flattened)	2	0.9855	0.8742
Brown (12, skewed)	3	0.8747	0.8947
HGC (32)	2	**0.9562**	**0.9570**
BNC (70)	4	0.9536	0.8039
Syracuse (52)	3	0.9404	0.8634

5.2 Distance Measures

We also scrutinise our distance measures as these are crucial for the structural approach. We notice that simple path length based measures perform well overall; again for the Brown corpus this is probably due to its balanced hierarchy which makes path length appropriate. There are other probable reasons why information content based measures do not perform better than path-length based ones. When measured via document frequency in a corpus we do not have sufficiently large, representative genre-annotated corpora to hand. When measured via genre label frequency, we run into at least two problems. Firstly, as mentioned in Section 3.2.1 genre label frequency does not have to correspond to class frequency of documents. Secondly, the labels used are often abbreviations (e.g. *W_institut_doc, W_newsp_brdsht_nat_social* in BNC Corpus), underspecified (*other, misc, unclassified*) or a collection of phrases (e.g. *belles letters, etc.* in Brown). This made search for frequency very approximate and also loosens the link between label and content.

We investigated in more depth how well the different distance measures are aligned. We adapt the alignment measure between kernels (Cristianini et al., 2002), to investigate how close the distance matrices are. For two distance matrices H_1 and H_2, their alignment $A(H_1, H_2)$ is defined as:

$$\frac{< H_1, H_2 >_F}{\sqrt{< H_1, H_1 >_F, < H_2, H_2 >_F}}, \quad (17)$$

where $< H_1, H_2 >_F = \sum_{i,j}^{k} H_1(g_i, g_j) H_2(g_i, g_j)$ which is the total sum of the entry-wise products between the two distance matrices. Figure 5 shows several distance matrices on the (original) 15 genre Brown corpus. The *plen* matrix has clear blocks for the super genres *press, informative, imaginative*, etc. The *IC-lin-gram-bnc* matrix refines distances in the blocks, due to the introduction of information content. It keeps an alignment score that is over 0.99 (the maximum is 1.00) toward the *plen* matrix, and still has visible block patterns. However, the *IC-jng-word-bnc* significantly adjusts the

[2] http://lshtc.iit.demokritos.gr/

distance entries, has a much lower alignment score with the *plen* matrix, and doesn't reveal apparent blocks. This partially explains the bad performance of the Jiang distance measure on the Brown corpus (see Section 4). The diagrams also show the high closeness between the best performing IC measure and the simple path length based measure.

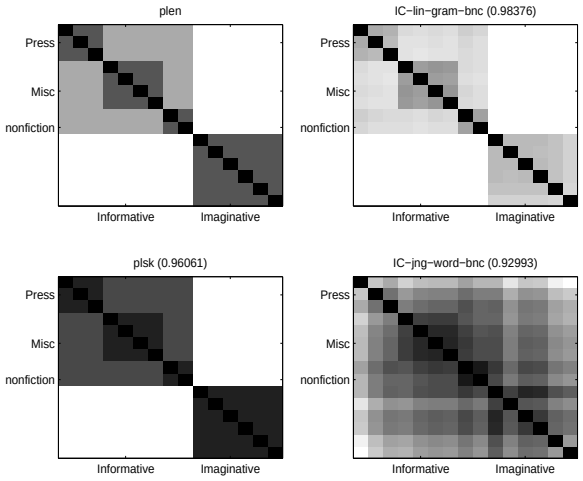

Figure 5: Distance Matrices on Brown. Values in bracket is the alignment with the *plen* matrix

An alternative to structural distance measures would be distance measures between the genres based on pairwise cosine similarities between them. To assess this, we aggregated all character 4-gram training vectors of each genre and calculated standard cosine similarities. Note that these similarities are based on the documents only and do not make use of the Brown hierarchy at all. After converting the similarities to distance, we plug the distance matrix into our structural SVM. However, accuracy on the Brown corpus (15 genres) was almost the same as for a flat SVM. Inspecting the distance matrix visually, we determined that the cosine similarity could clearly distinguish between Fiction and Non-Fiction texts but not between any other genres. This also indicates that the genre structural hierarchy clearly gives information not present in the simple character 4-gram features we use. For a more detailed discussion of the problems of the currently prevalently used character n-grams as features for genre classification, we refer the reader to (Sharoff et al., 2010).

6 Conclusions

In this paper, we have evaluated structural learning approaches to genre classification using several different genre distance measures. Although we were able to improve on non-structural approaches for the Brown corpus, we found it hard to improve over flat SVMs on other corpora. As potential reasons for this negative result, we suggest that current genre hierarchies are either not of sufficient depth or are visually or distributionally imbalanced. We think further investigation into the relationship between hierarchy balance and structural learning is warranted. Further investigation is also needed into the appropriateness of n-gram features for genre identification as well as good measures of genre distance.

In the future, an important task would be the refinement or unsupervised generation of new hierarchies, using information theoretic or data-driven approaches. For a full assessment of hierarchical learning for genre classification, the field of genre studies needs a testbed similar to the Reuters or 20 Newsgroups datasets used in topic-based IR with a balanced genre hierarchy and a representative corpus of reliably annotated webpages.

With regard to algorithms, we are also interested in other formulations for structural SVMs and their large-scale implementation as well as the combination of different distance measures, for example in ensemble learning.

Abstract

This paper presents a framework for automatically processing information coming from community Question Answering (cQA) portals with the purpose of generating a trustful, complete, relevant and succinct summary in response to a question. We exploit the metadata intrinsically present in User Generated Content (UGC) to bias automatic multi-document summarization techniques toward high quality information. We adopt a representation of concepts alternative to n-grams and propose two concept-scoring functions based on semantic overlap. Experimental results on data drawn from Yahoo! Answers demonstrate the effectiveness of our method in terms of ROUGE scores. We show that the information contained in the best answers voted by users of cQA portals can be successfully complemented by our method.

1 Introduction

Community Question Answering (cQA) portals are an example of Social Media where the information need of a user is expressed in the form of a question for which a best answer is picked among the ones generated by other users. cQA websites are becoming an increasingly popular complement to search engines: overnight, a user can expect a human-crafted, natural language answer tailored to her specific needs. We have to be aware, though, that User Generated Content (UGC) is often redundant, noisy and untrustworthy (Jeon et al., 2006; Wang et al., 2009b; Suryanto et al., 2009). Interestingly, a great amount of information is embedded in the metadata generated as a byproduct of users' action and interaction on Social Media. Much valuable information is contained in answers other than the chosen best one (Liu et al., 2008). Our work aims to show that such information can be successfully extracted and made available by exploiting metadata to distill cQA content. To this end, we casted the problem to an instance of the query-biased multi-document summarization task, where the question was seen as a query and the available answers as documents to be summarized. We mapped each characteristic that an ideal answer should present to a measurable property that we wished the final summary could exhibit:

- Quality to assess trustfulness in the source,
- Coverage to ensure completeness of the information presented,
- Relevance to keep focused on the user's information need and
- Novelty to avoid redundancy.

Quality of the information was assessed via Machine Learning (ML) techniques under best answer supervision in a vector space consisting of linguistic and statistical features about the answers and their authors. Coverage was estimated by semantic comparison with the knowledge space of a corpus of answers to similar questions which had been retrieved through the Yahoo! Answers API [1]. Relevance was computed as information overlap between an answer and its question, while Novelty was calculated as inverse overlap with all other answers to the same question. A score was assigned to each concept in an answer according to

The research was conducted while the first author was visiting Tsinghua University.

the above properties. A score-maximizing summary under a maximum coverage model was then computed by solving an associated Integer Linear Programming problem (Gillick and Favre, 2009; McDonald, 2007). We chose to express concepts in the form of Basic Elements (BE), a semantic unit developed at ISI[2] and modeled semantic overlap as intersection in the equivalence classes of two concepts (formal definitions will be given in section 2.3).

The objective of our work was to present what we believe is a valuable conceptual framework; more advance machine learning and summarization techniques would most likely improve the performances.

The remaining of this paper is organized as follows. In the next section Quality, Coverage, Relevance and Novelty measures are presented; we explain how they were calculated and combined to generate a final summary of all answers to a question. Experiments are illustrated in Section 3, where we give evidence of the effectiveness of our method. We list related work in Section 5, discuss possible alternative approaches in Section 4 and provide our conclusions in Section 6.

2 The summarization framework

2.1 Quality as a ranking problem

Quality assessing of information available on Social Media had been studied before mainly as a binary classification problem with the objective of detecting low quality content. We, on the other hand, treated it as a ranking problem and made use of quality estimates with the novel intent of successfully combining information from sources with different levels of trustfulness and writing ability. This is crucial when manipulating UGC, which is known to be subject to particularly great variance in credibility (Jeon et al., 2006; Wang et al., 2009b; Suryanto et al., 2009) and may be poorly written.

An answer a was given along with information about the user u that authored it, the set TA^q (Total Answers) of all answers to the same question q and the set TA^u of all answers by the same user. Making use of results available in the literature (Agichtein et al., 2008) [3], we designed a Quality feature space to capture the following syntactic, behavioral and statistical properties:

- ϑ, length of answer a
- ς, number of non-stopwords in a with a corpus frequency larger than n (set to 5 in our experiments)
- ϖ, points awarded to user u according to the Yahoo! Answers' points system
- ϱ, ratio of best answers posted by user u

The features mentioned above determined a space Ψ; An answer a, in such feature space, assumed the vectorial form:

$$\Psi^a = (\ \vartheta,\ \varsigma,\ \varpi,\ \varrho\ )$$

Following the intuition that chosen best answers ($a^\star$) carry high quality information, we used supervised ML techniques to predict the probability of a to have been selected as a best answer $a^\star$. We trained a Linear Regression classifier to learn the weight vector $W = (w_1, w_2, w_3, w_4)$ that would combine the above feature. Supervision was given in the form of a training set Tr^Q of labeled pairs defined as:

$$Tr^Q = \{\langle\ \Psi^a,\ isbest^a\ \rangle\}$$

$isbest^a$ was a boolean label indicating whether a was an $a^\star$ answer; the training set size was determined experimentally and will be discussed in Section 3.2. Although the value of $isbest^a$ was known for all answers, the output of the classifier offered us a real-valued prediction that could be interpreted as a quality score $Q(\Psi^a)$:

$$\begin{aligned} Q(\Psi^a) &\approx P(\ isbest^a = 1 \mid a, u, TA^u,\ ) \\ &\approx P(\ isbest^a = 1 \mid \Psi^a\ ) \\ &= W^T \cdot \Psi^a \end{aligned} \quad (1)$$

The Quality measure for an answer a was approximated by the probability of such answer to be a best answer ($isbest^a = 1$) with respect to its author u and the sets TA^u and TA^q. It was calculated as dot product between the learned weight vector W and the feature vector for answer Ψ^a.

Our decision to proceed in an unsupervised direction came from the consideration that any use of external human annotation would have made it impracticable to build an actual system on larger scale. An alternative, completely unsupervised approach to quality detection that has not undergone experimental analysis is discussed in Section 4.

[2] Information Sciences Institute, University of Southern California, http://www.isi.edu

[3] A long list of features is proposed; training a classifier on all of them would no doubt increase the performances.

2.2 Bag-of-BEs and semantic overlap

The properties that remain to be discussed, namely Coverage, Relevance and Novelty, are measures of semantic overlap between concepts; a concept is the smallest unit of meaning in a portion of written text. To represent sentences and answers we adopted an alternative approach to classical n-grams that could be defined bag-of-BEs. a BE is "a head|modifier|relation triple representation of a document developed at ISI" (Zhou et al., 2006). BEs are a strong theoretical instrument to tackle the ambiguity inherent in natural language that find successful practical applications in real-world query-based summarization systems. Different from n-grams, they are variant in length and depend on parsing techniques, named entity detection, part-of-speech tagging and resolution of syntactic forms such as hyponyms, pronouns, pertainyms, abbreviation and synonyms. To each BE is associated a class of semantically equivalent BEs as result of what is called a transformation of the original BE; the mentioned class uniquely defines the concept. What seemed to us most remarkable is that this makes the concept context-dependent. A sentence is defined as a set of concepts and an answer is defined as the union between the sets that represent its sentences.

The rest of this section gives formal definition of our model of concept representation and semantic overlap. From a set-theoretical point of view, each concepts c was uniquely associated with a set $E^c = \{c_1, c_2 \dots c_m\}$ such that:

$$\forall i, j \quad (c_i \approx^L c) \wedge (c_i \not\equiv c) \wedge (c_i \not\equiv c_j)$$

In our model, the "$\equiv$" relation indicated syntactic equivalence (exact pattern matching), while the "$\approx^L$" relation represented semantic equivalence under the convention of some language L (two concepts having the same meaning). E^c was defined as the set of semantically equivalent concepts to c, called its equivalence class; each concept c_i in E^c carried the same meaning ($\approx^L$) of concept c without being syntactically identical ($\equiv$); furthermore, no two concepts i and j in the same equivalence class were identical.

"Climbing a tree to escape a black bear is pointless because *they can climb* very well."

BE = they|climb
E^c = {climb|bears, bear|go_up, climbing|animals, climber|instincts, trees|go_up, claws|climb...}

Given two concepts c and k:

$$c \bowtie k \begin{cases} c \equiv k & \text{or} \\ E^c \cap E^k \neq \emptyset \end{cases}$$

We defined semantic overlap as occurring between c and k if they were syntactically identical or if their equivalence classes E^c and E^k had at least one element in common. In fact, given the above definition of equivalence class and the transitivity of "$\equiv$" relation, we have that if the equivalence classes of two concepts are not disjoint, then they must bare the same meaning under the convention of some language L; in that case we said that c semantically overlapped k. It is worth noting that relation "$\bowtie$" is symmetric, transitive and reflexive; as a consequence all concepts with the same meaning are part of a same equivalence class. BE and equivalence class extraction were performed by modifying the behavior of the BEwT-E-0.3 framework [4]. The framework itself is responsible for the operative definition of the "$\approx^L$" relation and the creation of the equivalence classes.

2.3 Coverage via concept importance

In the scenario we proposed, the user's information need is addressed in the form of a unique, summarized answer; information that is left out of the final summary will simply be unavailable. This raises the concern of completeness: besides ensuring that the information provided could be trusted, we wanted to guarantee that the posed question was being answered thoroughly. We adopted the general definition of Coverage as the portion of relevant information about a certain subject that is contained in a document (Swaminathan et al., 2009). We proceeded by treating each answer to a question q as a separate document and we retrieved through the Yahoo! Answers API a set TK^q (Total Knowledge) of 50 answers [5] to questions similar to q: the knowledge space of TK^q was chosen to approximate the entire knowledge space related to the queried question q. We calculated Coverage as a function of the portion of answers in TK^q that presented semantic overlap with a.

[4] The authors can be contacted regarding the possibility of sharing the code of the modified version. Original version available from `http://www.isi.edu/publications/licensed-sw/BE/index.html`.

[5] such limit was imposed by the current version of the API. Experiments with a greater corpus should be carried out in the future.

$$C(a,q) = \sum_{c_i \in a} \gamma(c_i) \cdot tf(c_i, a) \quad (2)$$

The Coverage measure for an answer a was calculated as the sum of term frequency $tf(c_i, a)$ for concepts in the answer itself, weighted by a concept importance function, $\gamma(c_i)$, for concepts in the total knowledge space TK^q. $\gamma(c)$ was defined as follows:

$$\gamma(c) = \frac{|TK^{q,c}|}{|TK^q|} \cdot \log_2 \frac{|TK^q|}{|TK^{q,c}|} \quad (3)$$

where $TK^{q,c} = \{d \in TK^q : \exists k \in d,\ k \bowtie c\}$

The function $\gamma(c)$ of concept c was calculated as a function of the cardinality of set TK^q and set $TK^{q,c}$, which was the subset of all those answers d that contained at least one concept k which presented semantical overlap with c itself. A similar idea of knowledge space coverage is addressed by Swaminathan et al. (2009), from which formulas (2) and (3) were derived.

A sensible alternative would be to estimate Coverage at the sentence level.

2.4 Relevance and Novelty via $\bowtie$ relation

To this point, we have addressed matters of trustfulness and completeness. Another widely shared concern for Information Retrieval systems is Relevance to the query. We calculated relevance by computing the semantic overlap between concepts in the answers and the question. Intuitively, we reward concepts that express meaning that could be found in the question to be answered.

$$R(c,q) = \frac{|q^c|}{|q|} \quad (4)$$

where $q^c = \{k \in q : k \bowtie c\}$

The Relevance measure $R(c,q)$ of a concept c with respect to a question q was calculated as the ratio of the cardinality of set q^c (containing all concepts in q that semantically overlapped with c) normalized by the total number of concepts in q.

Another property we found desirable, was to minimize redundancy of information in the final summary. Since all elements in TA^q (the set of all answers to q) would be used for the final summary, we positively rewarded concepts that were expressing novel meanings.

$$N(c,q) = 1 - \frac{|TA^{q,c}|}{|TA^q|} \quad (5)$$

where $TA^{q,c} = \{d \in TA^q : \exists k \in d,\ k \bowtie c\}$

The Novelty measure $N(c,q)$ of a concept c with respect to a question q was calculated as the ratio of the cardinality of set $TA^{q,c}$ over the cardinality of set TA^q; $TA^{q,c}$ was the subset of all those answers d in TA^q that contained at least one concept k which presented semantical overlap with c.

2.5 The concept scoring functions

We have now determined how to calculate the scores for each property in formulas (1), (2), (4) and (5); under the assumption that the Quality and Coverage of a concept are the same of its answer, every concept c part of an answer a to some question q, could be assigned a score vector as follows:

$$\Phi^c = (\ Q(\Psi^a),\ C(a,q),\ R(c,q),\ N(c,q)\ )$$

What we needed at this point was a function S of the above vector which would assign a higher score to concepts most worthy of being included in the final summary. Our intuition was that since Quality, Coverage, Novelty and Relevance were all virtues properties, S needed to be monotonically increasing with respect to all its dimensions. We designed two such functions. Function (6), which multiplied the scores, was based on the probabilistic interpretation of each score as an independent event. Further empirical considerations, brought us to later introduce a logarithmic component that would discourage inclusion of sentences shorter then a threshold t (a reasonable choice for this parameter is a value around 20). The score for concept c appearing in sentence s^c was calculated as:

$$S^{\Pi}(c) = \prod_{i=1}^{4} (\Phi_i^c) \cdot \log_t(length(s^c)) \quad (6)$$

A second approach that made use of human annotation to learn a vector of weights $V = (v_1, v_2, v_3, v_4)$ that linearly combined the scores was investigated. Analogously to what had been done with scoring function (6), the Φ space was augmented with a dimension representing the length of the answer.

$$S^{\Sigma}(c) = \sum_{i=1}^{4} (\Phi_i^c \cdot v_i) + length(s^c) \cdot v_5 \quad (7)$$

In order to learn the weight vector V that would combine the above scores, we asked three human annotators to generate question-biased extractive summaries based on all answers available for a certain question. We trained a Linear Regression

classifier with a set Tr^S of labeled pairs defined as:

$$Tr^S = \{\langle\, (\Phi^c,\ length(s^c)),\ include^c \,\rangle\}$$

$include^c$ was a boolean label that indicated whether s^c, the sentence containing c, had been included in the human-generated summary; $length(s^c)$ indicated the length of sentence s^c. Questions and relative answers for the generation of human summaries were taken from the "filtered dataset" described in Section 3.1.

The concept score for the same BE in two separate answers is very likely to be different because it belongs to answers with their own Quality and Coverage values: this only makes the scoring function context-dependent and does not interfere with the calculation the Coverage, Relevance and Novelty measures, which are based on information overlap and will regard two BEs with overlapping equivalence classes as being the same, regardless of their score being different.

2.6 Quality constrained summarization

The previous sections showed how we quantitatively determined which concepts were more worthy of becoming part of the final machine summary M. The final step was to generate the summary itself by automatically selecting sentences under a length constraint. Choosing this constraint carefully demonstrated to be of crucial importance during the experimental phase. We again opted for a metadata-driven approach and designed the length constraint as a function of the lengths of all answers to q (TA^q) weighted by the respective Quality measures:

$$length^M = \sum_{a \in TA^q} length(a) \cdot Q(\Psi^a) \quad (8)$$

The intuition was that the longer and the more trustworthy answers to a question were, the more space was reasonable to allocate for information in the final, machine summarized answer M.

M was generated so as to maximize the scores of the concepts it included. This was done under a maximum coverage model by solving the following Integer Linear Programming problem:

$$\text{maximize:} \quad \sum_i S(c_i) \cdot x_i \quad (9)$$

$$\text{subject to:} \quad \sum_j length(j) \cdot s_j \leq length^M$$

$$\sum_j y_j \cdot occ_{ij} \geq x_i \quad \forall i \quad (10)$$

$$occ_{ij},\ x_i,\ y_j \in \{0,1\} \quad \forall i,j$$

$$occ_{ij} = 1 \text{ if } c_i \in s_j, \quad \forall i,j$$

$$x_i = 1 \text{ if } c_i \in M, \quad \forall i$$

$$y_j = 1 \text{ if } s_j \in M, \quad \forall j$$

In the above program, M is the set of selected sentences: $M = \{s_j : y_j = 1, \quad \forall j\}$. The integer variables x_i and y_j were equals to one if the corresponding concept c_i and sentence s_j were included in M. Similarly occ_{ij} was equal to one if concept c_i was contained in sentence s_j. We maximized the sum of scores $S(c_i)$ (for S equals to S^Π or S^Σ) for each concept c_i in the final summary M. We did so under the constraint that the total length of all sentences s_j included in M must be less than the total expected length of the summary itself. In addition, we imposed a consistency constraint: if a concept c_i was included in M, then at least one sentence s_j that contained the concept must also be selected (constraint (10)). The described optimization problem was solved using lp_solve [6].

We conclude with an empirical side note: since solving the above can be computationally very demanding for large number of concepts, we found performance-wise very fruitful to skim about one fourth of the concepts with lowest scores.

3 Experiments

3.1 Datasets and filters

The initial dataset was composed of 216,563 questions and 1,982,006 answers written by 171,676 user in 100 categories from the Yahoo! Answers portal[7]. We will refer to this dataset as the "unfiltered version". The metadata described in section 2.1 was extracted and normalized; quality experiments (Section 3.2) were then conducted. The unfiltered version was later reduced to 89,814 question-answer pairs that showed statistical and linguistic properties which made them particularly adequate for our purpose. In particular, trivial, factoid and encyclopedia-answerable questions were

[6] the version used was lp_solve 5.5, available at `http://lpsolve.sourceforge.net/5.5`

[7] The reader is encouraged to contact the authors regarding the availability of data and filters described in this Section.

removed by applying a series of patterns for the identification of complex questions. The work by Liu et al. (2008) indicates some categories of questions that are particularly suitable for summarization, but due to the lack of high-performing question classifiers we resorted to human-crafted question patterns. Some pattern examples are the following:

- {Why,What is the reason} [...]
- How {to,do,does,did} [...]
- How {is,are,were,was,will} [...]
- How {could,can,would,should} [...]

We also removed questions that showed statistical values outside of convenient ranges: the number of answers, length of the longest answer and length of the sum of all answers (both absolute and normalized) were taken in consideration. In particular we discarded questions with the following characteristics:

- there were less than three answers [8]
- the longest answer was over 400 words (likely a copy-and-paste)
- the sum of the length of all answers outside of the $(100,\ 1000)$ words interval
- the average length of answers was outside of the $(50,\ 300)$ words interval

At this point a second version of the dataset was created to evaluate the summarization performance under scoring function (6) and (7); it was generated by manually selecting questions that arouse subjective, human interest from the previous 89,814 question-answer pairs. The dataset size was thus reduced to 358 answers to 100 questions that were manually summarized (refer to Section 3.3). From now on we will refer to this second version of the dataset as the "filtered version".

3.2 Quality assessing

In Section 2.1 we claimed to be able to identify high quality content. To demonstrate it, we conducted a set of experiments on the original unfiltered dataset to establish whether the feature space Ψ was powerful enough to capture the quality of answers; our specific objective was to estimate the amount of training examples needed to successfully train a classifier for the quality assessing task. The Linear Regression[9] method was chosen to determine the probability $Q(\Psi^a)$ of a to be a best answer to q; as explained in Section 2.1, those probabilities were interpreted as quality estimates. The evaluation of the classifier's output was based on the observation that given the set of all answers TA^q relative to q and the best answer $a^\star$, a successfully trained classifier should be able to rank $a^\star$ ahead of all other answers to the same question. More precisely, we defined Precision as follows:

$$\frac{|\{q \in Tr^Q :\ \forall a \in TA^q,\ Q(\Psi^{a^\star}) > Q(\Psi^a)\}|}{|Tr^Q|}$$

where the numerator was the number of questions for which the classifier was able to correctly rank $a^\star$ by giving it the highest quality estimate in TA^q and the denominator was the total number of examples in the training set Tr^Q. Figure 1 shows the precision values (Y-axis) in identifying best answers as the size of Tr^Q increases (X-axis). The experiment started from a training set of size 100 and was repeated adding 300 examples at a time until precision started decreasing. With each increase in training set size, the experiment was repeated ten times and average precision values were calculated. In all runs, training examples were picked randomly from the unfiltered dataset described in Section 3.1; for details on Tr^Q see Section 2.1. A training set of 12,000 examples was chosen for the summarization experiments.

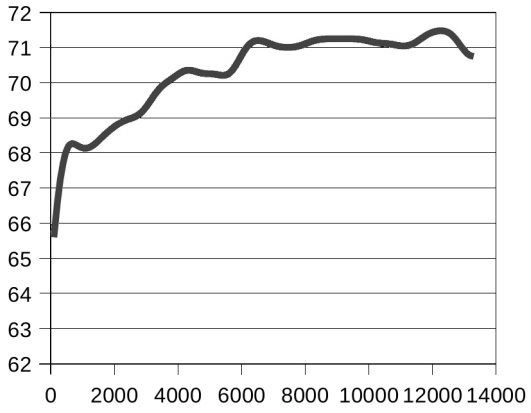

Figure 1: Precision values (Y-axis) in detecting best answers $a^\star$ with increasing training set size (X-axis) for a Linear Regression classifier on the unfiltered dataset.

[8] Being too easy to summarize or not requiring any summarization at all, those questions wouldn't constitute an valuable test of the system's ability to extract information.

[9] Performed with Weka 3.7.0 available at `http://www.cs.waikato.ac.nz/~ml/weka`

System	$a^\star$ (baseline)	S^Σ	S^Π

ROUGE-1_P	62.2%	54.0%	71.2%
ROUGE-1_F	52.9%	59.3%	66.1%
ROUGE-2_R	40.5%	52.2%	58.8%
ROUGE-2_P	49.0%	41.4%	63.1%
ROUGE-2_F	41.6%	45.9%	57.9%
ROUGE-L_R	50.3%	65.1%	66.3%
ROUGE-L_P	60.5%	52.3%	70.7%
ROUGE-L_F	51.5%	57.3%	65.1%

Table 1: Summarization Evaluation on filtered dataset (refer to Section 3.1 for details). ROUGE-L, ROUGE-1 and ROUGE-2 are presented; for each, Recall (R), Precision (P) and F-1 score (F) are given.

3.3 Evaluating answer summaries

The objective of our work was to summarize answers from cQA portals. Two systems were designed: Table 1 shows the performances using function S^Σ (see equation (7)), and function S^Π (see equation (6)). The chosen best answer $a^\star$ was used as a baseline. We calculated ROUGE-1 and ROUGE-2 scores[10] against human annotation on the filtered version of the dataset presented in Section 3.1. The filtered dataset consisted of 358 answers to 100 questions. For each questions q, three annotators were asked to produce an extractive summary of the information contained in TA^q by selecting sentences subject to a fixed length limit of 250 words. The annotation resulted in 300 summaries (larger-scale annotation is still ongoing). For the S^Σ system, 200 of the 300 generated summaries were used for training and the remaining were used for testing (see the definition of Tr^S Section 2.5). Cross-validation was conducted. For the S^Π system, which required no training, all of the 300 summaries were used as the test set.

S^Σ outperformed the baseline in Recall (R) but not in Precision (P); nevertheless, the combined F-1 score (F) was sensibly higher (around 5 points percentile). On the other hand, our S^Π system showed very consistent improvements of an order of 10 to 15 points percentile over the baseline on all measures; we would like to draw attention on the fact that even if Precision scores are higher, it is on Recall scores that greater improvements were achieved. This, together with the results obtained by S^Σ, suggest performances could benefit from the enforcement of a more stringent length constraint than the one proposed in (8). Further potential improvements on S^Σ could be obtained by choosing a classifier able to learn a more expressive underlying function.

[10]Available at `http://berouge.com/default.aspx`

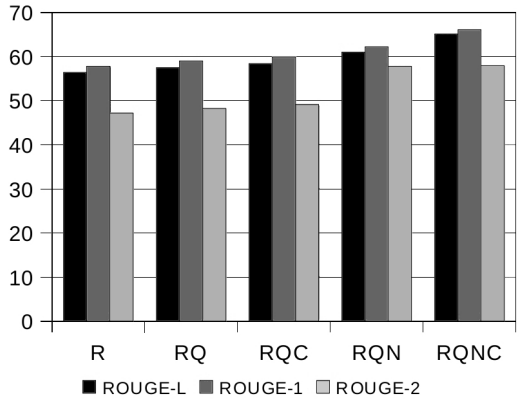

Figure 2: Increase in ROUGE-L, ROUGE-1 and ROUGE-2 performances of the S^Π system as more measures are taken in consideration in the scoring function, starting from Relevance alone (R) to the complete system (RQNC). F-1 scores are given.

In order to determine what influence the single measures had on the overall performance, we conducted a final experiment on the filtered dataset to evaluate (the S^Π scoring function was used). The evaluation was conducted in terms of F-1 scores of ROUGE-L, ROUGE-1 and ROUGE-2. First only Relevance was tested (R) and subsequently Quality was added (RQ); then, in turn, Coverage (RQC) and Novelty (RQN); Finally the complete system taking all measures in consideration (RQNC). Results are shown in Figure 2. In general performances increase smoothly with the exception of ROUGE-2 score, which seems to be particularly sensitive to Novelty: no matter what combination of measures is used (R alone, RQ, RQC), changes in ROUGE-2 score remain under one point percentile. Once Novelty is added, performances rise abruptly to the system's highest. A summary example, along with the question and the best answer, is presented in Table 2.

4 Discussion and Future Directions

We conclude by discussing a few alternatives to the approaches we presented. The $length^M$ constraint for the final summary (Section 2.6), could have been determined by making use of external knowledge such as TK^q: since TK^q represents

HOW TO PROTECT YOURSELF FROM A BEAR? http://answers.yahoo.com/question/index?qid=20060818062414AA7VldB
BEST ANSWER Great question. I have done alot of trekking through California, Montana and Wyoming and have met Black bears (which are quite dinky and placid but can go nuts if they have babies), and have been half an hour away from (allegedly) the mother of all grizzley s whilst on a trail through Glacier National park - so some other trekkerers told me... What the park wardens say is SING, SHOUT, MAKE NOISE...do it loudly, let them know you are there..they will get out of the way, it is a surprised bear wot will go mental and rip your little legs off..No fun permission: anything that will confuse them and stop them in their tracks...I have been told be an native american buddy that to keep a bottle of perfume in your pocket...throw it at the ground near your feet and make the place stink: they have good noses, them bears, and a mega concentrated dose of Britney Spears Obsessive Compulsive is gonna give em something to think about...Have you got a rape alarm? Def take that...you only need to distract them for a second then they will lose interest..Stick to the trails is the most important thing, and talk to everyone you see when trekking: make sure others know where you are.
SUMMARIZED ANSWER […] In addition if the bear actually approaches you or charges you.. still stand your ground. Many times they will not actually come in contact with you, they will charge, almost touch you than run away. […] The actions you should take are different based on the type of bear. for example adult Grizzlies can t climb trees, but Black bears can even when adults. They can not climb in general as thier claws are longer and not semi-retractable like a Black bears claws. […] I truly disagree with the whole play dead approach because both Grizzlies and Black bears are oppurtunistic animals and will feed on carrion as well as kill and eat animals. Although Black bears are much more scavenger like and tend not to kill to eat as much as they just look around for scraps. Grizzlies on the other hand are very accomplished hunters and will take down large prey animals when they want. […] I have lived in the wilderness of Northern Canada for many years and I can honestly say that Black bears are not at all likely to attack you in most cases they run away as soon as they see or smell a human, the only places where Black bears are agressive is in parks with visitors that feed them, everywhere else the bears know that usually humans shoot them and so fear us. […]

Table 2: A summarized answer composed of five different portions of text generated with the S^{Π} scoring function; the chosen best answer is presented for comparison. The richness of the content and the good level of readability make it a successful instance of metadata-aware summarization of information in cQA systems. Less satisfying examples include summaries to questions that require a specific order of sentences or a compromise between strongly discordant opinions; in those cases, the summarized answer might lack logical consistency.

the total knowledge available about q, a coverage estimate of the final answers against it would have been ideal. Unfortunately the lack of metadata about those answers prevented us from proceeding in that direction. This consideration suggests the idea of building TK^q using similar answers in the dataset itself, for which metadata is indeed available. Furthermore, similar questions in the dataset could have been used to augment the set of answers used to generate the final summary with answers coming from similar questions. Wang et al. (2009a) presents a method to retrieve similar questions that could be worth taking in consideration for the task. We suggest that the retrieval method could be made Quality-aware. A Quality feature space for questions is presented by Agichtein et al. (2008) and could be used to rank the quality of questions in a way similar to how we ranked the quality of answers.

The Quality assessing component itself could be built as a module that can be adjusted to the kind of Social Media in use; the creation of customized Quality feature spaces would make it possible to handle different sources of UGC (forums, collaborative authoring websites such as Wikipedia, blogs etc.). A great obstacle is the lack of systematically available high quality training examples: a tentative solution could be to make use of clustering algorithms in the feature space; high and low quality clusters could then be labeled by comparison with examples of virtuous behavior (such as Wikipedia's Featured Articles). The quality of a document could then be estimated as a function of distance from the centroid of the cluster it belongs to. More careful estimates could take the position of other clusters and the concentration of nearby documents in consideration.

Finally, in addition to the chosen best answer, a DUC-styled query-focused multi-document summary could be used as a baseline against which the performances of the system can be checked.

5 Related Work

A work with a similar objective to our own is that of Liu et al. (2008), where standard multi-document summarization techniques are employed along with taxonomic information about questions. Our approach differs in two fundamental aspects: it took in consideration the peculiarities of the data in input by exploiting the nature of UGC and available metadata; additionally, along with relevance, we addressed challenges that are specific to Question Answering, such as Coverage and Novelty. For an investigation of Coverage in the context of Search Engines, refer to Swaminathan et al. (2009).

At the core of our work laid information trustfulness, summarization techniques and alternative concept representation. A general approach to the broad problem of evaluating information credibility on the Internet is presented by Akamine et al. (2009) with a system that makes use of semantic-aware Natural Language Preprocessing techniques. With analogous goals, but a focus on UGC, are the papers of Stvilia et al. (2005), Mcguinness et al. (2006), Hu et al. (2007) and

Zeng et al. (2006), which present a thorough investigation of Quality and trust in Wikipedia. In the cQA domain, Jeon et al. (2006) presents a framework to use Maximum Entropy for answer quality estimation through non-textual features; with the same purpose, more recent methods based on the expertise of answerers are proposed by Suryanto et al. (2009), while Wang et al. (2009b) introduce the idea of ranking answers taking their relation to questions in consideration. The paper that we regard as most authoritative on the matter is the work by Agichtein et al. (2008) which inspired us in the design of the Quality feature space presented in Section 2.1.

Our approach merged trustfulness estimation and summarization techniques: we adapted the automatic concept-level model presented by Gillick and Favre (2009) to our needs; related work in multi-document summarization has been carried out by Wang et al. (2008) and McDonald (2007). A relevant selection of approaches that instead make use of ML techniques for query-biased summarization is the following: Wang et al. (2007), Metzler and Kanungo (2008) and Li et al. (2009). An aspect worth investigating is the use of partially labeled or totally unlabeled data for summarization in the work of Wong et al. (2008) and Amini and Gallinari (2002).

Our final contribution was to explore the use of Basic Elements document representation instead of the widely used n-gram paradigm: in this regard, we suggest the paper by Zhou et al. (2006).

6 Conclusions

We presented a framework to generate trustful, complete, relevant and succinct answers to questions posted by users in cQA portals. We made use of intrinsically available metadata along with concept-level multi-document summarization techniques. Furthermore, we proposed an original use for the BE representation of concepts and tested two concept-scoring functions to combine Quality, Coverage, Relevance and Novelty measures. Evaluation results on human annotated data showed that our summarized answers constitute a solid complement to best answers voted by the cQA users.

We are in the process of building a system that performs on-line summarization of large sets of questions and answers from Yahoo! Answers. Larger-scale evaluation of results against other state-of-the-art summarization systems is ongoing.

Abstract

In recent years, research in natural language processing has increasingly focused on normalizing SMS messages. Different well-defined approaches have been proposed, but the problem remains far from being solved: best systems achieve a 11% Word Error Rate. This paper presents a method that shares similarities with both spell checking and machine translation approaches. The normalization part of the system is entirely based on models trained from a corpus. Evaluated in French by 10-fold-cross validation, the system achieves a 9.3% Word Error Rate and a 0.83 BLEU score.

1 Introduction

Introduced a few years ago, Short Message Service (SMS) offers the possibility of exchanging written messages between mobile phones. SMS has quickly been adopted by users. These messages often greatly deviate from traditional spelling conventions. As shown by specialists (Thurlow and Brown, 2003; Fairon et al., 2006; Bieswanger, 2007), this variability is due to the simultaneous use of numerous coding strategies, like phonetic plays (*2m1* read 'demain', "tomorrow"), phonetic transcriptions (*kom* instead of 'comme', "like"), consonant skeletons (*tjrs* for 'toujours', "always"), misapplied, missing or incorrect separators (*j esper* for 'j'espère', "I hope"; *j'croibi1k*, instead of 'je crois bien que', "I am pretty sure that"), etc. These deviations are due to three main factors: the small number of characters allowed per text message by the service (140 bytes), the constraints of the small phones' keypads and, last but not least, the fact that people mostly communicate between friends and relatives in an informal register.

Whatever their causes, these deviations considerably hamper any standard natural language processing (NLP) system, which stumbles against so many Out-Of-Vocabulary words. For this reason, as noted by Sproat et al. (2001), an SMS normalization must be performed *before* a more conventional NLP process can be applied. As defined by Yvon (2008), "SMS normalization consists in rewriting an SMS text using a more conventional spelling, in order to make it more readable for a human or for a machine."

The SMS normalization we present here was developed in the general framework of an SMS-to-speech synthesis system[1]. This paper, however, only focuses on the normalization process.

Evaluated in French, our method shares similarities with both spell checking and machine translation. The machine translation-like module of the system performs the true normalization task. It is entirely based on models learned from an SMS corpus and its transcription, aligned at the character-level in order to get parallel corpora. Two spell checking-like modules surround the normalization module. The first one detects unambiguous tokens, like URLs or phone numbers, to keep them out of the normalization. The second one, applied on the normalized parts only, identifies non-alphabetic sequences, like punctuations, and labels them with the corresponding token. This greatly helps the system's print module to follow the basic rules of typography.

This paper is organized as follows. Section 2 proposes an overview of the state of the art. Section 3 presents the general architecture of our system, while Section 4 focuses on how we learn and combine our normalization models. Section 5 evaluates the system and compares it to

previous works. Section 6 draws conclusions and considers some future possible improvements of the method.

2 Related work

As highlighted by Kobus et al. (2008b), SMS normalization, up to now, has been handled through three well-known NLP metaphors: spell checking, machine translation and automatic speech recognition. In this section, we only present the pros and cons of these approaches. Their results are given in Section 5, focused on our evaluation.

The spell checking metaphor (Guimier de Neef et al., 2007; Choudhury et al., 2007; Cook and Stevenson, 2009) performs the normalization task on a word-per-word basis. On the assumption that most words should be correct for the purpose of communication, its principle is to keep In-Vocabulary words out of the correction process. Guimier de Neef et al. (2007) proposed a rule-based system that uses only a few linguistic resources dedicated to SMS, like specific lexicons of abbreviations. Choudhury et al. (2007) and Cook and Stevenson (2009) preferred to implement the noisy channel metaphor (Shannon, 1948), which assumes a communication process in which a sender emits the intended message W through an imperfect (noisy) communication channel, such that the sequence O observed by the recipient is a noisy version of the original message. On this basis, the idea is to recover the intended message W hidden behind the sequences of observations O, by maximizing:

$$\begin{aligned} W_{max} &= \arg\max P(W|O) \\ &= \arg\max \frac{P(O|W)\,P(W)}{P(O)} \end{aligned} \quad (1)$$

where $P(O)$ is ignored because constant, $P(O|W)$ models the channel's noise, and $P(W)$ models the language of the source. Choudhury et al. (2007) implemented the noisy channel through a Hidden-Markov Model (HMM) able to handle both graphemic variants and phonetic plays as proposed by (Toutanova and Moore, 2002), while Cook and Stevenson (2009) enhanced the model by adapting the channel's noise $P(O|W, wf)$ according to a list of predefined observed word formations $\{wf\}$: stylistic variation, word clipping, phonetic abbreviations, etc. Whatever the system, the main limitation of the spell checking approach is the excessive confidence it places in word boundaries.

The machine translation metaphor, which is historically the first proposed (Bangalore et al., 2002; Aw et al., 2006), considers the process of normalizing SMS as a translation task from a source language (the SMS) to a target language (its standard written form). This standpoint is based on the observation that, on the one side, SMS messages greatly differ from their standard written forms, and that, on the other side, most of the errors cross word boundaries and require a wide context to be handled. On this basis, Aw et al. (2006) proposed a statistical machine translation model working at the phrase-level, by splitting sentences into their k most probable phrases. While this approach achieves really good results, Kobus et al. (2008b) make the assertion that a phrase-based translation can hardly capture the lexical creativity observed in SMS messages. Moreover, the translation framework, which can handle many-to-many correspondences between sources and targets, exceeds the needs of SMS normalization, where the normalization task is almost deterministic.

Based on this analysis, Kobus et al. (2008b) proposed to handle SMS normalization through an automatic speech recognition (ASR) metaphor. The starting point of this approach is the observation that SMS messages present a lot of phonetic plays that sometimes make the SMS word (*sré*, *mwa*) closer to its phonetic representation ([sʁe], [mwa]) than to its standard written form (*serai*, "will be", *moi*, "me"). Typically, an ASR system tries to discover the best word sequence within a lattice of weighted phonetic sequences. Applied to the SMS normalization task, the ASR metaphor consists in first converting the SMS message into a phone lattice, before turning it into a word-based lattice using a phoneme-to-grapheme dictionary. A language model is then applied on the word lattice, and the most probable word sequence is finally chosen by applying a best-path algorithm on the lattice. One of the advantages of the grapheme-to-phoneme conversion is its intrinsic ability to handle word boundaries. However, this step also presents an important drawback, raised by the authors themselves: it prevents next normalization steps from knowing what graphemes were in the initial sequence.

Our approach, which is detailed in Sections 3 and 4, shares similarities with both the spell checking approach and the machine translation principles, trying to combine the advantages of these methods, while leaving aside their drawbacks: like in spell checking systems, we detect unambiguous units of text as soon as possible and try to rely on word boundaries when they seem *reliable enough*; but like in the machine translation task, our method intrinsically handles word boundaries in the normalization process if needed.

3 Overview of the system

3.1 Tools in use

In our system, all lexicons, language models and sets of rules are compiled into finite-state machines (FSMs) and combined with the input text by *composition* ($\circ$). The reader who is not familiar with FSMs and their fundamental theoretical properties, like composition, is urged to consult the state-of-the-art literature (Roche and Schabes, 1997; Mohri and Riley, 1997; Mohri et al., 2000; Mohri et al., 2001).

We used our own finite-state tools: a finite-state machine library and its associated compiler (Beaufort, 2008). In conformance with the format of the library, the compiler builds finite-state machines from weighted rewrite rules, weighted regular expressions and n-gram models.

3.2 Aims

We formulated four constraints before fixing the system's architecture. First, special tokens, like URLs, phones or currencies, should be identified as soon as possible, to keep them out of the normalization process.

Second, word boundaries should be taken into account, as far as they seem *reliable enough*. The idea, here, is to base the decision on a learning able to catch frequent SMS sequences to include in a dedicated In-Vocabulary (IV) lexicon.

Third, any other SMS sequence should be considered as Out-Of-Vocabulary (OOV), on which in-depth rewritings may be applied.

Fourth, the basic rules of typography and typesettings should be applied on the normalized version of the SMS message.

3.3 Architecture

The architecture depicted in Figure 1 directly relies on these considerations. In short, an SMS message first goes through three SMS modules, which normalize its noisy parts. Then, two standard NLP modules produce a morphosyntactic analysis of the normalized text. A last module, finally, takes advantage of this linguistic analysis either to print a text that follows the basic rules of typography, or to synthesize the corresponding speech signal.

Because this paper focuses on the normalization task, the rest of this section only presents the SMS modules and the "smart print" output. The morphosyntactic analysis, made of state-of-the-art algorithms, is described in (Beaufort, 2008), and the text-to-speech synthesis system we use is presented in (Colotte and Beaufort, 2005).

3.3.1 SMS modules

SMS preprocessing. This module relies on a set of manually-tuned rewrite rules. It identifies paragraphs and sentences, but also some

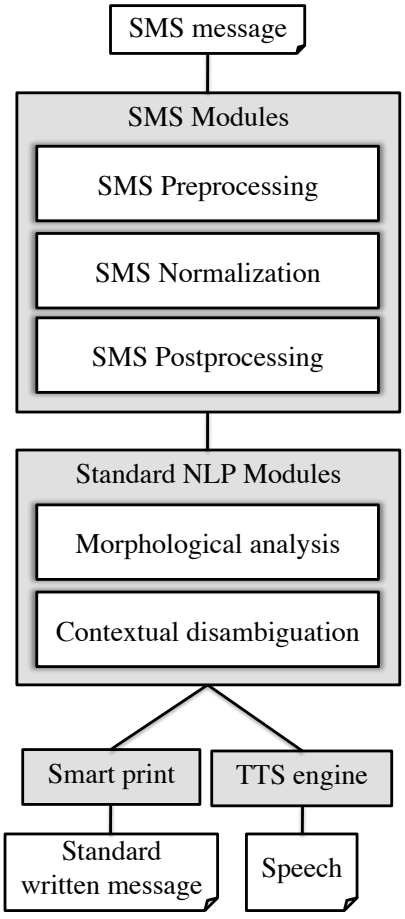

Figure 1: Architecture of the system

unambiguous tokens: URLs, phone numbers, dates, times, currencies, units of measurement and, last but not least in the context of SMS, smileys[2]. These tokens are kept out of the normalization process, while any other sequence of characters is considered – and labelled – as noisy.

SMS normalization. This module only uses models learned from a training corpus (cf. Section 4). It involves three steps. First, an SMS-dedicated lexicon look-up, which differentiates between known and unknown parts of a noisy token. Second, a rewrite process, which creates a lattice of weighted solutions. The rewrite model differs depending on whether the part to rewrite is known or not. Third, a combination of the lattice of solutions with a language model, and the choice of the best sequence of lexical units. At this stage, the normalization as such is completed.

SMS postprocessing. Like the preprocessor, the postprocessor relies on a set of manually-tuned rewrite rules. The module is only applied on the normalized version of the noisy tokens, with the intention to identify any non-alphabetic sequence and to isolate it in a distinct token. At this stage, for instance, a point becomes a 'strong punctuation'. Apart from the list of tokens already managed by the preprocessor, the postprocessor handles as well numeric and alphanumeric strings, fields of data (like bank account numbers), punctuations and symbols.

3.3.2 Smart print

The smart print module, based on manually-tuned rules, checks either the kind of token (chosen by the SMS pre-/post-processing modules) or the grammatical category (chosen by the morphosyntactic analysis) to make the right typography choices, such as the insertion of a space after certain tokens (URLs, phone numbers), the insertion of two spaces after a strong punctuation (point, question mark, exclamation mark), the insertion of two carriage returns at the end of a paragraph, or the upper case of the initial letter at the beginning of the sentence.

[2]Our list contains about 680 smileys.

4 The normalization models

4.1 Overview of the normalization algorithm

Our approach is an approximation of the noisy channel metaphor (cf. Section 2). It differs from this general framework, because we adapt the model of the channel's noise depending on whether the noisy token (our sequence of observations) is In-Vocabulary or Out-Of-Vocabulary:

$$P(O|W) = \begin{cases} P_{IV}(O|W) & \text{if } O \in IV \\ P_{OOV}(O|W) & \text{else} \end{cases} \quad (2)$$

Indeed, our algorithm is based on the assumption that applying different normalization models to IV and OOV words should both improve the results and reduce the processing time.

For this purpose, the first step of the algorithm consists in composing a noisy token T with an FST Sp whose task is to differentiate between sequences of IV words and sequences of OOV words, by labelling them with a special IV or OOV marker. The token is then split in n segments sg_i according to these markers:

$$\{sg\} = \text{Split}(T \circ Sp) \quad (3)$$

In a second step, each segment is composed with a rewrite model according to its kind: the IV rewrite model R_{IV} for sequences of IV words, and the OOV rewrite model R_{OOV} for sequences of OOV words:

$$sg'_i = \begin{cases} sg_i \circ R_{IV} & \text{if } sg_i \in IV \\ sg_i \circ R_{OOV} & \text{else} \end{cases} \quad (4)$$

All rewritten segments are then concatenated together in order to get back the complete token:

$$T = \odot_{i=1}^{n}(sg'_i) \quad (5)$$

where $\odot$ is the concatenation operator.

The third and last normalization step is applied on a complete sentence S. All tokens T_j of S are concatenated together and composed with the lexical language model LM. The result of this composition is a word lattice, of which we take the most probable word sequence S' by applying a best-path algorithm:

$$S' = \text{BestPath}(\ (\odot_{j=1}^{m} T_j) \circ LM\ ) \quad (6)$$

where m is the number of tokens of S. In S', each noisy token T_j of S is mapped onto its most probable normalization.

4.2 The corpus alignment

Our normalization models were trained on a French SMS corpus of 30,000 messages, gathered in Belgium, semi-automatically anonymized and manually normalized by the Catholic University of Louvain (Fairon and Paumier, 2006). Together, the SMS corpus and its transcription constitute *parallel corpora* aligned at the message-level.

However, in order to learn pieces of knowledge from these corpora, we needed a string alignment at the *character-level*.

One way of implementing this string alignment is to compute the edit-distance of two strings, which measures the minimum number of operations (substitutions, insertions, deletions) required to transform one string into the other (Levenshtein, 1966). Using this algorithm, in which each operation gets a cost of 1, two strings may be aligned in different ways with the same global cost. This is the case, for instance, for the SMS form *kozer* ([koze]) and its standard transcription *causé* ("talked"), as illustrated by Figure 2. However, from a linguistic standpoint, alignment (1) is preferable, because corresponding *graphemes* are aligned on their *first character*.

In order to automatically choose this preferred alignment, we had to distinguish the three edit-operations, according to the characters to be aligned. For that purpose, probabilities were required. Computing probabilities for each operation according to the characters to be aligned was performed through an iterative algorithm described in (Cougnon and Beaufort, 2009). In short, this algorithm gradually learns the best way of aligning strings. On our parallel corpora, it converged after 7 iterations and provided us with a result from which the learning could start.

(1)	ko_ser causé_		(2)	k_oser causé_
(3)	ko_ser caus_é		(4)	k_oser caus_é

Figure 2: Different equidistant alignments, using a standard edit-cost of 1. Underscores ('_') mean *insertion* in the upper string, and *deletion* in the lower string.

4.3 The split model Sp

In natural language processing, a word is commonly defined as "a sequence of alphabetic characters between separators", and an IV word is simply a word that belongs to the lexicon in use.

In SMS messages however, separators are surely indicative, but not reliable. For this reason, our definition of the *word* is far from the previous one, and originates from the string alignment. After examining our parallel corpora aligned at the character-level, we decided to consider as a word "the longest sequence of characters parsed without meeting the same separator on both sides of the alignment". For instance, the following alignment

```
J esper_ k___tu va_
J'espère que tu vas
```
(*I hope that you will*)

is split as follows according to our definition:

J esper_ J'espère		k___tu que tu		va_ vas

since the separator in "`J esper`" is different from its transcription, and "`ktu`" does not contain any separator. Thus, this SMS sequence corresponds to 3 SMS words: [*J esper*], [*ktu*] and [*va*].

A first parsing of our parallel corpora provided us with a list of SMS sequences corresponding to our IV lexicon. The FST Sp is built on this basis:

$$Sp = (\ S^*\ (I|O)\ \ (\ S^+(I|O)\ )^*\ S^*\ ) \circ G \quad (7)$$

where:

- I is an FST corresponding to the lexicon, in which IV words are mapped onto the IV marker.
- O is the complement of I[3]. In this OOV lexicon, OOV sequences are mapped onto the OOV marker.
- S is an FST corresponding to the list of separators (any non-alphabetic and non-numeric character), mapped onto a SEP marker.

[3]Actually, the true complement of I accepts sequences with separators, while these sequences were removed from O.

- G is an FST able to detect consecutive sequences of IV (resp. OOV) words, and to group them under a unique IV (resp. OOV) marker. By gathering sequences of IVs and OOVs, SEP markers disappear from Sp.

Figure 3 illustrates the composition of Sp with the SMS sequence *J esper kcv b1* (*J'espère que ça va bien*, "I hope you are well"). For the example, we make the assumption that *kcv* was never seen during the training.

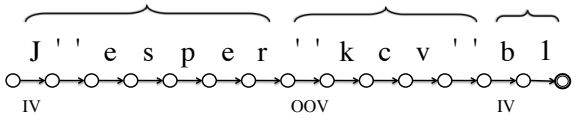

Figure 3: Application of the split model Sp. The OOV sequence starts and ends with separators.

4.4 The IV rewrite model R_{IV}

This model is built during a second parsing of our parallel corpora. In short, the parsing simply gathers all possible normalizations for each SMS sequence put, by the first parsing, in the IV lexicon. Contrary to the first parsing, this second one processes the corpus *without taking separators into account*, in order to make sure that *all* possible normalizations are collected.

Each normalization $\bar{w}$ for a given SMS sequence w is weighted as follows:

$$p(\bar{w}|w) = \frac{\text{Occ}(\bar{w}, w)}{\text{Occ}(w)} \tag{8}$$

where $\text{Occ}(x)$ is the number of occurrences of x in the corpus. The FST R_{IV} is then built as follows:

$$R_{IV} = \ {S_{IV}}^* \ IV_R \ \ (\ {S_{IV}}^+ \ IV_R \ )^* \ {S_{IV}}^* \tag{9}$$

where:

- IV_R is a weighted *lexicon* compiled into an FST, in which each IV sequence is mapped onto the list of its possible normalizations.
- S_{IV} is a weighted *lexicon* of separators, in which each separator is mapped onto the list of its possible normalizations. The deletion is often one of the possible normalization of a separator. Otherwise, the deletion is added and is weighted by the following smoothed probability:

$$p(\texttt{DEL}|w) = \frac{0.1}{\text{Occ}(w) + 0.1} \tag{10}$$

4.5 The OOV rewrite model R_{OOV}

In contrast to the other models, this one is not a regular expression made of weighted lexicons. It corresponds to a set of *weighted rewrite rules* (Chomsky and Halle, 1968; Johnson, 1972; Mohri and Sproat, 1996) learned from the alignment. Developed in the framework of generative phonology, rules take the form

$$\phi \rightarrow \psi : \lambda \ \_ \ \rho \ / \ w \tag{11}$$

which means that the replacement $\phi \rightarrow \psi$ is only performed when ϕ is surrounded by λ on the left and ρ on the right, and gets the weight w. However, in our case, rules take the simpler form

$$\phi \rightarrow \psi \ / \ w \tag{12}$$

which means that the replacement $\phi \rightarrow \psi$ is always performed, whatever the context.

Inputs of our rules (ϕ) are sequences of 1 to 5 characters taken from the SMS side of the alignment, while outputs (ψ) are their corresponding normalizations. Our rules are sorted in the reverse order of the length of their inputs: rules with longer inputs come first in the list.

Long-to-short rule ordering reduces the number of proposed normalizations for a given SMS sequence for two reasons:

1. the firing of a rule with a longer input blocks the firing of any shorter sub-rule. This is due to a constraint expressed on lists of rewrite rules: a given rule may be applied only if no more specific and relevant rule has been met higher in the list;
2. a rule with a longer input usually has fewer alternative normalizations than a rule with a shorter input does, because the longer SMS sequence likely occurred paired with fewer alternative normalizations in the training corpus than did the shorter SMS sequence.

Among the wide set of possible sequences of 2 to 5 characters gathered from the corpus, we only kept in our list of rules the sequences that allowed at least one normalization *solely made of IV words*. It is important to notice that here, we refer to the standard notion of *IV word*: while gathering the candidate sequences from the corpus, we systematically checked each word of the normalizations against a lexicon of French

standard written forms. The lexicon we used contains about 430,000 inflected forms and is derived from Morlex[4], a French lexical database.

Figure 4 illustrates these principles by focusing on 3 input sequences: *aussi*, *au* and *a*. As shown by the Figure, all rules of a set dedicated to the same input sequence (for instance, *aussi*) are optional (?→), except the last one, which is obligatory (→). In our finite-state compiler, this convention allows the application of all concurrent normalizations on the same input sequence, as depicted in Figure 5.

In our real list of OOV rules, the input sequence *a* corresponds to 231 normalizations, while *au* accepts 43 normalizations and *aussi*, only 3. This highlights the interest, in terms of efficiency, of the long-to-short rule ordering.

4.6 The language model

Our language model is an n-gram of lexical forms, smoothed by linear interpolation (Chen and Goodman, 1998), estimated on the normalized part of our training corpus and compiled into a weighted FST LM_w.

At this point, this FST cannot be combined with our other models, because it works on *lexical units* and not on *characters*. This problem is solved by composing LM_w with another FST L, which represents a lexicon mapping each input word, considered as a string of characters, onto the same output words, but considered here as a lexical unit. Lexical units are then permanently removed from the language model by keeping only the first projection (the input side) of the composition:

$$LM = \text{FirstProjection}(\ L \circ LM_w\ ) \qquad (13)$$

In this model, special characters, like punctuations or symbols, are represented by their categories (light, medium and strong punctuations, question mark, symbol, etc.), while special tokens, like URLs or phone numbers, are handled as token values (URL, phone, etc.) instead of as sequences of characters. This reduces the complexity of the model.

As we explained earlier, tokens of a same sentence S are concatenated together at the end of the second normalization step. During this concatenation process, sequences corresponding to special tokens are automatically replaced by their token values. Special characters, however,

Figure 4: Samples from the list of OOV rules. Rules' weights are negative logarithms of probabilities: smaller weights are thus better. Asterisks indicate normalizations solely made of French IV words.

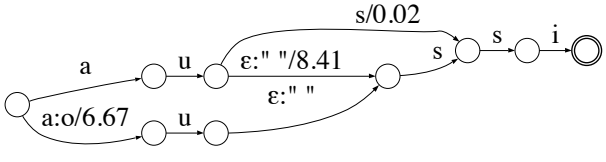

Figure 5: Application of the OOV rules on the input sequence *aussi*. All normalizations corresponding to this sequence were allowed, while rules corresponding to shorter input sequences were ignored.

are still present in S. For this reason, S is first composed with an FST $Reduce$, which maps each special character onto its corresponding category:

$$S \circ Reduce \circ LM \quad (14)$$

5 Evaluation

The performance and the efficiency of our system were evaluated on a MacBook Pro with a 2.4 GHz Intel Core 2 Duo CPU, 4 GB 667 MHz DDR2 SDRAM, running Mac OS X version 10.5.8.

The evaluation was performed on the corpus of 30,000 French SMS presented in Section 4.2, by ten-fold cross-validation (Kohavi, 1995). The principle of this method of evaluation is to split the initial corpus into 10 subsets of equal size. The system is then trained 10 times, each time leaving out one of the subsets from the training corpus, but using only this omitted subset as test corpus.

The language model of the evaluation is a 3-gram. We did not try a 4-gram. This choice was motivated by the experiments of Kobus et al. (2008a), who showed on a French corpus comparable to ours that, if using a larger language model is always rewarded, the improvement quickly decreases with every higher level and is already quite small between 2-gram and 3-gram.

Table 1 presents the results in terms of efficiency. The system seems efficient, while we cannot compare it with other methods, which did not provide us with this information.

Table 2, part 1, presents the performance of our approach (*Hybrid*) and compares it to a trivial copy-paste (*Copy*). The system was evaluated in terms of BLEU score (Papineni et al., 2001), Word Error Rate (WER) and Sentence Error Rate (SER). Concerning WER, the table presents the distribution between substitutions (Sub), deletions (Del) and insertions (Ins). The copy-paste results just inform about the real deviation of our corpus from the traditional spelling conventions, and highlight the fact that our system is still at pains to significantly reduce the SER, while results in terms of WER and BLEU score are quite encouraging.

Table 2, part 2, provides the results of the state-of-the-art approaches. The only results truly comparable to ours are those of Guimier de Neef et al. (2007), who evaluated their approach on the same corpus as ours[5]; clearly, our method outperforms theirs. Our results also seem a bit better than those of Kobus et al. (2008a), although the comparison with this system, also evaluated in French, is less easy: they combined the French corpus we used with another one and performed a single validation, using a bigger training corpus (36.704 messages) for a test corpus quite similar to one of our subsets (2.998 SMS). Other systems were evaluated in English, and results are more difficult to compare; at least, our results seem in line with them.

	mean	**dev.**
bps	1836.57	159.63
ms/SMS (140b)	76.23	22.34

Table 1: Efficiency of the system.

The analysis of the normalizations produced by our system pointed out that, most often, errors are contextual and concern the gender (*quel(le)*, "what"), the number (*bisou(s)*, "kiss"), the person (*[tu t']inquiète(s)*, "you are worried") or the tense (*arrivé/arriver*, "arrived"/"to arrive"). That contextual errors are frequent is not surprising. In French, as mentioned by Kobus et al. (2008b), n-gram models are unable to catch this information, as it is generally out of their scope.

On the other hand, this analysis confirmed our initial assumptions. First, special tokens (URLs, phones, etc.) are not modified. Second, agglutinated words are generally split (*Pensa ms* → *Pense à mes*, "think to my"), while misapplied separators tend to be deleted (*G t* → *J'étais*, "I was"). Of course, we also found some errors at word boundaries (*[il] l'arrange* → *[il] la range*, "[he] arranges" → "[he] pits in order"), but they were fairly rare.

6 Conclusion and perspectives

In this paper, we presented an SMS normalization framework based on finite-state machines and developed in the context of an SMS-to-speech synthesis system. With the intention to avoid wrong modifications of special tokens and to handle word boundaries as easily as possible, we designed a method that shares similarities with both spell checking and machine translation. Our

[5]They performed an evaluation without ten-fold cross-validation, because their rule-based system did not need any training.

Table 2: Performance of the system. (*) Kobus 2008-1 corresponds to the ASR-like system, while Kobus 2008-2 is a combination of this system with a series of open-source machine translation toolkits. (**) Scores obtained on noisy data only, out of the sentence's context.

normalization algorithm is original in two ways. First, it is entirely based on models learned from a training corpus. Second, the rewrite model applied to a noisy sequence differs depending on whether this sequence is known or not.

Evaluated by ten-fold cross-validation, the system seems efficient, and the performance in terms of BLEU score and WER are quite encouraging. However, the SER remains too high, which emphasizes the fact that the system needs several improvements.

First of all, the model should take phonetic similarities into account, because SMS messages contain a lot of phonetic plays. The phonetic model, for instance, should know that *o*, *au*, *eau*, ..., *aux* can all be pronounced [o], while *è*, *ais*, *ait*, ..., *aient* are often pronounced [ɛ]. However, unlike Kobus et al. (2008a), we feel that this model must avoid the normalization step in which the graphemic sequence is converted into phonemes, because this conversion prevents the next steps from knowing which graphemes were in the initial sequence. Instead, we propose to *learn* phonetic similarities from a dictionary of words with phonemic transcriptions, and to build *graphemes-to-graphemes* rules. These rules could then be automatically weighted, by learning their frequencies from our aligned corpora. Furthermore, this model should be able to allow for timbre variation, like [e]–[ɛ], in order to allow similarities between graphemes frequently confused in French, like *ai* ([e]) and *ais*/*ait*/*aient* ([ɛ]). Last but not least, the graphemes-to-graphemes rules should be contextualized, in order to reduce the complexity of the model.

It would also be interesting to test the impact of another lexical language model, learned on non-SMS sentences. Indeed, the lexical model must be learned from sequences of *standard written forms*, an obvious prerequisite that involves a major drawback when the corpus is made of SMS sentences: the corpus must first be *transcribed*, an expensive process that reduces the amount of data on which the model will be trained. For this reason, we propose to learn a lexical model from non-SMS sentences. However, the corpus of external sentences should still share two important features with the SMS language: it should mimic the oral language and be as spontaneous as possible. With this in mind, our intention is to gather sentences from Internet forums. But not just any forum, because often forums share another feature with the SMS language: their language is noisy. Thus, the idea is to choose a forum asking its members to pay attention to spelling mistakes and grammatical errors, and to avoid the use of the SMS language.

Letter-Phoneme Alignment: An Exploration

Sittichai Jiampojamarn and **Grzegorz Kondrak**
Department of Computing Science
University of Alberta
Edmonton, AB, T6G 2E8, Canada
{sj,kondrak}@cs.ualberta.ca

Abstract

Letter-phoneme alignment is usually generated by a straightforward application of the EM algorithm. We explore several alternative alignment methods that employ phonetics, integer programming, and sets of constraints, and propose a novel approach of refining the EM alignment by aggregation of best alignments. We perform both intrinsic and extrinsic evaluation of the assortment of methods. We show that our proposed EM-Aggregation algorithm leads to the improvement of the state of the art in letter-to-phoneme conversion on several different data sets.

1 Introduction

Letter-to-phoneme (L2P) conversion (also called grapheme-to-phoneme conversion) is the task of predicting the pronunciation of a word given its orthographic form by converting a sequence of letters into a sequence of phonemes. The L2P task plays a crucial role in speech synthesis systems (Schroeter et al., 2002), and is an important part of other applications, including spelling correction (Toutanova and Moore, 2001) and speech-to-speech machine translation (Engelbrecht and Schultz, 2005). Many data-driven techniques have been proposed for letter-to-phoneme conversion systems, including neural networks (Sejnowski and Rosenberg, 1987), decision trees (Black et al., 1998), pronunciation by analogy (Marchand and Damper, 2000), Hidden Markov Models (Taylor, 2005), and constraint satisfaction (Bosch and Canisius, 2006).

Letter-phoneme alignment is an important step in the L2P task. The training data usually consists of pairs of letter and phoneme sequences, which are not aligned. Since there is no explicit information indicating the relationships between individual letter and phonemes, these must be inferred by a letter-phoneme alignment algorithm before a prediction model can be trained. The quality of the alignment affects the accuracy of L2P conversion. Letter-phoneme alignment is closely related to transliteration alignment (Pervouchine et al., 2009), which involves graphemes representing different writing scripts. Letter-phoneme alignment may also be considered as a task in itself; for example, in the alignment of speech transcription with text in spoken corpora.

Most previous L2P approaches induce the alignment between letters and phonemes with the expectation maximization (EM) algorithm. In this paper, we propose a number of alternative alignment methods, and compare them to the EM-based algorithms using both intrinsic and extrinsic evaluations. The intrinsic evaluation is conducted by comparing the generated alignments to a manually-constructed gold standard. The extrinsic evaluation uses two different generation techniques to perform letter-to-phoneme conversion on several different data sets. We discuss the advantages and disadvantages of various methods, and show that better alignments tend to improve the accuracy of the L2P systems regardless of the actual technique. In particular, one of our proposed methods advances the state of the art in L2P conversion. We also examine the relationship between alignment entropy and alignment quality.

This paper is organized as follows. In Section 2, we enumerate the assumptions that the alignment methods commonly adopt. In Section 3, we review previous work that employs the EM approach. In Sections 4, 5 and 6, we describe alternative approaches based on phonetics, manually-constructed constraints, and Integer Programming, respectively. In Section 7, we propose an algorithm to refine the alignments produced by EM. Sections 8 and 9 are devoted to the intrinsic and extrinsic evaluation of various approaches. Section 10 concludes the paper.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 780–788,
Uppsala, Sweden, 11-16 July 2010.

2 Background

We define the letter-phoneme alignment task as the problem of inducing *links* between units that are related by pronunciation. Each link is an instance of a specific *mapping* between letters and phonemes. The leftmost example alignment of the word *accuse* [@kjuz] below includes 1-1, 1-0, 1-2, and 2-1 links. The letter e is considered to be linked to special *null phoneme*.

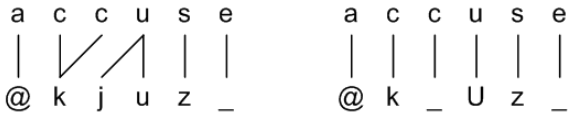

Figure 1: Two alignments of *accuse*.

The following constraints on links are assumed by some or all alignment models:

- the *monotonicity* constraint prevents links from crossing each other;
- the *representation* constraint requires each phoneme to be linked to at least one letter, thus precluding nulls on the letter side;
- the *one-to-one* constraint stipulates that each letter and phoneme may participate in at most one link.

These constraints increasingly reduce the search space and facilitate the training process for the L2P generation models.

We refer to an alignment model that assumes all three constraints as a pure one-to-one (1-1) model. By allowing only 1-1 and 1-0 links, the alignment task is thus greatly simplified. In the simplest case, when the number of letters is equal to the number of phonemes, there is only one possible alignment that satisfies all three constraints. When there are more letters than phonemes, the search is reduced to identifying letters that must be linked to null phonemes (the process referred to as "epsilon scattering" by Black et al. (1998)). In some words, however, one letter clearly represents more than one phoneme; for example, u in Figure 1. Moreover, a pure 1-1 approach cannot handle cases where the number of phonemes exceeds the number of letters. A typical solution to overcome this problems is to introduce so-called *double phonemes* by merging adjacent phonemes that could be represented as a single letter. For example, a double phoneme U would replace a sequence of the phonemes j and u in Figure 1. This solution requires a manual extension of the set of phonemes present in the data. By convention, we regard the models that include a restricted set of 1-2 mappings as 1-1 models.

Advanced L2P approaches, including the joint n-gram models (Bisani and Ney, 2008) and the joint discriminative approach (Jiampojamarn et al., 2007) eliminate the one-to-one constraint entirely, allowing for linking of multiple letters to multiple phonemes. We refer to such models as many-to-many (M-M) models.

3 EM Alignment

Early EM-based alignment methods (Daelemans and Bosch, 1997; Black et al., 1998; Damper et al., 2005) were generally pure 1-1 models. The 1-1 alignment problem can be formulated as a dynamic programming problem to find the maximum score of alignment, given a probability table of aligning letter and phoneme as a mapping function. The dynamic programming recursion to find the most likely alignment is the following:

$$C_{i,j} = \max \begin{cases} C_{i-1,j-1} + \delta(x_i, y_j) \\ C_{i-1,j} + \delta(x_i, \epsilon) \\ C_{i,j-1} + \delta(\epsilon, y_j) \end{cases} \quad (1)$$

where $\delta(x_i, \epsilon)$ denotes a probability that a letter x_i aligns with a null phoneme and $\delta(\epsilon, y_j)$ denotes a probability that a null letter aligns with a phoneme y_j. In practice, the latter probability is often set to zero in order to enforce the representation constraint, which facilitates the subsequent phoneme generation process. The probability table $\delta(x_i, y_j)$ can be initialized by a uniform distribution and is iteratively re-computed (M-step) from the most likely alignments found at each iteration over the data set (E-step). The final alignments are constructed after the probability table converges.

M2M-aligner (Jiampojamarn et al., 2007) is a many-to-many (M-M) alignment algorithm based on EM that allows for mapping of multiple letters to multiple phonemes. Algorithm 1 describes the E-step of the many-to-many alignment algorithm. γ represents partial counts collected over all possible mappings between substrings of letters and phonemes. The maximum lengths of letter and phoneme substrings are controlled by the

Algorithm 1: Many-to-many alignment

Input: $x, y, maxX, maxY, \gamma$
Output: γ

1 $\alpha :=$ FORWARD-M2M $(x, y, maxX, maxY)$
2 $\beta :=$ BACKWARD-M2M $(x, y, maxX, maxY)$
3 $T = |x| + 1$, $V = |y| + 1$
4 **if** $(\alpha_{T,V} = 0)$ **then**
5 return
6 **for** $t = 1..T$, $v = 1..V$ **do**
7 **for** $i = 1..maxX$ **st** $t - i \geq 0$ **do**
8 $\gamma(x_{t-i+1}^{t}, \epsilon) \mathrel{+}= \frac{\alpha_{t-i,v}\delta(x_{t-i+1}^{t}, \epsilon)\beta_{t,v}}{\alpha_{T,V}}$
9 **for** $i = 1..maxX$ **st** $t - i \geq 0$ **do**
10 **for** $j = 1..maxY$ **st** $v - j \geq 0$ **do**
11 $\gamma(x_{t-i+1}^{t}, y_{v-j+1}^{v}) \mathrel{+}= \frac{\alpha_{t-i,v-j}\delta(x_{t-i+1}^{t}, y_{v-j+1}^{v})\beta_{t,v}}{\alpha_{T,V}}$

$maxX$ and $maxY$ parameters. The forward probability α is estimated by summing the probabilities from left to right, while the backward probability β is estimated in the opposite direction. The FORWARD-M2M procedure is similar to line 3 to 10 of Algorithm 1, except that it uses Equation 2 in line 8 and 3 in line 11. The BACKWARD-M2M procedure is analogous to FORWARD-M2M.

$$\alpha_{t,v} \mathrel{+}= \delta(x_{t-i+1}^{t}, \epsilon)\alpha_{t-i,v} \quad (2)$$

$$\alpha_{t,v} \mathrel{+}= \delta(x_{t-i+1}^{t}, y_{v-j+1}^{v})\alpha_{t-i,v-j} \quad (3)$$

In M-step, the partial counts are normalized by using a conditional distribution to create the mapping probability table δ. The final many-to-many alignments are created by finding the most likely paths using the Viterbi algorithm based on the learned mapping probability table. The source code of M2M-aligner is publicly available.[1]

Although the many-to-many approach tends to create relatively large models, it generates more intuitive alignments and leads to improvement in the L2P accuracy (Jiampojamarn et al., 2007). However, since many links involve multiple letters, it also introduces additional complexity in the phoneme prediction phase. One possible solution is to apply a letter segmentation algorithm at test time to cluster letters according to the alignments in the training data. This is problematic because of error propagation inherent in such a process. A better solution is to combine segmentation and decoding using a phrasal decoder (e.g. (Zens and Ney, 2004)).

[1] `http://code.google.com/p/m2m-aligner/`

4 Phonetic alignment

The EM-based approaches to L2P alignment treat both letters and phonemes as abstract symbols. A completely different approach to L2P alignment is based on the phonetic similarity between phonemes. The key idea of the approach is to represent each letter by a phoneme that is likely to be represented by the letter. The actual phonemes on the phoneme side and the phonemes representing letters on the letter side can then be aligned on the basis of phonetic similarity between phonemes. The main advantage of the phonetic alignment is that it requires no training data, and so can be readily be applied to languages for which no pronunciation lexicons are available.

The task of identifying the phoneme that is most likely to be represented by a given letter may seem complex and highly language-dependent. For example, the letter a can represent no less than 12 different English vowels. In practice, however, absolute precision is not necessary. Intuitively, the letters that had been chosen (often centuries ago) to represent phonemes in any orthographic system tend to be close to the prototype phoneme in the original script. For example, the letter 'o' represented a mid-high rounded vowel in Classical Latin and is still generally used to represent similar vowels.

The following simple heuristic works well for a number of languages: treat every letter as if it were a symbol in the International Phonetic Alphabet (IPA). The set of symbols employed by the IPA includes the 26 letters of the Latin alphabet, which tend to correspond to the phonemes that they represent in the Latin script. For example, the IPA symbol [m] denotes a voiced bilabial nasal consonant, which is the phoneme represented by the letter m in most languages that utilize Latin script.

ALINE (Kondrak, 2000) performs phonetic alignment of two strings of phonemes. It combines a dynamic programming alignment algorithm with an appropriate scoring scheme for computing phonetic similarity on the basis of multivalued features. The example below shows the alignment of the word *sheath* to its phonetic transcription [ʃiθ]. ALINE correctly links the most similar pairs of phonemes (s:ʃ, e:i, t:θ).[2]

[2] ALINE can also be applied to non-Latin scripts by replacing every grapheme with the IPA symbol that is phonetically closest to it.

s	h	e	a	t	h
|	|	|	|	|	|
ʃ	-	i	-	θ	-

Since ALINE is designed to align phonemes with phonemes, it does not incorporate the representation constraint. In order to avoid the problem of unaligned phonemes, we apply a post-processing algorithm, which also handles 1-2 links. The algorithm first attempts to remove 0-1 links by merging them with the adjacent 1-0 links. If this is not possible, the algorithm scans a list of valid 1-2 mappings, attempting to replace a pair of 0-1 and 1-1 links with a single 1-2 link. If this also fails, the entire entry is removed from the training set. Such entries often represent unusual foreign-origin words or outright annotation errors. The number of unaligned entries rarely exceeds 1% of the data.

The post-processing algorithm produces an alignment that contains 1-0, 1-1, and 1-2 links. The list of valid 1-2 mappings must be prepared manually. The length of such lists ranges from 1 for Spanish and German (x:[ks]) to 17 for English. This approach is more robust than the double-phoneme technique because the two phonemes are clustered only if they can be linked to the corresponding letter.

5 Constraint-based alignment

One of the advantages of the phonetic alignment is its ability to rule out phonetically implausible letter-phoneme links, such as o:p. We are interested in establishing whether a set of allowable letter-phoneme mappings could be derived directly from the data without relying on phonetic features.

Black et al. (1998) report that constructing lists of possible phonemes for each letter leads to L2P improvement. They produce the lists in a "semi-automatic", interactive manner. The lists constrain the alignments performed by the EM algorithm and lead to better-quality alignments.

We implement a similar interactive program that incrementally expands the lists of possible phonemes for each letter by refining alignments constrained by those lists. However, instead of employing the EM algorithm, we induce alignments using the standard edit distance algorithm with substitution and deletion assigned the same cost. In cases when there are multiple alternative alignments that have the same edit distance, we randomly choose one of them. Furthermore, we extend this idea also to many-to-many alignments. In addition to lists of phonemes for each letter (1-1 mappings), we also construct lists of many-to-many mappings, such as ee:i, sch:ʃ, and ew:ju. In total, the English set contains 377 mappings, of which more than half are of the 2-1 type.

6 IP Alignment

The process of manually inducing allowable letter-phoneme mappings is time-consuming and involves a great deal of language-specific knowledge. The Integer Programming (IP) framework offers a way to induce similar mappings without a human expert in the loop. The IP formulation aims at identifying the smallest set of letter-phoneme mappings that is sufficient to align all instances in the data set.

Our IP formulation employs the three constraints enumerated in Section 2, except that the one-to-one constraint is relaxed in order to identify a small set of 1-2 mappings. We specify two types of binary variables that correspond to local alignment links and global letter-phoneme mappings, respectively. We distinguish three types of local variables, X, Y, and Z, which correspond to 1-0, 1-1, and 1-2 links, respectively. In order to minimize the number of global mappings, we set the following objective that includes variables corresponding to 1-1 and 1-2 mappings:

$$\text{minimize} : \sum_{l,p} G(l,p) + \sum_{l,p_1,p_2} G(l,p_1p_2) \quad (4)$$

We adopt a simplifying assumption that any letter can be linked to a null phoneme, so no global variables corresponding to 1-0 mappings are necessary.

In the lexicon entry k, let l_{ik} be the letter at position i, and p_{jk} the phoneme at position j. In order to prevent the alignments from utilizing letter-phoneme mappings which are not on the global list, we impose the following constraints:

$$\forall_{i,j,k} Y(i,j,k) \leq G(l_{ik}, p_{jk}) \quad (5)$$

$$\forall_{i,j,k} Z(i,j,k) \leq G(l_{ik}, p_{jk}p_{(j+1)k}) \quad (6)$$

For example, the local variable $Y(i,j,k)$ is set if l_{ik} is linked to p_{jk}. A corresponding global variable $G(l_{ik}, p_{jk})$ is set if the list of allowed letter-phoneme mappings includes the link (l_{ik}, p_{jk}). Activating the local variable implies activating the corresponding global variable, but not vice versa.

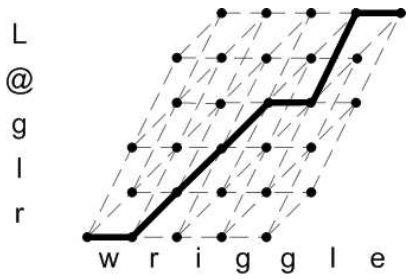

Figure 2: A network of possible alignment links.

We create a network of possible alignment links for each lexicon entry k, and assign a binary variable to each link in the network. Figure 2 shows an alignment network for the lexicon entry k: *wriggle* [r I g @ L]. There are three 1-0 links (level), three 1-1 links (diagonal), and one 1-2 link (steep). The local variables that receive the value of 1 are the following: X(1,0,k), Y(2,1,k), Y(3,2,k), Y(4,3,k), X(5,3,k), Z(6,5,k), and X(7,5,k). The corresponding global variables are: G(r,r), G(i,I), G(g,g), and G(l,@L).

We create constraints to ensure that the link variables receiving a value of 1 form a left-to-right path through the alignment network, and that all other link variables receive a value of 0. We accomplish this by requiring the sum of the links entering each node to equal the sum of the links leaving each node.

$$\forall_{i,j,k} \quad X(i,j,k) + Y(i,j,k) + Z(i,j,k) = X(i+1,j,k) + Y(i+1,j+1,k) + Z(i+1,j+2,k)$$

We found that inducing the IP model with the full set of variables gives too much freedom to the IP program and leads to inferior results. Instead, we first run the full set of variables on a subset of the training data which includes only the lexicon entries in which the number of phonemes exceeds the number of letters. This generates a small set of plausible 1-2 mappings. In the second pass, we run the model on the full data set, but we allow only the 1-2 links that belong to the initial set of 1-2 mappings induced in the first pass.

6.1 Combining IP with EM

The set of allowable letter-phoneme mappings can also be used as an input to the EM alignment algorithm. We call this approach *IP-EM*. After inducing the minimal set of letter-phoneme mappings, we constrain EM to use only those mappings with the exclusion of all others. We initialize the probability of the minimal set with a uniform distribution, and set it to zero for other mappings. We train the EM model in a similar fashion to the many-to-many alignment algorithm presented in Section 3, except that we limit the letter size to be one letter, and that any letter-phoneme mapping that is not in the minimal set is assigned zero count during the E-step. The final alignments are generated after the parameters converge.

7 Alignment by aggregation

During our development experiments, we observed that the technique that combines IP with EM described in the previous section generally leads to alignment quality improvement in comparison with the IP alignment. Nevertheless, because EM is constrained not to introduce any new letter-phoneme mappings, many incorrect alignments are still proposed. We hypothesized that instead of pre-constraining EM, a post-processing of EM's output may lead to better results.

M2M-aligner has the ability to create precise links involving more than one letter, such as *ph*:f. However, it also tends to create non-intuitive links such as *se*:z for the word *phrase* [f r e z], where e is clearly a case of a "silent" letter. We propose an alternative EM-based alignment method that instead utilizes a list of alternative *one-to-many* alignments created with M2M-aligner and aggregates 1-M links into M-M links in cases when there is a disagreement between alignments within the list. For example, if the list contains the two alignments shown in Figure 3, the algorithm creates a single many-to-many alignment by merging the first pair of 1-1 and 1-0 links into a single *ph:f* link. However, the two rightmost links are *not* merged because there is no disagreement between the two initial alignments. Therefore, the resulting alignment reinforces the *ph*:f mapping, but avoids the questionable *se*:z link.

```
p h r a s e      p h r a s e
| | | | | |      | | | | | |
f - r e z -      - f r e z -
```

Figure 3: Two alignments of *phrase*.

In order to generate the list of best alignments, we use Algorithm 2, which is an adaptation of the standard Viterbi algorithm. Each cell $Q_{t,v}$ contains a list of n-best scores that correspond to al-

Algorithm 2: Extracting n-best alignments

Input: x, y, δ
Output: $Q_{T,V}$

```
1  T = |x| + 1 , V = |y| + 1
2  for t = 1..T do
3      Q_{t,v} = ∅
4      for v = 1..V do
5          for q ∈ Q_{t-1,v} do
6              append q · δ(x_t, ϵ) to Q_{t,v}
7          for j = 1..maxY st v − j ≥ 0 do
8              for q ∈ Q_{t-1,v-j} do
9                  append q · δ(x_t, y^v_{v-j+1}) to Q_{t,v}
10         sort Q_{t,v}
11         Q_{t,v} = Q_{t,v}[1 : n]
```

ternative alignments during the forward pass. In line 9, we consider all possible 1-M links between letter x_t and phoneme substring y^v_{v-j+1}. At the end of the main loop, we keep at most n best alignments in each $Q_{t,v}$ list.

Algorithm 2 yields n-best alignments in the $Q_{T,V}$ list. However, in order to further restrict the set of high-quality alignments, we also discard the alignments with scores below threshold R with respect to the best alignment score. Based on the experiments with the development set, we set $R = 0.8$ and $n = 10$.

8 Intrinsic evaluation

For the intrinsic evaluation, we compared the generated alignments to gold standard alignments extracted from the the core vocabulary of the Combilex data set (Richmond et al., 2009). Combilex is a high quality pronunciation lexicon with explicit expert manual alignments. We used a subset of the lexicon composed of the core vocabulary containing 18,145 word-phoneme pairs. The alignments contain 550 mappings, which include complex 4-1 and 2-3 types.

Each alignment approach creates alignments from unaligned word-phoneme pairs in an unsupervised fashion. We distinguish between the 1-1 and M-M approaches. We report the alignment quality in terms of precision, recall and F-score. Since the gold standard includes many links that involve multiple letters, the theoretical upper bound for recall achieved by a one-to-one approach is 90.02%. However, it is possible to obtain the perfect precision because we count as correct all 1-1 links that are *consistent* with the M-M links in the gold standard. The F-score corresponding to perfect precision and the upper-bound recall is 94.75%.

Alignment entropy is a measure of alignment quality proposed by Pervouchine et al. (2009) in the context of transliteration. The entropy indicates the uncertainty of mapping between letter l and phoneme p resulting from the alignment: We compute the alignment entropy for each of the methods using the following formula:

$$H = -\sum_{l,p} P(l,p) \log P(l|p) \qquad (7)$$

Table 1 includes the results of the intrinsic evaluation. (the two rightmost columns are discussed in Section 9). The baseline *BaseEM* is an implementation of the one-to-one alignment method of (Black et al., 1998) *without* the allowable list. *ALINE* is the phonetic method described in Section 4. *SeedMap* is the hand-seeded method described in Section 5. *M-M-EM* is the M2M-aligner approach of Jiampojamarn et al. (2007). *1-M-EM* is equivalent to *M-M-EM* but with the restriction that each link contains exactly one letter. *IP-align* is the alignment generated by the IP formulation from Section 6. *IP-EM* is the method that combines IP with EM described in Section 6.1. *EM-Aggr* is our final many-to-many alignment method described in Section 7. *Oracle* corresponds to the gold-standard alignments from Combilex.

Overall, the M-M models obtain lower precision but higher recall and F-score than 1-1 models, which is to be expected as the gold standard is defined in terms of M-M links. *ALINE* produces the most accurate alignments among the 1-1 methods, with the precision and recall values that are very close to the theoretical upper bounds. Its precision is particularly impressive: on average, only one link in a thousand is not consistent with the gold standard. In terms of word accuracy, 98.97% words have no incorrect links. Out of 18,145 words, only 112 words contain incorrect links, and further 75 words could not be aligned. The ranking of the 1-1 methods is quite clear: *ALINE* followed by *IP-EM*, *1-M-EM*, *IP-align*, and BaseEM. Among the M-M methods, EM-Aggr has slightly better precision than M-M-EM, but its recall is much worse. This is probably caused by the aggregation strategy causing EM-Aggr to "lose" a significant number of correct links. In general, the entropy measure does not mirror the quality of the alignment.

Aligner	Precision	Recall	F_1 score	Entropy	L2P 1-1	L2P M-M
BaseEM	96.54	82.84	89.17	0.794	50.00	65.38

Table 2: L2P word accuracy using the TiMBL-based generation system.

9 Extrinsic evaluation

In order to investigate the relationship between the alignment quality and L2P performance, we feed the alignments to two different L2P systems. The first one is a classification-based learning system employing TiMBL (Daelemans et al., 2009), which can utilize either 1-1 or 1-M alignments. The second system is the state-of-the-art online discriminative training for letter-to-phoneme conversion (Jiampojamarn et al., 2008), which accepts both 1-1 and M-M types of alignment. Jiampojamarn et al. (2008) show that the online discriminative training system outperforms a number of competitive approaches, including joint n-grams (Demberg et al., 2007), constraint satisfaction inference (Bosch and Canisius, 2006), pronunciation by analogy (Marchand and Damper, 2006), and decision trees (Black et al., 1998). The decoder module uses standard Viterbi for the 1-1 case, and a phrasal decoder (Zens and Ney, 2004) for the M-M case. We report the L2P performance in terms of word accuracy, which rewards only the completely correct output phoneme sequences. The data set is randomly split into 90% for training and 10% for testing. For all experiments, we hold out 5% of our training data to determine when to stop the online training process.

Table 1 includes the results on the Combilex data set. The two rightmost columns correspond to our two test L2P systems. We observe that although better alignment quality does not always translate into better L2P accuracy, there is nevertheless a strong correlation between the two, especially for the weaker phoneme generation system. Interestingly, *EM-Aggr* matches the L2P accuracy obtained with the gold standard alignments. However, there is no reason to claim that the gold standard alignments are optimal for the L2P generation task, so that result should not be considered as an upper bound. Finally, we note that alignment entropy seems to match the L2P accuracy better than it matches alignment quality.

Tables 2 and 3 show the L2P results on several evaluation sets: English Celex, CMUDict, NETTalk, OALD, and French Brulex. The training sizes range from 19K to 106K words. We follow exactly the same data splits as in Bisani and Ney (2008).

The TiMBL L2P generation method (Table 2) is applicable only to the 1-1 alignment models. *ALINE* produces the highest accuracy on four out of six datasets (including Combilex). The performance of *IP-EM* is comparable to *1-M-EM*, but not consistently better. *IP-align* does not seem to measure up to the other algorithms.

The discriminative approach (Table 3) is flexible enough to utilize all kinds of alignments. However, the M-M models perform clearly better than 1-1 models. The only exception is NetTalk, which

Aligner	Celex-En	CMUDict	NETTalk	OALD	Brulex
BaseEM	85.66	71.49	68.60	80.76	88.41
ALINE	87.96	75.05	69.52	81.57	94.56
1-M-EM	88.08	75.11	70.78	81.78	94.54
IP-EM	88.00	75.09	70.10	81.76	94.96
M-M-EM	88.54	75.41	70.18	82.43	95.03
EM-Aggr	**89.11**	**75.52**	**71.10**	**83.32**	**95.07**
joint n-gram	88.58	75.47	69.00	82.51	93.75

Table 3: L2P word accuracy using the online discriminative system.

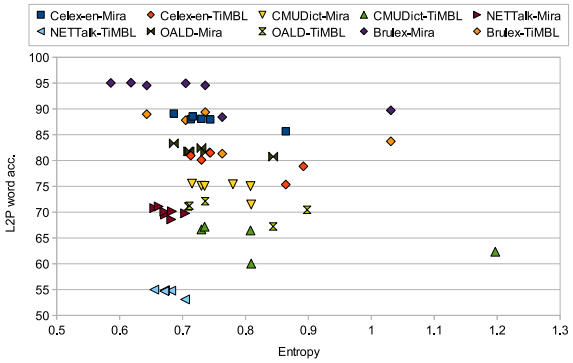

Figure 4: L2P word accuracy vs. alignment entropy.

can be attributed to the fact that NetTalk already includes double-phonemes in its original formulation. In general, the *1-M-EM* method achieves the best results among the 1-1 alignment methods, Overall, *EM-Aggr* achieves the best word accuracy in comparison to other alignment methods including the *joint n-gram* results, which are taken directly from the original paper of Bisani and Ney (2008). Except the Brulex and CMUDict data sets, the differences between *EM-Aggr* and *M-M-EM* are statistically significant according to McNemar's test at 90% confidence level.

Figure 4 contains a plot of alignment *entropy* values vs. L2P word accuracy. Each point represent an application of a particular alignment method to a different data sets. It appears that there is only weak correlation between alignment entropy and L2P accuracy. So far, we have been unable to find either direct or indirect evidence that alignment entropy is a reliable measure of letter-phoneme alignment quality.

10 Conclusion

We investigated several new methods for generating letter-phoneme alignments. The phonetic alignment is recommended for languages with little or no training data. The constraint-based approach achieves excellent accuracy at the cost of manual construction of seed mappings. The IP alignment requires no linguistic expertise and guarantees a minimal set of letter-phoneme mappings. The alignment by aggregation advances the state-of-the-art results in L2P conversion. We thoroughly evaluated the resulting alignments on several data sets by using them as input to two different L2P generation systems. Finally, we employed an independently constructed lexicon to demonstrate the close relationship between alignment quality and L2P conversion accuracy.

One open question that we would like to investigate in the future is whether L2P conversion accuracy could be improved by treating letter-phoneme alignment links as latent variables, instead of committing to a single best alignment.

Abstract

Event extraction is a particularly challenging type of information extraction (IE). Most current event extraction systems rely on local information at the phrase or sentence level. However, this local context may be insufficient to resolve ambiguities in identifying particular types of events; information from a wider scope can serve to resolve some of these ambiguities. In this paper, we use document level information to improve the performance of ACE event extraction. In contrast to previous work, we do not limit ourselves to information about events of the same type, but rather use information about other types of events to make predictions or resolve ambiguities regarding a given event. We learn such relationships from the training corpus and use them to help predict the occurrence of events and event arguments in a text. Experiments show that we can get 9.0% (absolute) gain in trigger (event) classification, and more than 8% gain for argument (role) classification in ACE event extraction.

1 Introduction

The goal of event extraction is to identify instances of a class of events in text. The ACE 2005 event extraction task involved a set of 33 generic event types and subtypes appearing frequently in the news. In addition to identifying the event itself, it also identifies all of the *participants* and *attributes* of each event; these are the *entities* that are involved in that event.

Identifying an event and its participants and attributes is quite difficult because a larger field of view is often needed to understand how facts tie together. Sometimes it is difficult even for people to classify events from isolated sentences. From the sentence:

*(1) He **left** the company.*

it is hard to tell whether it is a *Transport* event in ACE, which means that he left the place; or an *End-Position* event, which means that he retired from the company.

However, if we read the whole document, a clue like "*he planned to go shopping before he went home*" would give us confidence to tag it as a *Transport* event, while a clue like "*They held a party for his retirement*" would lead us to tag it as an *End-Position* event.

Such clues are evidence from the same event type. However, sometimes another event type is also a good predictor. For example, if we find a *Start-Position* event like "*he was named president three years ago*", we are also confident to tag (1) as *End-Position* event.

Event argument identification also shares this benefit. Consider the following two sentences:

*(2) A bomb **exploded** in Bagdad; seven people **died** while 11 were **injured**.*

*(3) A bomb **exploded** in Bagdad; the suspect got **caught** when he tried to escape.*

If we only consider the local context of the trigger "*exploded*", it is hard to determine that "*seven people*" is a likely *Target* of the *Attack* event in (2), or that the "*suspect*" is the *Attacker* of the *Attack* event, because the structures of (2) and (3) are quite similar. The only clue is from the semantic inference that a person who died may well have been a *Target* of the *Attack* event, and the person arrested is probably the *Attacker* of the *Attack* event. These may be seen as

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 789–797,
Uppsala, Sweden, 11-16 July 2010.

examples of a broader textual inference problem, and in general such knowledge is quite difficult to acquire and apply. However, in the present case we can take advantage of event extraction to learn these rules in a simpler fashion, which we present below.

Most current event extraction systems are based on phrase or sentence level extraction. Several recent studies use high-level information to aid local event extraction systems. For example, Finkel et al. (2005), Maslennikov and Chua (2007), Ji and Grishman (2008), and Patwardhan and Riloff (2007, 2009) tried to use discourse, document, or cross-document information to improve information extraction.

However, most of this research focuses on single event extraction, or focuses on high-level information within a single event type, and does not consider information acquired from other event types. We extend these approaches by introducing cross-event information to enhance the performance of multi-event-type extraction systems. Cross-event information is quite useful: first, some events co-occur frequently, while other events do not. For example, *Attack*, *Die*, and *Injure* events very frequently occur together, while *Attack* and *Marry* are less likely to co-occur. Also, typical relations among the arguments of different types of events can be helpful in predicting information to be extracted. For example, the *Victim* of a *Die* event is probably the *Target* of the *Attack* event. As a result, we extend the observation that "a document containing a certain event is likely to contain more events of the same type", and base our approach on the idea that "a document containing a certain type of event is likely to contain instances of related events". In this paper, automatically extracted within-event and cross-event information is used to aid traditional sentence level event extraction.

2 Task Description

Automatic Content Extraction (ACE) defines an event as a specific occurrence involving participants[1], and it annotates 8 types and 33 subtypes of events. We first present some ACE terminology to understand this task more easily:

- **Entity**: an object or a set of objects in one of the semantic categories of interest, referred to in the document by one or more (coreferential) entity mentions.
- **Entity mention**: a reference to an entity (typically, a noun phrase)
- **Timex:** a time expression including date, time of the day, season, year, etc.
- **Event mention**: a phrase or sentence within which an event is described, including trigger and arguments. An event mention must have one and only one trigger, and can have an arbitrary number of arguments.
- **Event trigger**: the main word that most clearly expresses an event occurrence. An ACE event trigger is generally a verb or a noun.
- **Event mention arguments (roles)**[2]: the entity mentions that are involved in an event mention, and their relation to the event. For example, event *Attack* might include participants like *Attacker, Target*, or attributes like *Time_within* and *Place*. Arguments will be taggable only when they occur within the scope of the corresponding event, typically the same sentence.

Consider the sentence:

*(4) Three **murders** occurred in **France today**, including the senseless **slaying** of **Bob Cole** and the **assassination** of **Joe Westbrook**. **Bob** was on his way home when **he** was **attacked**…*

Event extraction depends on previous phases like name identification, entity mention classification and coreference. Table 1 shows the results of this preprocessing. Note that entity mentions that share the same EntityID are coreferential and treated as the same object.

Entity(Timex) mention	head word	Entity ID	Entity type
0001-1-1	France	0001-1	GPE
0001-T1-1	Today	0001-T1	Timex
0001-2-1	Bob Cole	0001-2	PER
0001-3-1	Joe Westbrook	0001-3	PER
0001-2-2	Bob	0001-2	PER
0001-2-3	He	0001-2	PER

Table 1. An example of entities and entity mentions and their types

[1] See http://projects.ldc.upenn.edu/ace/docs/English-Events-Guidelines_v5.4.3.pdf for a description of this task.

[2] Note that we do not deal with event mention coreference in this paper, so each event mention is treated as a separate event.

There are three *Die* events, which share the same *Place* and *Time* roles, with different *Victim* roles. And there is one *Attack* event sharing the same *Place* and *Time* roles with the *Die* events.

Event type	Trigger	Role		
		Place	**Victim**	**Time**
Die	murder	0001-1-1		0001-T1-1
Die	death	0001-1-1	0001-2-1	0001-T1-1
Die	killing	0001-1-1	0001-3-1	0001-T1-1
Event type	**Trigger**	**Role**		
		Place	**Target**	**Time**
Attack	attack	0001-1-1	0001-2-3	0001-T1-1

Table2. An example of event trigger and roles

In this paper, we treat the 33 event subtypes as separate event types and do not consider the hierarchical structure among them.

3 Related Work

Almost all the current ACE event extraction systems focus on processing one sentence at a time (Grishman et al., 2005; Ahn, 2006; Hardy et al. 2006). However, there have been several studies using high-level information from a wider scope:

Maslennikov and Chua (2007) use discourse trees and local syntactic dependencies in a pattern-based framework to incorporate wider context to refine the performance of relation extraction. They claimed that discourse information could filter noisy dependency paths as well as increasing the reliability of dependency path extraction.

Finkel et al. (2005) used Gibbs sampling, a simple Monte Carlo method used to perform approximate inference in factored probabilistic models. By using simulated annealing in place of Viterbi decoding in sequence models such as HMMs, CMMs, and CRFs, it is possible to incorporate non-local structure while preserving tractable inference. They used this technique to augment an information extraction system with long-distance dependency models, enforcing label consistency and extraction template consistency constraints.

Ji and Grishman (2008) were inspired from the hypothesis of "One Sense Per Discourse" (Yarowsky, 1995); they extended the scope from a single document to a cluster of topic-related documents and employed a rule-based approach to propagate consistent trigger classification and event arguments across sentences and documents. Combining global evidence from related documents with local decisions, they obtained an appreciable improvement in both event and event argument identification.

Patwardhan and Riloff (2009) proposed an event extraction model which consists of two components: a model for sentential event recognition, which offers a probabilistic assessment of whether a sentence is discussing a domain-relevant event; and a model for recognizing plausible role fillers, which identifies phrases as role fillers based upon the assumption that the surrounding context is discussing a relevant event. This unified probabilistic model allows the two components to jointly make decisions based upon both the local evidence surrounding each phrase and the "peripheral vision".

Gupta and Ji (2009) used cross-event information within ACE extraction, but only for recovering implicit time information for events.

4 Motivation

We analyzed the sentence-level baseline event extraction, and found that many events are missing or spuriously tagged because the local information is not sufficient to make a confident decision. In some local contexts, it is easy to identify an event; in others, it is hard to do so. Thus, if we first tag the easier cases, and use such knowledge to help tag the harder cases, we might get better overall performance. In addition, global information can make the event tagging more consistent at the document level.

Here are some examples. For trigger classification:

*The pro-reform director of Iran's biggest-selling daily newspaper and official organ of Tehran's municipality has **stepped** down following the **appointment** of a conservative …it was **founded** a decade ago … but a conservative city council was **elected** in the February 28 municipal polls … Mahmud Ahmadi-Nejad, reported to be a hardliner among conservatives, was **appointed** mayor on Saturday …**Founded** by former mayor Gholamhossein Karbaschi, Hamshahri…*

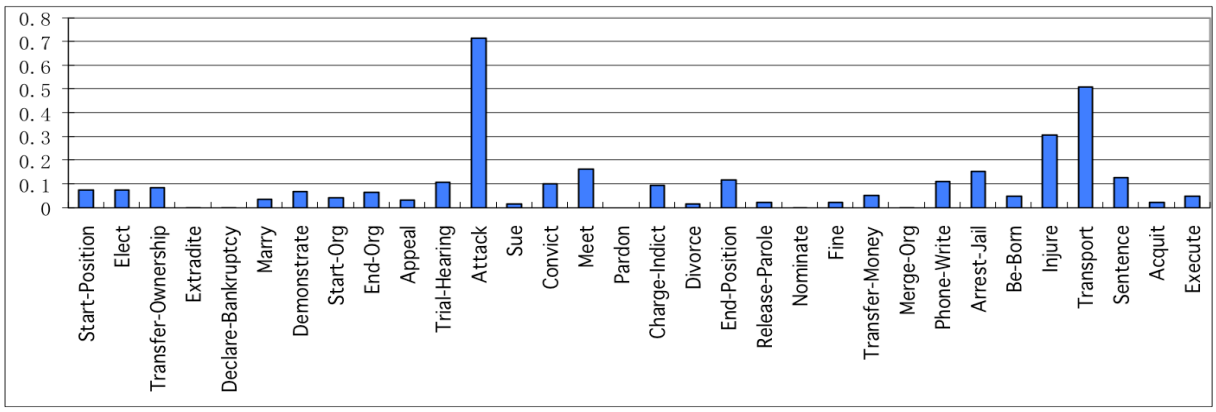

Figure 1. Conditional probability of the other 32 event types in documents where a *Die* event appears

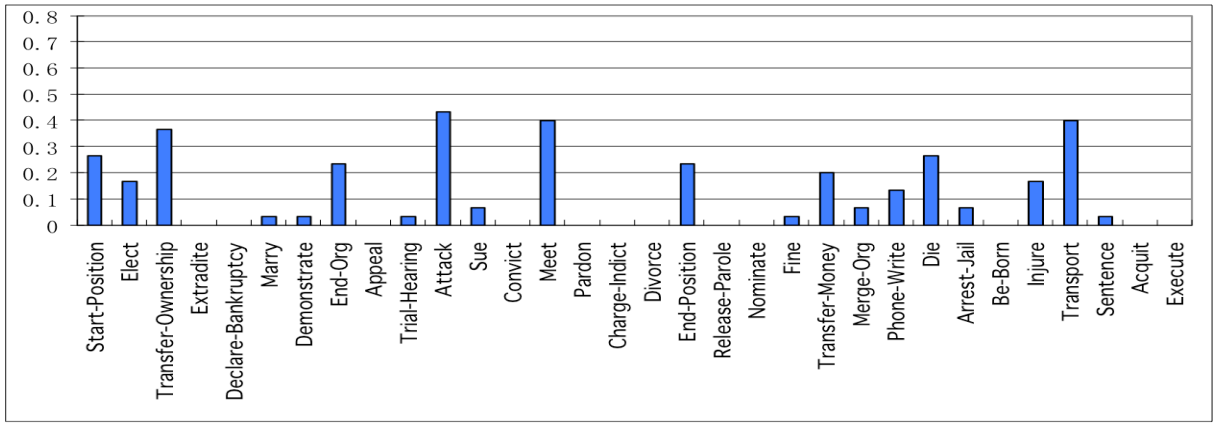

Figure 2. Conditional probability of the other 32 event types in documents where a *Start-Org* event appears

The sentence level baseline system finds event triggers like "*founded*" (trigger of *Start-Org*), "*elected*" (trigger of *Elect*), and "*appointment*" (trigger of *Start-Position*), which are easier to identify because these triggers have more specific meanings. However, it does not recognize the trigger "*stepped*" (trigger of *End-Position*) because in the training corpus "*stepped*" does not always appear as an *End-Position* event, and local context does not provide enough information for the MaxEnt model to tag it as a trigger. However, in the document that contains related events like *Start-Position*, "*stepped*" is more likely to be tagged as an *End-Position* event.

For argument classification, the cross-event evidence from the document level is also useful:

*British officials say they believe **Hassan** was a blindfolded woman seen being **shot** in the head by a hooded militant on a video obtained but not aired by the Arab television station Al-Jazeera. **She** would be the first foreign woman to **die** in the wave of kidnappings in Iraq…**she**'s been **killed** by (men in pajamas), turn Iraq upside down and find them.*

From this document, the local information is not enough for our system to tag "*Hassan*" as the target of an *Attack* event, because it is quite far from the trigger "*shot*" and the syntax is somewhat complex. However, it is easy to tag "*she*" as the *Victim* of a *Die* event, because it is the object of the trigger "*killed*". As "*she*" and "*Hassan*" are co-referred, we can use this easily tagged argument to help identify the harder one.

4.1 Trigger Consistency and Distribution

Within a document, there is a strong trigger consistency: if one instance of a word triggers an event, other instances of the same word will trigger events of the same type[3].

There are also strong correlations among event types in a document. To see this we calculated the conditional probability (in the ACE corpus) of a certain event type appearing in a document when another event type appears in the same document.

[3] This is true over 99.4% of the time in the ACE corpus.

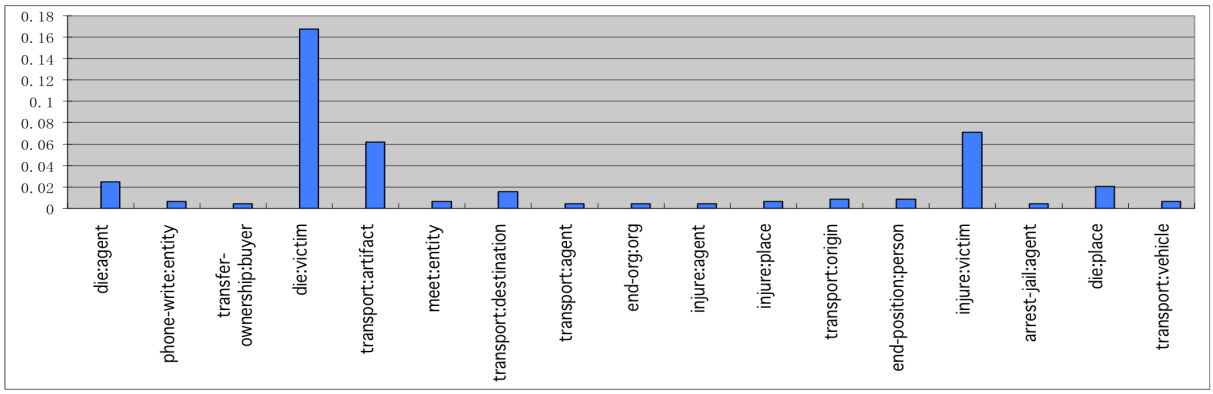

Figure 3. Conditional probability of all possible roles in other event types for entities that are the *Target*s of *Attack* events (roles with conditional probability below 0.002 are omitted)

Event	Cond. Prob.
Attack	0.714
Transport	0.507
Injure	0.306
Meet	0.164
Arrest-Jail	0.153
Sentence	0.126
Phone-Write	0.111
End-Position	0.116
Trial-Hearing	0.105
Convict	0.100

Table 3. Events co-occurring with *die* events with conditional probability > 10%

As there are 33 subtypes, there are potentially 33·32/2=528 event pairs. However, only a few of these appear with substantial frequency. For example, there are only 10 other event types that occur in more than 10% of the documents in which a *die* event appears. From Table 3, we can see that *Attack*, *Transport* and *Injure* events appear frequently with *Die*. We call these the related event types for *Die* (see Figure 1 and Table 3).

The same thing happens for *Start-Org* events, although its distribution is quite different from *Die* events. For *Start-Org*, there are more related events like *End-Org*, *Start-Position*, and *End-Position* (Figure 2). But there are 12 other event types which never appear in documents containing *Start-Org* events.

From the above, we can see that the distributions of different event types are quite different, and these distributions might be good predictors for event extraction.

4.2 Role Consistency and Distribution

Normally one entity, if it appears as an argument of multiple events *of the same type* in a single document, is assigned the same role each time.[4]

There is also a strong relationship between the roles when an entity participates in different types of events in a single document. For example, we checked all the entities in the ACE corpus that appear as the *Target* role for an *Attack* event, and recorded the roles they were assigned for other event types. Only 31 other event-role combinations appeared in total (out of 237 possible with ACE annotation), and 3 clearly dominated. In Figure 3, we can see that the most likely roles for the *Target* role of the *Attack* event are the *Victim* role of the *Die* or *Injure* event and the *Artifact* role of the *Transport* event. The last of these corresponds to troop movements prior to or in response to attacks.

5 Cross-event Approach

In this section we present our approach to using document-level event and role information to improve sentence-level ACE event extraction.

Our event extraction system is a two-pass system where the sentence-level system is first applied to make decisions based on local information. Then the confident local information is collected and gives an approximate view of the content of the document. The document level system is finally applied to deal with the cases which the local

[4] This is true over 97% of the time in the ACE corpus.

system can't handle, and achieve document consistency.

5.1 Sentence-level Baseline System

We use a state-of-the-art English IE system as our baseline (Grishman et al. 2005). This system extracts events independently for each sentence, because the definition of event mention argument constrains them to appear in the same sentence. The system combines pattern matching with statistical models. In the training process, for every event mention in the ACE training corpus, patterns are constructed based on the sequences of constituent heads separating the trigger and arguments. A set of Maximum Entropy based classifiers are also trained:

- **Argument Classifier:** to distinguish arguments of a potential trigger from non-arguments;
- **Role Classifier:** to classify arguments by argument role.
- **Reportable-Event Classifier (Trigger Classifier):** Given a potential trigger, an event type, and a set of arguments, to determine whether there is a reportable event mention.

In the test procedure, each document is scanned for instances of triggers from the training corpus. When an instance is found, the system tries to match the environment of the trigger against the set of patterns associated with that trigger. This pattern-matching process, if successful, will assign some of the mentions in the sentence as arguments of a potential event mention. The argument classifier is applied to the remaining mentions in the sentence; for any argument passing that classifier, the role classifier is used to assign a role to it. Finally, once all arguments have been assigned, the reportable-event classifier is applied to the potential event mention; if the result is successful, this event mention is reported.[5]

5.2 Document-level Confident Information Collector

To use document-level information, we need to collect information based on the sentence-level baseline system. As it is a statistically-based model, it can provide a value that indicates how likely it is that this word is a trigger, or that the mention is an argument and has a particular role. We want to see if this value can be trusted as a confidence score. To this end, we set different thresholds from 0.1 to 1.0 in the baseline system output, and only evaluate triggers, arguments or roles whose confidence score is above the threshold. Results show that as the threshold is raised, the precision generally increases and the recall falls. This indicates that the value is consistent and a useful indicator of event/argument confidence (see Figure 4).[6]

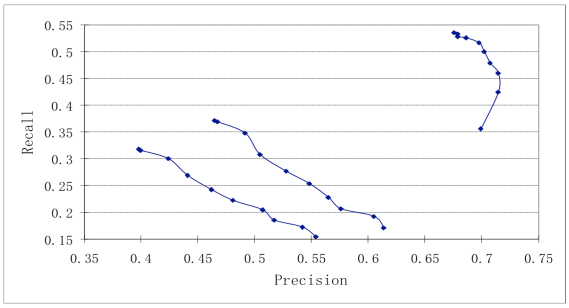

Figure 4. The performance of different confidence thresholds in the baseline system on the development set

To acquire confident document-level information, we only collect triggers and roles tagged with high confidence. Thus, a trigger threshold *t_threshold* and role threshold *r_threshold* are set to remove low confidence triggers and arguments. Finally, a table with *confident event* information is built. For every event, we collect its trigger and event type; for every argument, we use co-reference information and record every entity and its role(s) in events of a certain type.

To achieve document consistency, in cases where the baseline system assigns a word to triggers for more than one event type, if the margin between the probability of the highest and the second highest scores is above a threshold *m_threshold*, we only keep the event type with highest score and record this in the *confident-event* table. Otherwise (if the margin is smaller) the event type assignments will be recorded in a separate *conflict* table. The same strategy is applied to argument/role conflicts. We will not use information in the conflict table to infer the event type or argument/roles for other event mentions, because we cannot

[5] If the event arguments include some assigned by the pattern-matching process, the event mention is accepted unconditionally, bypassing the reportable- event classifier.

[6] The trigger classification curve doesn't follow the expected recall/precision trade-off, particularly at high thresholds. This is due, at least in part, to the fact that some events bypass the reportable-event classifier (trigger classifier) (see footnote 5). At high thresholds this is true of the bulk of the events.

confidently resolve the conflict. However, the event type and argument/role assignments in the conflict table will be included in the final output because the local confidence for the individual assignments is high.

As a result, we finally build two document-level confident-event tables: the event type table and the argument (role) table. A conflict table is also built but not used for further predictions (see Table 4).

Confident table		
Event type table		
Trigger	**Event Type**	
Met	Meet	
Exploded	Attack	
Went	Transport	
Injured	Injure	
Attacked	Attack	
Died	Die	
Argument role table		
Entity ID	**Event type**	**Role**
0004-T2	Die	Time Within
0004-6	Die	Place
0004-4	Die	Victim
0004-7	Die	Agent
0004-11	Attack	Target
0004-T3	Attack	Time Within
0004-12	Attack	Place
0004-10	Attack	Attacker
Conflict table		
Entity ID	**Event type**	**Roles**
0004-8	Attack	Victim, Agent

Table 4. Example of document-level confident-event table (event type and argument role entries) and conflict table

5.3 Statistical Cross-event Classifiers

To take advantage of cross-event relationships, we train two additional MaxEnt classifiers – a document-level trigger and argument classifier – and then use these classifiers to infer additional events and event arguments. In analyzing new text, the trigger classifier is first applied to tag an event, and then the argument (role) classifier is applied to tag possible arguments and roles of this event.

5.3.1 Document Level Trigger Classifier

From the document-level confident-event table, we have a rough view of what kinds of events are reported in this document. The trigger classifier predicts whether a word is the trigger of an event, and if so of what type, given the information (from the confident-event table) about other types of events in the document. Each feature of this classifier is the conjunction of:

- The base form of the word
- An event type
- A binary indicator of whether this event type is present elsewhere in the document

(There are 33 event types and so 33 features for each word).

5.3.2 Document Level Argument (Role) Classifier

The role classifier predicts whether a given mention is an argument of a given event and, if so, what role it takes on, again using information from the confident-event table about other events.

As noted above, we assume that the role of an entity is unique for a specific event type, although an entity can take on different roles for different event types. Thus, if there is a conflict in the document level table, the collector will only keep the one with highest confidence, or discard them all. As a result, every entity is assigned a unique role with respect to a particular event type, or *null* if it is not an argument of a certain event type.

Each feature is the conjunction of:

- The event type we are trying to assign an argument/role to.
- One of the 32 other event types
- The role of this entity with respect to the other event type elsewhere in the document, or *null* if this entity is not an argument of that type of event

5.4 Document Level Event Tagging

At this point, the low-confidence triggers and arguments (roles) have been removed and the document-level confident-event table has been built; the new classifiers are now used to *augment* the confident tags that were previously assigned based on local information.

For trigger tagging, we only apply the classifier to the words that do not have a confident local labeling; if the trigger is already in the document level confident-event table, we will not re-tag it.

performance / system/human	Trigger classification			Argument classification			Role classification		
	P	R	F	P	R	F	P	R	F
Sentence-level baseline system	67.56	53.54	59.74	46.45	37.15	41.29	41.02	32.81	36.46
Within-event-type rules	63.03	59.90	61.43	48.59	46.16	47.35	43.33	41.16	42.21
Cross-event statistical model	68.71	68.87	**68.79**	50.85	49.72	**50.28**	45.06	44.05	**44.55**
Human annotation1	59.2	59.4	59.3	60.0	69.4	64.4	51.6	59.5	55.3
Human annotation2	69.2	75.0	72.0	62.7	85.4	72.3	54.1	73.7	62.4

Table 5. Overall performance on blind test data

The argument/role tagger is then applied to all events—those in the confident-event table and those newly tagged. For argument tagging, we only consider the entity mentions in the same sentence as the trigger word, because by the ACE event guidelines, the arguments of an event should appear within the same sentence as the trigger. For a given event, we re-tag the entity mentions that have not already been assigned as arguments of that event by the confident-event or conflict table.

6 Experiments

We followed Ji and Grishman (2008)'s evaluation and randomly select 10 newswire texts from the ACE 2005 training corpora as our development set, which is used for parameter tuning, and then conduct a blind test on a separate set of 40 ACE 2005 newswire texts. We use the rest of the ACE training corpus (549 documents) as training data for both the sentence-level baseline event tagger and document-level event tagger.

To compare with previous work on within-event propagation, we reproduced Ji and Grishman (2008)'s approach for cross-sentence, within-event-type inference (see "within-event-type rules" in Table 5). We applied their within-document inference rules using the cross-sentence confident-event information. These rules basically serve to adjust trigger and argument classification to achieve document-wide consistency. This process treats each event type separately: information about events of a given type is used to infer information about other events of the same type.

We report the overall Precision (P), Recall (R), and F-Measure (F) on blind test data. In addition, we also report the performance of two human annotators on 28 ACE newswire texts (a subset of the blind test set).[7]

From the results presented in Table 5, we can see that using the document level cross-event information, we can improve the F score for trigger classification by 9.0%, argument classification by 9.0%, and role classification by 8.1%. Recall improved sharply, demonstrating that cross-event information could recover information that is difficult for the sentence-level baseline to extract; precision also improved over the baseline, although not as markedly.

Compared to the within-event-type rules, the cross-event model yields much more improvement for trigger classification: rule-based propagation gains 1.7% improvement while the cross-event model achieves a further 7.3% improvement. For argument and role classification, the cross-event model also gains 3% and 2.3% above that obtained by the rule-based propagation process.

7 Conclusion and Future Work

We propose a document-level statistical model for event trigger and argument (role) classification to achieve document level within-event and cross-event consistency. Experiments show that document-level information can improve the performance of a sentence-level baseline event extraction system.

The model presented here is a simple two-stage recognition process; nonetheless, it has proven sufficient to yield substantial improvements in event recognition and event

[7] The final key was produced by review and adjudication of the two annotations by a third annotator, which indicates that the event extraction task is quite difficult and human agreement is not very high.

argument recognition. Richer models, such as those based on joint inference, may produce even greater gains. In addition, extending the approach to cross-document information, following (Ji and Grishman 2008), may be able to further improve performance.

Now, where was I?
Resumption strategies for an in-vehicle dialogue system

Jessica Villing
Graduate School of Language Technology and
Department of Philosophy, Linguistics and Theory of Science
University of Gothenburg
jessica@ling.gu.se

Abstract

In-vehicle dialogue systems often contain more than one application, e.g. a navigation and a telephone application. This means that the user might, for example, interrupt the interaction with the telephone application to ask for directions from the navigation application, and then resume the dialogue with the telephone application. In this paper we present an analysis of interruption and resumption behaviour in human-human in-vehicle dialogues and also propose some implications for resumption strategies in an in-vehicle dialogue system.

1 Introduction

Making it useful and enjoyable to use a dialogue system is always important. The dialogue should be easy and intuitive, otherwise the user will not find it worth the effort and instead prefer to use manual controls or to speak to a human.

However, when designing an in-vehicle dialogue system there is one more thing that needs to be taken into consideration, namely the fact that the user is performing an additional, safety critical, task - driving. The so-called 100-car study (Neale et al., 2005) revealed that secondary task distraction is the largest cause of driver inattention, and that the handling of wireless devices is the most common secondary task. Even if spoken dialogue systems enables manouvering of devices without using hands or eyes, it is crucial to adjust the interaction to the in-vehicle environment in order to minimize distraction from the interaction itself. Therefore the dialogue system should consider the cognitive load of the driver and adjust the dialogue accordingly. One way of doing this is to continously measure the cognitive workload level of the driver and, if the workload is high, determine type of workload and act accordingly. If the workload is *dialogue-induced* (i.e. caused by the dialogue itself), it might be necessary to rephrase or offer the user help with the task. If the workload is *driving-induced* (i.e. caused by the driving task), the user might need information that is crucial for the driving task (e.g. get navigation instructions), or to pause the dialogue in order to enable the user to concentrate on the driving task (Villing, 2009). Both the driver and the system should be able to initiate interruptions.

When the interaction with a dialogue system has been interrupted, e.g. because the user has not answered a question, it is common that the system returns to the top menu. This means that if the user wants to finish the interrupted task she has to restart from the beginning, which is both time-consuming and annoying. Instead, the dialogue system should be able to either pause until the workload is low or change topic and/or domain, and then resume where the interruption took place. However, resumption of an interrupted topic needs to be done in a way that minimizes the risk that the cognitive workload increases again. Although a lot of research has been done regarding dialogue system output, very little work has been done regarding resumption of an interrupted topic. In this paper we will analyse human-human in-vehicle dialogue to find out how resumptions are done in human-human dialogue and propose some implications for resumption strategies in a dialogue system.

2 Related work

To study resumption behaviour, Yang (2009), carried out a data collection where the participants were switching between an ongoing task (a card game) and a real-time task (a picture game). The participants randomly had to interrupt the ongoing task to solve a problem in the real-time task. When studying the resumption behaviour after an

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 798–805,
Uppsala, Sweden, 11-16 July 2010.

interruption to the real-time task they found that the resuming utterance contained various amounts and types of redundant information depending on whether the interruption occured in the middle of a card discussion, at the end of a card or at the end of a card game. If the interruption occured in the middle of a card discussion it was possible to make a distinction between *utterance restatement* (repeat one's own utterance, repeat the dialogue partners utterance or clarification of the dialogue partners utterance) and *card review* (reviewing all the cards on hand although this information had already been given). They found that the behaviour is similar to grounding behaviour, where the speaker use repetition and requests for repetition to ensure that the utterance is understood.

3 Data collection

A data collection has been carried out within the DICO project (see, for example, (Larsson and Villing, 2007)) to study how an additional distraction or increase in the cognitive load would affect a driver's dialogue behaviour. The goal was to elicit a natural dialogue (as opposed to giving the driver a constructed task such as for example a math task) and make the participants engage in the conversation.

The participants (two female and six male) between the ages of 25 and 36 drove a car in pairs while interviewing each other. The interview questions and the driving instructions were given to the passenger, hence the driver knew neither what questions to discuss nor the route in advance. Therefore, the driver had to signal, implicitly or explicitly, when she wanted driving instructions and when she wanted a new question to discuss. The passenger too had to have a strategy for when to change topic. The reasons for this setup was to elicit a natural and fairly intense dialogue and to force the participants to frequently change topic and/or domain (e.g. to get driving instructions). The participants changed roles after 30 minutes, which meant that each participant acted both as driver and as passenger. The cognitive load of the driver was measured in two ways. The driver performed a Tactile Detection Task (TDT) (van Winsum et al., 1999). When using a TDT, a buzzer is attached to the driver's wrist. The driver is told to push a button each time the summer is activated. Cognitive load is determined by measuring hit-rate and reaction time. Although the TDT task in itself might cause an increased workload level, the task is performed during the whole session and thereby it is possible to distinguish high workload caused by something else but the TDT task.

Workload was also measured by using an IDIS system (Broström et al., 2006). IDIS determines workload based on the driver's behaviour (for example, steering wheel movements or applying the brake). What differs between the two measurements is that the TDT measures the actual workload of each driver, while IDIS makes its assumptions based on knowledge of what manouvres are usually cognitively demanding.

The participants were audio- and videotaped, the recordings are transcribed with the transcription tool ELAN[1], using an orthographic transcription. All in all 3590 driver utterances and 4382 passenger utterances are transcribed. An annotation scheme was designed to enable analysis of utterances with respect to topic change for each domain.

Domain and topic was defined as:

- *interview* domain: discussions about the interview questions where each interview question was defined as a topic
- *navigation* domain: navigation-related discussions where each navigation instruction was defined as a topic
- *traffic* domain: discussions about the traffic situation and fellow road-users where each comment not belonging to a previous event was defined as a topic
- *other* domain: anything that does not fit within the above domains where each comment not belonging to a previous event was defined as a topic

Topic changes has been coded as follows:

- *begin-topic*: whatever → new topic
  - I.e., the participants start discussing an interview question, a navigation instruction, make a remark about the traffic or anything else that has not been discussed before.
- *end-topic*: finished topic → whatever

[1] http://www.lat-mpi.eu/tools/elan/

  - A topic is considered finished if a question is answered or if an instruction or a remark is confirmed.

- *interrupt-topic*: unfinished topic → whatever
  - An utterance is considered to interrupt if it belongs to another topic than the previous utterance and the previous topic has not been ended with an *end-topic*.
- *resume-topic*: whatever → unfinished topic
  - A topic is considered to be resumed if it has been discussed earlier but was not been finished by an *end-topic* but instead interrupted with an *interrupt-topic*.
- *reraise-topic*: whatever → finished topic
  - A topic is considered to be reraised if it has been discussed before and then been finished with an *end-topic*.

The utterances have been categorised according to the following schema:

- DEC: declarative
  - (*"You are a Leo and I am a Gemini"*, *"This is Ekelund Street"*)
- INT: interrogative
  - (*"What do you eat for breakfast?"*, *"Should we go back after this?"*)
- IMP: imperative
  - (*"Go on!"*)
- ANS: *"yes"* or *"no"* answer (and variations such as *"sure, absolutely, nope, no way"*)
- NP: bare noun phrase
  - (*"Wolfmother"*, *"Otterhall Street"*)
- ADVP: bare adverbial phrase
  - (*"Further into Karlavagn Street"*)
- INC: incomplete phrase
  - (*"Well, did I answer the"*, *"Should we"*)

Cognitive load has been annotated as:

- **reliable workload**: annotated when workload is reliably high according to the TDT (reliability was low if response button was pressed more than 2 times after the event).
- **high**: high workload according to IDIS
- **low**: low workload according to IDIS

The annotation schema has not been tested for inter-coder reliability. While full reliability testing would have further strengthened the results, we believe that our results are still useful as a basis for future implementation and experimental work.

4 Results

The codings from the DICO data collection has been analysed with respect to interruption and resumption of topics (*interrupt-topic* and *resume-topic*, respectively). Interruption can be done in two ways, either to pause the dialogue or to change topic and/or domain. In the DICO corpus there are very few interruptions followed by a pause. The reason is probably that both the driver and the passenger were strongly engaged in the interview and navigation tasks. The fact that the driver did not know the route elicited frequent switches to the navigation domain done by both the driver and the passenger, as can be seen in Figure 1. Therefore, we have only analysed interruption and resumption from and to the interview and navigation domains.

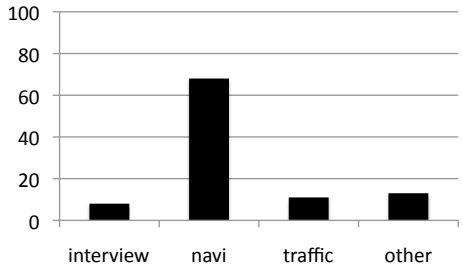

Figure 1: Distribution of utterances coded as *interrupt-topic* for each domain, when interrupting from an interview topic.

4.1 Redundancy

The easiest way of resuming an interrupted topic in a dialogue system is to repeat the last phrase that was uttered before the interruption. One disdavantage of this method is that the dialogue system might be seen as tedious, especially if there are several interruptions during the interaction. We wanted to see if the resuming utterances in human-human dialogue are redundant and if redundancy has anything to do with the length of the interruption. We therefore sorted all utterances coded

as *resume-topic* in two categories, those which contained redundant information when comparing with the last utterance before the interruption, and those which did not contain and redundant information. As a redundant utterance we counted all utterances that repeated one or more words from the last utterance before the interruption. We then counted the number of turns between the interruption and resumption. The number of turns varied between 1 and 42. The result can be seen in Figure 2.

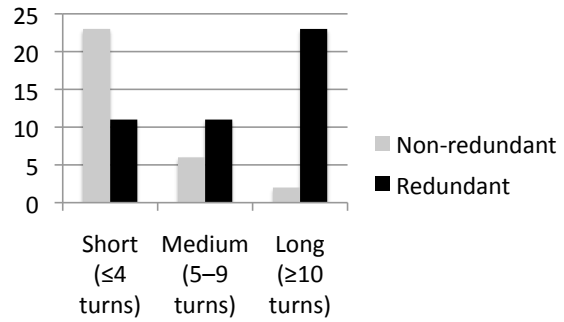

Figure 2: Number of redundant utterances depending on length of interruption.

As can be seen, there are twice as many non-redundant as redundant utterances after a short interruption ($\leq$4 turns), while there are almost solely redundant utterances after a long interruption ($\geq$10 turns). The average number of turns is 3,5 when no redundancy occur, and 11,5 when there are redundancy. When the number of turns exceeds 12, there are only redundant utterances.

4.2 Category

Figure 3 shows the distribution, sorted per category, of driver utterances when resuming to an interview and a navigation topic. Figure 4 shows the corresponding figures for passenger utterances.

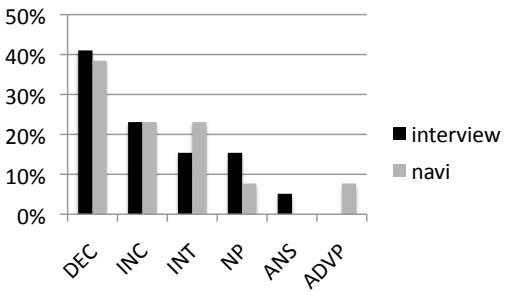

Figure 3: Driver resuming to the interview and navigation domains.

The driver's behaviour is similar both when resuming to an interview and a navigation topic. Declarative phrases are most common, followed by incomplete, interrogative (for interview topics) and noun phrases.

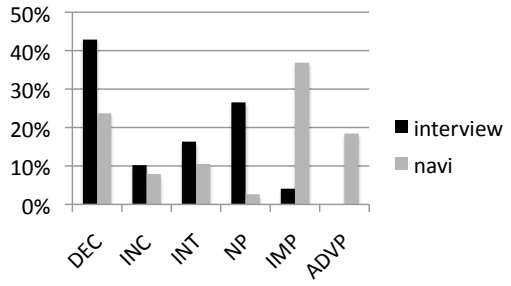

Figure 4: Passenger resuming to the interview and navigation domains.

When looking at the passenger utterances we see a lot of variation between the domains. When resuming to an interview topic the passenger uses mostly declarative phrases, followed by noun phrases and interrogative phrases. When resuming to a navigation topic imperative phrases are most common, followed by declarative phrases. Only the passenger use imperative phrases, probably since the passenger is managing both the interview questions and the navigation instructions and therefore is the one that is forcing both the interview and the navigation task through.

4.3 Workload level

The in-vehicle environment is forcing the driver to carry out tasks during high cognitive workload. To minimize the risk of increasing the workload further, an in-vehicle dialogue system should be able to decide when to interrupt and when to resume a topic depending on the driver's workload level.

The figures in this section shows workload level and type of workload during interruption and resumption to and from topics in the interview domain. When designing the interview and navigation tasks that were to be carried out during the data collection, we focused on designing them so that the participants were encouraged to discuss as much as possible with each other. Therefore, the navigation instructions sometimes were hard to understand, which forced the participants to discuss the instructions and together try to interpret them. Therefore we have not analysed the workload level while interrupting and resuming topics in the navigation domain since the result might be

misleading.

Type of workload is determined by analysing the TDT and IDIS signals described in 3. Workload is considered to be dialogue-induced when only the TDT is indicating high workload (since the TDT indicates that the driver is carrying out a task that is cognitively demanding but IDIS is not indicating that the driving task is demanding at the moment), driving-induced when both the TDT and IDIS is indicating high workload (since the TDT is indicating that the workload level is high and IDIS is indicating that the driving task is demanding) and possibly driving-induced when only IDIS is indicating high workload (since IDIS admittedly is indicating that the driving task is demanding but the TDT indicates that the driver's workload is low, it could then be that this particular driver does not experience the driving task demanding even though the average driver does) (Villing, 2009).

The data has been normalized for variation in workload time. The diagrams shows the distribution of interruption and resumption utterances made by the driver and the passenger, respectively.

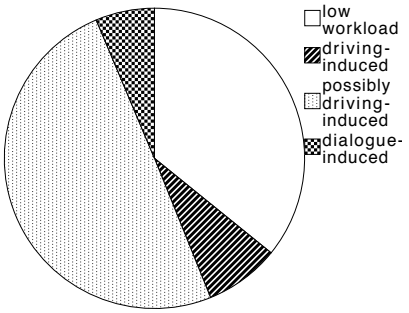

Figure 5: Workload while the driver is interrupting an interview topic.

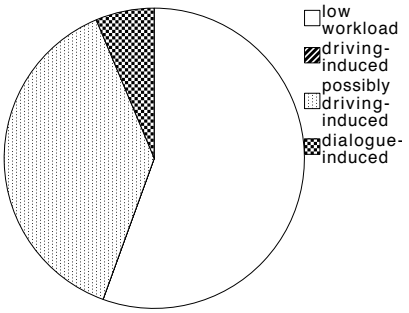

Figure 6: Workload while the passenger is interrupting an interview topic.

Figures 5 and 6 show driver workload level while the driver and the passenger (respectively) are interrupting from the interview domain. The driver most often interrupts during a possible driving-induced or low workload, the same goes for the passenger but in opposite order. It is least common for the driver to interrupt during dialogue- or driving-induced workload, while the passenger rarely interrupts during dialogue-induced and never during driving-induced workload.

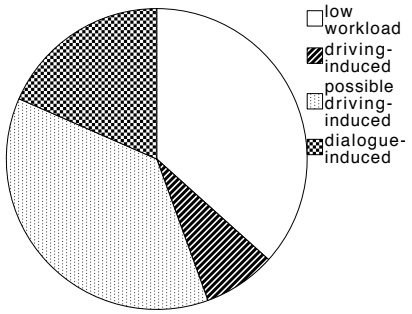

Figure 7: Workload while driver is resuming to the interview domain.

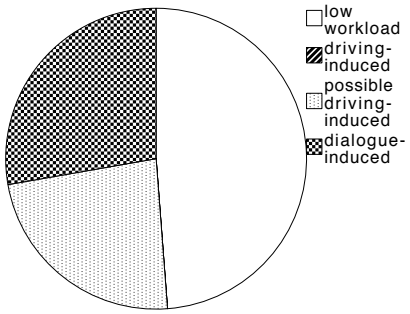

Figure 8: Workload while passenger is resuming to the interview domain.

Figures 7 and 8 show workload level while the driver and the passenger (respectively) are resuming to the interview domain. The driver most often resumes while the workload is low or possibly driving-induced, while the passenger is mostly resuming during low workload and never during driving-induced workload.

5 Discussion

For both driver and passenger, the most common way to resume an interview topic is to use a declarative utterance, which is illustrated in Figure 3. When studying the utterances in detail we can see that there is a difference when comparing information redundancy similar to what Yang (2009) describe in their paper. They compared grade of

redundancy based on where in the dialogue the interruption occur, what we have looked at in the DICO corpus is how many turns the interrupting discussion contains.

As Figure 2 shows, if the number of turns is about three (on average, 3,5), the participants tend to continue the interrupted topic exactly where it was interrupted, without considering that there had been any interruption. The speaker however often makes some sort of sequencing move to announce that he or she is about to switch domain and/or topic, either by using a standard phrase or by making an extra-lingustic sound like, for example, lipsmack or breathing (Villing et al., 2008). Example (1) shows how the driver interrupts a discussion about what book he is currently reading to get navigation instructions:

(1) Driver: What I read now is Sofie's world.

Driver (*interrupting*): Yes, where do you want me to drive?

Passenger: Straight ahead, straight ahead.

Driver: Straight ahead. Alright, I'll do that.

Passenger (*resuming*): Alright [*sequencing move*]. Enemy of the enemy was the last one I read. [*DEC*]

If the number of turns is higher than ten (on average, 11,5) the resuming speaker makes a redundant utterance, repeating one or more words from the last utterance before the interruption. See example (2):

(2) Driver: Actually, I have always been interested in computers and technology.

Passenger (*interrupting*): Turn right to Vasaplatsen. Is it here? No, this is Grönsakstorget.

Driver: This is Grönsakstorget. We have passed Vasaplatsen.

. . . (*Discussion about how to turn around and get back to Vasaplatsen, all in all 21 turns.*)

Driver (*resuming*): Well, as I said [*sequencing move*]. I have always been interested in computer and computers and technology and stuff like that. [*DEC*]

The passenger often uses a bare noun phrase to resume, the noun phrase can repeat a part of the interview question. For example, after a discussion about wonders of the world, which was interrupted by a discussion about which way to go next, the passenger resumed by uttering the single word "wonders" which was immediatly understood by the driver as a resumption to the interview topic. The noun phrase can also be a key phrase in the dialogue partner's answer as in example (3) where the participants discuss their favourite band:

(3) Driver: I like Wolfmother, do you know about them?

Passenger: I've never heard about them. [...] You have to bring a cd so I can listen to them.

Driver (*interrupting*): Where was I supposed to turn?

. . . (*Navigation discussion, all in all 13 turns.*)

Passenger (*resuming*): [*LAUGHS*]Wolfmother. [*NP*]

When resuming to the navigation domain, the driver mostly uses a declarative phrase, typically to clarify an instruction. It is also common to use an interrogative phrase or an incomplete phrase such as *"should I..."* which the passenger answers by clarifying which way to go. The passenger instead uses mostly imperative phrases as a reminder of the last instruction, such as *"keep straight on"*.

When the speakers interrupts an interview topic they mostly switch to the navigation domain, see Figure 1. That means that the most common reason for the speaker to interrupt is to ask for or give information that is crucial for the driving task (as opposed for the other and traffic domains, which are mostly used to signal that the speaker's cognitive load level is high (Villing et al., 2008)). As can be seen in Figures 5 and 6, the driver mostly interrupts the interview domain during a possible driving-induced workload while the passenger mostly interrupts during low workload. As noted above (see also Figure 3), the utterances are mostly declarative (*"this is Ekelund Street"*), interrogative (*"and now I turn left?"*) or incomplete (*"and then..."*), while the passenger gives additional information that the driver has not asked for explicitly but the passenger judges that the driver might need (*"just go straight ahead in the next crossing"*, *"here is where we should turn towards Järntorget"*). Hence, it seems like the driver interrupts to make clarification utterances that must be answered immediately, for example, right before a

crossing when the driver has pressed the brakes or turned on the turn signal (and therefore the IDIS system signals high workload which is interpreted as driving-induced workload) while the passenger take the chance to give additional information in advance, before it is needed, and the workload therefore is low.

Figure 7 shows that the driver mostly resumes to the interview domain during low or possible driving-induced workload. Since the IDIS system makes its assumption on driving behaviour, based on what the average driver finds cognitively demanding, it might sometimes be so that the system overgenerates and indicates high workload even though the driver at hand does not find the driving task cognitively demanding. This might be an explanation to these results, since the driver often resumes to an interview topic although he or she is, for example, driving through a roundabout or pushing the brakes. It is also rather common that the driver is resuming to an interview question during dialogue-induced workload, perhaps because she has started thinking about an answer to a question and therefore the TDT indicates high workload and the IDIS does not. The passenger mostly resumes to the interview domain during low workload, which indicates that the passenger analyses both the traffic situation and the state of mind of the driver before he or she wants to draw the drivers attention from the driving task.

6 Implications for in-vehicle dialogue systems

In this paper we point at some of the dialogue strategies that are used in human-human dialogue during high cognitive load when resuming to an interrupted topic. These strategies should be taken under consideration when implementing an in-vehicle dialogue system.

To make the dialogue natural and easy to understand the dialogue manager should consider which domain it will resume to and the number of turns between the interruption and resumption before deciding what phrase to use as output. For example, the results indicate that it might be more suitable to use a declarative phrase when resuming to a domain where the system is asking the user for information, for example when adding songs to a play list at the mp3-player (cf. the interview domain). If the number of turns are 4 or less, it probably does not have to make a redundant utterance at all, but may continue the discussion where it was interrupted. If the number of turns exceeds 4 it is probably smoother to let the system just repeat one or more keywords from the interrupted utterance to make the user understand what topic should be discussed, instead of repeating the whole utterance or even start the task from the beginning. This will make the system feel less tedious which should have a positive effect on the cognitive workload level. However, user tests are probably needed to decide how much redundant information is necessary when talking to a dialogue system, since it may well differ from talking to a human being who is able to help the listener understand by, for example, emphasizing certain words in a way that is currently impossible for a computer. When resuming to a domain where the system has information to give to the user it is suitable to make a short, informative utterance (e.g. *"turn left here", "traffic jam ahead, turn left instead"*).

Finally, it is also important to consider the cognitive workload level of the user to determine when - and if - to resume, and also whether the topic that is to be resumed belongs to a domain where the system has information to give to the user, or a domain where the user gives information to the system. For example, if the user is using a navigation system and he or she is experiencing driving-induced workload when approaching e.g. a crossing, it might be a good idea to give additional navigation information even though the user has not explicitly asked for it. If the user however is using a telephone application it is probably better to let the user initiate the resumption. The DICO corpus shows that it is the passenger that is most careful not to interrupt or resume when the driver's workload is high, indicating that the system should let the user decide whether it is suitable to resume during high workload, while it is more accepted to let the system interrupt and resume when the workload is low.

When resuming to the interview domain the driver (i.e. the user) mostly uses declarative phrases, either as an answer to a question or as a redundant utterance to clarify what was last said before the interruption. Therefore the dialogue system should be able to store not only what has been agreed upon regarding the interrupted task, but also the last few utterances to make it possible to interpret the user utterance as a resumption.

It is common that the driver utterances are incomplete, perhaps due to the fact that the driver's primary task is the driving and therefore his or her mind is not always set on the dialogue task. Lindström (2008) showed that deletions are the most common disfluency during high cognitive load, which is supported by the results in this paper. The dialogue system should therefore be robust regarding ungrammatical utterances.

7 Future work

Next we intend to implement strategies for interruption and resumption in the DICO dialogue system. The strategies will then be evaluated through user tests where the participants will compare an application with these strategies with an application without them. Cognitive workload will be measured as well as driving ability (for example, by using a Lane Change Task (Mattes, 2003)). The participants will also be interviewed in order to find out which version of the system is more pleasant to use.

Learning to Follow Navigational Directions

Adam Vogel and **Dan Jurafsky**
Department of Computer Science
Stanford University
{acvogel,jurafsky}@stanford.edu

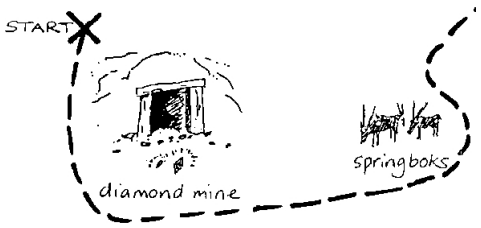
Abstract

We present a system that learns to follow navigational natural language directions. Where traditional models learn from linguistic annotation or word distributions, our approach is grounded in the world, learning by apprenticeship from routes through a map paired with English descriptions. Lacking an explicit alignment between the text and the reference path makes it difficult to determine what portions of the language describe which aspects of the route. We learn this correspondence with a reinforcement learning algorithm, using the deviation of the route we follow from the intended path as a reward signal. We demonstrate that our system successfully grounds the meaning of spatial terms like *above* and *south* into geometric properties of paths.

1 Introduction

Spatial language usage is a vital component for physically grounded language understanding systems. Spoken language interfaces to robotic assistants (Wei et al., 2009) and Geographic Information Systems (Wang et al., 2004) must cope with the inherent ambiguity in spatial descriptions.

The semantics of imperative and spatial language is heavily dependent on the physical setting it is situated in, motivating automated learning approaches to acquiring meaning. Traditional accounts of learning typically rely on linguistic annotation (Zettlemoyer and Collins, 2009) or word distributions (Curran, 2003). In contrast, we present an apprenticeship learning system which learns to imitate human instruction following, without linguistic annotation. Solved using a reinforcement learning algorithm, our system acquires the meaning of spatial words through grounded interaction with the world. This draws on the intuition that children learn to use spatial language through a mixture of observing adult language usage and situated interaction in the world, usually without explicit definitions (Tanz, 1980).



1. go vertically down until you're underneath eh diamond mine
2. then eh go right until you're
3. you're between springbok and highest viewpoint

Figure 1: A path appears on the instruction giver's map, who describes it to the instruction follower.

Our system learns to follow navigational directions in a route following task. We evaluate our approach on the HCRC Map Task corpus (Anderson et al., 1991), a collection of spoken dialogs describing paths to take through a map. In this setting, two participants, the *instruction giver* and *instruction follower*, each have a map composed of named landmarks. Furthermore, the *instruction giver* has a route drawn on her map, and it is her task to describe the path to the *instruction follower*, who cannot see the reference path. Our system learns to interpret these navigational directions, without access to explicit linguistic annotation.

We frame direction following as an apprenticeship learning problem and solve it with a reinforcement learning algorithm, extending previous work on interpreting instructions by Branavan et al. (2009). Our task is to learn a policy, or mapping

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 806–814,
Uppsala, Sweden, 11-16 July 2010.

from world state to action, which most closely follows the reference route. Our state space combines world and linguistic features, representing both our current position on the map and the communicative content of the utterances we are interpreting. During training we have access to the reference path, which allows us to measure the utility, or reward, for each step of interpretation. Using this reward signal as a form of supervision, we learn a policy to maximize the expected reward on unseen examples.

2 Related Work

Levit and Roy (2007) developed a spatial semantics for the Map Task corpus. They represent instructions as Navigational Information Units, which decompose the meaning of an instruction into orthogonal constituents such as the reference object, the type of movement, and quantitative aspect. For example, they represent the meaning of "move two inches toward the house" as a reference object (the house), a path descriptor (towards), and a quantitative aspect (two inches). These representations are then combined to form a path through the map. However, they do not learn these representations from text, leaving natural language processing as an open problem. The semantics in our paper is simpler, eschewing quantitative aspects and path descriptors, and instead focusing on reference objects and frames of reference. This simplifies the learning task, without sacrificing the core of their representation.

Learning to follow instructions by interacting with the world was recently introduced by Branavan et al. (2009), who developed a system which learns to follow Windows Help guides. Our reinforcement learning formulation follows closely from their work. Their approach can incorporate expert supervision into the reward function in a similar manner to this paper, but is also able to learn effectively from environment feedback alone. The Map Task corpus is free form conversational English, whereas the Windows instructions are written by a professional. In the Map Task corpus we only observe expert route following behavior, but are not told how portions of the text correspond to parts of the path, leading to a difficult learning problem.

The semantics of spatial language has been studied for some time in the linguistics literature. Talmy (1983) classifies the way spatial meaning is

Figure 2: The instruction giver and instruction follower face each other, and cannot see each others maps.

encoded syntactically, and Fillmore (1997) studies spatial terms as a subset of deictic language, which depends heavily on non-linguistic context. Levinson (2003) conducted a cross-linguistic semantic typology of spatial systems. Levinson categorizes the frames of reference, or spatial coordinate systems[1], into

1. *Egocentric*: Speaker/hearer centered frame of reference. Ex: "the ball to your left".

2. *Allocentric*: Speaker independent. Ex: "the road to the north of the house"

Levinson further classifies allocentric frames of reference into absolute, which includes the cardinal directions, and intrinsic, which refers to a featured side of an object, such as "the front of the car". Our spatial feature representation follows this egocentric/allocentric distinction. The intrinsic frame of reference occurs rarely in the Map Task corpus and is ignored, as speakers tend not to mention features of the landmarks beyond their names.

Regier (1996) studied the learning of spatial language from static 2-D diagrams, learning to distinguish between terms with a connectionist model. He focused on the meaning of individual terms, pairing a diagram with a given word. In contrast, we learn from whole texts paired with a

[1]Not all languages exhibit all frames of reference. Terms for 'up' and 'down' are exhibited in most all languages, while 'left' and 'right' are absent in some. Gravity breaks the symmetry between 'up' and 'down' but no such physical distinction exists for 'left' and 'right', which contributes to the difficulty children have learning them.

path, which requires learning the correspondence between text and world. We use similar geometric features as Regier, capturing the allocentric frame of reference.

Spatial semantics have also been explored in physically grounded systems. Kuipers (2000) developed the Spatial Semantic Hierarchy, a knowledge representation formalism for representing different levels of granularity in spatial knowledge. It combines sensory, metrical, and topological information in a single framework. Kuipers et al. demonstrate its effectiveness on a physical robot, but did not address the learning problem.

More generally, apprenticeship learning is well studied in the reinforcement learning literature, where the goal is to mimic the behavior of an expert in some decision making domain. Notable examples include (Abbeel and Ng, 2004), who train a helicopter controller from pilot demonstration.

3 The Map Task Corpus

The HCRC Map Task Corpus (Anderson et al., 1991) is a set of dialogs between an *instruction giver* and an *instruction follower*. Each participant has a map with small named landmarks. Additionally, the instruction giver has a path drawn on her map, and must communicate this path to the instruction follower in natural language. Figure 1 shows a portion of the instruction giver's map and a sample of the instruction giver language which describes part of the path.

The Map Task Corpus consists of 128 dialogs, together with 16 different maps. The speech has been transcribed and segmented into utterances, based on the length of pauses. We restrict our attention to just the utterances of the instruction giver, ignoring the instruction follower. This is to reduce redundancy and noise in the data - the instruction follower rarely introduces new information, instead asking for clarification or giving confirmation. The landmarks on the instruction follower map sometimes differ in location from the instruction giver's. We ignore this caveat, giving the system access to the instruction giver's landmarks, without the reference path.

Our task is to build an automated *instruction follower*. Whereas the original participants could speak freely, our system does not have the ability to query the instruction giver and must instead rely only on the previously recorded dialogs.

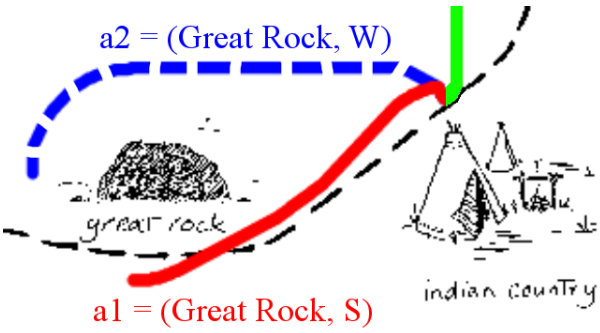


Figure 3: Sample state transition. Both actions get credit for visiting the great rock after the indian country. Action a1 also gets credit for passing the great rock on the correct side.

4 Reinforcement Learning Formulation

We frame the direction following task as a sequential decision making problem. We interpret utterances in order, where our interpretation is expressed by moving on the map. Our goal is to construct a series of moves in the map which most closely matches the expert path.

We define intermediate steps in our interpretation as *states* in a set S, and interpretive steps as *actions* drawn from a set A. To measure the fidelity of our path with respect to the expert, we define a *reward* function $R : S \times A \rightarrow \mathbb{R}^+$ which measures the utility of choosing a particular action in a particular state. Executing action a in state s carries us to a new state s', and we denote this transition function by $s' = T(s, a)$. All transitions are deterministic in this paper.[2]

For training we are given a set of dialogs D. Each dialog $d \in D$ is segmented into utterances $(u_1, \ldots, u_m)$ and is paired with a map, which is composed of a set of named landmarks $(l_1, \ldots, l_n)$.

4.1 State

The states of our decision making problem combine both our position in the dialog d and the path we have taken so far on the map. A state $s \in S$ is composed of $s = (u_i, l, c)$, where l is the named landmark we are located next to and c is a cardinal direction drawn from $\{\text{North}, \text{South}, \text{East}, \text{West}\}$ which determines which side of l we are on. Lastly, u_i is the utterance in d we are currently interpreting.

[2]Our learning algorithm is not dependent on a deterministic transition function and can be applied to domains with stochastic transitions, such as robot locomotion.

4.2 Action

An action $a \in A$ is composed of a named landmark l, the *target* of the action, together with a cardinal direction c which determines which side to pass l on. Additionally, a can be the null action, with $l = l'$ and $c = c'$. In this case, we interpret an utterance without moving on the map. A target l together with a cardinal direction c determine a point on the map, which is a fixed distance from l in the direction of c.

We make the assumption that at most one instruction occurs in a given utterance. This does not always hold true - the instruction giver sometimes chains commands together in a single utterance.

4.3 Transition

Executing action $a = (l', c')$ in state $s = (u_i, l, c)$ leads us to a new state $s' = T(s, a)$. This transition moves us to the next utterance to interpret, and moves our location to the target of the action. If a is the null action, $s = (u_{i+1}, l, c)$, otherwise $s' = (u_{i+1}, l', c')$. Figure 3 displays the state transitions two different actions.

To form a path through the map, we connect these state waypoints with a path planner[3] based on A^*, where the landmarks are obstacles. In a physical system, this would be replaced with a robot motion planner.

4.4 Reward

We define a reward function $R(s, a)$ which measures the utility of executing action a in state s. We wish to construct a route which follows the expert path as closely as possible. We consider a proposed route P close to the expert path P_e if P visits landmarks in the same order as P_e, and also passes them on the correct side.

For a given transition $s = (u_i, l, c)$, $a = (l', c')$, we have a binary feature indicating if the expert path moves from l to l'. In Figure 3, both a_1 and a_2 visit the next landmark in the correct order.

To measure if an action is to the correct side of a landmark, we have another binary feature indicating if P_e passes l' on side c. In Figure 3, only a_1 passes l' on the correct side.

In addition, we have a feature which counts the number of words in u_i which also occur in the name of l'. This encourages us to choose policies which interpret language relevant to a given landmark.

Our reward function is a linear combination of these features.

4.5 Policy

We formally define an interpretive strategy as a *policy* $\pi : S \rightarrow A$, a mapping from states to actions. Our goal is to find a policy π which maximizes the expected reward $\mathbb{E}_\pi[R(s, \pi(s))]$. The expected reward of following policy π from state s is referred to as the *value* of s, expressed as

$$V^\pi(s) = \mathbb{E}_\pi[R(s, \pi(s))] \quad (1)$$

When comparing the utilities of executing an action a in a state s, it is useful to define a function

$$\begin{aligned} Q^\pi(s, a) &= R(s, a) + V^\pi(T(s, a)) \\ &= R(s, a) + Q^\pi(T(s, a), \pi(s)) \end{aligned} \quad (2)$$

which measures the utility of executing a, and following the policy π for the remainder. A given Q function implicitly defines a policy π by

$$\pi(s) = \max_a Q(s, a). \quad (3)$$

Basic reinforcement learning methods treat states as atomic entities, in essence estimating V^π as a table. However, at test time we are following new directions for a map we haven't previously seen. Thus, we represent state/action pairs with a feature vector $\phi(s, a) \in \mathbb{R}^K$. We then represent the Q function as a linear combination of the features,

$$Q(s, a) = \theta^{\mathrm{T}} \phi(s, a) \quad (4)$$

and learn weights θ which most closely approximate the true expected reward.

4.6 Features

Our features $\phi(s, a)$ are a mixture of world and linguistic information. The linguistic information in our feature representation includes the instruction giver utterance and the names of landmarks on the map. Additionally, we furnish our algorithm with a list of English spatial terms, shown in Table 1. Our feature set includes approximately 200 features. Learning exactly which words influence decision making is difficult; reinforcement learning algorithms have problems with the large, sparse feature vectors common in natural language processing.

For a given state $s = (u, l, c)$ and action $a = (l', c')$, our feature vector $\phi(s, a)$ is composed of the following:

[3] We used the Java Path Planning Library, available at `http://www.cs.cmu.edu/~ggordon/PathPlan/`.

above, below, under, underneath, over, bottom, top, up, down, left, right, north, south, east, west, on

Table 1: The list of given spatial terms.

- **Coherence**: The number of words $w \in u$ that occur in the name of l'
- **Landmark Locality**: Binary feature indicating if l' is the closest landmark to l
- **Direction Locality**: Binary feature indicating if cardinal direction c' is the side of l' closest to (l, c)
- **Null Action**: Binary feature indicating if $l' =$ NULL
- **Allocentric Spatial**: Binary feature which conjoins the side c we pass the landmark on with each spatial term $w \in u$. This allows us to capture that the word *above* tends to indicate passing to the north of the landmark.
- **Egocentric Spatial**: Binary feature which conjoins the cardinal direction we move in with each spatial term $w \in u$. For instance, if (l, c) is above (l', c'), the direction from our current position is south. We conjoin this direction with each spatial term, giving binary features such as "the word *down* appears in the utterance and we move to the south".

5 Approximate Dynamic Programming

Given this feature representation, our problem is to find a parameter vector $\theta \in \mathbb{R}^K$ for which $Q(s, a) = \theta^{\mathrm{T}}\phi(s, a)$ most closely approximates $\mathbb{E}[R(s, a)]$. To learn these weights θ we use SARSA (Sutton and Barto, 1998), an online learning algorithm similar to Q-learning (Watkins and Dayan, 1992).

Algorithm 1 details the learning algorithm, which we follow here. We iterate over training documents $d \in D$. In a given state s_t, we act according to a probabilistic policy defined in terms of the Q function. After every transition we update θ, which changes how we act in subsequent steps.

Exploration is a key issue in any RL algorithm. If we act greedily with respect to our current Q function, we might never visit states which are actually higher in value. We utilize Boltzmann exploration, for which

$$\Pr(a_t|s_t;\theta) = \frac{\exp(\frac{1}{\tau}\theta^{\mathrm{T}}\phi(s_t, a_t))}{\sum_{a'}\exp(\frac{1}{\tau}\theta^{\mathrm{T}}\phi(s_t, a'))} \quad (5)$$

The parameter τ is referred to as the *temperature*, with a higher temperature causing more exploration, and a lower temperature causing more exploitation. In our experiments $\tau = 2$.

Acting with this exploration policy, we iterate through the training dialogs, updating our feature weights θ as we go. The update step looks at two successive state transitions. Suppose we are in state s_t, execute action a_t, receive reward $r_t = R(s_t, a_t)$, transition to state s_{t+1}, and there choose action a_{t+1}. The variables of interest are $(s_t, a_t, r_t, s_{t+1}, a_{t+1})$, which motivates the name SARSA.

Our current estimate of the Q function is $Q(s, a) = \theta^{\mathrm{T}}\phi(s, a)$. By the Bellman equation, for the true Q function

$$Q(s_t, a_t) = R(s_t, a_t) + \max_{a'} Q(s_{t+1}, a') \quad (6)$$

After each action, we want to move θ to minimize the *temporal difference*,

$$R(s_t, a_t) + Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t) \quad (7)$$

Input: Dialog set D
Reward function R
Feature function ϕ
Transition function T
Learning rate α_t
Output: Feature weights θ

Initialize θ to small random values
until θ *converges* **do**
  foreach *Dialog* $d \in D$ **do**
    Initialize $s_0 = (l_1, u_1, \emptyset)$,
    $a_0 \sim \Pr(a_0|s_0;\theta)$
    for $t = 0$*;* s_t *non-terminal;* $t{+}{+}$ **do**
      Act: $s_{t+1} = T(s_t, a_t)$
      Decide: $a_{t+1} \sim \Pr(a_{t+1}|s_{t+1};\theta)$
      Update:
      $\Delta \leftarrow R(s_t, a_t) + \theta^{\mathrm{T}}\phi(s_{t+1}, a_{t+1})$
        $- \theta^{\mathrm{T}}\phi(s_t, a_t)$
      $\theta \leftarrow \theta + \alpha_t\phi(s_t, a_t)\Delta$
    end
  end
end
return θ

Algorithm 1: The SARSA learning algorithm.

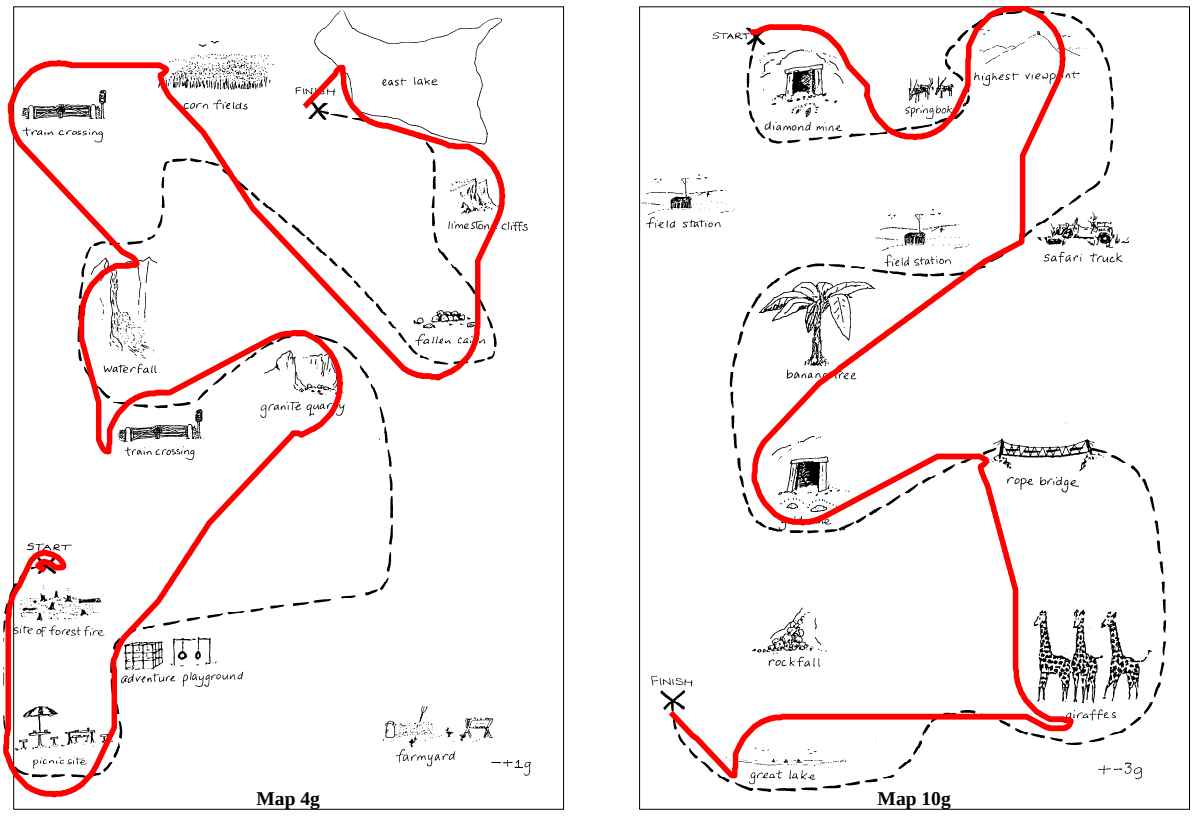

Figure 4: Sample output from the SARSA policy. The dashed black line is the reference path and the solid red line is the path the system follows.

For each feature $\phi_i(s_t, a_t)$, we change θ_i proportional to this temporal difference, tempered by a learning rate α_t. We update θ according to

$$\theta = \theta + \alpha_t \phi(s_t, a_t)(R(s_t, a_t) + \theta^{\mathrm{T}} \phi(s_{t+1}, a_{t+1}) - \theta^{\mathrm{T}} \phi(s_t, a_t)) \quad (8)$$

Here α_t is the learning rate, which decays over time[4]. In our case, $\alpha_t = \frac{10}{10+t}$, which was tuned on the training set. We determine convergence of the algorithm by examining the magnitude of updates to θ. We stop the algorithm when

$$||\theta_{t+1} - \theta_t||_\infty < \epsilon \quad (9)$$

6 Experimental Design

We evaluate our system on the Map Task corpus, splitting the corpus into 96 training dialogs and 32 test dialogs. The whole corpus consists of approximately 105,000 word tokens. The maps seen at test time do not occur in the training set, but some of the human participants are present in both.

[4]To guarantee convergence, we require $\sum_t \alpha_t = \infty$ and $\sum_t \alpha_t^2 < \infty$. Intuitively, the sum diverging guarantees we can still learn arbitrarily far into the future, and the sum of squares converging guarantees that our updates will converge at some point.

6.1 Evaluation

We evaluate how closely the path P generated by our system follows the expert path P_e. We measure this with respect to two metrics: the order in which we visit landmarks and the side we pass them on.

To determine the order P_e visits landmarks we compute the minimum distance from P_e to each landmark, and threshold it at a fixed value.

To score path P, we compare the order it visits landmarks to the expert path. A transition $l \rightarrow l'$ which occurs in P counts as correct if the same transition occurs in P_e. Let $|P|$ be the number of landmark transitions in a path P, and N the number of correct transitions in P. We define the *order precision* as $N/|P|$, and the *order recall* as $N/|P_e|$.

We also evaluate how well we are at passing landmarks on the correct side. We calculate the distance of P_e to each side of the landmark, considering the path to visit a side of the landmark if the distance is below a threshold. This means that a path might be considered to visit multiple sides of a landmark, although in practice it is usu-

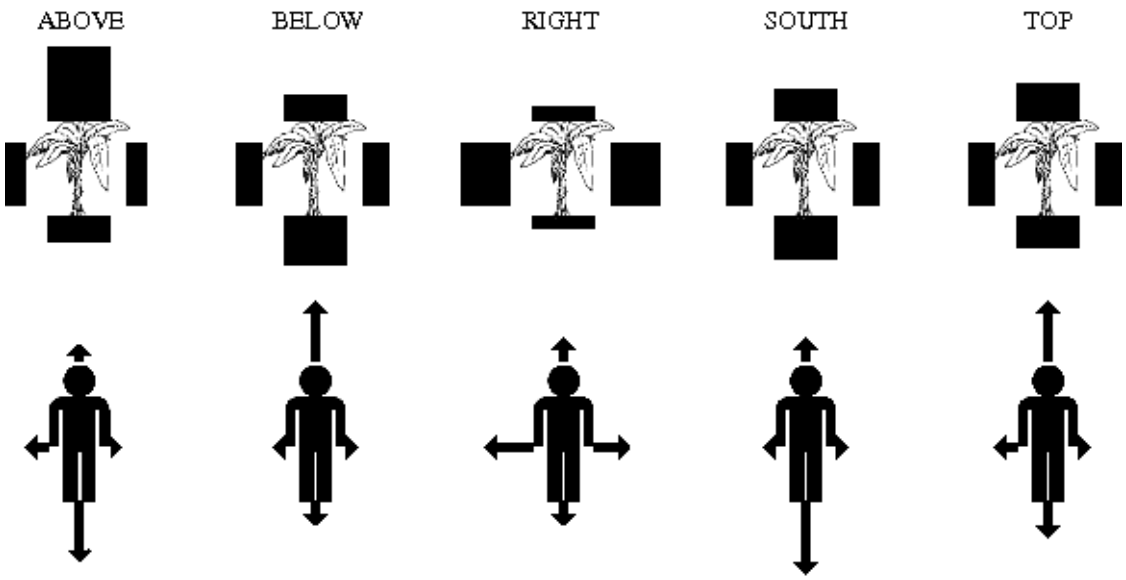

Figure 5: This figure shows the relative weights of spatial features organized by spatial word. The top row shows the weights of allocentric (landmark-centered) features. For example, the top left figure shows that when the word *above* occurs, our policy prefers to go to the north of the target landmark. The bottom row shows the weights of egocentric (absolute) spatial features. The bottom left figure shows that given the word *above*, our policy prefers to move in a southerly cardinal direction.

ally one. If C is the number of landmarks we pass on the correct side, define the *side precision* as $C/|P|$, and the *side recall* as $C/|P_e|$.

6.2 Comparison Systems

The baseline policy simply visits the closest landmark at each step, taking the side of the landmark which is closest. It pays no attention to the direction language.

We also compare against the policy gradient learning algorithm of Branavan et al. (2009). They parametrize a probabilistic policy $\Pr(s|a;\theta)$ as a log-linear model, in a similar fashion to our exploration policy. During training, the learning algorithm adjusts the weights θ according to the gradient of the value function defined by this distribution.

Reinforcement learning algorithms can be classified into *value* based and *policy* based. Value methods estimate a value function V for each state, then act greedily with respect to it. Policy learning algorithms directly search through the space of policies. SARSA is a value based method, and the policy gradient algorithm is policy based.

	Visit Order			Side		
	P	R	F_1	P	R	F_1
Baseline	28.4	37.2	32.2	46.1	60.3	52.2
PG	31.1	43.9	36.4	49.5	**69.9**	57.9
SARSA	**45.7**	**51.0**	**48.2**	**58.0**	64.7	**61.2**

Table 2: Experimental results. Visit order shows how well we follow the order in which the answer path visits landmarks. 'Side' shows how successfully we pass on the correct side of landmarks.

7 Results

Table 2 details the quantitative performance of the different algorithms. Both SARSA and the policy gradient method outperform the baseline, but still fall significantly short of expert performance. The baseline policy performs surprisingly well, especially at selecting the correct side to visit a landmark.

The disparity between learning approaches and gold standard performance can be attributed to several factors. The language in this corpus is conversational, frequently ungrammatical, and contains troublesome aspects of dialog such as conversational repairs and repetition. Secondly, our action and feature space are relatively primitive, and don't capture the full range of spatial expression. Path descriptors, such as the difference between *around* and *past* are absent, and our feature

representation is relatively simple.

The SARSA learning algorithm accrues more reward than the policy gradient algorithm. Like most gradient based optimization methods, policy gradient algorithms oftentimes get stuck in local maxima, and are sensitive to the initial conditions. Furthermore, as the size of the feature vector K increases, the space becomes even more difficult to search. There are no guarantees that SARSA has reached the best policy under our feature space, and this is difficult to determine empirically. Thus, some accuracy might be gained by considering different RL algorithms.

8 Discussion

Examining the feature weights θ sheds some light on our performance. Figure 5 shows the relative strength of weights for several spatial terms. Recall that the two main classes of spatial features in ϕ are egocentric (what direction we move in) and allocentric (on which side we pass a landmark), combined with each spatial word.

Allocentric terms such as *above* and *below* tend to be interpreted as going to the north and south of landmarks, respectively. Interestingly, our system tends to move in the opposite cardinal direction, i.e. the agent moves south in the egocentric frame of reference. This suggests that people use *above* when we are already above a landmark. *South* slightly favors passing on the south side of landmarks, and has a heavy tendency to move in a southerly direction. This suggests that south is used more frequently in an egocentric reference frame.

Our system has difficulty learning the meaning of *right*. *Right* is often used as a conversational filler, and also for dialog alignment, such as

> "right okay right go vertically up then between the springboks and the highest viewpoint."

Furthermore, *right* can be used in both an egocentric or allocentric reference frame. Compare

> "go to the uh right of the mine"

which utilizes an allocentric frame, with

> "right then go eh uh to your right horizontally"

which uses an egocentric frame of reference. It is difficult to distinguish between these meanings without syntactic features.

9 Conclusion

We presented a reinforcement learning system which learns to interpret natural language directions. Critically, our approach uses no semantic annotation, instead learning directly from human demonstration. It successfully acquires a subset of spatial semantics, using reinforcement learning to derive the correspondence between instruction language and features of paths. While our results are still preliminary, we believe our model represents a significant advance in learning natural language meaning, drawing its supervision from human demonstration rather than word distributions or hand-labeled semantic tags. Framing language acquisition as apprenticeship learning is a fruitful research direction which has the potential to connect the symbolic, linguistic domain to the non-symbolic, sensory aspects of cognition.

Abstract

Scoring sentences in documents given abstract summaries created by humans is important in extractive multi-document summarization. In this paper, we formulate extractive summarization as a two step learning problem building a generative model for pattern discovery and a regression model for inference. We calculate scores for sentences in document clusters based on their latent characteristics using a hierarchical topic model. Then, using these scores, we train a regression model based on the lexical and structural characteristics of the sentences, and use the model to score sentences of new documents to form a summary. Our system advances current state-of-the-art improving ROUGE scores by ∼7%. Generated summaries are less redundant and more coherent based upon manual quality evaluations.

1 Introduction

Extractive approach to multi-document summarization (MDS) produces a summary by selecting sentences from original documents. Document Understanding Conferences (DUC), now TAC, fosters the effort on building MDS systems, which take document clusters (documents on a same topic) and description of the desired summary focus as input and output a word length limited summary. Human summaries are provided for training summarization models and measuring the performance of machine generated summaries.

Extractive summarization methods can be classified into two groups: supervised methods that rely on provided document-summary pairs, and unsupervised methods based upon properties derived from document clusters. Supervised methods treat the summarization task as a classification/regression problem, e.g., (Shen et al., 2007; Yeh et al., 2005). Each candidate sentence is classified as summary or non-summary based on the features that they pose and those with highest scores are selected. Unsupervised methods aim to score sentences based on semantic groupings extracted from documents, e.g., (Daumé III and Marcu, 2006; Titov and McDonald, 2008; Tang et al., 2009; Haghighi and Vanderwende, 2009; Radev et al., 2004; Branavan et al., 2009), etc. Such models can yield comparable or better performance on DUC and other evaluations, since representing documents as topic distributions rather than bags of words diminishes the effect of lexical variability. To the best of our knowledge, there is no previous research which utilizes the best features of both approaches for MDS as presented in this paper.

In this paper, we present a novel approach that formulates MDS as a prediction problem based on a two-step hybrid model: a generative model for hierarchical topic discovery and a regression model for inference. We investigate if a hierarchical model can be adopted to discover salient characteristics of sentences organized into hierarchies utilizing human generated summary text.

We present a probabilistic topic model on sentence level building on hierarchical Latent Dirichlet Allocation (hLDA) (Blei et al., 2003a), which is a generalization of LDA (Blei et al., 2003b). We construct a hybrid learning algorithm by extracting salient features to characterize summary sentences, and implement a regression model for inference (Fig.3). Contributions of this work are:
− construction of hierarchical probabilistic model designed to discover the topic structures of all sentences. Our focus is on identifying similarities of candidate sentences to summary sentences using a novel tree based sentence scoring algorithm, concerning topic distributions at different levels of the discovered hierarchy as described in § 3 and § 4,
− representation of sentences by meta-features to

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 815–824,
Uppsala, Sweden, 11-16 July 2010.

characterize their candidacy for inclusion in summary text. Our aim is to find features that can best represent summary sentences as described in § 5,
– implementation of a feasible inference method based on a regression model to enable scoring of sentences in test document clusters without retraining, (which has not been investigated in generative summarization models) described in § 5.2.

We show in § 6 that our hybrid summarizer achieves comparable (if not better) ROUGE score on the challenging task of extracting the summaries of multiple newswire documents. The human evaluations confirm that our hybrid model can produce coherent and non-redundant summaries.

2 Background and Motivation

There are many studies on the principles governing multi-document summarization to produce coherent and semantically relevant summaries. Previous work (Nenkova and Vanderwende, 2005; Conroy et al., 2006), focused on the fact that frequency of words plays an important factor. While, earlier work on summarization depend on a word score function, which is used to measure sentence rank scores based on (semi-)supervised learning methods, recent trend of purely data-driven methods, (Barzilay and Lee, 2004; Daumé III and Marcu, 2006; Tang et al., 2009; Haghighi and Vanderwende, 2009), have shown remarkable improvements. Our work builds on both methods by constructing a hybrid approach to summarization.

Our objective is to discover from document clusters, the latent topics that are organized into hierarchies following (Haghighi and Vanderwende, 2009). A hierarchical model is particularly appealing to summarization than a "flat" model, e.g. LDA (Blei et al., 2003b), in that one can discover "abstract" and "specific" topics. For instance, discovering that "baseball" and "football" are both contained in an abstract class "sports" can help to identify summary sentences. It follows that summary topics are commonly shared by many documents, while specific topics are more likely to be mentioned in rather a small subset of documents.

Feature based learning approaches to summarization methods discover salient features by measuring similarity between candidate sentences and summary sentences (Nenkova and Vanderwende, 2005; Conroy et al., 2006). While such methods are effective in extractive summarization, the fact that some of these methods are based on greedy algorithms can limit the application areas. Moreover, using information on the hidden semantic structure of document clusters would improve the performance of these methods.

Recent studies focused on the discovery of latent topics of document sets in extracting summaries. In these models, the challenges of inferring topics of test documents are not addressed in detail. One of the challenges of using a previously trained topic model is that the new document might have a totally new vocabulary or may include many other specific topics, which may or may not exist in the trained model. A common method is to re-build a topic model for new sets of documents (Haghighi and Vanderwende, 2009), which has proven to produce coherent summaries. An alternative yet feasible solution, presented in this work, is building a model that can summarize new document clusters using characteristics of topic distributions of training documents. Our approach differs from the early work, in that, we combine a generative hierarchical model and regression model to score sentences in new documents, eliminating the need for building a generative model for new document clusters.

3 Summary-Focused Hierarchical Model

Our MDS system, hybrid hierarchical summarizer, **HybHSum**, is based on an hybrid learning approach to extract sentences for generating summary. We discover hidden topic distributions of sentences in a given document cluster along with provided summary sentences based on hLDA described in (Blei et al., 2003a)[1]. We build a summary-focused hierarchical probabilistic topic model, sumHLDA, for each document cluster at sentence level, because it enables capturing expected topic distributions in given sentences directly from the model. Besides, document clusters contain a relatively small number of documents, which may limit the variability of topics if they are evaluated on the document level. As described in § 4, we present a new method for scoring candidate sentences from this hierarchical structure.

Let a given document cluster D be represented with sentences O=$\{o_m\}_{m=1}^{|O|}$ and its corresponding human summary be represented with sentences S=$\{s_n\}_{n=1}^{|S|}$. All sentences are comprised of words $V = \{w_1, w_2, ..w_{|V|}\}$ in $\{O \cup S\}$.

[1]Please refer to (Blei et al., 2003b) and (Blei et al., 2003a) for details and demonstrations of topic models.

Summary hLDA (sumHLDA): The hLDA represents distribution of topics in sentences by organizing topics into a tree of a fixed depth L (Fig.1.a). Each candidate sentence o_m is assigned to a path c_{o_m} in the tree and each word w_i in a given sentence is assigned to a hidden topic z_{o_m} at a level l of c_{o_m}. Each node is associated with a topic distribution over words. The sampler method alternates between choosing a new path for each sentence through the tree and assigning each word in each sentence to a topic along that path. The structure of tree is learnt along with the topics using a nested Chinese restaurant process (nCRP) (Blei et al., 2003a), which is used as a prior.

The nCRP is a stochastic process, which assigns probability distributions to infinitely branching and infinitely deep trees. In our model, nCRP specifies a distribution of words into paths in an L-level tree. The assignments of sentences to paths are sampled sequentially: The first sentence takes the initial L-level path, starting with a single branch tree. Later, mth subsequent sentence is assigned to a path drawn from the distribution:

$$\begin{aligned} p(path_{old}, c|m, m_c) &= \frac{m_c}{\gamma+m-1} \\ p(path_{new}, c|m, m_c) &= \frac{\gamma}{\gamma+m-1} \end{aligned} \quad (1)$$

$path_{old}$ and $path_{new}$ represent an existing and novel (branch) path consecutively, m_c is the number of previous sentences assigned to path c, m is the total number of sentences seen so far, and γ is a hyper-parameter which controls the probability of creating new paths. Based on this probability each node can branch out a different number of child nodes proportional to γ. Small values of γ suppress the number of branches.

Summary sentences generally comprise abstract concepts of the content. With sumHLDA we want to capture these abstract concepts in candidate sentences. The idea is to represent each path shared by similar candidate sentences with representative summary sentence(s). We let summary sentences share existing paths generated by similar candidate sentences instead of sampling new paths and influence the tree structure by introducing two separate hyper-parameters for nCRP prior:

- if a summary sentence is sampled, use $\gamma = \gamma_s$,
- if a candidate sentence is sampled, use $\gamma = \gamma_o$.

At each node, we let summary sentences sample a path by choosing only from the existing children of that node with a probability proportional to the number of other sentences assigned to that child. This can be achieved by using a small value for γ_s ($0 < \gamma_s \lll 1$). We only let candidate sentences to have an option of creating a new child node with a probability proportional to γ_o. By choosing $\gamma_s \lll \gamma_o$ we suppress the generation of new branches for summary sentences and modify the γ of nCRP prior in Eq.(1) using γ_s and γ_o hyper-parameters for different sentence types. In the experiments, we discuss the effects of this modification on the hierarchical topic tree.

The following is the generative process for sumHLDA used in our `HybHSum` :

(1) For each topic $k \in T$, sample a distribution $\beta_k \backsim$ Dirichlet(η).

(2) For each sentence $d \in \{O \cup S\}$,

(a) if $d \in O$, draw a path $c_d \backsim$ nCRP(γ_o), else if $d \in S$, draw a path $c_d \backsim$ nCRP(γ_s).

(b) Sample L-vector θ_d mixing weights from Dirichlet distribution $\theta_d \sim Dir(\alpha)$.

(c) For each word n, choose: (*i*) level $z_{d,n}|\theta_d$ and (*ii*) word $w_{d,n}|\{z_{d,n}, c_d, \beta\}$

Given sentence d, θ_d is a vector of topic proportions from L dimensional Dirichlet parameterized by α (distribution over levels in the tree.) The nth word of d is sampled by first choosing a level $z_{d,n} = l$ from the discrete distribution θ_d with probability $\theta_{d,l}$. Dirichlet parameter η and γ_o control the size of tree effecting the number of topics. (Small values of γ_s do not effect the tree.) Large values of η favor more topics (Blei et al., 2003a).

Model Learning: Gibbs sampling is a common method to fit the hLDA models. The aim is to obtain the following samples from the posterior of: (*i*) the latent tree T, (*ii*) the level assignment **z** for all words, (*iii*) the path assignments **c** for all sentences conditioned on the observed words **w**.

Given the assignment of words **w** to levels **z** and assignments of sentences to paths **c**, the expected posterior probability of a particular word w at a given topic **z**=l of a path **c**=c is proportional to the number of times w was generated by that topic:

$$p(w|\mathbf{z}, \mathbf{c}, \mathbf{w}, \eta) \propto n_{(\mathbf{z}=l, \mathbf{c}=c, \mathbf{w}=w)} + \eta \quad (2)$$

Similarly, posterior probability of a particular topic z in a given sentence d is proportional to number of times z was generated by that sentence:

$$p(z|\mathbf{z}, \mathbf{c}, \alpha) \propto n_{(\mathbf{c}=c_d, \mathbf{z}=l)} + \alpha \quad (3)$$

$n_{(.)}$ is the count of elements of an array satisfying the condition. Note from Eq.(3) that two sentences d_1 and d_2 on the same path **c** would have

different words, and hence different posterior topic probabilities. Posterior probabilities are normalized with total counts and their hyperparameters.

4 Tree-Based Sentence Scoring

The sumHLDA constructs a hierarchical tree structure of candidate sentences (per document cluster) by positioning summary sentences on the tree. Each sentence is represented by a path in the tree, and each path can be shared by many sentences. The assumption is that sentences sharing the same path should be more similar to each other because they share the same topics. Moreover, if a path includes a summary sentence, then candidate sentences on that path are more likely to be selected for summary text. In particular, the similarity of a candidate sentence o_m to a summary sentence s_n sharing the same path is a measure of strength, indicating how likely o_m is to be included in the generated summary (Algorithm 1):

Let c_{o_m} be the path for a given o_m. We find summary sentences that share the same path with o_m via: $M = \{s_n \in S | c_{s_n} = c_{o_m}\}$. The score of each sentence is calculated by similarity to the best matching summary sentence in M:

$$score(o_m) = \max_{s_n \in M} sim(o_m, s_n) \quad (4)$$

If *M*=∅, then *score(*o_m*)*=∅. The efficiency of our similarity measure in identifying the best matching summary sentence, is tied to how expressive the extracted topics of our sumHLDA models are. Given path c_{o_m}, we calculate the similarity of o_m to each s_n, *n*=1..$|M|$ by measuring similarities on:

⋆ **sparse unigram distributions** (sim_1) at each topic l on c_{o_m}: similarity between $p(\mathbf{w}_{o_m,l}|\mathbf{z}_{o_m} = l, c_{o_m}, v_l)$ and $p(\mathbf{w}_{s_n,l}|\mathbf{z}_{s_n} = l, c_{o_m}, v_l)$

⋆⋆ **distributions of topic proportions** (sim_2); similarity between $p(\mathbf{z}_{o_m}|c_{o_m})$ and $p(\mathbf{z}_{s_n}|c_{o_m})$.

− ***sim***$_1$***:*** We define two sparse (discrete) unigram distributions for candidate o_m and summary s_n at each node l on a vocabulary identified with words generated by the topic at that node, $v_l \subset V$. Given $\mathbf{w}_{o_m} = \{w_1, ..., w_{|o_m|}\}$, let $\mathbf{w}_{o_m,l} \subset \mathbf{w}_{o_m}$ be the set of words in o_m that are generated from topic $\mathbf{z}_{o_m}$ at level l on path c_{o_m}. The discrete unigram distribution $p_{o_m l} = p(\mathbf{w}_{o_m,l}|\mathbf{z}_{o_m} = l, c_{o_m}, v_l)$ represents the probability over all words v_l assigned to topic $\mathbf{z}_{o_m}$ at level l, by sampling only for words in $\mathbf{w}_{o_m,l}$. Similarly, $p_{s_n,l} = p(\mathbf{w}_{s_n,l}|\mathbf{z}_{s_n}, c_{o_m}, v_l)$ is the probability of words $\mathbf{w}_{s_n}$ in s_n of the same topic. The probability of each word in $p_{o_m,l}$ and $p_{s_n,l}$ are obtained using Eq. (2) and then normalized (see Fig.1.b).

Algorithm 1 Tree-Based Sentence Scoring

```
Given tree T from sumHLDA, candidate and summary
  sentences:  O = {o_1, ..., o_m} , S = {s_1, ..., s_n}
for sentences m ← 1, ..., |O| do
    - Find path c_{o_m} on tree T and summary sentences
    on path c_{o_m}: M = {s_n ∈ S | c_{s_n} = c_{o_m}}
    for summary sentences n ← 1, ..., |M| do
        - Find score(o_m)=max_{s_n} sim(o_m, s_n),
        where sim(o_m, s_n) = sim_1 * sim_2
        using Eq.(7) and Eq.(8)
    end for
end for
Obtain scores Y = {score(o_m)}_{m=1}^{|O|}
```

The similarity between $p_{o_m,l}$ and $p_{s_n,l}$ is obtained by first calculating the divergence with *information radius- IR* based on Kullback-Liebler(KL) divergence, *p*=$p_{o_m,l}$, *q*=$p_{s_n,l}$:

$$IR_{c_{o_m},l}(p_{o_m,l}, p_{s_n,l}) = KL\left(p||\tfrac{p+q}{2}\right) + KL\left(q||\tfrac{p+q}{2}\right) \quad (5)$$

where, $KL(p||q) = \sum_i p_i \log \frac{p_i}{q_i}$. Then the divergence is transformed into a similarity measure (Manning and Schuetze, 1999):

$$W_{c_{o_m},l}(p_{o_m,l}, p_{s_n,l}) = 10^{-IR_{c_{o_m},l}(p_{o_m,l}, p_{s_n,l})} \quad (6)$$

IR is a measure of total divergence from the average, representing how much information is lost when two distributions p and q are described in terms of average distributions. We opted for *IR* instead of the commonly used *KL* because with *IR* there is no problem with infinite values since $\frac{p_i+q_i}{2} \neq 0$ if either $p_i \neq 0$ or $q_i \neq 0$. Moreover, unlike *KL*, *IR* is symmetric, i.e., *KL(p,q)≠KL(q,p)*.

Finally sim_1 is obtained by average similarity of sentences using Eq.(6) at each level of c_{o_m} by:

$$sim_1(o_m, s_n) = \frac{1}{L} \sum_{l=1}^{L} W_{c_{o_m},l}(p_{o_m,l}, p_{s_n,l}) * l \quad (7)$$

The similarity between $p_{o_m,l}$ and $p_{s_n,l}$ at each level is weighted proportional to the level l because the similarity between sentences should be rewarded if there is a specific word overlap at child nodes.

−***sim***$_2$***:*** We introduce another measure based on sentence-topic mixing proportions to calculate the concept-based similarities between o_m and s_n. We calculate the topic proportions of o_m and s_n, represented by $p_{z_{o_m}} = p(\mathbf{z}_{o_m}|c_{o_m})$ and $p_{z_{s_n}} = p(\mathbf{z}_{s_n}|c_{o_m})$ via Eq.(3). The similarity between the distributions is then measured with transformed IR

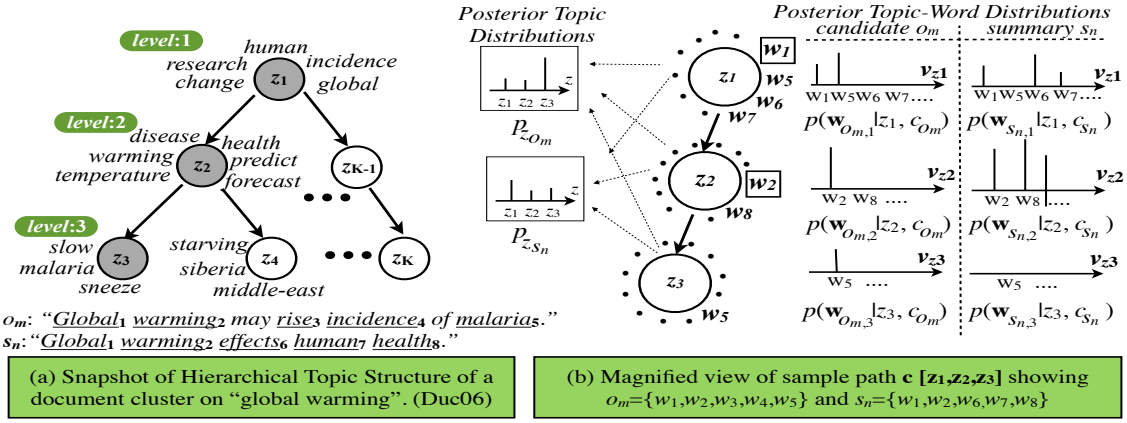

Figure 1: (a) A sample 3-level tree using sumHLDA. Each sentence is associated with a path c through the hierarchy, where each node $z_{l,c}$ is associated with a distribution over terms (Most probable terms are illustrated). (b) magnified view of a path (darker nodes) in (a). Distribution of words in given two sentences, a candidate (o_m) and a summary (s_n) using sub-vocabulary of words at each topic v_{z_l}. Discrete distributions on the left are topic mixtures for each sentence, $p_{z_{o_m}}$ and $p_{z_{s_n}}$.

as in Eq.(6) by:

$$sim_2(o_m, s_n) = 10^{-IR_{c_{o_m}}(p_{z_{o_m}}, p_{z_{s_n}})} \quad (8)$$

sim_1 provides information about the similarity between two sentences, o_m and s_n based on topic-word distributions. Similarly, sim_2 provides information on the similarity between the weights of the topics in each sentence. They jointly effect the sentence score and are combined in one measure:

$$sim(o_m, s_n) = sim_1(o_m, s_n) * sim_2(o_m, s_n) \quad (9)$$

The final score for a given o_m is calculated from Eq.(4). Fig.1.b depicts a sample path illustrating sparse unigram distributions of o_m and s_m at each level as well as their topic proportions, $p_{z_{o_m}}$, and $p_{z_{s_n}}$. In experiment 3, we discuss the effect of our tree-based scoring on summarization performance in comparison to a classical scoring method presented as our *baseline* model.

5 Regression Model

Each candidate sentence o_m, $m = 1..|O|$ is represented with a multi-dimensional vector of q features $\mathbf{f}_m = \{f_{m1}, ..., f_{mq}\}$. We build a regression model using sentence scores as output and selected salient features as input variables described below:

5.1 Feature Extraction

We compile our training dataset using sentences from different document clusters, which do not necessarily share vocabularies. Thus, we create n-gram *meta*-features to represent sentences instead of word n-gram frequencies:

(I) nGram Meta-Features (NMF): For each document cluster D, we identify most frequent (non-stop word) unigrams, i.e., $v_{freq} = \{w_i\}_{i=1}^{r} \subset V$, where r is a model parameter of number of most frequent unigram features. We measure observed unigram probabilities for each $w_i \in v_{freq}$ with $p_D(w_i) = n_D(w_i)/\sum_{j=1}^{|V|} n_D(w_j)$, where $n_D(w_i)$ is the number of times w_i appears in D and $|V|$ is the total number of unigrams. For any ith feature, the value is $f_{mi} = 0$, if given sentence does not contain w_i, otherwise $f_{mi} = p_D(w_i)$. These features can be extended for any n-grams. We similarly include bigram features in the experiments.

(II) Document Word Frequency Meta-Features (DMF): The characteristics of sentences at the document level can be important in summary generation. DMF identify whether a word in a given sentence is specific to the document in consideration or it is commonly used in the document cluster. This is important because summary sentences usually contain abstract terms rather than specific terms.

To characterize this feature, we re-use the r most frequent unigrams, i.e., $w_i \in v_{freq}$. Given sentence o_m, let d be the document that o_m belongs to, i.e., $o_m \in d$. We measure unigram probabilities for each w_i by $p(w_i \in o_m) = n_d(w_i \in o_m)/n_D(w_i)$, where $n_d(w_i \in o_m)$ is the number of times w_i appears in d and $n_D(w_i)$ is the number of times w_i appears in D. For any ith feature, the value is $f_{mi} = 0$, if given sentence does not contain w_i, otherwise $f_{mi} = p(w_i \in o_m)$. We also include bigram extensions of DMF features.

(III) Other Features (OF): Term frequency of sentences such as SUMBASIC are proven to be good predictors in sentence scoring (Nenkova and Vanderwende, 2005). We measure the average unigram probability of a sentence by: $p(o_m) = \sum_{w \in o_m} \frac{1}{|o_m|} P_D(w)$, where $P_D(w)$ is the observed unigram probability in the document collection D and $|o_m|$ is the total number of words in o_m. We use sentence bigram frequency, sentence rank in a document, and sentence size as additional features.

5.2 Predicting Scores for New Sentences

Due to the large feature space to explore, we chose to work with support vector regression (SVR) (Drucker et al., 1997) as the learning algorithm to predict sentence scores. Given training sentences $\{\mathbf{f}_m, y_m\}_{m=1}^{|O|}$, where $f_m = \{f_{m1}, ..., f_{mq}\}$ is a multi-dimensional vector of features and y_m=*score*$(o_m) \in \mathbb{R}$ are their scores obtained via Eq.(4), we train a regression model. In experiments we use non-linear Gaussian kernel for SVR. Once the SVR model is trained, we use it to predict the scores of n_{test} number of sentences in test (*unseen*) document clusters, $O_{test} = \{o_1, ...o_{|O_{test}|}\}$.

Our HybHSum captures the sentence characteristics with a regression model using sentences in different document clusters. At test time, this valuable information is used to score testing sentences.

Redundancy Elimination: To eliminate redundant sentences in the generated summary, we incrementally add onto the summary the highest ranked sentence o_m and check if o_m significantly repeats the information already included in the summary until the algorithm reaches word count limit. We use a word overlap measure between sentences normalized to sentence length. A o_m is discarded if its similarity to any of the previously selected sentences is greater than a threshold identified by a greedy search on the training dataset.

6 Experiments and Discussions

In this section we describe a number of experiments using our hybrid model on 100 document clusters each containing 25 news articles from DUC2005-2006 tasks. We evaluate the performance of HybHSum using 45 document clusters each containing 25 news articles from DUC2007 task. From these sets, we collected $\backsim$80K and $\backsim$25K sentences to compile training and testing data respectively. The task is to create max. 250 word long summary for each document cluster.

We use Gibbs sampling for inference in hLDA and sumHLDA. The hLDA is used to capture abstraction and specificity of words in documents (Blei et al., 2009). Contrary to typical hLDA models, to efficiently represent sentences in summarization task, we set ascending values for Dirichlet hyper-parameter η as the level increases, encouraging mid to low level distributions to generate as many words as in higher levels, e.g., for a tree of depth=3, $\eta = \{0.125, 0.5, 1\}$. This causes sentences share paths only when they include similar concepts, starting higher level topics of the tree. For SVR, we set $\epsilon = 0.1$ using the default choice, which is the inverse of the average of $\phi(\mathbf{f})^T \phi(\mathbf{f})$ (Joachims, 1999), dot product of kernelized input vectors. We use greedy optimization during training based on ROUGE scores to find best regularizer $C = \{10^{-1}..10^{2}\}$ using the Gaussian kernel.

We applied feature extraction of § 5.1 to compile the training and testing datasets. ROUGE is used for performance measure (Lin and Hovy, 2003; Lin, 2004), which evaluates summaries based on the maxium number of overlapping units between generated summary text and a set of human summaries. We use R-1 (recall against unigrams), R-2 (recall against bigrams), and R-SU4 (recall against skip-4 bigrams).

Experiment 1: sumHLDA Parameter Analysis: In sumHLDA we introduce a prior different than the standard nested CRP (nCRP). Here, we illustrate that this prior is practical in learning hierarchical topics for summarization task.

We use sentences from the human generated summaries during the discovery of hierarchical topics of sentences in document clusters. Since summary sentences generally contain abstract words, they are indicative of sentences in documents and should produce minimal amount of new topics (if not none). To implement this, in nCRP prior of sumHLDA, we use dual hyper-parameters and choose a very small value for summary sentences, $\gamma_s = 10e^{-4} \ll \gamma_o$. We compare the results to hLDA (Blei et al., 2003a) with nCRP prior which uses only one free parameter, γ. To analyze this prior, we generate a corpus of $\backsim$1300 sentences of a document cluster in DUC2005. We repeated the experiment for 9 other clusters of similar size and averaged the total number of generated topics. We show results for different values of γ and γ_o hyper-parameters and tree depths.

$\gamma = \gamma_o$	**0.1**			**1**			**10**		
depth	**3**	**5**	**8**	**3**	**5**	**8**	**3**	**5**	**8**
hLDA	3	5	8	41	267	1509	1522	4080	8015
sumHLDA	3	5	8	27	162	671	1207	3598	7050

Table 1: Average # of topics per document cluster from sumHLDA and hLDA for different γ and γ_o and tree depths. $\gamma_s = 10e^{-4}$ is used for sumHLDA for each depth.

Features	Baseline			HybHSum		
	R-1	R-2	R-SU4	R-1	R-2	R-SU4
NMF (1)	40.3	7.8	13.7	41.6	8.4	12.3
DMF (2)	41.3	7.5	14.3	41.3	8.0	13.9
OF (3)	40.3	7.4	13.7	**42.4**	8.0	14.4
(1+2)	41.5	7.9	14.0	41.8	8.5	14.5
(1+3)	40.8	7.5	13.8	41.6	8.2	14.1
(2+3)	40.7	7.4	13.8	**42.7**	**8.7**	**14.9**
(1+2+3)	41.4	8.1	13.7	**43.0**	9.1	**15.1**

Table 2: ROUGE results (with stop-words) on DUC2006 for different features and methods. Results in bold show statistical significance over baseline in corresponding metric.

As shown in Table 1, the nCRP prior for sumHLDA is more effective than hLDA prior in the summarization task. Less number of topics(nodes) in sumHLDA suggests that summary sentences share pre-existing paths and no new paths or nodes are sampled for them. We also observe that using $\gamma_o = 0.1$ causes the model to generate minimum number of topics (# of topics=depth), while setting $\gamma_o = 10$ creates excessive amount of topics. $\gamma_0 = 1$ gives reasonable number of topics, thus we use this value for the rest of the experiments. In experiment 3, we use both nCRP priors in HybHSum to analyze whether there is any performance gain with the new prior.

Experiment 2: Feature Selection Analysis

Here we test individual contribution of each set of features on our HybHSum (using sumHLDA). We use a **Baseline** by replacing the scoring algorithm of HybHSum with a simple cosine distance measure. The score of a candidate sentence is the cosine similarity to the maximum matching summary sentence. Later, we build a regression model with the same features as our HybHSum to create a summary. We train models with DUC2005 and evaluate performance on DUC2006 documents for different parameter values as shown in Table 2.

As presented in § 5, NMF is the bundle of frequency based meta-features on document cluster level, DMF is a bundle of frequency based meta-features on individual document level and OF represents sentence term frequency, location, and size features. In comparison to the baseline, OF has a significant effect on the ROUGE scores. In addition, DMF together with OF has shown to improve all scores, in comparison to baseline, on average by 10%. Although the NMF have minimal individual improvement, all these features can statistically improve R-2 without stop words by 12% (significance is measured by t-test statistics).

Experiment 3: ROUGE Evaluations

We use the following multi-document summarization models along with the Baseline presented in Experiment 2 to evaluate HybSumm.

⋆ **PYTHY :** (Toutanova et al., 2007) A state-of-the-art supervised summarization system that ranked first in overall ROUGE evaluations in DUC2007. Similar to HybHSum, human generated summaries are used to train a sentence ranking system using a classifier model.

⋆ **HIERSUM :** (Haghighi and Vanderwende, 2009) A generative summarization method based on topic models, which uses sentences as an additional level. Using an approximation for inference, sentences are greedily added to a summary so long as they decrease KL-divergence.

⋆ **HybFSum (Hybrid Flat Summarizer):** To investigate the performance of hierarchical topic model, we build another hybrid model using flat LDA (Blei et al., 2003b). In LDA each sentence is a superposition of all K topics with sentence specific weights, there is no hierarchical relation between topics. We keep the parameters and the features of the regression model of hierarchical HybHSum intact for consistency. We only change the sentence scoring method. Instead of the new tree-based sentence scoring (§ 4), we present a similar method using topics from LDA on sentence level. Note that in LDA the topic-word distributions ϕ are over entire vocabulary, and topic mixing proportions for sentences θ are over all the topics discovered from sentences in a document cluster. Hence, we define sim_1 and sim_2 measures for LDA using topic-word proportions ϕ (in place of discrete topic-word distributions from each level in Eq.2) and topic mixing weights θ in sentences (in place of topic proportions in Eq.3) respectively. Maximum matching score is calculated as same as in HybHSum.

⋆ **HybHSum**$_1$ and **HybHSum**$_2$: To analyze the effect of the new nCRP prior of sumHLDA on sum-

ROUGE	w/o stop words			w/ stop words		
	R-1	R-2	R-4	R-1	R-2	R-4
Baseline	32.4	7.4	10.6	41.0	9.3	15.2
PYTHY	35.7	8.9	**12.1**	42.6	11.9	16.8
HIERSUM	33.8	**9.3**	11.6	42.4	11.8	16.7
HybFSum	34.5	8.6	10.9	43.6	9.5	15.7
HybHSum_1	34.0	7.9	11.5	44.8	11.0	16.7
HybHSum_2	35.1	8.3	11.8	**45.6**	11.4	**17.2**

Table 3: ROUGE results of the best systems on DUC2007 dataset (best results are **bolded**.)

marization model performance, we build two different versions of our hybrid model: $\textbf{HybHSum}_1$ using standard hLDA (Blei et al., 2003a) and $\textbf{HybHSum}_2$ using our sumHLDA.

The ROUGE results are shown in Table 3. The HybHSum_2 achieves the best performance on R-1 and R-4 and comparable on R-2. When stop words are used the HybHSum_2 outperforms state-of-the-art by 2.5-7% except R-2 (with statistical significance). Note that R-2 is a measure of bigram recall and sumHLDA of HybHSum_2 is built on unigrams rather than bigrams. Compared to the HybFSum built on LDA, both $\text{HybHSum}_{1\&2}$ yield better performance indicating the effectiveness of using hierarchical topic model in summarization task. HybHSum_2 appear to be less redundant than HybFSum capturing not only common terms but also specific words in Fig. 2, due to the new hierarchical tree-based sentence scoring which characterizes sentences on deeper level. Similarly, $\text{HybHSum}_{1\&2}$ far exceeds baseline built on simple classifier. The results justify the performance gain by using our novel tree-based scoring method. Although the ROUGE scores for HybHSum_1 and HybHSum_2 are not significantly different, the sumHLDA is more suitable for summarization tasks than hLDA.

HybHSum_2 is comparable to (if not better than) fully generative HIERSUM. This indicates that with our regression model built on training data, summaries can be efficiently generated for test documents (suitable for online systems).

Experiment 4: Manual Evaluations

Here, we manually evaluate quality of summaries, a common DUC task. Human annotators are given two sets of summary text for each document set, generated from two approaches: best hierarchical hybrid HybHSum_2 and flat hybrid HybFSum models, and are asked to mark the better summary

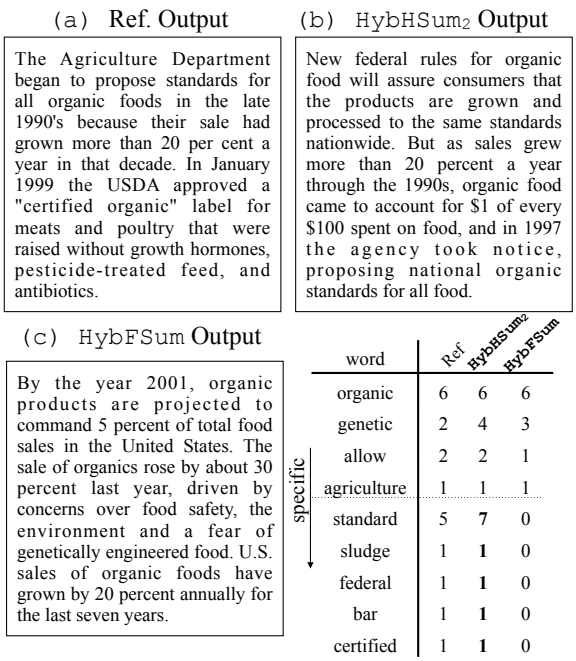

Figure 2: Example summary text generated by systems compared in Experiment 3. (Id:D0744 in DUC2007). Ref. is the human generated summary.

Criteria	HybFSum	HybHSum_2	Tie
Non-redundancy	26	44	22
Coherence	24	56	12
Focus	24	56	12
Responsiveness	30	50	12
Overall	24	66	2

Table 4: Frequency results of manual quality evaluations. Results are statistically significant based on t-test. Tie indicates evaluations where two summaries are rated equal.

according to five criteria: *non-redundancy* (which summary is less redundant), *coherence* (which summary is more coherent), *focus and readability* (content and not include unnecessary details), *responsiveness* and *overall* performance.

We asked 4 annotators to rate DUC2007 predicted summaries (45 summary pairs per annotator). A total of 92 pairs are judged and evaluation results in frequencies are shown in Table 4. The participants rated HybHSum_2 generated summaries more coherent and focused compared to HybFSum. All results in Table 4 are statistically significant (based on t-test on 95% confidence level.) indicating that HybHSum_2 summaries are rated significantly better.

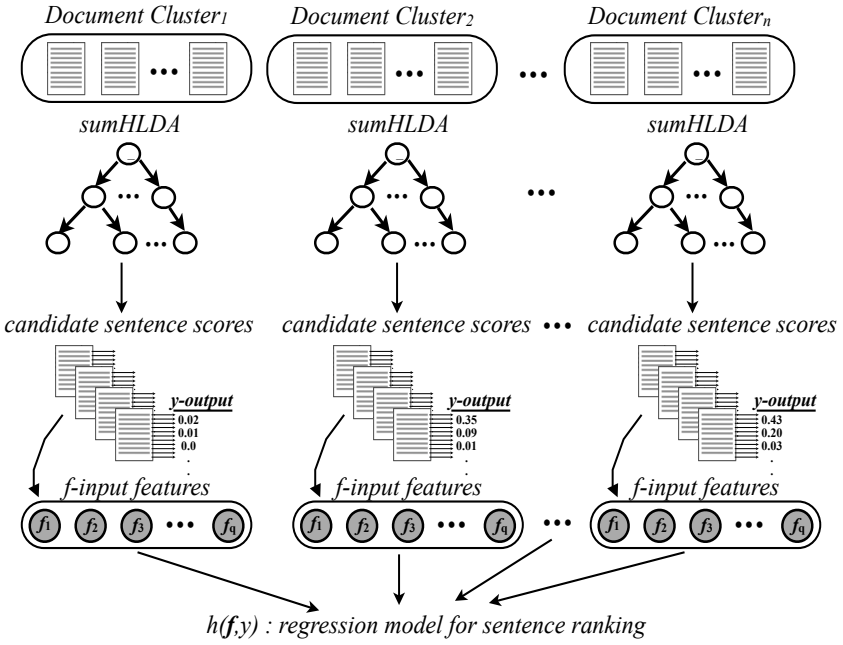

Figure 3: Flow diagram for Hybrid Learning Algorithm for Multi-Document Summarization.

7 Conclusion

In this paper, we presented a hybrid model for multi-document summarization. We demonstrated that implementation of a summary focused hierarchical topic model to discover sentence structures as well as construction of a discriminative method for inference can benefit summarization quality on manual and automatic evaluation metrics.

Abstract

This paper proposes to use monolingual collocations to improve Statistical Machine Translation (SMT). We make use of the collocation probabilities, which are estimated from monolingual corpora, in two aspects, namely improving word alignment for various kinds of SMT systems and improving phrase table for phrase-based SMT. The experimental results show that our method improves the performance of both word alignment and translation quality significantly. As compared to baseline systems, we achieve absolute improvements of 2.40 BLEU score on a phrase-based SMT system and 1.76 BLEU score on a parsing-based SMT system.

1 Introduction

Statistical bilingual word alignment (Brown et al. 1993) is the base of most SMT systems. As compared to single-word alignment, multi-word alignment is more difficult to be identified. Although many methods were proposed to improve the quality of word alignments (Wu, 1997; Och and Ney, 2000; Marcu and Wong, 2002; Cherry and Lin, 2003; Liu et al., 2005; Huang, 2009), the correlation of the words in multi-word alignments is not fully considered.

In phrase-based SMT (Koehn et al., 2003), the phrase boundary is usually determined based on the bi-directional word alignments. But as far as we know, few previous studies exploit the collocation relations of the words in a phrase. Some researches used soft syntactic constraints to predict whether source phrase can be translated together (Marton and Resnik, 2008; Xiong et al., 2009). However, the constraints were learned from the parsed corpus, which is not available for many languages.

In this paper, we propose to use monolingual collocations to improve SMT. We first identify potentially collocated words and estimate collocation probabilities from monolingual corpora using a Monolingual Word Alignment (MWA) method (Liu et al., 2009), which does not need any additional resource or linguistic preprocessing, and which outperforms previous methods on the same experimental data. Then the collocation information is employed to improve Bilingual Word Alignment (BWA) for various kinds of SMT systems and to improve phrase table for phrase-based SMT.

To improve BWA, we re-estimate the alignment probabilities by using the collocation probabilities of words in the same cept. A cept is the set of source words that are connected to the same target word (Brown et al., 1993). An alignment between a source multi-word cept and a target word is a many-to-one multi-word alignment.

To improve phrase table, we calculate phrase collocation probabilities based on word collocation probabilities. Then the phrase collocation probabilities are used as additional features in phrase-based SMT systems.

The evaluation results show that the proposed method in this paper significantly improves multi-word alignment, achieving an absolute error rate reduction of 29%. The alignment improvement results in an improvement of 2.16 BLEU score on phrase-based SMT system and an improvement of 1.76 BLEU score on parsing-based SMT system. If we use phrase collocation probabilities as additional features, the phrase-based

This work was partially done at Toshiba (China) Research and Development Center.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 825–833,
Uppsala, Sweden, 11-16 July 2010.

SMT performance is further improved by 0.24 BLEU score.

The paper is organized as follows: In section 2, we introduce the collocation model based on the MWA method. In section 3 and 4, we show how to improve the BWA method and the phrase table using collocation models respectively. We describe the experimental results in section 5, 6 and 7. Lastly, we conclude in section 8.

2 Collocation Model

Collocation is generally defined as a group of words that occur together more often than by chance (McKeown and Radev, 2000). A collocation is composed of two words occurring as either a consecutive word sequence or an interrupted word sequence in sentences, such as "by accident" or "take ... advice". In this paper, we use the MWA method (Liu et al., 2009) for collocation extraction. This method adapts the bilingual word alignment algorithm to monolingual scenario to extract collocations only from monolingual corpora. And the experimental results in (Liu et al., 2009) showed that this method achieved higher precision and recall than previous methods on the same experimental data.

2.1 Monolingual word alignment

The monolingual corpus is first replicated to generate a parallel corpus, where each sentence pair consists of two identical sentences in the same language. Then the monolingual word alignment algorithm is employed to align the potentially collocated words in the monolingual sentences.

According to Liu et al. (2009), we employ the MWA Model 3 (corresponding to IBM Model 3) to calculate the probability of the monolingual word alignment sequence, as shown in Eq. (1).

$$p_{\mathrm{MWAModel3}}(S, A \mid S) \propto \prod_{i=1}^{l} n(\phi_i \mid w_i) \cdot \prod_{j=1}^{l} t(w_j \mid w_{a_j}) \cdot d(j \mid a_j, l) \quad (1)$$

Where $S = w_1^l$ is a monolingual sentence, ϕ_i denotes the number of words that are aligned with w_i. Since a word never collocates with itself, the alignment set is denoted as $A = \{(i, a_i) \mid i \in [1, l] \,\&\, a_i \neq i\}$. Three kinds of probabilities are involved in this model: word collocation probability $t(w_j \mid w_{a_j})$, position collocation probability $d(j \mid a_j, l)$ and fertility probability $n(\phi_i \mid w_i)$.

In the MWA method, the similar algorithm to bilingual word alignment is used to estimate the parameters of the models, except that a word cannot be aligned to itself.

Figure 1 shows an example of the potentially collocated word pairs aligned by the MWA method.

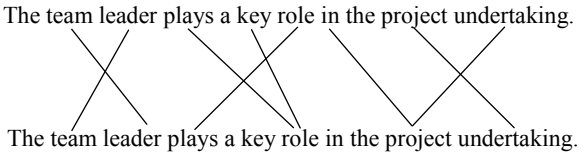

Figure 1. MWA Example

2.2 Collocation probability

Given the monolingual word aligned corpus, we calculate the frequency of two words aligned in the corpus, denoted as $freq(w_i, w_j)$. We filtered the aligned words occurring only once. Then the probability for each aligned word pair is estimated as follows:

$$p(w_i \mid w_j) = \frac{freq(w_i, w_j)}{\sum_{w'} freq(w', w_j)} \quad (2)$$

$$p(w_j \mid w_i) = \frac{freq(w_i, w_j)}{\sum_{w'} freq(w_i, w')} \quad (3)$$

In this paper, the words of collocation are symmetric and we do not determine which word is the head and which word is the modifier. Thus, the collocation probability of two words is defined as the average of both probabilities, as in Eq. (4).

$$r(w_i, w_j) = \frac{p(w_i \mid w_j) + p(w_j \mid w_i)}{2} \quad (4)$$

If we have multiple monolingual corpora to estimate the collocation probabilities, we interpolate the probabilities as shown in Eq. (5).

$$r(w_i, w_j) = \sum_k \alpha_k r_k(w_i, w_j) \quad (5)$$

α_k denotes the interpolation coefficient for the probabilities estimated on the k^{th} corpus.

3 Improving Statistical Bilingual Word Alignment

We use the collocation information to improve both one-directional and bi-directional bilingual word alignments. The alignment probabilities are re-estimated by using the collocation probabilities of words in the same cept.

3.1 Improving one-directional bilingual word alignment

According to the BWA method, given a bilingual sentence pair $E = e_1^l$ and $F = f_1^m$, the optimal alignment sequence A between E and F can be obtained as in Eq. (6).

$$A^* = \arg\max_A p(F, A \mid E) \quad (6)$$

The method is implemented in a series of five models (IBM Models). IBM Model 1 only employs the word translation model to calculate the probabilities of alignments. In IBM Model 2, both the word translation model and position distribution model are used. IBM Model 3, 4 and 5 consider the fertility model in addition to the word translation model and position distribution model. And these three models are similar, except for the word distortion models.

One-to-one and many-to-one alignments could be produced by using IBM models. Although the fertility model is used to restrict the number of source words in a cept and the position distortion model is used to describe the correlation of the positions of the source words, the quality of many-to-one alignments is lower than that of one-to-one alignments.

Intuitively, the probability of the source words aligned to a target word is not only related to the fertility ability and their relative positions, but also related to lexical tokens of words, such as common phrase or idiom. In this paper, we use the collocation probability of the source words in a cept to measure their correlation strength. Given source words $\{f_j \mid a_j = i\}$ aligned to e_i, their collocation probability is calculated as in Eq. (7).

$$r(\{f_j \mid a_j = i\}) = \frac{2\sum_{k=1}^{\phi_i - 1}\sum_{g=k+1}^{\phi_i} r(f_{[i]k}, f_{[i]g})}{\phi_i * (\phi_i - 1)} \quad (7)$$

Here, $f_{[i]k}$ and $f_{[i]g}$ denote the k^{th} word and g^{th} word in $\{f_j \mid a_j = i\}$; $r(f_{[i]k}, f_{[i]g})$ denotes the collocation probability of $f_{[i]k}$ and $f_{[i]g}$, as shown in Eq. (4).

Thus, the collocation probability of the alignment sequence of a sentence pair can be calculated according to Eq. (8).

$$r(F, A \mid E) = \prod_{i=1}^{l} r(\{f_j \mid a_j = i\}) \quad (8)$$

Based on maximum entropy framework, we combine the collocation model and the BWA model to calculate the word alignment probability of a sentence pair, as shown in Eq. (9).

$$p_r(F, A \mid E) = \frac{\exp(\sum_i \lambda_i h_i(F, E, A))}{\sum_{A'} \exp(\sum_i \lambda_i h_i(F, E, A'))} \quad (9)$$

Here, $h_i(F, E, A)$ and λ_i denote features and feature weights, respectively. We use two features in this paper, namely alignment probabilities and collocation probabilities.

Thus, we obtain the decision rule:

$$A^* = \arg\max_A \{\sum_i \lambda_i h_i(F, E, A)\} \quad (10)$$

Based on the GIZA++ package[1], we implemented a tool for the improved BWA method. We first train IBM Model 4 and collocation model on bilingual corpus and monolingual corpus respectively. Then we employ the hill-climbing algorithm (Al-Onaizan et al., 1999) to search for the optimal alignment sequence of a given sentence pair, where the score of an alignment sequence is calculated as in Eq. (10).

We note that Eq. (8) only deals with many-to-one alignments, but the alignment sequence of a sentence pair also includes one-to-one alignments. To calculate the collocation probability of the alignment sequence, we should also consider the collocation probabilities of such one-to-one alignments. To solve this problem, we use the collocation probability of the whole source sentence, $r(F)$, as the collocation probability of one-word cept.

3.2 Improving bi-directional bilingual word alignments

In word alignment models implemented in GIZA++, only one-to-one and many-to-one word alignment links can be found. Thus, some multi-word units cannot be correctly aligned. The symmetrization method is used to effectively overcome this deficiency (Och and Ney, 2003). Bi-directional alignments are generally obtained from source-to-target alignments A_{s2t} and target-to-source alignments A_{t2s}, using some heuristic rules (Koehn et al., 2005). This method ignores the correlation of the words in the same alignment unit, so an alignment may include many unrelated words[2], which influences the performances of SMT systems.

[1] http://www.fjoch.com/GIZA++.html

[2] In our experiments, a multi-word unit may include up to 40 words.

In order to solve the above problem, we incorporate the collocation probabilities into the bi-directional word alignment process.

Given alignment sets A_{s2t} and A_{t2s}. We can obtain the union $A_{s\leftrightarrow t} = A_{s2t} \bigcup A_{t2s}$. The source sentence f_1^m can be segmented into m' cepts $\bar{f}_1^{m'}$. The target sentence e_1^l can also be segmented into l' cepts $\bar{e}_1^{l'}$. The words in the same cept can be a consecutive word sequence or an interrupted word sequence.

Finally, the optimal alignments $\bar{A}$ between $\bar{f}_1^{m'}$ and $\bar{e}_1^{l'}$ can be obtained from $A_{s\leftrightarrow t}$ using the following decision rule.

$$(\bar{e}_1^{l'}, \bar{f}_1^{m'}, \bar{A})^* = \arg\max_{\bar{A}\subseteq A_{s\leftrightarrow t}} \{ \prod_{(\bar{e}_i,\bar{f}_j)\in\bar{A}} p(\bar{e}_i,\bar{f}_j)^{\tau_1} \cdot r(\bar{e}_i)^{\tau_2} \cdot r(\bar{f}_j)^{\tau_3} \} \quad (11)$$

Here, $r(\bar{f}_j)$ and $r(\bar{e}_i)$ denote the collocation probabilities of the words in the source language and target language respectively, which are calculated by using Eq. (7). $p(\bar{e}_i,\bar{f}_j)$ denotes the word translation probability that is calculated according to Eq. (12). τ_i denotes the weights of these probabilities.

$$p(\bar{e}_i,\bar{f}_j) = \frac{\sum_{e\in\bar{e}_i}\sum_{f\in\bar{f}_j}(p(e|f)+p(f|e))/2}{|\bar{e}_i|*|\bar{f}_j|} \quad (12)$$

$p(e|f)$ and $p(f|e)$ are the source-to-target and target-to-source translation probabilities trained from the word aligned bilingual corpus.

4 Improving Phrase Table

Phrase-based SMT system automatically extracts bilingual phrase pairs from the word aligned bilingual corpus. In such a system, an idiomatic expression may be split into several fragments, and the phrases may include irrelevant words. In this paper, we use the collocation probability to measure the possibility of words composing a phrase.

For each bilingual phrase pair automatically extracted from word aligned corpus, we calculate the collocation probabilities of source phrase and target phrase respectively, according to Eq. (13).

$$r(w_1^n) = \frac{2\sum_{i=1}^{n-1}\sum_{j=i+1}^{n} r(w_i,w_j)}{n*(n-1)} \quad (13)$$

Here, w_1^n denotes a phrase with n words; $r(w_i,w_j)$ denotes the collocation probability of a word pair calculated according to Eq. (4). For the phrase only including one word, we set a fixed collocation probability that is the average of the collocation probabilities of the sentences on a development set. These collocation probabilities are incorporated into the phrase-based SMT system as features.

Corpora	Chinese words	English words
Bilingual corpus	6.3M	8.5M
Additional monolingual corpora	312M	203M

Table 1. Statistics of training data

5 Experiments on Word Alignment

5.1 Experimental settings

We use a bilingual corpus, FBIS (LDC2003E14), to train the IBM models. To train the collocation models, besides the monolingual parts of FBIS, we also employ some other larger Chinese and English monolingual corpora, namely, Chinese Gigaword (LDC2007T38), English Gigaword (LDC2007T07), UN corpus (LDC2004E12), Sinorama corpus (LDC2005T10), as shown in Table 1.

Using these corpora, we got three kinds of collocation models:

CM-1: the training data is the additional monolingual corpora;
CM-2: the training data is either side of the bilingual corpus;
CM-3: the interpolation of CM-1 and CM-2.

To investigate the quality of the generated word alignments, we randomly selected a subset from the bilingual corpus as test set, including 500 sentence pairs. Then word alignments in the subset were manually labeled, referring to the guideline of the Chinese-to-English alignment (LDC2006E93), but we made some modifications for the guideline. For example, if a preposition appears after a verb as a phrase aligned to one single word in the corresponding sentence, then they are glued together.

There are several different evaluation metrics for word alignment (Ahrenberg et al., 2000). We use precision (P), recall (R) and alignment error ratio (AER), which are similar to those in Och and Ney (2000), except that we consider each alignment as a sure link.

Experiments		Single word alignments			Multi-word alignments		
		P	R	AER	P	R	AER
Baseline		0.77	0.45	0.43	0.23	0.71	0.65
Improved BWA methods	CM-1	0.70	0.50	0.42	0.35	0.86	0.50
	CM-2	0.73	0.48	0.42	0.36	0.89	0.49
	CM-3	0.73	0.48	0.41	0.39	0.78	0.47

Table 2. English-to-Chinese word alignment results

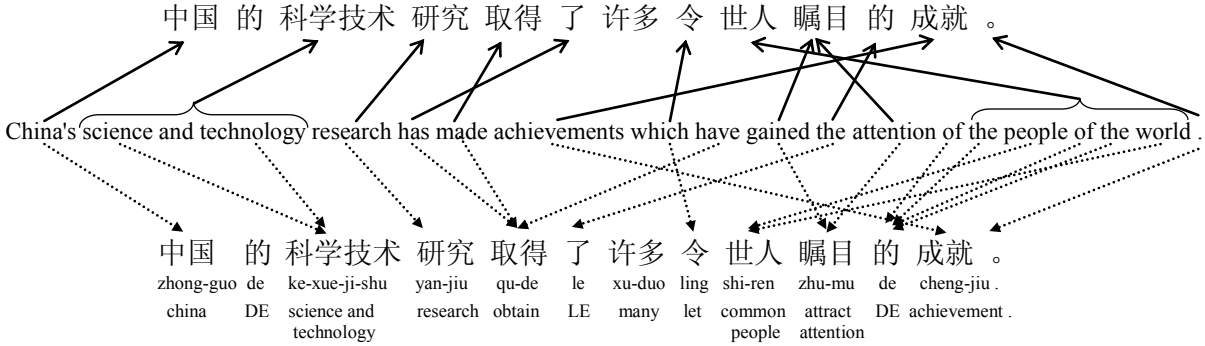

Figure 2. Example of the English-to-Chinese word alignments generated by the BWA method and the improved BWA method using CM-3. "⟶" denotes the alignments of our method; "⋯→" denotes the alignments of the baseline method.

$$P = \frac{|S_g \cap S_r|}{|S_g|} \tag{14}$$

$$R = \frac{|S_g \cap S_r|}{|S_r|} \tag{15}$$

$$AER = 1 - \frac{2*|S_g \cap S_r|}{|S_g| + |S_r|} \tag{16}$$

Where, S_g and S_r denote the automatically generated alignments and the reference alignments.

In order to tune the interpolation coefficients in Eq. (5) and the weights of the probabilities in Eq. (11), we also manually labeled a development set including 100 sentence pairs, in the same manner as the test set. By minimizing the AER on the development set, the interpolation coefficients of the collocation probabilities on CM-1 and CM-2 were set to 0.1 and 0.9. And the weights of probabilities were set as $\tau_1 = 0.6$, $\tau_2 = 0.2$ and $\tau_3 = 0.2$.

5.2 Evaluation results

One-directional alignment results

To train a Chinese-to-English SMT system, we need to perform both Chinese-to-English and English-to-Chinese word alignment. We only evaluate the English-to-Chinese word alignment here. GIZA++ with the default settings is used as the baseline method. The evaluation results in Table 2 indicate that the performances of our methods on single word alignments are close to that of the baseline method. For multi-word alignments, our methods significantly outperform the baseline method in terms of both precision and recall, achieving up to 18% absolute error rate reduction.

Although the size of the bilingual corpus is much smaller than that of additional monolingual corpora, our methods using CM-1 and CM-2 achieve comparable performances. It is because CM-2 and the BWA model are derived from the same resource. By interpolating CM1 and CM2, i.e. CM-3, the error rate of multi-word alignment results is further reduced.

Figure 2 shows an example of word alignment results generated by the baseline method and the improved method using CM-3. In this example, our method successfully identifies many-to-one alignments such as "the people of the world ⟶ 世人". In our collocation model, the collocation probability of "the people of the world" is much higher than that of "people world". And our method is also effective to prevent the unrelated

Experiments		Single word alignments			Multi-word alignments			All alignments		
		P	R	AER	P	R	AER	P	R	AER
Baseline		0.84	0.43	0.42	0.18	0.74	0.70	0.52	0.45	0.51
Our methods	WA-1	0.80	0.51	0.37	0.30	0.89	0.55	0.58	0.51	0.45
	WA-2	0.81	0.50	0.37	0.33	0.81	0.52	0.62	0.50	0.44
	WA-3	0.78	0.56	0.34	0.44	0.88	0.41	0.63	0.54	0.40

Table 3. Bi-directional word alignment results

words from being aligned. For example, in the baseline alignment "has made ... have ⋯▸取得", "have" and "has" are unrelated to the target word, while our method only generated "made → 取得", this is because that the collocation probabilities of "has/have" and "made" are much lower than that of the whole source sentence.

Bi-directional alignment results

We build a bi-directional alignment baseline in two steps: (1) GIZA++ is used to obtain the source-to-target and target-to-source alignments; (2) the bi-directional alignments are generated by using "grow-diag-final". We use the methods proposed in section 3 to replace the corresponding steps in the baseline method. We evaluate three methods:

WA-1: one-directional alignment method proposed in section 3.1 and grow-diag-final;
WA-2: GIZA++ and the bi-directional bilingual word alignments method proposed in section 3.2;
WA-3: both methods proposed in section 3.

Here, CM-3 is used in our methods. The results are shown in Table 3.

We can see that WA-1 achieves lower alignment error rate as compared to the baseline method, since the performance of the improved one-directional alignment method is better than that of GIZA++. This result indicates that improving one-directional word alignment results in bi-directional word alignment improvement.

The results also show that the AER of WA-2 is lower than that of the baseline. This is because the proposed bi-directional alignment method can effectively recognize the correct alignments from the alignment union, by leveraging collocation probabilities of the words in the same cept.

Our method using both methods proposed in section 3 produces the best alignment performance, achieving 11% absolute error rate reduction.

Experiments			BLEU (%)
Baseline			29.62
Our methods	WA-1	CM-1	30.85
		CM-2	31.28
		CM-3	31.48
	WA-2	CM-1	31.00
		CM-2	31.33
		CM-3	31.51
	WA-3	CM-1	31.43
		CM-2	31.62
		CM-3	31.78

Table 4. Performances of Moses using the different bi-directional word alignments (Significantly better than baseline with $p < 0.01$)

6 Experiments on Phrase-Based SMT

6.1 Experimental settings

We use FBIS corpus to train the Chinese-to-English SMT systems. Moses (Koehn et al., 2007) is used as the baseline phrase-based SMT system. We use SRI language modeling toolkit (Stolcke, 2002) to train a 5-gram language model on the English sentences of FBIS corpus. We used the NIST MT-2002 set as the development set and the NIST MT-2004 test set as the test set. And Koehn's implementation of minimum error rate training (Och, 2003) is used to tune the feature weights on the development set.

We use BLEU (Papineni et al., 2002) as evaluation metrics. We also calculate the statistical significance differences between our methods and the baseline method by using paired bootstrap re-sample method (Koehn, 2004).

6.2 Effect of improved word alignment on phrase-based SMT

We investigate the effectiveness of the improved word alignments on the phrase-based SMT system. The bi-directional alignments are obtained

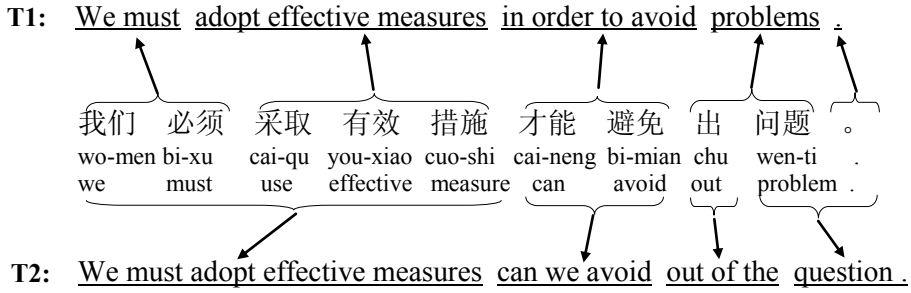

Figure 3. Example of the translations generated by the baseline system and the system where the phrase collocation probabilities are added

Experiments	BLEU (%)
Moses	29.62
+ Phrase collocation probability	30.47
+ Improved word alignments + Phrase collocation probability	32.02

Table 5. Performances of Moses employing our proposed methods (Significantly better than baseline with $p < 0.01$)

using the same methods as those shown in Table 3. Here, we investigate three different collocation models for translation quality improvement. The results are shown in Table 4.

From the results of Table 4, it can be seen that the systems using the improved bi-directional alignments achieve higher quality of translation than the baseline system. If the same alignment method is used, the systems using CM-3 got the highest BLEU scores. And if the same collocation model is used, the systems using WA-3 achieved the higher scores. These results are consistent with the evaluations of word alignments as shown in Tables 2 and 3.

6.3 Effect of phrase collocation probabilities

To investigate the effectiveness of the method proposed in section 4, we only use the collocation model CM-3 as described in section 5.1. The results are shown in Table 5. When the phrase collocation probabilities are incorporated into the SMT system, the translation quality is improved, achieving an absolute improvement of 0.85 BLEU score. This result indicates that the collocation probabilities of phrases are useful in determining the boundary of phrase and predicting whether phrases should be translated together, which helps to improve the phrase-based SMT performance.

Figure 3 shows an example: T1 is generated by the system where the phrase collocation probabilities are used and T2 is generated by the baseline system. In this example, since the collocation probability of "出 问题" is much higher than that of "问题 。", our method tends to split "出 问题 。" into "(出 问题) (。)", rather than "(出) (问题 。)". For the phrase "才能 避免" in the source sentence, the collocation probability of the translation "in order to avoid" is higher than that of the translation "can we avoid". Thus, our method selects the former as the translation. Although the phrase "我们 必须 采取 有效 措施" in the source sentence has the same translation "We must adopt effective measures", our method splits this phrase into two parts "我们 必须" and "采取 有效 措施", because two parts have higher collocation probabilities than the whole phrase.

We also investigate the performance of the system employing both the word alignment improvement and phrase table improvement methods. From the results in Table 5, it can be seen that the quality of translation is future improved. As compared with the baseline system, an absolute improvement of 2.40 BLEU score is achieved. And this result is also better than the results shown in Table 4.

7 Experiments on Parsing-Based SMT

We also investigate the effectiveness of the improved word alignments on the parsing-based SMT system, Joshua (Li et al., 2009). In this system, the Hiero-style SCFG model is used (Chiang, 2007), without syntactic information. The rules are extracted only based on the FBIS corpus, where words are aligned by "MW-3 & CM-3". And the language model is the same as that in Moses. The feature weights are tuned on the development set using the minimum error

Experiments	BLEU (%)
Joshua	30.05
+ Improved word alignments	31.81

Table 6. Performances of Joshua using the different word alignments (Significantly better than baseline with $p < 0.01$)

rate training method. We use the same evaluation measure as described in section 6.1.

The translation results on Joshua are shown in Table 6. The system using the improved word alignments achieves an absolute improvement of 1.76 BLEU score, which indicates that the improvements of word alignments are also effective to improve the performance of the parsing-based SMT systems.

8 Conclusion

We presented a novel method to use monolingual collocations to improve SMT. We first used the MWA method to identify potentially collocated words and estimate collocation probabilities only from monolingual corpora, no additional resource or linguistic preprocessing is needed. Then the collocation information was employed to improve BWA for various kinds of SMT systems and to improve phrase table for phrase-based SMT.

To improve BWA, we re-estimate the alignment probabilities by using the collocation probabilities of words in the same cept. To improve phrase table, we calculate phrase collocation probabilities based on word collocation probabilities. Then the phrase collocation probabilities are used as additional features in phrase-based SMT systems.

The evaluation results showed that the proposed method significantly improved word alignment, achieving an absolute error rate reduction of 29% on multi-word alignment. The improved word alignment results in an improvement of 2.16 BLEU score on a phrase-based SMT system and an improvement of 1.76 BLEU score on a parsing-based SMT system. When we also used phrase collocation probabilities as additional features, the phrase-based SMT performance is finally improved by 2.40 BLEU score as compared with the baseline system.

Abstract

This paper proposes new algorithms to compute the sense similarity between two units (words, phrases, rules, *etc.*) from parallel corpora. The sense similarity scores are computed by using the vector space model. We then apply the algorithms to statistical machine translation by computing the sense similarity between the source and target side of translation rule pairs. Similarity scores are used as additional features of the translation model to improve translation performance. Significant improvements are obtained over a state-of-the-art hierarchical phrase-based machine translation system.

1 Introduction

The sense of a term can generally be inferred from its context. The underlying idea is that a term is characterized by the contexts it co-occurs with. This is also well known as *the Distributional Hypothesis* (Harris, 1954): terms occurring in similar contexts tend to have similar meanings. There has been a lot of work to compute the sense similarity between terms based on their distribution in a corpus, such as (Hindle, 1990; Lund and Burgess, 1996; Landauer and Dumais, 1997; Lin, 1998; Turney, 2001; Pantel and Lin, 2002; Pado and Lapata, 2007).

In the work just cited, a common procedure is followed. Given two terms to be compared, one first extracts various features for each term from their contexts in a corpus and forms a vector space model (VSM); then, one computes their similarity by using similarity functions. The features include words within a surface window of a fixed size (Lund and Burgess, 1996), grammatical dependencies (Lin, 1998; Pantel and Lin 2002; Pado and Lapata, 2007), *etc.* The similarity function which has been most widely used is cosine distance (Salton and McGill, 1983); other similarity functions include Euclidean distance, City Block distance (Bullinaria and Levy; 2007), and Dice and Jaccard coefficients (Frakes and Baeza-Yates, 1992), *etc.* Measures of monolingual sense similarity have been widely used in many applications, such as synonym recognizing (Landauer and Dumais, 1997), word clustering (Pantel and Lin 2002), word sense disambiguation (Yuret and Yatbaz 2009), *etc.*

Use of the vector space model to compute sense similarity has also been adapted to the multilingual condition, based on the assumption that two terms with similar meanings often occur in comparable contexts across languages. Fung (1998) and Rapp (1999) adopted VSM for the application of extracting translation pairs from comparable or even unrelated corpora. The vectors in different languages are first mapped to a common space using an initial bilingual dictionary, and then compared.

However, there is no previous work that uses the VSM to compute sense similarity for terms from parallel corpora. The sense similarities, i.e. the translation probabilities in a translation model, for units from parallel corpora are mainly based on the co-occurrence counts of the two units. Therefore, questions emerge: how good is the sense similarity computed via VSM for two units from parallel corpora? Is it useful for multilingual applications, such as statistical machine translation (SMT)?

In this paper, we try to answer these questions, focusing on sense similarity applied to the SMT task. For this task, translation rules are heuristically extracted from automatically word-aligned sentence pairs. Due to noise in the training corpus or wrong word alignment, the source and target sides of some rules are not semantically equivalent, as can be seen from the following

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 834–843,
Uppsala, Sweden, 11-16 July 2010.

real examples which are taken from the rule table built on our training data (Section 5.1):

世界 上 X 之一 ||| *one of X* (*)
世界 上 X 之一 ||| *one of X in the world*
许多 市民 ||| *many citizens*
许多 市民 ||| *many hong kong residents* (*)

The source and target sides of the rules with (*) at the end are not semantically equivalent; it seems likely that measuring the semantic similarity from their context between the source and target sides of rules might be helpful to machine translation.

In this work, we first propose new algorithms to compute the sense similarity between two units (unit here includes word, phrase, rule, *etc*.) in different languages by using their contexts. Second, we use the sense similarities between the source and target sides of a translation rule to improve statistical machine translation performance.

This work attempts to measure directly the sense similarity for units from different languages by comparing their contexts[1]. Our contribution includes proposing new bilingual sense similarity algorithms and applying them to machine translation.

We chose a hierarchical phrase-based SMT system as our baseline; thus, the units involved in computation of sense similarities are hierarchical rules.

2 Hierarchical phrase-based MT system

The hierarchical phrase-based translation method (Chiang, 2005; Chiang, 2007) is a formal syntax-based translation modeling method; its translation model is a weighted synchronous context free grammar (SCFG). No explicit linguistic syntactic information appears in the model. An SCFG rule has the following form:

$$X \rightarrow \langle \alpha, \gamma, \sim \rangle$$

where X is a non-terminal symbol shared by all the rules; each rule has at most two non-terminals. α (γ) is a source (target) string consisting of terminal and non-terminal symbols. $\sim$ defines a one-to-one correspondence between non-terminals in α and γ.

[1] There has been a lot of work (more details in Section 7) on applying word sense disambiguation (WSD) techniques in SMT for translation selection. However, WSD techniques for SMT do so indirectly, using source-side context to help select a particular translation for a source rule.

	source	target
Ini. phr.	*他 出席 了 会议*	*he attended the meeting*
Rule 1 Context 1	*他 出席 了 X_1* *会议*	*he attended X_1* *the, meeting*
Rule 2 Context 2	*会议* *他, 出席, 了*	*the meeting* *he, attended*
Rule 3 Context 3	*他 X_1 会议* *出席, 了*	*he X_1 the meeting* *attended*
Rule 4 Context 4	*出席 了* *他,会议*	*attended* *he, the, meeting*

Figure 1: example of hierarchical rule pairs and their context features.

Rule frequencies are counted during rule extraction over word-aligned sentence pairs, and they are normalized to estimate features on rules. Following (Chiang, 2005; Chiang, 2007), 4 features are computed for each rule:

- $P(\gamma|\alpha)$ and $P(\alpha|\gamma)$ are direct and inverse rule-based conditional probabilities;
- $P_w(\gamma|\alpha)$ and $P_w(\alpha|\gamma)$ are direct and inverse lexical weights (Koehn et al., 2003).

Empirically, this method has yielded better performance on language pairs such as Chinese-English than the phrase-based method because it permits phrases with gaps; it generalizes the normal phrase-based models in a way that allows long-distance reordering (Chiang, 2005; Chiang, 2007). We use the *Joshua* implementation of the method for decoding (Li et al., 2009).

3 Bag-of-Words Vector Space Model

To compute the sense similarity via VSM, we follow the previous work (Lin, 1998) and represent the source and target side of a rule by feature vectors. In our work, each feature corresponds to a context word which co-occurs with the translation rule.

3.1 Context Features

In the hierarchical phrase-based translation method, the translation rules are extracted by abstracting some words from an initial phrase pair (Chiang, 2005). Consider a rule with non-terminals on the source and target side; for a given instance of the rule (a particular phrase pair in the training corpus), the context will be the words instantiating the non-terminals. In turn, the context for the sub-phrases that instantiate the non-terminals will be the words in the remainder of the phrase pair. For example in Figure 1, if we

have an initial phrase pair *他 出席 了 会议 ||| he attended the meeting*, and we extract four rules from this initial phrase: *他 出席 了 X_1 ||| he attended X_1*, *会议 ||| the meeting*, *他 X_1 会议 ||| he X_1 the meeting*, and *出席 了 ||| attended*. Therefore, *the* and *meeting* are context features of target pattern *he attended X_1*; *he* and *attended* are the context features of *the meeting*; *attended* is the context feature of *he X_1 the meeting*; also *he, the* and *meeting* are the context feature of *attended* (in each case, there are also source-side context features).

3.2 Bag-of-Words Model

For each side of a translation rule pair, its context words are all collected from the training data, and two "bags-of-words" which consist of collections of source and target context words co-occurring with the rule's source and target sides are created.

$$B_f = \{f_1, f_2, ..., f_I\}$$
$$B_e = \{e_1, e_2, ..., e_J\} \quad (1)$$

where $f_i (1 \le i \le I)$ are source context words which co-occur with the source side of rule α, and $e_j (1 \le j \le J)$ are target context words which co-occur with the target side of rule γ.

Therefore, we can represent source and target sides of the rule by vectors $\vec{v}_f$ and $\vec{v}_e$ as in Equation (2):

$$\vec{v}_f = \{w_{f_1}, w_{f_2}, ..., w_{f_I}\}$$
$$\vec{v}_e = \{w_{e_1}, w_{e_2}, ..., w_{e_J}\} \quad (2)$$

where w_{f_i} and w_{e_j} are values for each source and target context feature; normally, these values are based on the counts of the words in the corresponding bags.

3.3 Feature Weighting Schemes

We use pointwise mutual information (Church et al., 1990) to compute the feature values. Let c ($c \in B_f$ or $c \in B_e$) be a context word and $F(r,c)$ be the frequency count of a rule r (α or γ) co-occurring with the context word c. The pointwise mutual information $MI(r,c)$ is defined as:

$$w(r,c) = MI(r,c) = \frac{\log \frac{F(r,c)}{N}}{\log \frac{F(r)}{N} \times \log \frac{F(c)}{N}} \quad (3)$$

where N is the total frequency counts of all rules and their context words. Since we are using this value as a weight, following (Turney, 2001), we drop *log, N* and $F(r)$. Thus (3) simplifies to:

$$w(r,c) = \frac{F(r,c)}{F(c)} \quad (4)$$

It can be seen as an estimate of $P(r \mid c)$, the empirical probability of observing r given c.

A problem with $P(r \mid c)$ is that it is biased towards infrequent words/features. We therefore smooth $w(r,c)$ with *add-k* smoothing:

$$w(r,c) = \frac{F(r,c)+k}{\sum_{i=1}^{R}(F(r_i,c)+k)} = \frac{F(r,c)+k}{F(c)+kR} \quad (5)$$

where k is a tunable global smoothing constant, and R is the number of rules.

4 Similarity Functions

There are many possibilities for calculating similarities between bags-of-words in different languages. We consider IBM model 1 probabilities and cosine distance similarity functions.

4.1 IBM Model 1 Probabilities

For the IBM model 1 similarity function, we take the geometric mean of symmetrized conditional IBM model 1 (Brown et al., 1993) bag probabilities, as in Equation (6).

$$sim(\alpha, \gamma) = sqrt(P(B_f \mid B_e) \cdot P(B_e \mid B_f)) \quad (6)$$

To compute $P(B_f \mid B_e)$, IBM model 1 assumes that all source words are conditionally independent, so that:

$$P(B_f \mid B_e) = \prod_{i=1}^{I} p(f_i \mid B_e) \quad (7)$$

To compute, we use a "Noisy-OR" combination which has shown better performance than standard IBM model 1 probability, as described in (Zens and Ney, 2004):

$$p(f_i \mid B_e) = 1 - p(\bar{f}_i \mid B_e) \quad (8)$$

$$p(f_i \mid B_e) \approx 1 - \prod_{j=1}^{J}(1 - p(f_i \mid e_j)) \quad (9)$$

where $p(\bar{f}_i \mid B_e)$ is the probability that f_i is *not* in the translation of B_e, and is the IBM model 1 probability.

4.2 Vector Space Mapping

A common way to calculate semantic similarity is by vector space cosine distance; we will also

use this similarity function in our algorithm. However, the two vectors in Equation (2) cannot be directly compared because the axes of their spaces represent different words in different languages, and also their dimensions *I* and *J* are not assured to be the same. Therefore, we need to first map a vector into the space of the other vector, so that the similarity can be calculated. Fung (1998) and Rapp (1999) map the vector one-dimension-to-one-dimension (a context word is a dimension in each vector space) from one language to another language via an initial bilingual dictionary. We follow (Zhao et al., 2004) to do vector space mapping.

Our goal is – given a source pattern – to distinguish between the senses of its associated target patterns. Therefore, we map all vectors in target language into the vector space in the source language. What we want is a representation $\vec{v}_a$ in the source language space of the target vector $\vec{v}_e$. To get $\vec{v}_a$, we can let $w_a^{f_i}$, the weight of the i^{th} source feature, be a linear combination over target features. That is to say, given a source feature weight for f_i, each target feature weight is linked to it with some probability. So that we can calculate a transformed vector from the target vectors by calculating weights $w_a^{f_i}$ using a translation lexicon:

$$w_a^{f_i} = \sum_{j=1}^{J} \Pr(f_i \mid e_j) w_{e_j} \tag{10}$$

where $p(f_i \mid e_j)$ is a lexical probability (we use IBM model 1 probability). Now the source vector and the mapped vector $\vec{v}_a$ have the same dimensions as shown in (11):

$$\begin{aligned} \vec{v}_f &= \{w_{f_1}, w_{f_2}, ..., w_{f_I}\} \\ \vec{v}_a &= \{w_a^{f_1}, w_a^{f_2}, ..., w_a^{f_I}\} \end{aligned} \tag{11}$$

4.3 Naïve Cosine Distance Similarity

The standard cosine distance is defined as the inner product of the two vectors $\vec{v}_f$ and $\vec{v}_a$ normalized by their norms. Based on Equation (10) and (11), it is easy to derive the similarity as follows:

$$\begin{aligned} sim(\alpha,\gamma) &= \cos(\vec{v}_f, \vec{v}_a) = \frac{\vec{v}_f \cdot \vec{v}_a}{|\vec{v}_f| \cdot |\vec{v}_a|} \\ &= \frac{\sum_{i=1}^{I}\sum_{j=1}^{J} w_{f_i} \Pr(f_i \mid e_j) w_{e_j}}{sqrt(\sum_{I=1}^{I} w_{f_i}^2) sqrt(\sum_{i=1}^{I} {w_a^{f_i}}^2)} \end{aligned} \tag{12}$$

where *I* and *J* are the number of the words in source and target bag-of-words; w_{f_i} and w_{e_j} are values of source and target features; $w_a^{f_i}$ is the transformed weight mapped from all target features to the source dimension at word f_i.

4.4 Improved Similarity Function

To incorporate more information than the original similarity functions – IBM model 1 probabilities in Equation (6) and naïve cosine distance similarity function in Equation (12) – we refine the similarity function and propose a new algorithm.

As shown in Figure 2, suppose that we have a rule pair (α, γ). C_f^{full} and C_e^{full} are the contexts extracted according to the definition in section 3 from the full training data for α and for γ, respectively. C_f^{cooc} and C_e^{cooc} are the contexts for α and γ when α and γ co-occur. Obviously, they satisfy the constraints: $C_f^{cooc} \subseteq C_f^{full}$ and $C_e^{cooc} \subseteq C_e^{full}$. Therefore, the original similarity functions are to compare the two context vectors built on full training data directly, as shown in Equation (13).

$$sim(\alpha,\gamma) = sim(C_f^{full}, C_e^{full}) \tag{13}$$

Then, we propose a new similarity function as follows:

$$\begin{aligned} &sim(\alpha,\gamma) = \\ &sim(C_f^{full}, C_f^{cooc})^{\lambda_1} \cdot sim(C_f^{cooc}, C_e^{cooc})^{\lambda_2} \cdot sim(C_e^{full}, C_e^{cooc})^{\lambda_3} \end{aligned} \tag{14}$$

where the parameters λ_i (i=1,2,3) can be tuned via minimal error rate training (MERT) (Och, 2003).

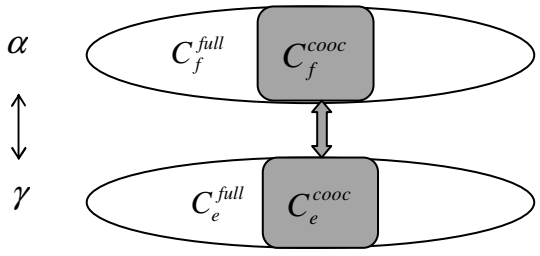

Figure 2: contexts for rule α and γ.

A unit's sense is defined by all its contexts in the whole training data; it may have a lot of different senses in the whole training data. However, when it is linked with another unit in the other language, its sense pool is constrained and is just

a subset of the whole sense set. $sim(C_f^{full}, C_f^{cooc})$ is the metric which evaluates the similarity between the whole sense pool of α and the sense pool when α co-occurs with γ; $sim(C_e^{full}, C_e^{cooc})$ is the analogous similarity metric for γ. They range from 0 to 1. These two metrics both evaluate the similarity for two vectors in the same language, so using cosine distance to compute the similarity is straightforward. And we can set a relatively large size for the vector, since it is not necessary to do vector mapping as the vectors are in the same language. $sim(C_f^{cooc}, C_e^{cooc})$ computes the similarity between the context vectors when α and γ co-occur. We may compute $sim(C_f^{cooc}, C_e^{cooc})$ by using IBM model 1 probability and cosine distance similarity functions as Equation (6) and (12). Therefore, on top of the degree of bilingual semantic similarity between a source and a target translation unit, we have also incorporated the monolingual semantic similarity between all occurrences of a source or target unit, and that unit's occurrence as part of the given rule, into the sense similarity measure.

5 Experiments

We evaluate the algorithm of bilingual sense similarity via machine translation. The sense similarity scores are used as feature functions in the translation model.

5.1 Data

We evaluated with different language pairs: Chinese-to-English, and German-to-English. For Chinese-to-English tasks, we carried out the experiments in two data conditions. The first one is the *large data* condition, based on training data for the NIST [2] 2009 evaluation Chinese-to-English track. In particular, all the allowed bilingual corpora except the *UN corpus* and *Hong Kong Hansard corpus* have been used for estimating the translation model. The second one is the *small data* condition where only the *FBIS*[3] corpus is used to train the translation model. We trained two language models: the first one is a 4-gram LM which is estimated on the target side of the texts used in the *large data* condition. The second LM is a 5-gram LM trained on the so-called English *Gigaword corpus*. Both language models are used for both tasks.

We carried out experiments for translating Chinese to English. We use the same development and test sets for the two data conditions. We first created a development set which used mainly data from the NIST 2005 test set, and also some balanced-genre web-text from the NIST training material. Evaluation was performed on the NIST 2006 and 2008 test sets. Table 1 gives figures for training, development and test corpora; |S| is the number of the sentences, and |W| is the number of running words. Four references are provided for all dev and test sets.

			Chi	Eng
Parallel Train	Large Data	|S|	3,322K	
		|W|	64.2M	62.6M
	Small Data	|S|	245K	
		|W|	9.0M	10.5M
Dev		|S|	1,506	1,506×4
Test	NIST06	|S|	1,664	1,664×4
	NIST08	|S|	1,357	1,357×4
Gigaword		|S|	-	11.7M

Table 1: Statistics of training, dev, and test sets for Chinese-to-English task.

For German-to-English tasks, we used WMT 2006[4] data sets. The parallel training data contains 21 million target words; both the dev set and test set contain 2000 sentences; one reference is provided for each source input sentence. Only the target-language half of the parallel training data are used to train the language model in this task.

5.2 Results

For the baseline, we train the translation model by following (Chiang, 2005; Chiang, 2007) and our decoder is *Joshua*[5], an open-source hierarchical phrase-based machine translation system written in Java. Our evaluation metric is IBM BLEU (Papineni et al., 2002), which performs case-insensitive matching of *n*-grams up to $n = 4$. Following (Koehn, 2004), we use the bootstrap-resampling test to do significance testing.

By observing the results on dev set in the additional experiments, we first set the smoothing constant k in Equation (5) to 0.5.

Then, we need to set the sizes of the vectors to balance the computing time and translation accu-

[2] http://www.nist.gov/speech/tests/mt

[5] http://www.cs.jhu.edu/~ccb/joshua/index.html

racy, *i.e.*, we keep only the top N context words with the highest feature value for each side of a rule [6]. In the following, we use "Alg1" to represent the original similarity functions which compare the two context vectors built on full training data, as in Equation (13); while we use "Alg2" to represent the improved similarity as in Equation (14). "IBM" represents IBM model 1 probabilities, and "COS" represents cosine distance similarity function.

After carrying out a series of additional experiments on the *small data* condition and observing the results on the dev set, we set the size of the vector to 500 for Alg1; while for Alg2, we set the sizes of C_f^{full} and C_e^{full} N_1 to 1000, and the sizes of C_f^{cooc} and C_e^{cooc} N_2 to 100.

The sizes of the vectors in Alg2 are set in the following process: first, we set N_2 to 500 and let N_1 range from 500 to 3,000, we observed that the dev set got best performance when N_1 was 1000; then we set N_1 to 1000 and let N_1 range from 50 to 1000, we got best performance when N_1=100. We use this setting as the default setting in all remaining experiments.

Algorithm	NIST'06	NIST'08
Baseline	27.4	21.2
Alg1 IBM	27.8*	21.5
Alg1 COS	27.8*	21.5
Alg2 IBM	27.9*	21.6*
Alg2 COS	**28.1****	**21.7***

Table 2: Results (BLEU%) of *small data* Chinese-to-English NIST task. Alg1 represents the original similarity functions as in Equation (13); while Alg2 represents the improved similarity as in Equation (14). IBM represents IBM model 1 probability, and COS represents cosine distance similarity function. * or ** means result is significantly better than the baseline ($p < 0.05$ or $p < 0.01$, respectively).

	Ch-En		De-En
Algorithm	NIST'06	NIST'08	Test'06
Baseline	31.0	23.8	26.9
Alg2 IBM	31.5*	24.5**	27.2*
Alg2 COS	**31.6****	**24.5****	**27.3***

Table 3: Results (BLEU%) of *large data* Chinese-to-English NIST task and German-to-English WMT task.

[6] We have also conducted additional experiments by removing the stop words from the context vectors; however, we did not observe any consistent improvement. So we filter the context vectors by only considering the feature values.

Table 2 compares the performance of Alg1 and Alg2 on the Chinese-to-English *small data* condition. Both Alg1 and Alg2 improved the performance over the baseline, and Alg2 obtained slight and consistent improvements over Alg1. The improved similarity function Alg2 makes it possible to incorporate monolingual semantic similarity on top of the bilingual semantic similarity, thus it may improve the accuracy of the similarity estimate. Alg2 significantly improved the performance over the baseline. The Alg2 cosine similarity function got 0.7 BLEU-score (p<0.01) improvement over the baseline for NIST 2006 test set, and a 0.5 BLEU-score (p<0.05) for NIST 2008 test set.

Table 3 reports the performance of Alg2 on Chinese-to-English NIST *large data* condition and German-to-English WMT task. We can see that IBM model 1 and cosine distance similarity function both obtained significant improvement on all test sets of the two tasks. The two similarity functions obtained comparable results.

6 Analysis and Discussion

6.1 Effect of Single Features

In Alg2, the similarity score consists of three parts as in Equation (14): $sim(C_f^{full}, C_f^{cooc})$, $sim(C_e^{full}, C_e^{cooc})$, and $sim(C_f^{cooc}, C_e^{cooc})$; where $sim(C_f^{cooc}, C_e^{cooc})$ could be computed by IBM model 1 probabilities $sim_{IBM}(C_f^{cooc}, C_e^{cooc})$ or cosine distance similarity function $sim_{COS}(C_f^{cooc}, C_e^{cooc})$. Therefore, our first study is to determine which one of the above four features has the most impact on the result. Table 4 shows the results obtained by using each of the 4 features. First, we can see that $sim_{IBM}(C_f^{cooc}, C_e^{cooc})$ always gives a better improvement than $sim_{COS}(C_f^{cooc}, C_e^{cooc})$. This is because $sim_{IBM}(C_f^{cooc}, C_e^{cooc})$ scores are more diverse than the latter when the number of context features is small (there are many rules that have only a few contexts.) For an extreme example, suppose that there is only one context word in each vector of source and target context features, and the translation probability of the two context words is not 0. In this case, $sim_{IBM}(C_f^{cooc}, C_e^{cooc})$ reflects the translation probability of the context word pair, while $sim_{COS}(C_f^{cooc}, C_e^{cooc})$ is always 1.

Second, $sim(C_f^{full}, C_f^{cooc})$ and $sim(C_e^{full}, C_e^{cooc})$ also give some improvements even when used

independently. For a possible explanation, consider the following example. The Chinese word "红" can translate to "red", "communist", or "hong" (the transliteration of 红, when it is used in a person's name). Since these translations are likely to be associated with very different source contexts, each will have a low $sim(C_f^{full}, C_f^{cooc})$ score. Another Chinese word 小溪 may translate into synonymous words, such as "brook", "stream", and "rivulet", each of which will have a high $sim(C_f^{full}, C_f^{cooc})$ score. Clearly, 红 is a more "dangerous" word than 小溪, since choosing the wrong translation for it would be a bad mistake. But if the two words have similar translation distributions, the system cannot distinguish between them. The monolingual similarity scores give it the ability to avoid "dangerous" words, and choose alternatives (such as larger phrase translations) when available.

Third, the similarity function of Alg2 consistently achieved further improvement by incorporating the monolingual similarities computed for the source and target side. This confirms the effectiveness of our algorithm.

	CE_LD		CE_SD	
testset (NIST)	'06	'08	'06	'08
Baseline	31.0	23.8	27.4	21.2
$sim(C_f^{full}, C_f^{cooc})$	31.1	24.3	27.5	21.3
$sim(C_e^{full}, C_e^{cooc})$	31.1	23.9	27.9	21.5
$sim_{IBM}(C_f^{cooc}, C_e^{cooc})$	31.4	24.3	27.9	21.5
$sim_{COS}(C_f^{cooc}, C_e^{cooc})$	31.2	23.9	27.7	21.4
Alg2 IBM	31.5	24.5	27.9	21.6
Alg2 COS	**31.6**	**24.5**	**28.1**	**21.7**

Table 4: Results (BLEU%) of Chinese-to-English *large data* (CE_LD) and *small data* (CE_SD) NIST task by applying one feature.

6.2 Effect of Combining the Two Similarities

We then combine the two similarity scores by using both of them as features to see if we could obtain further improvement. In practice, we use the four features in Table 4 together.

Table 5 reports the results on the *small data* condition. We observed further improvement on dev set, but failed to get the same improvements on test sets or even lost performance. Since the IBM+COS configuration has one extra feature, it is possible that it overfits the dev set.

Algorithm	Dev	NIST'06	NIST'08
Baseline	20.2	27.4	21.2
Alg2 IBM	20.5	27.9	21.6
Alg2 COS	20.6	28.1	21.7
Alg2 IBM+COS	20.8	27.9	21.5

Table 5: Results (BLEU%) for combination of two similarity scores. Further improvement was only obtained on dev set but not on test sets.

6.3 Comparison with Simple Contextual Features

Now, we try to answer the question: can the similarity features computed by the function in Equation (14) be replaced with some other simple features? We did additional experiments on *small data* Chinese-to-English task to test the following features: (15) and (16) represent the sum of the counts of the context words in C^{full}, while (17) represents the proportion of words in the context of α that appeared in the context of the rule (α, γ); similarly, (18) is related to the properties of the words in the context of γ.

$$N_f(\alpha) = \sum_{f_i \in C_f^{full}} F(\alpha, f_i) \quad (15)$$

$$N_e(\gamma) = \sum_{e_j \in C_e^{full}} F(\gamma, e_j) \quad (16)$$

$$E_f(\alpha, \gamma) = \frac{\sum_{f_i \in C_f^{cooc}} F(\alpha, f_i)}{N_f(\alpha)} \quad (17)$$

$$E_e(\alpha, \gamma) = \frac{\sum_{e_j \in C_e^{cooc}} F(\gamma, e_j)}{N_e(\gamma)} \quad (18)$$

where $F(\alpha, f_i)$ and $F(\gamma, e_j)$ are the frequency counts of rule α or γ co-occurring with the context word f_i or e_j respectively.

Feature	Dev	NIST'06	NIST'08
Baseline	20.2	27.4	21.2
$+N_f$	20.5	27.6	21.4
$+N_e$	20.5	27.5	21.3
$+E_f$	20.4	27.5	21.2
$+E_e$	20.4	27.3	21.2
$+N_f+N_e$	20.5	27.5	21.3

Table 6: Results (BLEU%) of using simple features based on context on *small data* NIST task. Some improvements are obtained on dev set, but there was no significant effect on the test sets.

Table 6 shows results obtained by adding the above features to the system for the *small data*

condition. Although all these features have obtained some improvements on dev set, there was no significant effect on the test sets. This means simple features based on context, such as the sum of the counts of the context features, are not as helpful as the sense similarity computed by Equation (14).

6.4 Null Context Feature

There are two cases where no context word can be extracted according to the definition of context in Section 3.1. The first case is when a rule pair is always a full sentence-pair in the training data. The second case is when for some rule pairs, either their source or target contexts are out of the span limit of the initial phrase, so that we cannot extract contexts for those rule-pairs. For Chinese-to-English NIST task, there are about 1% of the rules that do not have contexts; for German-to-English task, this number is about 0.4%. We assign a uniform number as their bilingual sense similarity score, and this number is tuned through MERT. We call it the *null context* feature. It is included in all the results reported from Table 2 to Table 6. In Table 7, we show the weight of the *null context* feature tuned by running MERT in the experiments reported in Section 5.2. We can learn that penalties always discourage using those rules which have no context to be extracted.

	Task		
Alg.	CE_SD	CE_LD	DE
Alg2 IBM	-0.09	-0.37	-0.15
Alg2 COS	-0.59	-0.42	-0.36

Table 7: Weight learned for employing the *null context* feature. CE_SD, CE_LD and DE are Chinese-to-English *small data* task, *large data* task and German-to-English task respectively.

6.5 Discussion

Our aim in this paper is to characterize the semantic similarity of bilingual hierarchical rules. We can make several observations concerning our features:

1) Rules that are largely syntactic in nature, such as *的 X ||| the X of*, will have very diffuse "meanings" and therefore lower similarity scores. It could be that the gains we obtained come simply from biasing the system against such rules. However, the results in table 6 show that this is unlikely to be the case: features that just count context words help very little.

2) In addition to bilingual similarity, Alg2 relies on the degree of monolingual similarity between the sense of a source or target unit within a rule, and the sense of the unit in general. This has a bias in favor of less ambiguous rules, i.e. rules involving only units with closely related meanings. Although this bias is helpful on its own, possibly due to the mechanism we outline in section 6.1, it appears to have a synergistic effect when used along with the bilingual similarity feature.

3) Finally, we note that many of the features we use for capturing similarity, such as the context "*the, of*" for instantiations of *X* in the unit *the X of*, are arguably more syntactic than semantic. Thus, like other "semantic" approaches, ours can be seen as blending syntactic and semantic information.

7 Related Work

There has been extensive work on incorporating semantics into SMT. Key papers by Carpuat and Wu (2007) and Chan et al (2007) showed that word-sense disambiguation (WSD) techniques relying on source-language context can be effective in selecting translations in phrase-based and hierarchical SMT. More recent work has aimed at incorporating richer disambiguating features into the SMT log-linear model (Gimpel and Smith, 2008; Chiang et al, 2009); predicting coherent sets of target words rather than individual phrase translations (Bangalore et al, 2009; Mauser et al, 2009); and selecting applicable rules in hierarchical (He et al, 2008) and syntactic (Liu et al, 2008) translation, relying on source as well as target context. Work by Wu and Fung (2009) breaks new ground in attempting to match semantic roles derived from a semantic parser across source and target languages.

Our work is different from all the above approaches in that we attempt to discriminate among hierarchical rules based on: 1) the degree of bilingual semantic similarity between source and target translation units; and 2) the monolingual semantic similarity between occurrences of source or target units as part of the given rule, and in general. In another words, WSD explicitly tries to choose a translation given the current source context, while our work rates rule pairs independent of the current context.

8 Conclusions and Future Work

In this paper, we have proposed an approach that uses the vector space model to compute the sense

similarity for terms from parallel corpora and applied it to statistical machine translation. We saw that the bilingual sense similarity computed by our algorithm led to significant improvements. Therefore, we can answer the questions proposed in Section 1. We have shown that the sense similarity computed between units from parallel corpora by means of our algorithm is helpful for at least one multilingual application: statistical machine translation.

Finally, although we described and evaluated bilingual sense similarity algorithms applied to a hierarchical phrase-based system, this method is also suitable for syntax-based MT systems and phrase-based MT systems. The only difference is the definition of the context. For a syntax-based system, the context of a rule could be defined similarly to the way it was defined in the work described above. For a phrase-based system, the context of a phrase could be defined as its surrounding words in a given size window. In our future work, we may try this algorithm on syntax-based MT systems and phrase-based MT systems with different context features. It would also be possible to use this technique during training of an SMT system – for instance, to improve the bilingual word alignment or reduce the training data noise.

Abstract

Wikipedia articles in different languages are connected by interwiki links that are increasingly being recognized as a valuable source of cross-lingual information. Unfortunately, large numbers of links are imprecise or simply wrong. In this paper, techniques to detect such problems are identified. We formalize their removal as an optimization task based on graph repair operations. We then present an algorithm with provable properties that uses linear programming and a region growing technique to tackle this challenge. This allows us to transform Wikipedia into a much more consistent multilingual register of the world's entities and concepts.

1 Introduction

Motivation. The open community-maintained encyclopedia Wikipedia has not only turned the Internet into a more useful and linguistically diverse source of information, but is also increasingly being used in computational applications as a large-scale source of linguistic and encyclopedic knowledge. To allow cross-lingual navigation, Wikipedia offers cross-lingual *interwiki* links that for instance connect the Indonesian article about Albert Einstein to the corresponding articles in over 100 other languages. Such links are extraordinarily valuable for cross-lingual applications.

In the ideal case, a set of articles connected directly or indirectly via such links would all describe the same entity or concept. Due to conceptual drift, different granularities, as well as mistakes made by editors, we frequently find concepts as different as *economics* and *manager* in the same connected component. Filtering out inaccurate links enables us to exploit Wikipedia's multilinguality in a much safer manner and allows us to create a multilingual register of named entities.

Contribution. Our research contributions are: 1) We identify criteria to detect inaccurate connections in Wikipedia's cross-lingual link structure. 2) We formalize the task of removing such links as an optimization problem. 3) We introduce an algorithm that attempts to repair the cross-lingual graph in a minimally invasive way. This algorithm has an approximation guarantee with respect to optimal solutions. 4) We show how this algorithm can be used to combine all editions of Wikipedia into a single large-scale multilingual register of named entities and concepts.

2 Detecting Inaccurate Links

In this paper, we model the union of cross-lingual links provided by all editions of Wikipedia as an undirected graph $G = (V, E)$ with edge weights $w(e)$ for $e \in E$. In our experiments, we simply honour each individual link equally by defining $w(e) = 2$ if there are reciprocal links between the two pages, 1 if there is a single link, and 0 otherwise. However, our framework is flexible enough to deal with more advanced weighting schemes, e.g. one could easily plug in cross-lingual measures of semantic relatedness between article texts.

It turns out that an astonishing number of connected components in this graph harbour inaccurate links between articles. For instance, the Esperanto article '*Germana Imperiestro*' is about German emporers and another Esperanto article '*Germana Imperiestra Regno*' is about the German Empire, but, as of June 2010, both are linked to the English and German articles about the German Empire. Over time, some inaccurate links may be fixed, but in this and in large numbers of other cases, the imprecise connection has persisted for many years. In order to detect such cases, we need to have some way of specifying that two articles are likely to be distinct.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 844–853,
Uppsala, Sweden, 11-16 July 2010.

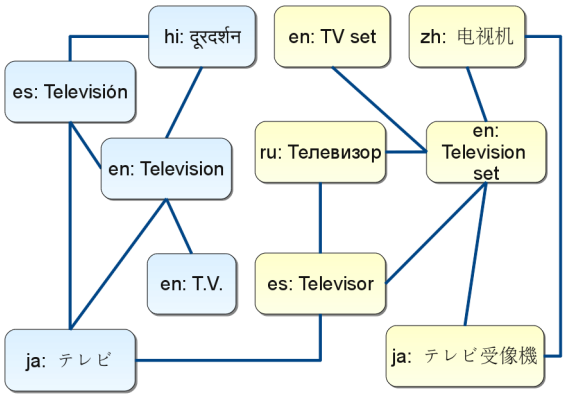

Figure 1: Connected component with inaccurate links (simplified)

2.1 Distinctness Assertions

Figure 1 shows a connected component that conflates the concept of television as a medium with the concept of TV sets as devices. Among other things, we would like to state that '*Television*' and '*T.V.*' are distinct from '*Television set*' and '*TV set*'. In general, we may have several sets of entities $D_{i,1}, \ldots, D_{i,l_i}$, for which we assume that any two entities u,v from different sets are pairwise distinct with some degree of confidence or weight. In our example, $D_{i,1} = \{$'*Television*','*T.V.*'$\}$ would be one set, and $D_{i,2} = \{$'*Television set*','*TV set*'$\}$ would be another set, which means that we are assuming '*Television*', for example, to be distinct from both '*Television set*' and '*TV set*'.

Definition 1. *(Distinctness Assertions) Given a set of nodes V, a* distinctness assertion *is a collection $D_i = (D_{i,1}, \ldots, D_{i,l_i})$ of pairwise disjoint (i.e. $D_{i,j} \cap D_{i,k} = \emptyset$ for $j \neq k$) subsets $D_{i,j} \subset V$ that expresses that any two nodes $u \in D_{i,j}$, $v \in D_{i,k}$ from different subsets ($j \neq k$) are asserted to be distinct from each other with some weight $w(D_i) \in \mathbb{R}$.*

We found that many components with inaccurate links can be identified automatically with the following distinctness assertions.

Criterion 1. *(Distinctness between articles from the same Wikipedia edition)* For each language-specific edition of Wikipedia, a separate assertion $(D_{i,1}, D_{i,2}, \ldots)$ can be made, where each $D_{i,j}$ contains an individual *article* together with its respective redirection pages. Two articles from the same Wikipedia very likely describe distinct concepts unless they are redirects of each other. For example, '*Georgia (country)*' is distinct from '*Georgia (U.S. State)*'. Additionally, there are also redirects that are clearly marked by a category or template as involving topic drift, e.g. redirects from songs to albums or artists, from products to companies, etc. We keep such redirects in a $D_{i,j}$ distinct from the one of their redirect targets.

Criterion 2. *(Distinctness between categories from the same Wikipedia edition)* For each language-specific edition of Wikipedia, a separate assertion $(D_{i,1}, D_{i,2}, \ldots)$ is made, where each $D_{i,j}$ contains a *category* page together with any redirects. For instance, '*Category:Writers*' is distinct from '*Category:Writing*'.

Criterion 3. *(Distinctness for links with anchor identifiers)* The English '*Division by zero*', for instance, links to the German '*Null#Division*'. The latter is only a part of a larger article about the number zero in general, so we can make a distinctness assertion to separate '*Division by zero*' from '*Null*'. In general, for each interwiki link or redirection with an anchor identifier, we add an assertion $(D_{i,1}, D_{i,2})$ where $D_{i,1}$,$D_{i,2}$ represent the respective articles without anchor identifiers.

These three types of distinctness assertions are instantiated for all articles and categories of all Wikipedia editions. The assertion weights are tunable; the simplest choice is using a uniform weight for all assertions (note that these weights are different from the edge weights in the graph). We will revisit this issue in our experiments.

2.2 Enforcing Consistency

Given a graph G representing cross-lingual links between Wikipedia pages, as well as distinctness assertions $D_1, \ldots, D_n$ with weights $w(D_i)$, we may find that nodes that are asserted to be distinct are in the same connected component. We can then try to apply repair operations to reconcile the graph's link structure with the distinctness asssertions and obtain global consistency. There are two ways to modify the input, and for each we can also consider the corresponding weights as a sort of *cost* that quantifies how much we are changing the original input:

a) **Edge cutting:** We may remove an edge $e \in E$ from the graph, paying cost $w(e)$.
b) **Distinctness assertion relaxation:** We may remove a node $v \in V$ from a distinctness assertion D_i, paying cost $w(D_i)$.

Removing edges allows us to split connected components into multiple smaller components, thereby ensuring that two nodes asserted to be distinct are no longer connected directly or indirectly. In Figure 1, for instance, we could delete the edge from the Spanish '*TV set*' article to the Japanese '*television*' article. In constrast, removing nodes from distinctness assertions means that we decide to give up our claim of them being distinct, instead allowing them to share a connected component.

Our reliance on costs is based on the assumption that the link structure or topology of the graph provides the best indication of which cross-lingual links to remove. In Figure 1, we have distinctness assertions between nodes in two densely connected clusters that are tied together only by a single spurious link. In such cases, edge removals can easily yield separate connected components. When, however, the two nodes are strongly connected via many different paths with high weights, we may instead opt for removing one of the two nodes from the distinctness assertion.

The aim will be to balance the costs for removing edges from the graph with the costs for removing nodes from distinctness assertions to produce a consistent solution with a minimal total repair cost. We accommodate our knowledge about distinctness while staying as close as possible to what Wikipedia provides as input.

This can be formalized as the **Weighted Distinctness-Based Graph Separation (WDGS)** problem. Let G be an undirected graph with a set of vertices V and a set of edges E weighted by $w : E \to \mathbb{R}$. If we use a set $C \subseteq V$ to specify which edges we want to cut from the original graph, and sets U_i to specify which nodes we want to remove from distinctness assertions, we can begin by defining WDGS solutions as follows.

Definition 2. *(**WDGS** Solution). Given a graph $G = (V, E)$ and n distinctness assertions $D_1, \ldots, D_n$, a tuple $(C, U_1, \ldots, U_n)$ is a valid* WDGS *solution if and only if $\forall i, j, k \neq j, u \in D_{i,j} \setminus U_i$, $v \in D_{i,k} \setminus U_i$: $\mathrm{P}(u, v, E \setminus C) = \emptyset$, i.e. the set of paths from u to v in the graph $(V, E \setminus C)$ is empty.*

Definition 3. *(**WDGS** Cost). Let $w : E \to \mathbb{R}$ be a weight function for edges $e \in E$, and $w(D_i)$ $(i = 1 \ldots n)$ be weights for the distinctness assertions. The (total) cost of a* WDGS *solution $S = (C, U_1, \ldots, U_n)$ is then defined as*

$$c(S) = c(C, U_1, \ldots, U_n) = \left[\sum_{e \in C} w(e)\right] + \left[\sum_{i=1}^{n} |U_i|\, w(D_i)\right]$$

Definition 4. *(**WDGS**). A* WDGS *problem instance P consists of a graph $G = (V, E)$ with edge weights $w(e)$ and n distinctness assertions D_1, $\ldots$, D_n with weights $w(D_i)$. The objective consists in finding a solution $(C, U_1, \ldots, U_n)$ with minimal cost $c(C, U_1, \ldots, U_n)$.*

It turns out that finding optimal solutions efficiently is a hard problem (proofs in Appendix A).

Theorem 1. WDGS *is NP-hard and APX-hard. If the Unique Games Conjecture (Khot, 2002) holds, then it is NP-hard to approximate* WDGS *within any constant factor $\alpha > 0$.*

3 Approximation Algorithm

Due to the hardness of WDGS, we devise a polynomial-time approximation algorithm with an approximation factor of $4 \ln(nq + 1)$ where n is the number of distinctness assertions and $q = \max_{i,j} |D_{i,j}|$. This means that for all problem instances P, we can guarantee

$$\frac{c(S(P))}{c(S^*(P))} \leq 4 \ln(nq + 1),$$

where $S(P)$ is the solution determined by our algorithm, and $S^*(P)$ is an optimal solution. Note that this approximation guarantee is independent of how long each D_i is, and that it merely represents an upper bound on the worst case scenario. In practice, the results tend to be much closer to the optimum, as will be shown in Section 4.

Our algorithm first solves a linear program (LP) relaxation of the original problem, which gives us hints as to which edges should most likely be cut and which nodes should most likely be removed from distinctness assertions. Note that this is a continuous LP, not an integer linear program (ILP); the latter would not be tractable due to the large number of variables and constraints of the problem. After solving the linear program, a new – extended – graph is constructed and the optimal LP solution is used to define a distance metric on it. The final solution is obtained by smartly selecting regions in this extended graph as the individual output components, employing a region

growing technique in the spirit of the seminal work by Leighton and Rao (1999). Edges that cross the boundaries of these regions are cut.

Definition 5. *Given a* WDGS *instance, we define a linear program of the following form:*

minimize

$$\sum_{e \in E} d_e w(e) + \sum_{i=1}^{n} \sum_{j=1}^{l_i} \sum_{v \in D_{i,j}} u_{i,v} w(D_i)$$

subject to

$$p_{i,j,v} = u_{i,v} \qquad \forall i,\, j{<}l_i,\, v \in D_{i,j} \qquad (1)$$

$$p_{i,j,v} + u_{i,v} \geq 1 \qquad \forall i,\, j{<}l_i,\, v \in \bigcup_{k>j} D_{i,k} \qquad (2)$$

$$p_{i,j,v} \leq p_{i,j,u} + d_e \qquad \forall i,\, j{<}l_i,\, e{=}(u,v) \in E \qquad (3)$$

$$d_e \geq 0 \qquad \forall e \in E \qquad (4)$$

$$u_{i,v} \geq 0 \qquad \forall i,\, v \in \bigcup_{j=1}^{l_i} D_{i,j} \qquad (5)$$

$$p_{i,j,v} \geq 0 \qquad \forall i,\, j{<}l_i,\, v{\in}V \qquad (6)$$

The LP uses decision variables d_e and $u_{i,v}$, and auxiliary variables $p_{i,j,v}$ that we refer to as *potential variables*. The d_e variables indicate whether (in the continuous LP: to what degree) an edge e should be deleted, and the $u_{i,v}$ variables indicate whether (to what degree) v should be removed from a distinctness assertion D_i. The LP objective function corresponds to Definition 3, aiming to minimize the total costs. A potential variable $p_{i,j,v}$ reflects a sort of potential difference between an assertion $D_{i,j}$ and a node v. If $p_{i,j,v} = 0$, then v is still connected to nodes in $D_{i,j}$. Constraints (1) and (2) enforce potential differences between $D_{i,j}$ and all nodes in $D_{i,k}$ with $k > j$. For instance, for distinctness between '*New York City*' and '*New York*' (the state), they might require '*New York*' to have a potential of 1, while '*New York City*' has a potential of 0. The potential variables are tied to the deletion variables d_e for edges in Constraint (3) as well as to the $u_{i,v}$ in Constraints (1) and (2). This means that the potential difference $p_{i,j,v} + u_{i,v} \geq 1$ can only be obtained if edges are deleted on every path between '*New York City*' and '*New York*', or if at least one of these two nodes is removed from the distinctness assertion (by setting the corresponding $u_{i,v}$ to non-zero values). Constraints (4), (5), (6) ensure non-negativity.

Having solved the linear program, the next major step is to convert the optimal LP solution into the final – discrete – solution. We cannot rely on standard rounding methods to turn the optimal fractional values of the d_e and $u_{i,v}$ variables into a valid solution. Often, all solution variables have small values and rounding will merely produce an empty $(C, U_1, \ldots, U_n) = (\emptyset, \emptyset, \ldots, \emptyset)$. Instead, a more sophisticated technique is necessary. The optimal solution of the LP can be used to define an extended graph G' with a distance metric d between nodes. The algorithm then operates on this graph, in each iteration selecting regions that become output components and removing them from the graph. A simple example is shown in Figure 2. The extended graph contains additional nodes and edges representing distinctness assertions. Cutting one of these additional edges corresponds to removing a node from a distinctness assertion.

Definition 6. *Given $G = (V, E)$ and distinctness assertions $D_1, \ldots, D_n$ with weights $w(D_i)$, we define an undirected graph $G' = (V', E')$ where $V' = V \cup \{\mathrm{v}_{i,v} \mid i = 1 \ldots n, w(D_i) > 0, v \in \bigcup_j D_{i,j}\}$, $E' = \{e \in E \mid w(e) > 0\} \cup \{(v, \mathrm{v}_{i,v}) \mid v \in D_{i,j}, w(D_i) > 0\}$. We accordingly extend the definition of $w(e)$ to additionally cover the new edges by defining $w(e) = w(D_i)$ for $e = (v, \mathrm{v}_{i,v})$. We also extend it for sets S of edges by defining $w(S) = \sum_{e \in S} w(e)$. Finally, we define a node distance metric*

$$d(u,v) = \begin{cases} 0 & u = v \\ d_e & (u,v) \in E \\ u_{i,v} & u = \mathrm{v}_{i,v} \\ u_{i,u} & v = \mathrm{v}_{i,u} \\ \min\limits_{p \in \mathrm{P}(u,v,E')} \sum\limits_{(u',v') \in p} d(u',v') & \textit{otherwise,} \end{cases}$$

where $\mathrm{P}(u, v, E')$ denotes the set of acyclic paths between two nodes in E'. We further fix

$$\hat{c}_\mathrm{f} = \sum_{(u,v) \in E'} d(u,v)\, w(e)$$

as the weight of the fractional solution of the LP ($\hat{c}_\mathrm{f}$ is a constant based on the original E', irrespective of later modifications to the graph).

Definition 7. *Around a given node v in G', we consider regions $R(v, r) \subseteq V$ with radius r. The cut $C(v, r)$ of a given region is defined as the set of edges in G' with one endpoint within the region and one outside the region:*

$$R(v,r) = \{v' \in V' \mid d(v,v') \leq r\}$$

$$C(v,r) = \{e \in E' \mid |e \cap R(v,r)| = 1\}$$

For sets of nodes $S \subseteq V$, we define $R(S, r) = \bigcup_{v \in S} R(v, r)$ and $C(S, r) = \bigcup_{v \in S} C(v, r)$.

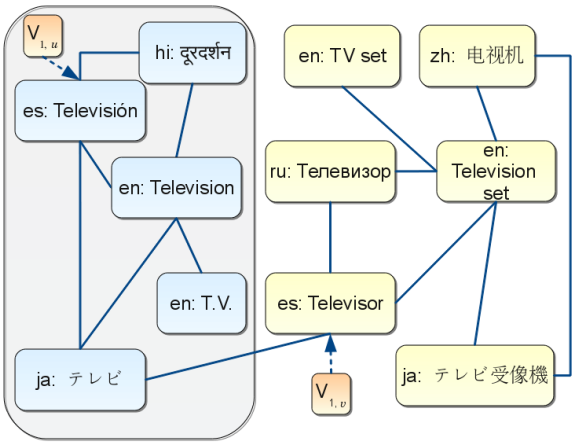

Figure 2: Extended graph with two added nodes $v_{1,u}$, $v_{1,v}$ representing distinctness between '*Televisión*' and '*Televisor*', and a region around $v_{1,u}$ that would cut the link from the Japanese '*Television*' to '*Televisor*'

Definition 8. *Given* $q = \max_{i,j} |D_{i,j}|$*, we approximate the optimal cost of regions as:*

$$\hat{c}(v,r) = \sum_{\substack{e=(u,u')\in E':\\ e\subseteq R(v,r)}} d(u,u')\, w(e) \quad (1)$$
$$+ \sum_{\substack{e\in C(v,r)\\ v'\in e\cap R(v,r)}} (r - d(v,v'))\, w(e)$$

$$\hat{c}(S,r) = \frac{1}{nq}\hat{c}_{\mathrm{f}} + \sum_{v\in S} \hat{c}(v,r) \quad (2)$$

The first summand accounts for the edges entirely within the region, and the second one accounts for the edges in $C(v,r)$ to the extent that they are within the radius. The definition of $\hat{c}(S,r)$ contains an additional slack component that is required for the approximation guarantee proof.

Based on these definitions, Algorithm 3.1 uses the LP solution to construct the extended graph. It then repeatedly, as long as there is an unsatisfied assertion D_i, chooses a set S of nodes containing one node from each relevant $D_{i,j}$. Around the nodes in S it simultaneously grows $|S|$ regions with the same radius, a technique previously suggested by Avidor and Langberg (2007). These regions are essentially output components that determine the solution. Repeatedly choosing the radius that minimizes $\frac{w(C(S,r))}{\hat{c}(S,r)}$ allows us to obtain the approximation guarantee, because the distances in this extended graph are based on the solution of the LP. The properties of this algorithm are given by the following two theorems (proofs in Appendix A).

Theorem 2. *The algorithm yields a* valid WDGS *solution* $(C, U_1, \ldots, U_n)$.

Theorem 3. *The algorithm yields a solution* $(C, U_1, \ldots, U_n)$ *with an approximation factor of* $4\ln(nq+1)$ *with respect to the cost of the optimal* WDGS *solution* $(C^*, U_1^*, \ldots, U_n^*)$*, where* n *is the number of distinctness assertions and* $q = \max_{i,j} |D_{i,j}|$*. This solution can be obtained in polynomial time.*

4 Results

4.1 Wikipedia

We downloaded February 2010 XML dumps of all available editions of Wikipedia, in total 272 editions that amount to 86.5 GB uncompressed. From these dumps we produced two datasets. Dataset A captures cross-lingual interwiki links between pages, in total 77.07 million undirected edges (146.76 million original links). Dataset B additionally includes 2.2 million redirect-based edges. Wikipedia deals with interwiki links to redirects transparently, however there are many redirects with titles that do not co-refer, e.g. redirects from members of a band to the band, or from aspects of a topic to the topic in general. We only included redirects in the following cases:

- the titles of redirect and redirect target match after Unicode NFKD normalization, diacritics removal, case conversion, and removal of punctuation characters
- the redirect uses certain templates or categories that indicate co-reference with the target (alternative names, abbreviations, etc.)

We treated them like reciprocal interwiki links by assigning them a weight of 2.

4.2 Application of Algorithm

The choice of distinctness assertion weights depends on how lenient we wish to be towards conceptual drift, allowing us to opt for more fine- or more coarse-grained distinctions. In our experiments, we decided to prefer fine-grained conceptual distinctions, and settled on a weight of 100.

We analysed over 20 million connected components in each dataset, checking for distinctness assertions. For the roughly 110,000 connected components with relevant distinctness assertions,

Algorithm 3.1 WDGS Approximation Algorithm

procedure SELECT($V, E, V', E', w, D_1, \ldots, D_n, l_1, \ldots, l_n$)
  solve linear program given by Definition 5 ▷ determine optimal fractional solution
  construct $G' = (V', E')$ ▷ extended graph (Definition 6)
  $C \leftarrow \{e \in E \mid w(e) = 0\}$ ▷ cut zero-weighted edges
  $U_i \leftarrow \bigcup_{j=1}^{l_i - 1} D_{i,j} \quad \forall i : w(D_i) = 0$ ▷ remove zero-weighted D_i

  return $(C, U_1, \ldots, U_n)$

we applied our algorithm, relying on the commercial CPLEX tool to solve the linear programs. In most cases, the LP solving took less than a second, however the LP sizes grow exponentially with the number of nodes and hence the time complexity increases similarly. In about 300 cases per dataset, CPLEX took too long and was automatically killed or the linear program was a priori deemed too large to complete in a short amount of time. For these cases, we adopted an alternative strategy described later on.

Table 1 provides the experimental results for the two datasets. Dataset B is more connected and thus has fewer connected components with more pairs of nodes asserted to be distinct by distinctness assertions. The LP given by Definition 5 provides fractional solutions that constitute lower bounds on the optimal solution (cf. also Lemma 5 in Appendix A), so the optimal solution cannot have a cost lower than the fractional LP solution. Table 1 shows that in practice, our algorithm achieves near-optimal results.

Table 1: Algorithm Results

	Dataset A	Dataset B
Connected components	23,356,027	21,161,631
– with distinctness assertions	112,857	113,714
– algorithm applied successfully	112,580	113,387
Distinctness assertions	380,694	379,724
Node pairs considered distinct	916,554	1,047,299
Lower bound on optimal cost	1,255,111	1,245,004
Cost of our solution	1,306,747	1,294,196
Factor	1.04	1.04
Edges to be deleted (undirected)	1,209,798	1,199,181
Nodes to be merged	603	573

4.3 Linguistic Adequacy

The near-optimal results of our algorithm apply with respect to our problem formalization, which aims at repairing the graph in a minimally invasive way. It may happen, however, that the graph's topology is misleading, and that in a specific case deleting many cross-lingual links to separate two entities is more appropriate than looking for a conservative way to separate them. This led us

to study the linguistic adequacy. Two annotators evaluated 200 randomly selected separated pairs from Dataset A consisting of an English and a German article, with an inter-annotator agreement (Cohen κ) of 0.656. Examples are given in Table 2. We obtained a precision of $87.97\% \pm 0.04\%$ (Wilson score interval) against the consensus annotation. Many of the errors are the result of articles having many inaccurate outgoing links, in which case they may be assigned to the wrong component. In other cases, we noted duplicate articles in Wikipedia.

Occasionally, we also observed differences in scope, where one article would actually describe two related concepts in a single page. Our algorithm will then either make a somewhat arbitrary assignment to the component of either the first or second concept, or the broader generalization of the two concepts becomes a separate, more general connected component.

4.4 Large Problem Instances

When problem instances become too large, the linear programs can become too unwieldy for linear optimization software to cope with on current hardware. In such cases, the graphs tend to be very sparsely connected, consisting of many smaller, more densely connected subgraphs. We thus investigated graph partitioning heuristics to decompose larger graphs into smaller parts that can more easily be handled with our algorithm. The METIS algorithms (Karypis and Kumar, 1998) can decompose graphs with hundreds of thousands of nodes almost instantly, but favour equally sized clusters over lower cut costs. We obtained partitionings with costs orders of magnitude lower using the heuristic by Dhillon et al. (2007).

4.5 Database of Named Entities

The partitioning heuristics allowed us to process all entries in the complete set of Wikipedia dumps and produce a clean output set of connected components where each Wikipedia article or category belongs to a connected component consisting of pages about the same entity or concept. We can regard these connected components as equivalence classes. This means that we obtain a large-scale multilingual database of named entities and their translations. We are also able to more safely transfer information cross-lingually between editions. For example, when an article a has a category c in the French Wikipedia, we can suggest the corresponding Indonesian category for the corresponding Indonesian article.

Moreover, we believe that this database will help extend resources like DBPedia and YAGO that to date have exclusively used the English Wikipedia as their repository of entities and classes. With YAGO's category heuristics, even entirely non-English connected components can be assigned a class in WordNet as long as at least one of the relevant categories has an English page. So, the French Wikipedia article on the Dutch schooner '*JR Tolkien*', despite the lack of a corresponding English article, can be assigned to the WordNet synset for '*ship*'. Using YAGO's plural heuristic to distinguish classes (Einstein *is a* physicist) from topic descriptors (Einstein *belongs to the topic* physics), we determined that over 4.8 million connected components can be linked to WordNet, greatly surpassing the 3.2 million articles covered by the English Wikipedia alone.

5 Related Work

A number of projects have used Wikipedia as a database of named entities (Ponzetto and Strube, 2007; Silberer et al., 2008). The most well-known are probably DBpedia (Auer et al., 2007), which serves as a hub in the Linked Data Web, Freebase[1], which combines human input and automatic extractors, and YAGO (Suchanek et al., 2007), which adds an ontological structure on top of Wikipedia's entities. Wikipedia has been used cross-lingually for cross-lingual IR (Nguyen et al., 2009), question answering (Ferrández et al., 2007) as well as for learning transliterations (Pasternack and Roth, 2009), among other things.

Mihalcea and Csomai (2007) have studied predicting new links within a single edition of Wikipedia. Sorg and Cimiano (2008) considered the problem of suggesting new cross-lingual links, which could be used as additional inputs in our problem. Adar et al. (2009) and Bouma et al. (2009) show how cross-lingual links can be used to propagate information from one Wikipedia's infoboxes to another edition.

Our aggregation consistency algorithm uses theoretical ideas put forward by researchers studying graph cuts (Leighton and Rao, 1999; Garg et al., 1996; Avidor and Langberg, 2007). Our problem setting is related to that of correlation clustering (Bansal et al., 2004), where a graph consist-

Table 2: Examples of separated concepts

English concept	German concept (translated)	Explanation
Coffee percolator	French Press	different types of brewing devices
Baqa-Jatt	Baqa al-Gharbiyye	Baqa-Jatt is a city resulting from a merger of Baqa al-Gharbiyye and Jatt
Leucothoe (plant)	Leucothea (Orchamos)	the second refers to a figure of Greek mythology
Old Belarusian language	Ruthenian language	the second is often considered slightly broader

ing of positively and negatively labelled similarity edges is clustered such that similar items are grouped together, however our approach is much more generic than conventional correlation clustering. Charikar et al. (2005) studied a variation of correlation clustering that is similar to WDGS, but since a negative edge would have to be added between each relevant pair of entities in a distinctness assertion, the approximation guarantee would only be $O(\log(n\ |V|^2))$. Minimally invasive repair operations on graphs have also been studied for graph similarity computation (Zeng et al., 2009), where two graphs are provided as input.

6 Conclusions and Future Work

We have presented an algorithmic framework for the problem of co-reference that produces consistent partitions by intelligently removing edges or allowing nodes to remain connected. This algorithm has successfully been applied to Wikipedia's cross-lingual graph, where we identified and eliminated surprisingly large numbers of inaccurate connections, leading to a large-scale multilingual register of names.

In future work, we would like to investigate how our algorithm behaves in extended settings, e.g. we can use heuristics to connect isolated, unconnected articles to likely candidates in other Wikipedias using weighted edges. This can be extended to include mappings from multiple languages to WordNet synsets, with the hope that the weights and link structure will then allow the algorithm to make the final disambiguation decision. Additional scenarios include dealing with co-reference on the Linked Data Web or mappings between thesauri. As such resources are increasingly being linked to Wikipedia and DBpedia, we believe that our techniques will prove useful in making mappings more consistent.

A Proofs

Proof (Theorem 1). We shall reduce the minimum multicut problem to WDGS. The hardness claims then follow from Chawla et al. (2005). Given a graph $G = (V, E)$ with a positive cost $c(e)$ for each $e \in E$, and a set $D = \{(s_i, t_i) \mid i = 1 \dots k\}$ of k demand pairs, our goal is to find a multicut M with respect to D with minimum total cost $\sum_{e \in M} c(e)$. We convert each demand pair (s_i, t_i) into a distinctness assertion $D_i = (\{s_i\}, \{t_i\})$ with weight $w(D_i) = 1 + \sum_{e \in E} c(e)$. An optimal WDGS solution $(C, U_1, \dots, U_k)$ with cost c then implies a multicut C with the same weight, because each $w(D_i) > \sum_{e \in E} c(e)$, so all demand pairs will be satisfied. C is a minimal multicut because any multicut C' with lower cost would imply a valid WDGS solution $(C', \emptyset, \dots, \emptyset)$ with a cost lower than the optimal one, which is a contradiction. □

Lemma 4. *The linear program given by Definition 5 enforces that for any i,j,k ≠ j,u ∈ $D_{i,j}$, $v \in D_{i,k}$, and any path $v_0, \dots, v_t$ with $v_0 = u$, $v_t = v$ we obtain $u_{i,u} + \sum_{l=0}^{t-1} d_{(v_l, v_{l+1})} + u_{i,v} \geq 1$. The integer linear program obtained by augmenting Definition 5 with integer constraints $d_e, u_{i,v}, p_{i,j,v} \in \{0, 1\}$ (for all applicable e, i, j, v) produces optimal solutions $(C, U_1, \dots, U_k)$ for* WDGS *problems, obtained as $C = (\{e \in E \mid d_e = 1\}$, $U_i = \{v \mid u_{i,v} = 1\}$.*

Proof. Without loss of generality, let us assume that $j < k$. The LP constraints give us $p_{i,j,v_t} \leq p_{i,j,v_{t-1}} + d_{(v_{t-1}, v_t)}, \dots, p_{i,j,v_1} \leq p_{i,j,v_0} + d_{(v_0, v_1)}$, as well as $p_{i,j,v_0} = u_{i,u}$ and $p_{i,j,v_t} + u_{i,v} \geq 1$. Hence $1 \leq p_{i,j,v_t} + u_{i,v} \leq u_{i,u} + \sum_{l=0}^{t-1} d_{(v_l, v_{l+1})} + u_{i,v}$.

With added integrality constraints, we obtain either $u \in U_i$, $v \in U_i$, or at least one edge along any path from u to v is cut, i.e. $\mathrm{P}(u, v, E \setminus C) = \emptyset$.

This proves that any ILP solution enduces a valid WDGS solution (Definition 2).

Clearly, the integer program's objective function minimizes $c(C, U_1, \ldots, U_n)$ (Definition 3) if $C = (\{e \in E \mid d_e = 1\}$, $U_i = \{v \mid u_{i,v} = 1\}$. To see that the solutions are optimal, it thus suffices to observe that any optimal WDGS solution $(C^*, U_1^*, \ldots, U_n^*)$ yields a feasible ILP solution $d_e = I_{C^*}(e)$, $u_{i,v} = I_{U_i^*}(v)$. □

Proof (Theorem 2). $r_i < \frac{1}{2}$ holds for any radius r_i chosen by the algorithm, so for any region $R(v_0, r)$ grown around a node v_0, and any two nodes u, v within that region, the triangle inequality gives us $d(u, v) \leq d(u, v_0) + d(v_0, v) < \frac{1}{2} + \frac{1}{2} = 1$ (maximal distance condition). At the same time, by Lemma 4 and Definition 6 for any $u \in D_{i,j}$, $v \in D_{i,k}$ $(j \neq k)$, we obtain $d(\mathrm{v}_{i,u}, \mathrm{v}_{i,v}) = d(\mathrm{v}_{i,u}, u) + d(u, v) + d(v, \mathrm{v}_{i,v}) \geq 1$. With the maximal distance condition above, this means that $\mathrm{v}_{i,u}$ and $\mathrm{v}_{i,v}$ cannot be in the same region. Hence u, v cannot be in the same region, unless the edge from $\mathrm{v}_{i,u}$ to u is cut (in which case u will be placed in U_i) or the edge from v to $\mathrm{v}_{i,v}$ is cut (in which case v will be placed in U_i). Since each region is separated from other regions via C, we obtain that $\forall i, j, k \neq j, u, v$: $u \in D_{i,j} \setminus U_i$, $v \in D_{i,k} \setminus U_i$ implies $\mathrm{P}(u, v, E \setminus C) = \emptyset$, so a valid solution is obtained. □

Lemma 5 (essentially due to Garg et al. (1996))**.** *For any i where $\exists j, k > j, u \in D_{i,j}, v \in D_{i,k}$: $\mathrm{P}(\mathrm{v}_{i,u}, \mathrm{v}_{i,v}, E') \neq \emptyset$ and $w(D_i) > 0$, there exists an r such that $w(C(S, r)) \leq 2\ln(nq+1)\,\hat{c}(S, r)$, $0 \leq r < \frac{1}{2}$ for any set S consisting of $\mathrm{v}_{i,v}$ nodes.*

Proof. Define $w(S, r) = \sum_{v \in S} w(C(v, r))$. We will prove that there exists an appropriate r with $w(C(S, r)) \leq w(S, r) \leq 2\ln(nq+1)\,\hat{c}(S, r)$. Assume, for reductio ad absurdum, that $\forall r \in [0, \frac{1}{2})$: $w(S, r) > 2\ln(nq+1)\hat{c}(S, r)$. As we expand the radius r, we note that $\hat{c}(S, r)\frac{d}{dr} = w(S, r)$ whereever $\hat{c}$ is differentiable with respect to r. There are only a finite number of points $r_1, \ldots, r_{l-1}$ in $(0, \frac{1}{2})$ where this is not the case (namely, when $\exists u \in S,\ v \in V' : d(u, v) = r_i$). Also note that $\hat{c}$ increases monotonically for increasing values of r, and that it is universally greater than zero (since there is a path between $\mathrm{v}_{i,u}$, $\mathrm{v}_{i,v}$). Set $r_0 = 0$, $r_l = \frac{1}{2}$ and choose ϵ such that $0 < \epsilon \ll \min\{r_{j+1} - r_j \mid j < l\}$. Our assumption then implies:

$$\sum_{j=1}^{l} \int_{r_{j-1}+\epsilon}^{r_j-\epsilon} \frac{w(S,r)}{\hat{c}(S,r)}\, dr > \left[\sum_{j=1}^{l} r_j - r_{j-1} - 2\epsilon\right] 2\ln(nq+1)$$

$$\sum_{j=1}^{l} \ln \hat{c}(S, r_j - \epsilon) - \ln \hat{c}(S, r_{j-1} + \epsilon) > \left(\tfrac{1}{2} - 2l\epsilon\right) 2\ln(nq+1)$$

$$\ln \hat{c}(S, \tfrac{1}{2} - \epsilon) - \ln \hat{c}(S, 0) > (1 - 4l\epsilon)\ln(nq+1)$$

$$\frac{\hat{c}(S, \frac{1}{2}-\epsilon)}{\hat{c}(S,0)} > (nq+1)^{1-4l\epsilon}$$

$$\hat{c}(S, \tfrac{1}{2} - \epsilon) > (nq+1)^{1-4l\epsilon}\hat{c}(S, 0)$$

For small ϵ, the right term can get arbitrarily close to $(nq+1)\hat{c}(S, 0) \geq \hat{c}_{\mathrm{f}} + \hat{c}(S, 0)$, which is strictly larger than $\hat{c}(S, \frac{1}{2} - \epsilon)$ no matter how small ϵ becomes, so the initial assumption is false. □

Proof (Theorem 3). Let S_i, r_i denote the set S and radius r chosen in particular iterations, and c_i the corresponding costs incurred: $c_i = w(C(S_i, r) \cap E) + |U_i| w(D_i) = w(C(D_i, r))$. Note that any r_i chosen by the algorithm will in fact fulfil the criterion described by Lemma 5, because r_i is chosen to minimize the ratio between the two terms, and the minimizing $r \in [0, \frac{1}{2})$ must be among the r considered by the algorithm ($w(C(D_i, r))$ only changes at one of those points, so the minimum is reached by approaching the points from the left). Hence, we obtain $c_i \leq 2\ln(n+1)\hat{c}(S_i, r_i)$. For our global solution, note that there is no overlap between the regions chosen within an iteration, since regions have a radius strictly smaller than $\frac{1}{2}$, while $\mathrm{v}_{i,u}$, $\mathrm{v}_{i,v}$ for $u \in D_{i,j}$, $v \in D_{i,k}$, $j \neq k$ have a distance of at least 1. Nor is there any overlap between regions from different iterations, because in each iteration the selected regions are removed from G'. Globally, we therefore obtain $c(C, U_1, \ldots, U_n) = \sum_i c_i < 2\ln(nq+1) \sum_i \hat{c}(S_i, r_i) \leq 2\ln(nq+1)2\hat{c}_{\mathrm{f}}$ (observe that $i \leq nq$). Since $\hat{c}_{\mathrm{f}}$ is the objective score for the fractional LP relaxation solution of the WDGS ILP (Lemma 4), we obtain $\hat{c}_{\mathrm{f}} \leq c(C^*, U_1^*, \ldots, U_n^*)$, and thus $c(C, U_1, \ldots, U_n) < 4\ln(n+1)c(C^*, U_1^*, \ldots, U_n^*)$.

To obtain a solution in polynomial time, note that the LP size is polynomial with respect to nq and may be solved using a polynomial algorithm (Karmarkar, 1984). The subsequent steps run in $O(nq)$ iterations, each growing up to $|V|$ regions using $O(|V|^2)$ uniform cost searches. □

Abstract

We explore how to improve machine translation systems by adding more translation data in situations where we already have substantial resources. The main challenge is how to buck the trend of diminishing returns that is commonly encountered. We present an active learning-style data solicitation algorithm to meet this challenge. We test it, gathering annotations via Amazon Mechanical Turk, and find that we get an order of magnitude increase in performance rates of improvement.

1 Introduction

Figure 1 shows the learning curves for two state of the art statistical machine translation (SMT) systems for Urdu-English translation. Observe how the learning curves rise rapidly at first but then a trend of diminishing returns occurs: put simply, the curves flatten.

This paper investigates whether we can buck the trend of diminishing returns, and if so, how we can do it effectively. Active learning (AL) has been applied to SMT recently (Haffari et al., 2009; Haffari and Sarkar, 2009) but they were interested in starting with a tiny seed set of data, and they stopped their investigations after only adding a relatively tiny amount of data as depicted in Figure 1.

In contrast, we are interested in applying AL when a large amount of data already exists as is the case for many important lanuage pairs. We develop an AL algorithm that focuses on keeping annotation costs (measured by time in seconds) low. It succeeds in doing this by only soliciting translations for parts of sentences. We show that this gets a savings in human annotation time above and beyond what the reduction in # words annotated would have indicated by a factor of about three and speculate as to why.

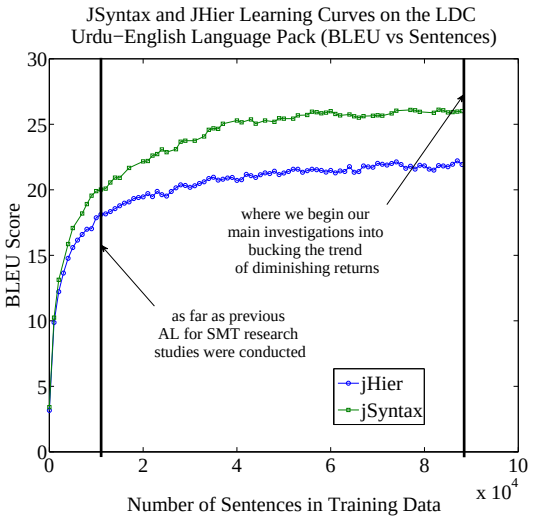

Figure 1: Syntax-based and Hierarchical Phrase-Based MT systems' learning curves on the LDC Urdu-English language pack. The x-axis measures the number of sentence pairs in the training data. The y-axis measures BLEU score. Note the diminishing returns as more data is added. Also note how relatively early on in the process previous studies were terminated. In contrast, the focus of our main experiments doesn't even begin until much higher performance has already been achieved with a period of diminishing returns firmly established.

We conduct experiments for Urdu-English translation, gathering annotations via Amazon Mechanical Turk (MTurk) and show that we can indeed buck the trend of diminishing returns, achieving an order of magnitude increase in the rate of improvement in performance.

Section 2 discusses related work; Section 3 discusses preliminary experiments that show the guiding principles behind the algorithm we use; Section 4 explains our method for soliciting new translation data; Section 5 presents our main results; and Section 6 concludes.

2 Related Work

Active learning has been shown to be effective for improving NLP systems and reducing annotation burdens for a number of NLP tasks (see, e.g., (Hwa, 2000; Sassano, 2002; Bloodgood and Vijay-Shanker, 2008; Bloodgood and Vijay-Shanker, 2009b; Mairesse et al., 2010; Vickrey et al., 2010)). The current paper is most highly related to previous work falling into three main areas: use of AL when large corpora already exist; cost-focused AL; and AL for SMT.

In a sense, the work of Banko and Brill (2001) is closely related to ours. Though their focus is mainly on investigating the performance of learning methods on giant corpora many orders of magnitude larger than previously used, they do lay out how AL might be useful to apply to acquire data to augment a large set cheaply because they recognize the problem of diminishing returns that we discussed in Section 1.

The second area of work that is related to ours is previous work on AL that is cost-conscious. The vast majority of AL research has not focused on accurate cost accounting and a typical assumption is that each annotatable has equal annotation cost. An early exception in the AL for NLP field was the work of Hwa (2000), which makes a point of using # of brackets to measure cost for a syntactic analysis task instead of using # of sentences. Another relatively early work in our field along these lines was the work of Ngai and Yarowsky (2000), which measured actual times of annotation to compare the efficacy of rule writing versus annotation with AL for the task of BaseNP chunking. Osborne and Baldridge (2004) argued for the use of discriminant cost over unit cost for the task of Head Phrase Structure Grammar parse selection. King et al. (2004) design a robot that tests gene functions. The robot chooses which experiments to conduct by using AL and takes monetary costs (in pounds sterling) into account during AL selection and evaluation. Unlike our situation for SMT, their costs are all known beforehand because they are simply the cost of materials to conduct the experiments, which are already known to the robot. Hachey et al. (2005) showed that selectively sampled examples for an NER task took longer to annotate and had lower inter-annotator agreement. This work is related to ours because it shows that how examples are selected can impact the cost of annotation, an idea we turn around to use for our advantage when developing our data selection algorithm. Haertel et al. (2008) emphasize measuring costs carefully for AL for POS tagging. They develop a model based on a user study that can estimate the time required for POS annotating. Kapoor et al. (2007) assign costs for AL based on message length for a voicemail classification task. In contrast, we show for SMT that annotation times do not scale according to length in words and we show our method can achieve a speedup in annotation time above and beyond what the reduction in words would indicate. Tomanek and Hahn (2009) measure cost by # of tokens for an NER task. Their AL method only solicits labels for parts of sentences in the interest of reducing annotation effort. Along these lines, our method is similar in the respect that we also will only solicit annotation for parts of sentences, though we prefer to measure cost with time and we show that time doesn't track with token length for SMT.

Haffari et al. (2009), Haffari and Sarkar (2009), and Ambati et al. (2010) investigate AL for SMT. There are two major differences between our work and this previous work. One is that our intended use cases are very different. They deal with the more traditional AL setting of starting from an extremely small set of seed data. Also, by SMT standards, they only add a very tiny amount of data during AL. All their simulations top out at 10,000 sentences of labeled data and the models learned have relatively low translation quality compared to the state of the art.

On the other hand, in the current paper, we demonstrate how to apply AL in situations where we already have large corpora. Our goal is to buck the trend of diminishing returns and use AL to add data to build some of the highest-performing MT systems in the world while keeping annotation costs low. See Figure 1 from Section 1, which contrasts where (Haffari et al., 2009; Haffari and Sarkar, 2009) *stop* their investigations with where we *begin* our studies.

The other major difference is that (Haffari et al., 2009; Haffari and Sarkar, 2009) measure annotation cost by # of sentences. In contrast, we bring to light some potential drawbacks of this practice, showing it can lead to different conclusions than if other annotation cost metrics are used, such as time and money, which are the metrics that we use.

3 Simulation Experiments

Here we report on results of simulation experiments that help to illustrate and motivate the design decisions of the algorithm we present in Section 4. We use the Urdu-English language pack[1] from the Linguistic Data Consortium (LDC), which contains ≈ 88000 Urdu-English sentence translation pairs, amounting to ≈ 1.7 million Urdu words translated into English. All experiments in this paper evaluate on a genre-balanced split of the NIST2008 Urdu-English test set. In addition, the language pack contains an Urdu-English dictionary consisting of ≈ 114000 entries. In all the experiments, we use the dictionary at every iteration of training. This will make it harder for us to show our methods providing substantial gains since the dictionary will provide a higher base performance to begin with. However, it would be artificial to ignore dictionary resources when they exist.

We experiment with two translation models: hierarchical phrase-based translation (Chiang, 2007) and syntax augmented translation (Zollmann and Venugopal, 2006), both of which are implemented in the Joshua decoder (Li et al., 2009). We hereafter refer to these systems as jHier and jSyntax, respectively.

We will now present results of experiments with different methods for growing MT training data. The results are organized into three areas of investigations:

1. annotation costs;
2. managing uncertainty; and
3. how to automatically detect when to stop soliciting annotations from a pool of data.

3.1 Annotation Costs

We begin our cost investigations with four simple methods for growing MT training data: random, shortest, longest, and *VocabGrowth* sentence selection. The first three methods are self-explanatory. *VocabGrowth* (hereafter *VG*) selection is modeled after the best methods from previous work (Haffari et al., 2009; Haffari and Sarkar, 2009), which are based on preferring sentences that contain phrases that occur frequently in unlabeled data and infrequently in the so-far labeled data. Our *VG* method selects sentences for translation that contain n-grams (for n in {1,2,3,4}) that do not occur at all in our so-far labeled data. We call an n-gram "covered" if it occurs at least once in our so-far labeled data. *VG* has a preference for covering frequent n-grams before covering infrequent n-grams. The *VG* method is depicted in Figure 2.

Init:
Go through all available training data (labeled and unlabeled) and obtain frequency counts for every n-gram (n in $\{1, 2, 3, 4\}$) that occurs.
$sortedNGrams \leftarrow$ Sort n-grams by frequency in descending order.

Loop
until stopping criterion (see Section 3.3) is met
1. $trigger \leftarrow$ Go down $sortedNGrams$ list and find the first n-gram that isn't covered in the so far labeled training data.
2. $selectedSentence \leftarrow$ Find a sentence that contains $trigger$.
3. Remove $selectedSentence$ from unlabeled data and add it to labeled training data.

End Loop

Figure 2: The *VG* sentence selection algorithm

Figure 3 shows the learning curves for both jHier and jSyntax for *VG* selection and random selection. The y-axis measures BLEU score (Papineni et al., 2002),which is a fast automatic way of measuring translation quality that has been shown to correlate with human judgments and is perhaps the most widely used metric in the MT community. The x-axis measures the number of sentence translation pairs in the training data. The *VG* curves are cut off at the point at which the stopping criterion in Section 3.3 is met. From Figure 3 it might appear that *VG* selection is better than random selection, achieving higher-performing systems with fewer translations in the labeled data.

However, it is important to take care when measuring annotation costs (especially for relatively complicated tasks such as translation). Figure 4 shows the learning curves for the same systems and selection methods as in Figure 3 but now the x-axis measures the number of foreign words in the training data. The difference between *VG* and random selection now appears smaller.

For an extreme case, to illustrate the ramifica-

[1] LDC Catalog No.: LDC2006E110.

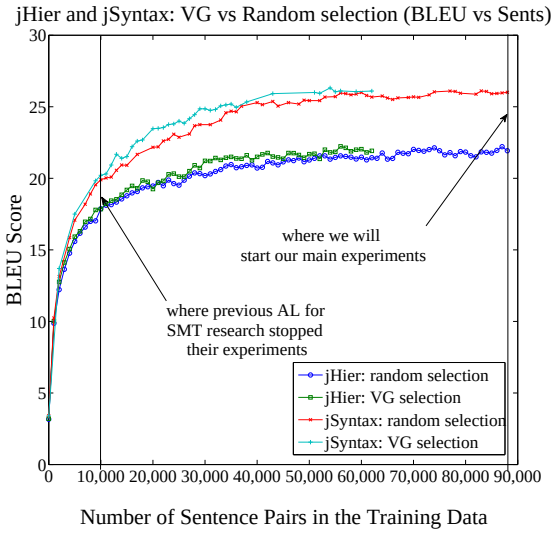

Figure 3: Random vs *VG* selection. The x-axis measures the number of sentence pairs in the training data. The y-axis measures BLEU score.

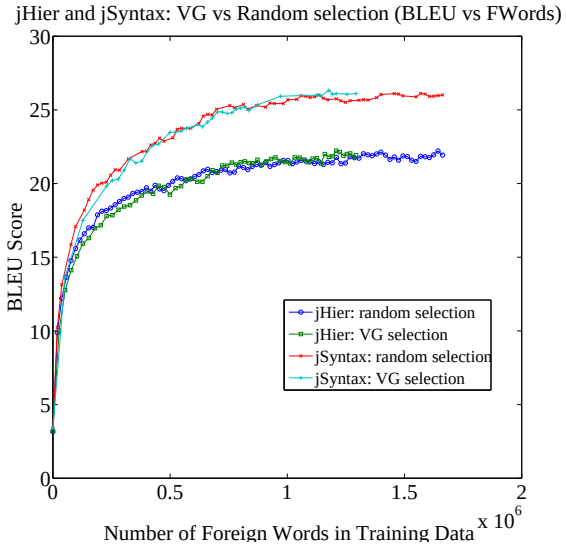

Figure 4: Random vs *VG* selection. The x-axis measures the number of foreign words in the training data. The y-axis measures BLEU score.

tions of measuring translation annotation cost by # of sentences versus # of words, consider Figures 5 and 6. They both show the same three selection methods but Figure 5 measures the x-axis by # of sentences and Figure 6 measures by # of words. In Figure 5, one would conclude that shortest is a far inferior selection method to longest but in Figure 6 one would conclude the opposite.

Measuring annotation time and cost in dollars are probably the most important measures of annotation cost. We can't measure these for the simulated experiments but we will use time (in seconds) and money (in US dollars) as cost measures in Section 5, which discusses our non-simulated AL experiments. If # sentences or # words track these other more relevant costs in predictable known relationships, then it would suffice to measure # sentences or # words instead. But it's clear that different sentences can have very different annotation time requirements according to how long and complicated they are so we will not use # sentences as an annotation cost any more. It is not as clear how # words tracks with annotation time. In Section 5 we will present evidence showing that time per word can vary considerably and also show a method for soliciting annotations that reduces time per word by nearly a factor of three.

As it is prudent to evaluate using accurate cost accounting, so it is also prudent to develop new AL algorithms that take costs carefully into account. Hence, reducing annotation time burdens instead of the # of sentences translated (which might be quite a different thing) will be a cornerstone of the algorithm we describe in Section 4.

3.2 Managing Uncertainty

One of the most successful of all AL methods developed to date is uncertainty sampling and it has been applied successfully many times (e.g.,(Lewis and Gale, 1994; Tong and Koller, 2002)). The intuition is clear: much can be learned (potentially) if there is great uncertainty. However, with MT being a relatively complicated task (compared with binary classification, for example), it might be the case that the uncertainty approach has to be re-considered. If words have never occurred in the training data, then uncertainty can be expected to be high. But we are concerned that if a sentence is translated for which (almost) no words have been seen in training yet, though uncertainty will be high (which is usually considered good for AL), the word alignments may be incorrect and then subsequent learning from that translation pair will be severely hampered.

We tested this hypothesis and Figure 7 shows empirical evidence that it is true. Along with *VG*, two other selection methods' learning curves are charted in Figure 7: mostNew, which prefers to select those sentences which have the largest # of unseen words in them; and moderateNew, which aims to prefer sentences that have a moderate # of unseen words, preferring sentences with $\approx$ ten

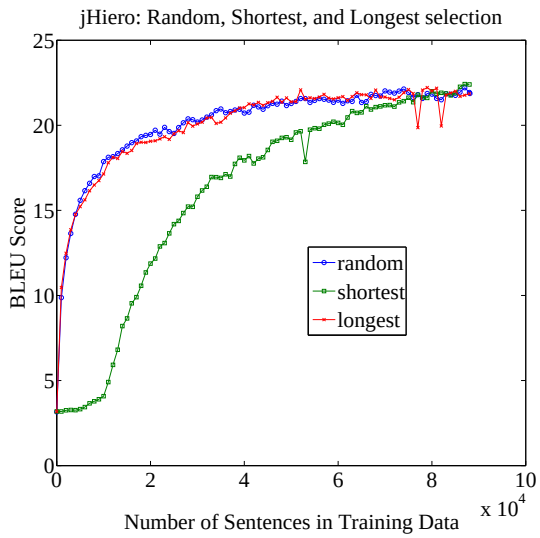

Figure 5: Random vs Shortest vs Longest selection. The x-axis measures the number of sentence pairs in the training data. The y-axis measures BLEU score.

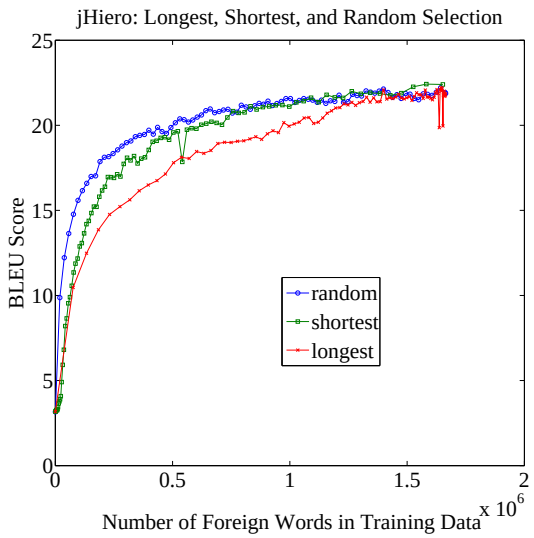

Figure 6: Random vs Shortest vs Longest selection. The x-axis measures the number of foreign words in the training data. The y-axis measures BLEU score.

unknown words in them. One can see that mostNew underperforms *VG*. This could have been due to *VG*'s frequency component, which mostNew doesn't have. But moderateNew also doesn't have a frequency preference so it is likely that mostNew winds up overwhelming the MT training system, word alignments are incorrect, and less is learned as a result. In light of this, the algorithm we develop in Section 4 will be designed to avoid this word alignment danger.

3.3 Automatic Stopping

The problem of automatically detecting when to stop AL is a substantial one, discussed at length in the literature (e.g., (Bloodgood and Vijay-Shanker, 2009a; Schohn and Cohn, 2000; Vlachos, 2008)). In our simulation, we stop *VG* once all n-grams (n in {1,2,3,4}) have been covered. Though simple, this stopping criterion seems to work well as can be seen by where the curve for *VG* is cut off in Figures 3 and 4. It stops after 1,293,093 words have been translated, with jHier's BLEU=21.92 and jSyntax's BLEU=26.10 at the stopping point. The ending BLEU scores (with the full corpus annotated) are 21.87 and 26.01 for jHier and jSyntax, respectively. So our stopping criterion saves 22.3% of the annotation (in terms of words) and actually achieves slightly higher BLEU scores than if all the data were used. Note: this "less is more" phenomenon has been commonly observed in AL settings (e.g., (Bloodgood and Vijay-Shanker, 2009a; Schohn and Cohn, 2000)).

4 Highlighted N-Gram Method

In this section we describe a method for soliciting human translations that we have applied successfully to improving translation quality in real (not simulated) conditions. We call the method the *Highlighted N-Gram* method, or *HNG*, for short. *HNG* solicits translations only for trigger n-grams and not for entire sentences. We provide sentential context, highlight the trigger n-gram that we want translated, and ask for a translation of just the highlighted trigger n-gram. *HNG* asks for translations for triggers in the same order that the triggers are encountered by the algorithm in Figure 2. A screenshot of our interface is depicted in Figure 8. The same stopping criterion is used as was used in the last section. When the stopping criterion becomes true, it is time to tap a new unlabeled pool of foreign text, if available.

Our motivations for soliciting translations for only parts of sentences are twofold, corresponding to two possible cases. Case one is that a translation model learned from the so-far labeled data will be able to translate most of the non-trigger words in the sentence correctly. Thus, by asking a human to translate only the trigger words, we avoid wasting human translation effort. (We will show in

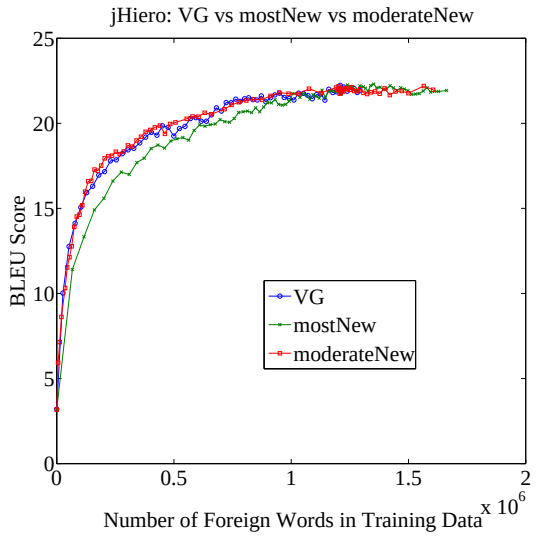

Figure 7: *VG* vs MostNew vs ModerateNew selection. The x-axis measures the number of sentence pairs in the training data. The y-axis measures BLEU score.

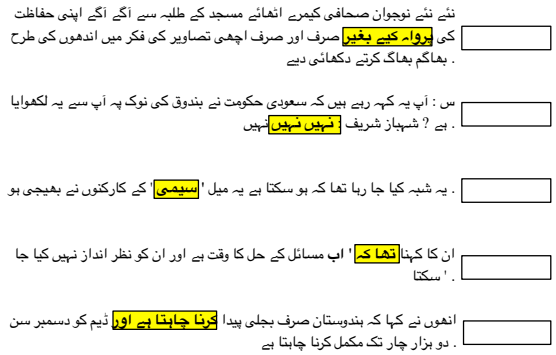

Figure 8: Screenshot of the interface we used for soliciting translations for triggers.

the next section that we even get a much larger speedup above and beyond what the reduction in number of translated words would give us.) Case two is that a translation model learned from the so-far labeled data will (in addition to not being able to translate the trigger words correctly) also not be able to translate most of the non-trigger words correctly. One might think then that this would be a great sentence to have translated because the machine can potentially learn a lot from the translation. Indeed, one of the overarching themes of AL research is to query examples where uncertainty is greatest. But, as we showed evidence for in the last section, for the case of SMT, too much uncertainty could in a sense overwhelm the machine and it might be better to provide new training data in a more gradual manner. A sentence with large #s of unseen words is likely to get word-aligned incorrectly and then learning from that translation could be hampered. By asking for a translation of only the trigger words, we expect to be able to circumvent this problem in large part.

The next section presents the results of experiments that show that the *HNG* algorithm is indeed practically effective. Also, the next section analyzes results regarding various aspects of *HNG*'s behavior in more depth.

5 Experiments and Discussion

5.1 General Setup

We set out to see whether we could use the *HNG* method to achieve translation quality improvements by gathering additional translations to add to the training data of the entire LDC language pack, including its dictionary. In particular, we wanted to see if we could achieve translation improvements on top of already state-of-the-art performing systems trained already on the *entire* LDC corpus. Note that at the outset this is an ambitious endeavor (recall the flattening of the curves in Figure 1 from Section 1).

Snow et al. (2008) explored the use of the Amazon Mechanical Turk (MTurk) web service for gathering annotations for a variety of natural language processing tasks and recently MTurk has been shown to be a quick, cost-effective way to gather Urdu-English translations (Bloodgood and Callison-Burch, 2010). We used the MTurk web service to gather our annotations. Specifically, we first crawled a large set of BBC articles on the internet in Urdu and used this as our unlabeled pool from which to gather annotations. We applied the *HNG* method from Section 4 to determine what to post on MTurk for workers to translate.[2] We gathered 20,580 n-gram translations for which we paid $0.01 USD per translation, giving us a total cost of $205.80 USD. We also gathered 1632 randomly chosen Urdu sentence translations as a control set, for which we paid $0.10 USD per sentence translation.[3]

[2]For practical reasons we restricted ourselves to not considering sentences that were longer than 60 Urdu words, however.

[3]The prices we paid were not market-driven. We just chose prices we thought were reasonable. In hindsight, given how much quicker the phrase translations are for people we could have had a greater disparity in price.

5.2 Accounting for Translation Time

MTurk returns with each assignment the "WorkTimeInSeconds." This is the amount of time between when a worker accepts an assignment and when the worker submits the completed assignment. We use this value to estimate annotation times.[4]

Figure 9 shows *HNG* collection versus random collection from MTurk. The x-axis measures the number of seconds of annotation time. Note that *HNG* is more effective. A result that may be particularly interesting is that *HNG* results in a time speedup by more than just the reduction in translated words would indicate. The average time to translate a word of Urdu with the sentence postings to MTurk was 32.92 seconds. The average time to translate a word with the *HNG* postings to MTurk was 11.98 seconds. This is nearly three times faster. Figure 10 shows the distribution of speeds (in seconds per word) for *HNG* postings versus complete sentence postings. Note that the *HNG* postings consistently result in faster translation speeds than the sentence postings[5].

We hypothesize that this speedup comes about because when translating a full sentence, there's the time required to examine each word and translate them in some sense (even if not one-to-one) and then there is an extra significant overhead time to put it all together and synthesize into a larger sentence translation. The factor of three speedup is evidence that this overhead is significant effort compared to just quickly translating short n-grams from a sentence. This speedup is an additional benefit of the *HNG* approach.

5.3 Bucking the Trend

We gathered translations for ≈ 54,500 Urdu words via the use of *HNG* on MTurk. This is a relatively small amount, ≈ 3% of the LDC corpus. Figure 11 shows the performance when we add this training data to the LDC corpus. The rectangle around the last 700,000 words of the LDC data is wide and short (it has a height of 0.9 BLEU points and a width of 700,000 words) but the rectangle around the newly added translations is narrow and tall (a height of 1 BLEU point and a width of 54,500 words). Visually, it appears we are succeeding in bucking the trend of diminishing returns. We further confirmed this by running a least-squares linear regression on the points of the last 700,000 words annotated in the LDC data and also for the points in the new data that we acquired via MTurk for $205.80 USD. We find that the slope fit to our new data is 6.6245E-06 BLEU points per Urdu word, or 6.6245 BLEU points for a million Urdu words. The slope fit to the LDC data is only 7.4957E-07 BLEU points per word, or only 0.74957 BLEU points for a million words. This is already an order of magnitude difference that would make the difference between it being worth adding more data and not being worth it; and this is leaving aside the added time speedup that our method enjoys.

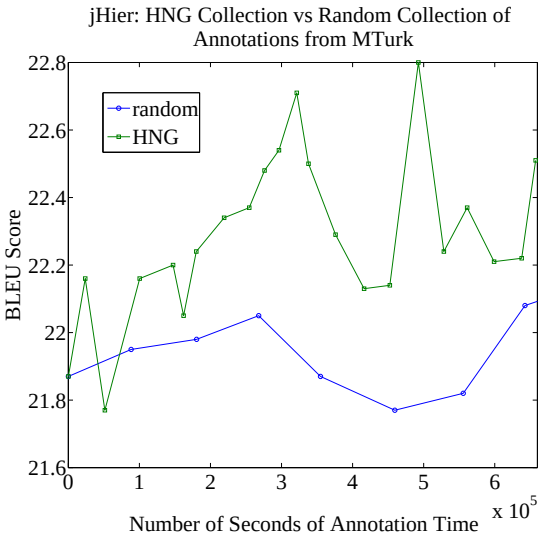

Figure 9: *HNG* vs Random collection of new data via MTurk. y-axis measures BLEU. x-axis measures annotation time in seconds.

Still, we wondered why we could not have raised BLEU scores even faster. The main hurdle seems to be one of coverage. Of the 20,580 n-grams we collected, only 571 (i.e., 2.77%) of them ever even occur in the test set.

5.4 Beyond BLEU Scores

BLEU is an imperfect metric (Callison-Burch et al., 2006). One reason is that it rates all ngram

[4]It's imperfect because of network delays and if a person is multitasking or pausing between their accept and submit times. Nonetheless, the times ought to be better estimates as they are taken over larger samples.

[5]The average speed for the *HNG* postings seems to be slower than the histogram indicates. This is because there were a few extremely slow outlier speeds for a handful of *HNG* postings. These are almost certainly not cases when the turker is working continuously on the task and so the average speed we computed for the *HNG* postings might be slower than the actual speed and hence the true speedup may even be faster than indicated by the difference between the average speeds we reported.

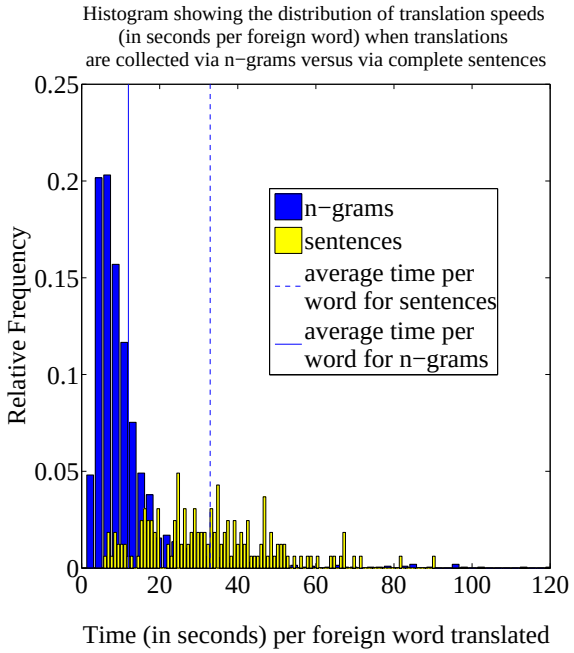

Figure 10: Distribution of translation speeds (in seconds per word) for *HNG* postings versus complete sentence postings. The y-axis measures relative frequency. The x-axis measures translation speed in seconds per word (so farther to the left is faster).

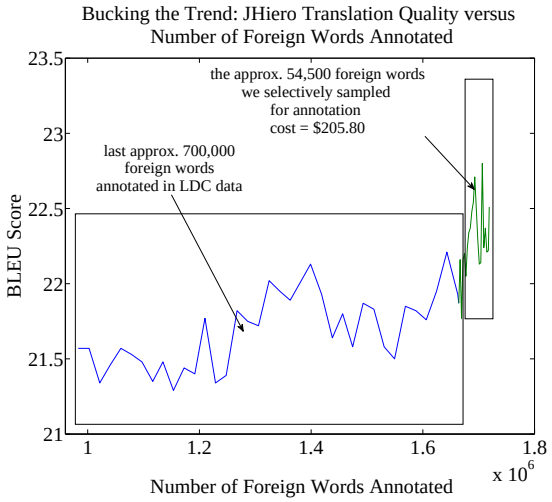

Figure 11: Bucking the trend: performance of *HNG*-selected additional data from BBC web crawl data annotated via Amazon Mechanical Turk. y-axis measures BLEU. x-axis measures number of words annotated.

- Learned phrase: "ناگالینڈ" means "nagaland"
- The "Before System" translation:
  - according to police the number of hundreds of ناگالینڈarmed tribesmen in the گلیکیof assam and fell سیبساset fire in three villages .
- The "After System" translation:
  - according to police the number of hundreds of nagaland armed tribesmen in the گلیکیof assam and fell سیبساset fire in three villages .
- Reference Translation:
  - according to the police , hundreds of armed nagaland tribesmen set on fire three villages in galleci and sebsagarh areas of assam .

Figure 12: Example of strategy working.

mismatches equally although some are much more important than others. Another reason is it's not intuitive what a gain of x BLEU points means in practice. Here we show some concrete example translations to show the types of improvements we're achieving and also some examples which suggest improvements we can make to our AL selection algorithm in the future. Figure 12 shows a prototypical example of our system working.

Figure 13 shows an example where the strategy is working partially but not as well as it might. The Urdu phrase was translated by turkers as "gowned veil". However, since the word aligner just aligns the word to "gowned", we only see "gowned" in our output. This prompts a number of discussion points. First, the 'after system' has better translations but they're not rewarded by BLEU scores because the references use the words 'burqah' or just 'veil' without 'gowned'. Second, we hypothesize that we may be able to see improvements by overriding the automatic alignment software whenever we obtain a many-to-one or one-to-many (in terms of words) translation for one of our trigger phrases. In such cases, we'd like to make sure that every word on the 'many' side is aligned to the single word on the 'one' side. For example, we would force both 'gowned' and 'veil' to be aligned to the single Urdu word instead of allowing the automatic aligner to only align 'gowned'.

Figure 14 shows an example where our "before" system already got the translation correct without the need for the additional phrase translation. This is because though the "before" system had never seen the Urdu expression for "12 May", it had seen the Urdu words for "12" and "May" in isolation and was able to successfully compose them. An area of future work is to use the "before" system to determine such cases automatically and avoid asking humans to provide translations in such cases.

- Learned phrase: "برقعے" means "gowned veil"
- The "Before System" translation:
  - ' in برقعےmaulana in برقعےgeneral is not islam in ! برقعے
- The "After System" translation:
  - ' is in gowned , maulana gowned , in general is not islam in gowned !
- Reference translations:
  - in burqah , there is the maulana . in burqah , there is the general . in burqah , there is no islam .
  - molana is under veil , and the general is under veil , but islam is not under veil .

Figure 13: Example showing where we can improve our selection strategy.

- Example: "بارہ مئی" means "12 may"
  - The "Before System" translation:
    - all party conference in speeches during the meeting two days of karachi on 12 may in connection with the incidents , was strongly criticized the mqm .
  - The "After System" translation:
    - during the meeting two days of all party conference held in karachi on 12 may in the speeches about the incidents were strongly criticized the mqm .

Figure 14: Example showing where we can improve our selection strategy.

6 Conclusions and Future Work

We succeeded in bucking the trend of diminishing returns and improving translation quality while keeping annotation costs low. In future work we would like to apply these ideas to domain adaptation (say, general-purpose MT system to work for scientific domain such as chemistry). Also, we would like to test with more languages, increase the amount of data we can gather, and investigate stopping criteria further. Also, we would like to investigate increasing the efficiency of the selection algorithm by addressing issues such as the one raised by the 12 May example presented earlier.

Abstract

In this paper, we systematically assess the value of using web-scale N-gram data in state-of-the-art supervised NLP classifiers. We compare classifiers that include or exclude features for the counts of various N-grams, where the counts are obtained from a web-scale auxiliary corpus. We show that including N-gram count features can advance the state-of-the-art accuracy on standard data sets for adjective ordering, spelling correction, noun compound bracketing, and verb part-of-speech disambiguation. More importantly, when operating on new domains, or when labeled training data is not plentiful, we show that using web-scale N-gram features is essential for achieving robust performance.

1 Introduction

Many NLP systems use web-scale N-gram counts (Keller and Lapata, 2003; Nakov and Hearst, 2005; Brants et al., 2007). Lapata and Keller (2005) demonstrate good performance on eight tasks using unsupervised web-based models. They show web counts are superior to counts from a large corpus. Bergsma et al. (2009) propose unsupervised and supervised systems that use counts from Google's N-gram corpus (Brants and Franz, 2006). Web-based models perform particularly well on *generation* tasks, where systems choose between competing sequences of output text (such as different spellings), as opposed to *analysis* tasks, where systems choose between abstract labels (such as part-of-speech tags or parse trees).

In this work, we address two natural and related questions which these previous studies leave open:

1. Is there a benefit in combining web-scale counts with the features used in state-of-the-art supervised approaches?
2. How well do web-based models perform on new domains or when labeled data is scarce?

We address these questions on two generation and two analysis tasks, using both existing N-gram data and a novel web-scale N-gram corpus that includes part-of-speech information (Section 2). While previous work has combined web-scale features with other features in specific classification problems (Modjeska et al., 2003; Yang et al., 2005; Vadas and Curran, 2007b), we provide a multi-task, multi-domain comparison.

Some may question why supervised approaches are needed at all for generation problems. Why not solely rely on direct evidence from a giant corpus? For example, for the task of prenominal adjective ordering (Section 3), a system that needs to describe a ball that is both big and red can simply check that *big red* is more common on the web than *red big*, and order the adjectives accordingly.

It is, however, suboptimal to only use N-gram data. For example, ordering adjectives by direct web evidence performs 7% worse than our best supervised system (Section 3.2). No matter how large the web becomes, there will always be plausible constructions that never occur. For example, there are currently no pages indexed by Google with the preferred adjective ordering for *bedraggled 56-year-old [professor]*. Also, in a particular domain, words may have a non-standard usage. Systems trained on labeled data can learn the domain usage and leverage other regularities, such as suffixes and transitivity for adjective ordering.

With these benefits, systems trained on labeled data have become the dominant technology in academic NLP. There is a growing recognition, however, that these systems are highly domain dependent. For example, parsers trained on annotated newspaper text perform poorly on other genres (Gildea, 2001). While many approaches have adapted NLP systems to specific domains (Tsuruoka et al., 2005; McClosky et al., 2006; Blitzer

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 865–874,
Uppsala, Sweden, 11-16 July 2010.

et al., 2007; Daumé III, 2007; Rimell and Clark, 2008), these techniques assume the system knows on which domain it is being used, and that it has access to representative data in that domain. These assumptions are unrealistic in many real-world situations; for example, when automatically processing a heterogeneous collection of web pages. How well do supervised and unsupervised NLP systems perform when used uncustomized, *out-of-the-box* on new domains, and how can we best design our systems for robust *open-domain* performance?

Our results show that using web-scale N-gram data in supervised systems advances the state-of-the-art performance on standard analysis and generation tasks. More importantly, when operating out-of-domain, or when labeled data is not plentiful, using web-scale N-gram data not only helps achieve good performance – it is essential.

2 Experiments and Data

2.1 Experimental Design

We evaluate the benefit of N-gram data on multi-class classification problems. For each task, we have some labeled data indicating the correct output for each example. We evaluate with **accuracy**: the percentage of examples correctly classified in test data. We use one *in-domain* and two *out-of-domain* test sets for each task. Statistical significance is assessed with McNemar's test, $p<0.01$.

We provide results for unsupervised approaches and the majority-class baseline for each task.

For our supervised approaches, we represent the examples as feature vectors, and learn a classifier on the training vectors. There are two feature classes: features that use N-grams (N-GM) and those that do not (LEX). N-GM features are real-valued features giving the log-count of a particular N-gram in the auxiliary web corpus. LEX features are binary features that indicate the presence or absence of a particular string at a given position in the input. The name LEX emphasizes that they identify specific lexical items. The instantiations of both types of features depend on the task and are described in the corresponding sections.

Each classifier is a linear Support Vector Machine (SVM), trained using LIBLINEAR (Fan et al., 2008) on the standard domain. We use the one-vs-all strategy when there are more than two classes (in Section 4). We plot learning curves to measure the accuracy of the classifier when the number of labeled training examples varies. The size of the N-gram data and its counts remain constant. We always optimize the SVM's (L2) regularization parameter on the in-domain development set. We present results with L2-SVM, but achieve similar results with L1-SVM and logistic regression.

2.2 Tasks and Labeled Data

We study two generation tasks: prenominal adjective ordering (Section 3) and context-sensitive spelling correction (Section 4), followed by two analysis tasks: noun compound bracketing (Section 5) and verb part-of-speech disambiguation (Section 6). In each section, we provide references to the origin of the labeled data. For the out-of-domain Gutenberg and Medline data used in Sections 3 and 4, we generate examples ourselves.[1] We chose Gutenberg and Medline in order to provide challenging, distinct domains from our training corpora. Our Gutenberg corpus consists of out-of-copyright books, automatically downloaded from the Project Gutenberg website.[2] The Medline data consists of a large collection of online biomedical abstracts. We describe how labeled adjective and spelling examples are created from these corpora in the corresponding sections.

2.3 Web-Scale Auxiliary Data

The most widely-used N-gram corpus is the Google 5-gram Corpus (Brants and Franz, 2006).

For our tasks, we also use **Google V2**: a new N-gram corpus (also with N-grams of length one-to-five) that we created from the same one-trillion-word snapshot of the web as the Google 5-gram Corpus, but with several enhancements. These include: 1) Reducing noise by removing duplicate sentences and sentences with a high proportion of non-alphanumeric characters (together filtering about 80% of the source data), 2) pre-converting all digits to the 0 character to reduce sparsity for numeric expressions, and 3) including the part-of-speech (POS) tag distribution for each N-gram. The source data was automatically tagged with TnT (Brants, 2000), using the Penn Treebank tag set. Lin et al. (2010) provide more details on the

[1] `http://webdocs.cs.ualberta.ca/~bergsma/Robust/` provides our Gutenberg corpus, a link to Medline, and also the generated examples for both Gutenberg and Medline.

[2] `www.gutenberg.org`. All books just released in 2009 and thus unlikely to occur in the source data for our N-gram corpus (from 2006). Of course, with removal of sentence duplicates and also N-gram thresholding, the possible presence of a test sentence in the massive source data is unlikely to affect results. Carlson et al. (2008) reach a similar conclusion.

N-gram data and N-gram search tools.

The third enhancement is especially relevant here, as we can use the POS distribution to collect counts for N-grams of mixed words and tags. For example, we have developed an N-gram search engine that can count how often the adjective *unprecedented* precedes another adjective in our web corpus (113K times) and how often it follows one (11K times). Thus, even if we haven't seen a particular adjective pair directly, we can use the positional preferences of each adjective to order them.

Early web-based models used search engines to collect N-gram counts, and thus could not use capitalization, punctuation, and annotations such as part-of-speech (Kilgarriff and Grefenstette, 2003). Using a POS-tagged web corpus goes a long way to addressing earlier criticisms of web-based NLP.

3 Prenominal Adjective Ordering

Prenominal adjective ordering strongly affects text readability. For example, while *the unprecedented statistical revolution* is fluent, *the statistical unprecedented revolution* is not. Many NLP systems need to handle adjective ordering robustly. In machine translation, if a noun has two adjective modifiers, they must be ordered correctly in the target language. Adjective ordering is also needed in Natural Language Generation systems that produce information from databases; for example, to convey information (in sentences) about medical patients (Shaw and Hatzivassiloglou, 1999).

We focus on the task of ordering a pair of adjectives independently of the noun they modify and achieve good performance in this setting. Following the set-up of Malouf (2000), we experiment on the 263K adjective pairs Malouf extracted from the British National Corpus (BNC). We use 90% of pairs for training, 5% for testing, and 5% for development. This forms our in-domain data.[3]

We create out-of-domain examples by tokenizing Medline and Gutenberg (Section 2.2), then POS-tagging them with CRFTagger (Phan, 2006). We create examples from all sequences of two adjectives followed by a noun. Like Malouf (2000), we assume that edited text has adjectives ordered fluently. We extract 13K and 9.1K out-of-domain pairs from Gutenberg and Medline, respectively.[4]

[3]BNC is not a domain *per se* (rather a balanced corpus), but has a style and vocabulary distinct from our OOD data.

[4]Like Malouf (2000), we convert our pairs to lower-case. Since the N-gram data includes case, we merge counts from the upper and lower case combinations.

The input to the system is a pair of adjectives, (a_1, a_2), ordered alphabetically. The task is to classify this order as correct (the positive class) or incorrect (the negative class). Since both classes are equally likely, the majority-class **baseline** is around 50% on each of the three test sets.

3.1 Supervised Adjective Ordering

3.1.1 LEX features

Our adjective ordering model with LEX features is a novel contribution of this paper.

We begin with two features for each pair: an indicator feature for a_1, which gets a feature value of $+1$, and an indicator feature for a_2, which gets a feature value of -1. The parameters of the model are therefore weights on specific adjectives. The higher the weight on an adjective, the more it is preferred in the first position of a pair. If the alphabetic ordering is correct, the weight on a_1 should be higher than the weight on a_2, so that the classifier returns a positive score. If the reverse ordering is preferred, a_2 should receive a higher weight. Training the model in this setting is a matter of assigning weights to all the observed adjectives such that the training pairs are maximally ordered correctly. The feature weights thus implicitly produce a linear ordering of all observed adjectives. The examples can also be regarded as rank constraints in a discriminative ranker (Joachims, 2002). Transitivity is achieved naturally in that if we correctly order pairs $a \prec b$ and $b \prec c$ in the training set, then $a \prec c$ by virtue of the weights on a and c.

While exploiting transitivity has been shown to improve adjective ordering, there are many conflicting pairs that make a strict linear ordering of adjectives impossible (Malouf, 2000). We therefore provide an indicator feature for the pair $a_1 a_2$, so the classifier can memorize exceptions to the linear ordering, breaking strict order transitivity. Our classifier thus operates along the lines of rankers in the *preference-based setting* as described in Ailon and Mohri (2008).

Finally, we also have features for all suffixes of length 1-to-4 letters, as these encode useful information about adjective class (Malouf, 2000). Like the adjective features, the suffix features receive a value of $+1$ for adjectives in the first position and -1 for those in the second.

3.1.2 N-GM features

Lapata and Keller (2005) propose a web-based approach to adjective ordering: take the most-

System	IN	O1	O2
Malouf (2000)	91.5	65.6	71.6
web $c(a_1, a_2)$ vs. $c(a_2, a_1)$	87.1	83.7	86.0
SVM with N-GM features	90.0	**85.8**	**88.5**
SVM with LEX features	93.0	70.0	73.9
SVM with N-GM + LEX	**93.7**	83.6	85.4

Table 1: Adjective ordering accuracy (%). SVM and Malouf (2000) trained on BNC, tested on BNC (IN), Gutenberg (O1), and Medline (O2).

frequent order of the words on the web, $c(a_1, a_2)$ vs. $c(a_2, a_1)$. We adopt this as our unsupervised approach. We merge the counts for the adjectives occurring contiguously and separated by a comma.

These are indubitably the most important N-GM features; we include them but also other, tag-based counts from Google V2. Raw counts include cases where one of the adjectives is not used as a modifier: "the *special present* was" vs. "the *present special* issue." We include log-counts for the following, more-targeted patterns:[5] $c(a_1\ a_2$ N.*), $c(a_2\ a_1$ N.*), c(DT $a_1\ a_2$ N.*), c(DT $a_2\ a_1$ N.*). We also include features for the log-counts of each adjective preceded or followed by a word matching an adjective-tag: $c(a_1$ J.*), c(J.* a_1), $c(a_2$ J.*), c(J.* a_2). These assess the positional preferences of each adjective. Finally, we include the log-frequency of each adjective. The more frequent adjective occurs first 57% of the time.

As in all tasks, the counts are features in a classifier, so the importance of the different patterns is weighted discriminatively during training.

3.2 Adjective Ordering Results

In-domain, with both feature classes, we set a strong new standard on this data: 93.7% accuracy for the N-GM+LEX system (Table 1). We trained and tested Malouf (2000)'s program on our data; our LEX classifier, which also uses no auxiliary corpus, makes 18% fewer errors than Malouf's system. Our web-based N-GM model is also superior to the direct evidence web-based approach of Lapata and Keller (2005), scoring 90.0% vs. 87.1% accuracy. These results show the benefit of our new lexicalized and web-based features.

Figure 1 gives the in-domain learning curve. With fewer training examples, the systems with N-GM features strongly outperform the LEX-only system. Note that with tens of thousands of test examples, all differences are highly significant.

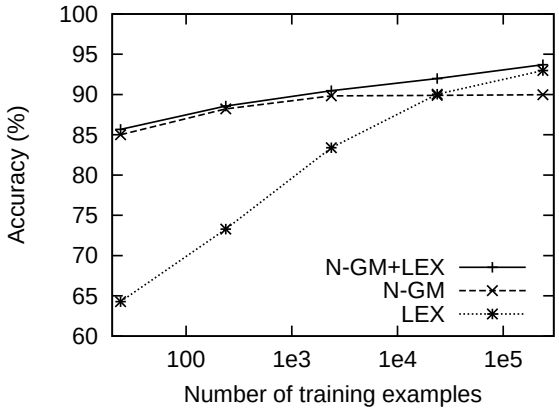

Figure 1: In-domain learning curve of adjective ordering classifiers on BNC.

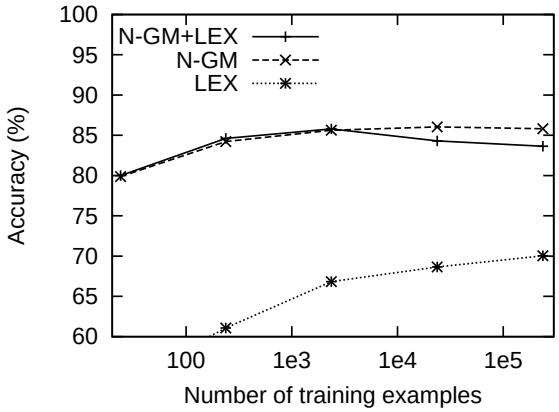

Figure 2: Out-of-domain learning curve of adjective ordering classifiers on Gutenberg.

Out-of-domain, LEX's accuracy drops a shocking 23% on Gutenberg and 19% on Medline (Table 1). Malouf (2000)'s system fares even worse. The overlap between training and test pairs helps explain. While 59% of the BNC test pairs were seen in the training corpus, only 25% of Gutenberg and 18% of Medline pairs were seen in training.

While other ordering models have also achieved "very poor results" out-of-domain (Mitchell, 2009), we expected our expanded set of LEX features to provide good generalization on new data. Instead, LEX is very unreliable on new domains.

N-GM features do not rely on specific pairs in training data, and thus remain fairly robust cross-domain. Across the three test sets, 84-89% of examples had the correct ordering appear at least once on the web. On new domains, the learned N-GM system maintains an advantage over the unsupervised $c(a_1, a_2)$ vs. $c(a_2, a_1)$, but the difference is reduced. Note that training with 10-fold

[5] In this notation, capital letters (and regular expressions) are matched against tags while a_1 and a_2 match words.

cross validation, the N-GM system can achieve up to 87.5% on Gutenberg (90.0% for N-GM + LEX).

The learning curve showing performance on Gutenberg (but still training on BNC) is particularly instructive (Figure 2, performance on Medline is very similar). The LEX system performs much worse than the web-based models across all training sizes. For our top in-domain system, N-GM + LEX, as you add more labeled examples, performance begins *decreasing* out-of-domain. The system disregards the robust N-gram counts as it is more and more confident in the LEX features, and it suffers the consequences.

4 Context-Sensitive Spelling Correction

We now turn to the generation problem of context-sensitive spelling correction. For every occurrence of a word in a pre-defined set of confusable words (like *peace* and *piece*), the system must select the most likely word from the set, flagging possible usage errors when the predicted word disagrees with the original. Contextual spell checkers are one of the most widely used NLP technologies, reaching millions of users via compressed N-gram models in Microsoft Office (Church et al., 2007).

Our in-domain examples are from the New York Times (NYT) portion of Gigaword, from Bergsma et al. (2009). They include the 5 confusion sets where accuracy was below 90% in Golding and Roth (1999). There are 100K training, 10K development, and 10K test examples for each confusion set. Our results are averages across confusion sets.

Out-of-domain examples are again drawn from Gutenberg and Medline. We extract all instances of words that are in one of our confusion sets, along with surrounding context. By assuming the extracted instances represent correct usage, we label 7.8K and 56K out-of-domain test examples for Gutenberg and Medline, respectively.

We test three unsupervised systems: 1) Lapata and Keller (2005) use one token of context on the left and one on the right, and output the candidate from the confusion set that occurs most frequently in this pattern. 2) Bergsma et al. (2009) measure the frequency of the candidates in all the 3-to-5-gram patterns that span the confusable word. For each candidate, they sum the log-counts of all patterns filled with the candidate, and output the candidate with the highest total. 3) The **baseline** predicts the most frequent member of each confusion set, based on frequencies in the NYT training data.

System	IN	O1	O2
Baseline	66.9	44.6	60.6
Lapata and Keller (2005)	88.4	78.0	87.4
Bergsma et al. (2009)	94.8	87.7	94.2
SVM with N-GM features	95.7	**92.1**	93.9
SVM with LEX features	95.2	85.8	91.0
SVM with N-GM + LEX	**96.5**	91.9	**94.8**

Table 2: Spelling correction accuracy (%). SVM trained on NYT, tested on NYT (IN) and out-of-domain Gutenberg (O1) and Medline (O2).

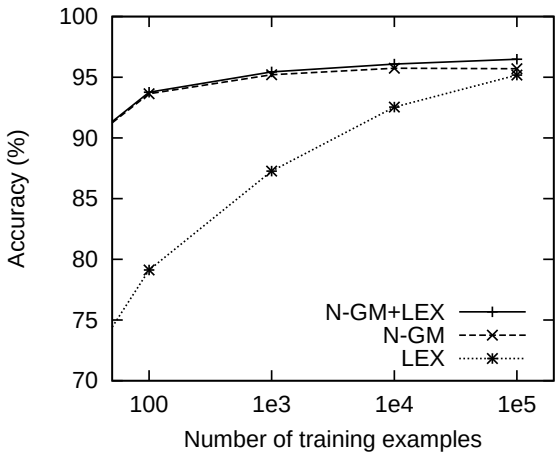

Figure 3: In-domain learning curve of spelling correction classifiers on NYT.

4.1 Supervised Spelling Correction

Our LEX features are typical disambiguation features that flag specific aspects of the context. We have features for the words at all positions in a 9-word window (called collocation features by Golding and Roth (1999)), plus indicators for a particular word preceding or following the confusable word. We also include indicators for all N-grams, and their position, in a 9-word window.

For N-GM count features, we follow Bergsma et al. (2009). We include the log-counts of all N-grams that span the confusable word, with each word in the confusion set filling the N-gram pattern. These features do not use part-of-speech. Following Bergsma et al. (2009), we get N-gram counts using the original Google N-gram Corpus.

While neither our LEX nor N-GM features are novel on their own, they have, perhaps surprisingly, not yet been evaluated in a single model.

4.2 Spelling Correction Results

The N-GM features outperform the LEX features, 95.7% vs. 95.2% (Table 2). Together, they achieve a very strong 96.5% in-domain accuracy.

This is 2% higher than the best unsupervised approach (Bergsma et al., 2009). Web-based models again perform well across a range of training data sizes (Figure 3).

The error rate of LEX nearly triples on Gutenberg and almost doubles on Medline (Table 2). Removing N-GM features from the N-GM + LEX system, errors increase around 75% on both Gutenberg and Medline. The LEX features provide no help to the combined system on Gutenberg, while they do help significantly on Medline. Note the learning curves for N-GM+LEX on Gutenberg and Medline (not shown) do not display the decrease that we observed in adjective ordering (Figure 2).

Both the baseline and LEX perform poorly on Gutenberg. The baseline predicts the majority class from NYT, but it's not always the majority class in Gutenberg. For example, while in NYT *site* occurs 87% of the time for the *(cite, sight, site)* confusion set, *sight* occurs 90% of the time in Gutenberg. The LEX classifier exploits this bias as it is regularized toward a more economical model, but the bias does not transfer to the new domain.

5 Noun Compound Bracketing

About 70% of web queries are noun phrases (Barr et al., 2008) and methods that can reliably parse these phrases are of great interest in NLP. For example, a web query for *zebra hair straightener* should be bracketed as *(zebra (hair straightener))*, a stylish hair straightener with zebra print, rather than *((zebra hair) straightener)*, a useless product since the fur of zebras is already quite straight.

The noun compound (NC) bracketing task is usually cast as a decision whether a 3-word NC has a left or right bracketing. Most approaches are unsupervised, using a large corpus to compare the statistical association between word pairs in the NC. The adjacency model (Marcus, 1980) proposes a left bracketing if the association between words one and two is higher than between two and three. The dependency model (Lauer, 1995a) compares one-two vs. *one-three*. We include dependency model results using PMI as the association measure; results were lower with the adjacency model.

As in-domain data, we use Vadas and Curran (2007a)'s Wall-Street Journal (WSJ) data, an extension of the Treebank (which originally left NPs flat). We extract all sequences of three consecutive common nouns, generating 1983 examples from sections 0-22 of the Treebank as training, 72 from section 24 for development and 95 from section 23 as a test set. As out-of-domain data, we use 244 NCs from Grolier Encyclopedia (Lauer, 1995a) and 429 NCs from Medline (Nakov, 2007).

The majority class **baseline** is left-bracketing.

System	IN	O1	O2
Baseline	70.5	66.8	84.1
Dependency model	74.7	**82.8**	84.4
SVM with N-GM features	89.5	81.6	86.2
SVM with LEX features	81.1	70.9	79.0
SVM with N-GM + LEX	**91.6**	81.6	**87.4**

Table 3: NC-bracketing accuracy (%). SVM trained on WSJ, tested on WSJ (IN) and out-of-domain Grolier (O1) and Medline (O2).

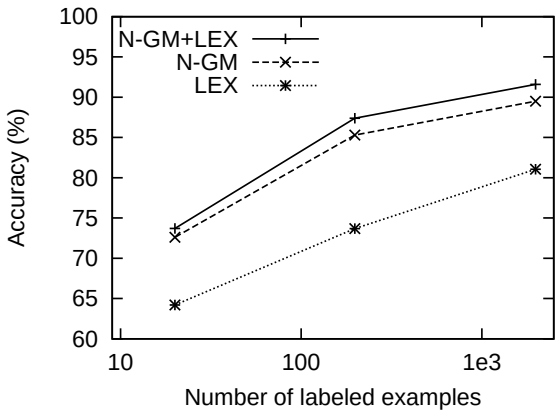

Figure 4: In-domain NC-bracketer learning curve

5.1 Supervised Noun Bracketing

Our LEX features indicate the specific noun at each position in the compound, plus the three pairs of nouns and the full noun triple. We also add features for the capitalization pattern of the sequence.

N-GM features give the log-count of all subsets of the compound. Counts are from Google V2. Following Nakov and Hearst (2005), we also include counts of noun pairs collapsed into a single token; if a pair occurs often on the web as a single unit, it strongly indicates the pair is a constituent.

Vadas and Curran (2007a) use simpler features, e.g. they do not use collapsed pair counts. They achieve 89.9% in-domain on WSJ and 80.7% on Grolier. Vadas and Curran (2007b) use comparable features to ours, but do not test out-of-domain.

5.2 Noun Compound Bracketing Results

N-GM systems perform much better on this task (Table 3). N-GM+LEX is statistically significantly

better than LEX on all sets. In-domain, errors more than double without N-GM features. LEX performs poorly here because there are far fewer training examples. The learning curve (Figure 4) looks much like earlier in-domain curves (Figures 1 and 3), but truncated before LEX becomes competitive. The absence of a sufficient amount of labeled data explains why NC-bracketing is generally regarded as a task where corpus counts are crucial.

All web-based models (including the dependency model) exceed 81.5% on Grolier, which is the level of human agreement (Lauer, 1995b). N-GM + LEX is highest on Medline, and close to the 88% human agreement (Nakov and Hearst, 2005). Out-of-domain, the LEX approach performs very poorly, close to or below the baseline accuracy. With little training data and cross-domain usage, N-gram features are essential.

6 Verb Part-of-Speech Disambiguation

Our final task is POS-tagging. We focus on one frequent and difficult tagging decision: the distinction between a past-tense verb (VBD) and a past participle (VBN). For example, in *the troops stationed in Iraq*, the verb *stationed* is a VBN; *troops* is the head of the phrase. On the other hand, for *the troops vacationed in Iraq*, the verb *vacationed* is a VBD and also the head. Some verbs make the distinction explicit (*eat* has VBD *ate*, VBN *eaten*), but most require context for resolution.

Conflating VBN/VBD is damaging because it affects downstream parsers and semantic role labelers. The task is difficult because nearby POS tags can be identical in both cases. When the verb follows a noun, tag assignment can hinge on world-knowledge, i.e., the global lexical relation between the noun and verb (E.g., *troops* tends to be the object of *stationed* but the subject of *vacationed*).[6] Web-scale N-gram data might help improve the VBN/VBD distinction by providing relational evidence, even if the verb, noun, or verb-noun pair were not observed in training data.

We extract nouns followed by a VBN/VBD in the WSJ portion of the Treebank (Marcus et al., 1993), getting 23K training, 1091 development and 1130 test examples from sections 2-22, 24, and 23, respectively. For out-of-domain data, we get 21K examples from the Brown portion of the Treebank and 6296 examples from tagged Medline abstracts in the PennBioIE corpus (Kulick et al., 2004).

The majority class **baseline** is to choose VBD.

6.1 Supervised Verb Disambiguation

There are two orthogonal sources of information for predicting VBN/VBD: 1) the noun-verb pair, and 2) the context around the pair. Both N-GM and LEX features encode both these sources.

6.1.1 LEX features

For 1), we use indicators for the noun and verb, the noun-verb pair, whether the verb is on an in-house list of *said*-verb (like *warned*, *announced*, etc.), whether the noun is capitalized and whether it's upper-case. Note that in training data, 97.3% of capitalized nouns are followed by a VBD and 98.5% of *said*-verbs are VBDs. For 2), we provide indicator features for the words before the noun and after the verb.

6.1.2 N-GM features

For 1), we characterize a noun-verb relation via features for the pair's distribution in Google V2. Characterizing a word by its distribution has a long history in NLP; we apply similar techniques to *relations*, like Turney (2006), but with a larger corpus and richer annotations. We extract the 20 most-frequent N-grams that contain both the noun and the verb in the pair. For each of these, we convert the tokens to POS-tags, except for tokens that are among the most frequent 100 unigrams in our corpus, which we include in word form. We mask the noun of interest as *N* and the verb of interest as *V*. This converted N-gram is the feature label. The value is the pattern's log-count. A high count for patterns like *(N that V)*, *(N have V)* suggests the relation is a VBD, while patterns *(N that were V)*, *(N V by)*, *(V some N)* indicate a VBN. As always, the classifier learns the association between patterns and classes.

For 2), we use counts for the verb's context co-occurring with a VBD or VBN tag. E.g., we see whether VBD cases like *troops ate* or VBN cases like *troops eaten* are more frequent. Although our corpus contains many VBN/VBD errors, we hope the errors are random enough for aggregate counts to be useful. The context is an N-gram spanning the VBN/VBD. We have log-count features for all five such N-grams in the (previous-word, noun, verb, next-word) quadruple. The log-count is in-

[6] HMM-style taggers, like the fast TnT tagger used on our web corpus, do not use bilexical features, and so perform especially poorly on these cases. One motivation for our work was to develop a fast post-processor to fix VBN/VBD errors.

System	IN	O1	O2
Baseline	89.2	85.2	79.6
ContextSum	92.5	91.1	90.4
SVM with N-GM features	96.1	93.4	93.8
SVM with LEX features	95.8	93.4	93.0
SVM with N-GM + LEX	**96.4**	**93.5**	**94.0**

Table 4: Verb-POS-disambiguation accuracy (%) trained on WSJ, tested on WSJ (IN) and out-of-domain Brown (O1) and Medline (O2).

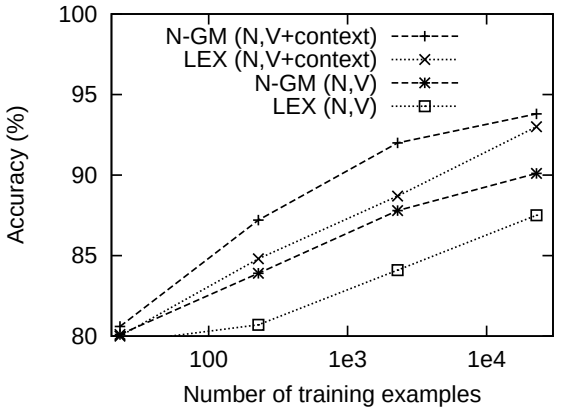

Figure 5: Out-of-domain learning curve of verb disambiguation classifiers on Medline.

dexed by the position and length of the N-gram. We include separate count features for contexts matching the specific noun and for when the noun token can match any word tagged as a noun.

ContextSum: We use these context counts in an unsupervised system, ContextSum. Analogously to Bergsma et al. (2009), we separately sum the log-counts for all contexts filled with VBD and then VBN, outputting the tag with the higher total.

6.2 Verb POS Disambiguation Results

As in all tasks, N-GM+LEX has the best in-domain accuracy (96.4%, Table 4). Out-of-domain, when N-grams are excluded, errors only increase around 14% on Medline and 2% on Brown (the differences are not statistically significant). Why? Figure 5, the learning curve for performance on Medline, suggests some reasons. We omit N-GM+LEX from Figure 5 as it closely follows N-GM.

Recall that we grouped the features into two views: 1) noun-verb (N,V) and 2) context. If we use just (N,V) features, we do see a large drop out-of-domain: LEX (N,V) lags N-GM (N,V) even using all the training examples. The same is true using only context features (not shown). Using both views, the results are closer: 93.8% for N-GM and 93.0% for LEX. With two views of an example, LEX is more likely to have domain-neutral features to draw on. Data sparsity is reduced.

Also, the Treebank provides an atypical number of labeled examples for analysis tasks. In a more typical situation with less labeled examples, N-GM strongly dominates LEX, even when two views are used. E.g., with 2285 training examples, N-GM+LEX is statistically significantly better than LEX on both out-of-domain sets.

All systems, however, perform log-linearly with training size. In other tasks we only had a handful of N-GM features; here there are 21K features for the distributional patterns of N,V pairs. Reducing this feature space by pruning or performing transformations may improve accuracy in and out-of-domain.

7 Discussion and Future Work

Of all classifiers, LEX performs worst on all cross-domain tasks. Clearly, many of the regularities that a typical classifier exploits in one domain do not transfer to new genres. N-GM features, however, do not depend directly on training examples, and thus work better cross-domain. Of course, using web-scale N-grams is not the only way to create robust classifiers. Counts from any large auxiliary corpus may also help, but web counts should help more (Lapata and Keller, 2005). Section 6.2 suggests that another way to mitigate domain-dependence is having multiple feature views.

Banko and Brill (2001) argue "a logical next step for the research community would be to direct efforts towards increasing the size of annotated training collections." Assuming we really do want systems that operate beyond the specific domains on which they are trained, the community also needs to identify which systems behave as in Figure 2, where the accuracy of the best in-domain system actually decreases with more training examples. Our results suggest better features, such as web pattern counts, may help more than expanding training data. Also, systems using web-scale unlabeled data will improve automatically as the web expands, without annotation effort.

In some sense, using web counts as features is a form of domain adaptation: adapting a web model to the training domain. How do we ensure these features are adapted well and not used in domain-specific ways (especially with many features to adapt, as in Section 6)? One option may

be to regularize the classifier specifically for out-of-domain accuracy. We found that adjusting the SVM misclassification penalty (for more regularization) can help or hurt out-of-domain. Other regularizations are possible. In each task, there are domain-neutral unsupervised approaches. We could encode these systems as linear classifiers with corresponding weights. Rather than a typical SVM that minimizes the weight-norm $||w||$ (plus the slacks), we could regularize toward domain-neutral weights. This regularization could be optimized on creative splits of the training data.

8 Conclusion

We presented results on tasks spanning a range of NLP research: generation, disambiguation, parsing and tagging. Using web-scale N-gram data improves accuracy on each task. When less training data is used, or when the system is used on a different domain, N-gram features greatly improve performance. Since most supervised NLP systems do not use web-scale counts, further cross-domain evaluation may reveal some very brittle systems. Continued effort in new domains should be a priority for the community going forward.

Convolution Kernel over Packed Parse Forest

Min Zhang Hui Zhang Haizhou Li

Abstract

This paper proposes a convolution forest kernel to effectively explore rich structured features embedded in a packed parse forest. As opposed to the convolution tree kernel, the proposed forest kernel does not have to commit to a single best parse tree, is thus able to explore very large object spaces and much more structured features embedded in a forest. This makes the proposed kernel more robust against parsing errors and data sparseness issues than the convolution tree kernel. The paper presents the formal definition of convolution forest kernel and also illustrates the computing algorithm to fast compute the proposed convolution forest kernel. Experimental results on two NLP applications, relation extraction and semantic role labeling, show that the proposed forest kernel significantly outperforms the baseline of the convolution tree kernel.

1 Introduction

Parse tree and packed forest of parse trees are two widely used data structures to represent the syntactic structure information of sentences in natural language processing (NLP). The structured features embedded in a parse tree have been well explored together with different machine learning algorithms and proven very useful in many NLP applications (Collins and Duffy, 2002; Moschitti, 2004; Zhang et al., 2007). A forest (Tomita, 1987) compactly encodes an exponential number of parse trees. In this paper, we study how to effectively explore structured features embedded in a forest using convolution kernel (Haussler, 1999).

As we know, feature-based machine learning methods are less effective in modeling highly structured objects (Vapnik, 1998), such as parse tree or semantic graph in NLP. This is due to the fact that it is usually very hard to represent structured objects using vectors of reasonable dimensions without losing too much information. For example, it is computationally infeasible to enumerate all subtree features (using subtree a feature) for a parse tree into a linear feature vector. Kernel-based machine learning method is a good way to overcome this problem. Kernel methods employ a kernel function, that must satisfy the properties of being symmetric and positive, to measure the similarity between two objects by computing implicitly the dot product of certain features of the input objects in high (or even infinite) dimensional feature spaces without enumerating all the features (Vapnik, 1998).

Many learning algorithms, such as SVM (Vapnik, 1998), the Perceptron learning algorithm (Rosenblatt, 1962) and Voted Perceptron (Freund and Schapire, 1999), can work directly with kernels by replacing the dot product with a particular kernel function. This nice property of kernel methods, that implicitly calculates the dot product in a high-dimensional space over the original representations of objects, has made kernel methods an effective solution to modeling structured objects in NLP.

In the context of parse tree, convolution tree kernel (Collins and Duffy, 2002) defines a feature space consisting of all subtree types of parse trees and counts the number of common subtrees as the syntactic similarity between two parse trees. The tree kernel has shown much success in many NLP applications like parsing (Collins and Duffy, 2002), semantic role labeling (Moschitti, 2004; Zhang et al., 2007), relation extraction (Zhang et al., 2006), pronoun resolution (Yang et al., 2006), question classification (Zhang and Lee, 2003) and machine translation (Zhang and Li, 2009), where the tree kernel is used to compute the similarity between two NLP application instances that are usually represented by parse trees. However, in those studies, the tree kernel only covers the features derived from single 1-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 875–885,
Uppsala, Sweden, 11-16 July 2010.

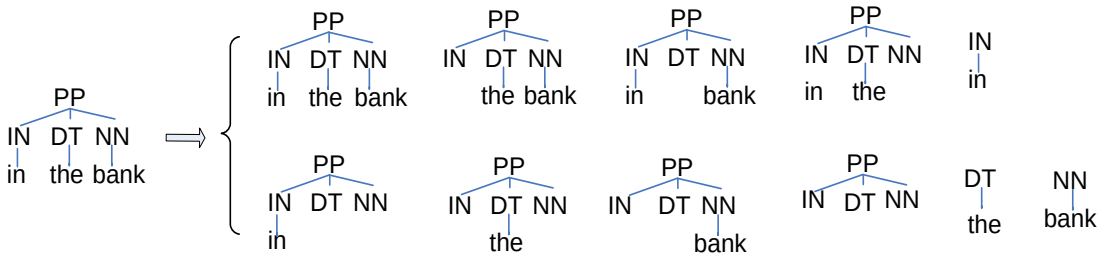

Figure 1. A parse tree and its 11 subtree features covered by convolution tree kernel

best parse tree. This may largely compromise the performance of tree kernel due to parsing errors and data sparseness.

To address the above issues, this paper constructs a forest-based convolution kernel to mine structured features directly from packed forest. A packet forest compactly encodes exponential number of n-best parse trees, and thus containing much more rich structured features than a single parse tree. This advantage enables the forest kernel not only to be more robust against parsing errors, but also to be able to learn more reliable feature values and help to solve the data sparseness issue that exists in the traditional tree kernel. We evaluate the proposed kernel in two real NLP applications, relation extraction and semantic role labeling. Experimental results on the benchmark data show that the forest kernel significantly outperforms the tree kernel.

The rest of the paper is organized as follows. Section 2 reviews the convolution tree kernel while section 3 discusses the proposed forest kernel in details. Experimental results are reported in section 4. Finally, we conclude the paper in section 5.

2 Convolution Kernel over Parse Tree

Convolution kernel was proposed as a concept of kernels for discrete structures by Haussler (1999) and related but independently conceived ideas on string kernels first presented in (Watkins, 1999). The framework defines the kernel function between input objects as the convolution of "sub-kernels", i.e. the kernels for the decompositions (parts) of the input objects.

The parse tree kernel (Collins and Duffy, 2002) is an instantiation of convolution kernel over syntactic parse trees. Given a parse tree, its features defined by a tree kernel are all of its subtree types and the value of a given feature is the number of the occurrences of the subtree in the parse tree. Fig. 1 illustrates a parse tree with all of its 11 subtree features covered by the convolution tree kernel. In the tree kernel, a parse tree T is represented by a vector of integer counts of each *subtree type* (i.e., *subtree* regardless of its ancestors, descendants and span covered):

$$\phi(T) = (\#\ subtreetype_1(T),\ \ldots,\ \#\ subtreetype_n(T))$$

where $\#\ subtreetype_i(T)$ is the occurrence number of the i^{th} subtree type in T. The tree kernel counts the number of common subtrees as the syntactic similarity between two parse trees. Since the number of subtrees is exponential with the tree size, it is computationally infeasible to directly use the feature vector $\phi(T)$. To solve this computational issue, Collins and Duffy (2002) proposed the following tree kernel to calculate the dot product between the above high dimensional vectors implicitly.

$$\begin{aligned} K(T_1,T_2) &= <\phi(T_1),\phi(T_2)> \\ &= \sum_i \#subtreetype_i(T_1)\cdot\#subtreetype_i(T_2) \\ &= \sum_i \left(\sum_{n_1\in N_1} I_{subtree_i}(n_1) \right)\cdot\left(\sum_{n_2\in N_2} I_{subtree_i}(n_2) \right) \\ &= \sum_{n_1\in N_1}\sum_{n_2\in N_2} \Delta(n_1,n_2) \end{aligned}$$

where N_1 and N_2 are the sets of nodes in trees T_1 and T_2, respectively, and $I_{subtree_i}(n)$ is a function that is 1 iff the $subtreetype_i$ occurs with root at node n and zero otherwise, and $\Delta(n_1,n_2)$ is the number of the common *subtrees* rooted at n_1 and n_2, i.e.,

$$\Delta(n_1,n_2) = \sum_i I_{subtree_i}(n_1)\cdot I_{subtree_i}(n_2)$$

$\Delta(n_1,n_2)$ can be computed by the following recursive rules:

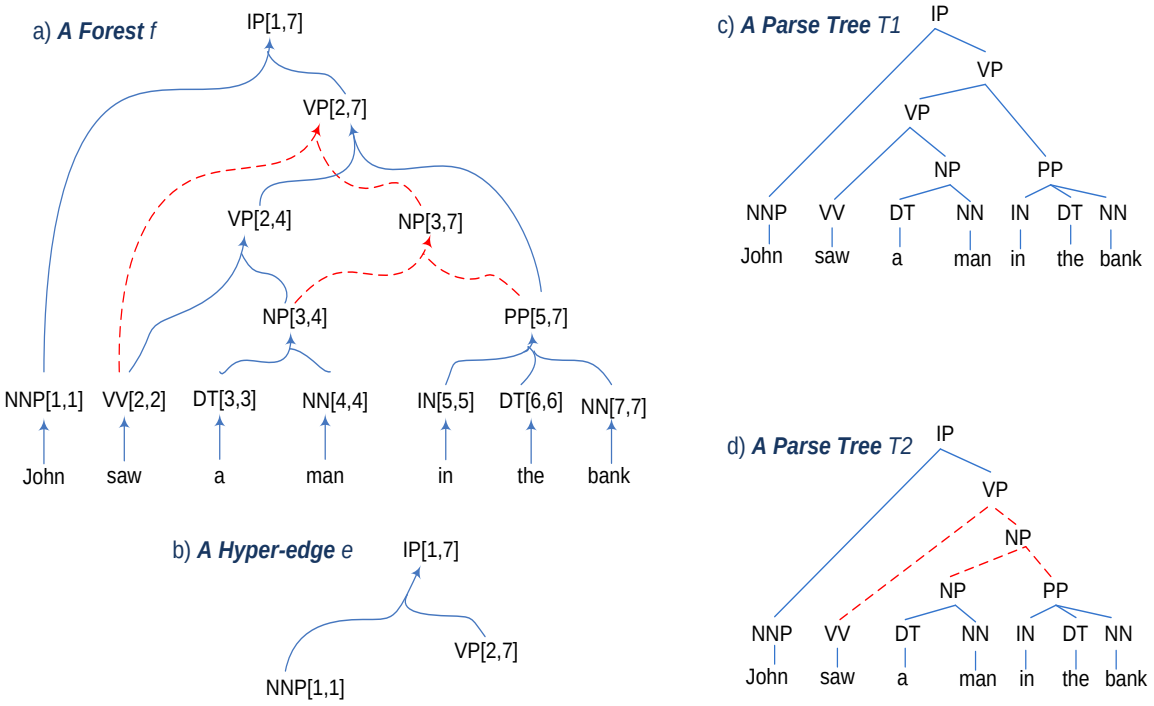

Figure 2. An example of a packed forest, a hyper-edge and two parse trees covered by the packed forest

Rule 1: if the productions (CFG rules) at n_1 and n_2 are different, $\Delta(n_1, n_2) = 0$;

Rule 2: else if both n_1 and n_2 are pre-terminals (POS tags), $\Delta(n_1, n_2) = 1 \times \lambda$;

Rule 3: else,

$$\Delta(n_1, n_2) = \lambda \cdot \prod_{j=1}^{nc(n_1)} (1 + \Delta(ch(n_1, j), ch(n_2, j)))\,,$$

where $nc(n_1)$ is the child number of n_1, $ch(n,j)$ is the j^{th} child of node n and λ ($0 < \lambda \leq 1$) is the decay factor in order to make the kernel value less variable with respect to the *subtree* sizes (Collins and Duffy, 2002). The recursive **Rule 3** holds because given two nodes with the same children, one can construct common subtrees using these children and common subtrees of further offspring. The time complexity for computing this kernel is $O(|N_1| \cdot |N_2|)$.

As discussed in previous section, when convolution tree kernel is applied to NLP applications, its performance is vulnerable to the errors from the single parse tree and data sparseness. In this paper, we present a convolution kernel over packed forest to address the above issues by exploring structured features embedded in a forest.

3 Convolution Kernel over Forest

In this section, we first illustrate the concept of packed forest and then give a detailed discussion on the covered feature space, fractional count, feature value and the forest kernel function itself.

3.1 Packed forest of parse trees

Informally, a packed parse forest, or (packed) forest in short, is a compact representation of all the derivations (i.e. parse trees) for a given sentence under context-free grammar (Tomita, 1987; Billot and Lang, 1989; Klein and Manning, 2001). It is the core data structure used in natural language parsing and other downstream NLP applications, such as syntax-based machine translation (Zhang et al., 2008; Zhang et al., 2009a). In parsing, a sentence corresponds to exponential number of parse trees with different tree probabilities, where a forest can compact all the parse trees by sharing their common subtrees in a bottom-up manner. Formally, a packed forest F can be described as a triple:

$$F = < V, E, S >$$

where V is the set of non-terminal nodes, E is the set of hyper-edges and S is a sentence

represented as an ordered word sequence. A hyper-edge e is a group of edges in a parse tree which connects a father node and its all child nodes, representing a CFG rule. A non-terminal node in a forest is represented as a "label [start, end]", where the "label" is its syntax category and "[start, end]" is the span of words it covers. As shown in Fig. 2, these two parse trees ($T1$ and $T2$) can be represented as a single forest by sharing their common subtrees (such as NP[3,4] and PP[5,7]) and merging common non-terminal nodes covering the same span (such as VP[2,7], where there are two hyper-edges attach to it).

Given the definition of forest, we introduce the concepts of inside probability $\beta(.)$ and outside probability $\alpha(.)$ that are widely-used in parsing (Baker, 1979; Lari and Young, 1990) and are also to be used in our kernel calculation.

$$\beta(v[p,p]) = P(v \to S[p])$$

$$\beta(v[p,q]) = \sum_{\substack{e \text{ is a hyper-edge} \\ \text{attached to } v}} \left(P(e) \cdot \prod_{\substack{c_i[p_i,q_i] \text{is a leaf} \\ \text{node of } e}} \beta(c_i[p_i,q_i]) \right)$$

$$\alpha(root(f)) = 1$$

$$\alpha(v[p,q]) = \sum_{\substack{e \text{ is a hyper-edge and } v \\ \text{is its one leaf node}}} \left(\alpha(root(e)) \cdot P(e) \cdot \prod_{\substack{c_i[p_i,q_i] \text{is a children node} \\ \text{of e except } v}} \beta(c_i[p_i,q_i]) \right)$$

where v is a forest node, $S[p]$ is the p^{th} word of input sentence S, $P(v \to S[p])$ is the probability of the CFG rule $v \to S[p]$, $root(.)$ returns the root node of input structure, $[p_i, q_i]$ is a sub-span of $[p, q]$, being covered by c_i, and $P(e)$ is the PCFG probability of e. From these definitions, we can see that the inside probability is total probability of generating words $S[p,q]$ from non-terminal node $v[p,q]$ while the outside probability is the total probability of generating node $v[p,q]$ and words outside $S[p,q]$ from the root of forest. The inside probability can be calculated using dynamic programming in a bottom-up fashion while the outside probability can be calculated using dynamic programming in a top-to-down way.

3.2 Convolution forest kernel

In this subsection, we first define the feature space covered by forest kernel, and then define the forest kernel function.

3.2.1 Feature space, object space and feature value

The forest kernel counts the number of common subtrees as the syntactic similarity between two forests. Therefore, in the same way as tree kernel, its feature space is also defined as all the possible subtree types that a CFG grammar allows. In a forest kernel, forest *F* is represented by a vector of *fractional counts* of each *subtree type* (subtree regardless of its ancestors, descendants and span covered):

$$\begin{aligned} \phi(F) &= (\#\ subtreetype_1(F), \ldots, \\ &\quad \#\ subtreetype_n(F)) \\ &= (\#subtreetype_1(n\text{-}best\ parse\ trees), \ldots, \\ &\quad \#\ subtreetype_n(n\text{-}best\ parse\ trees)) \end{aligned} \quad (1)$$

where # $subtreetype_i(F)$ is the occurrence number of the i^{th} subtree type ($subtreetype_i$) in forest *F*, i.e., a *n*-best parse tree lists with a huge *n*.

Although the feature spaces of the two kernels are the same, their object spaces (tree *vs.* forest) and feature values (integer counts *vs.* fractional counts) differ very much. A forest encodes exponential number of parse trees, and thus containing exponential times more subtrees than a single parse tree. This ensures forest kernel to learn more reliable feature values and is also able to help to address the data sparseness issues in a better way than tree kernel does. Forest kernel is also expected to yield more non-zero feature values than tree kernel. Furthermore, different parse tree in a forest represents different derivation and interpretation for a given sentence. Therefore, forest kernel should be more robust to parsing errors than tree kernel.

In tree kernel, one occurrence of a subtree contributes 1 to the value of its corresponding feature (*subtree type*), so the feature value is an integer count. However, the case turns out very complicated in forest kernel. In a forest, each of its parse trees, when enumerated, has its own

probability. So one subtree extracted from different parse trees should have different *fractional count* with regard to the probabilities of different parse trees. Following the previous work (Charniak and Johnson, 2005; Huang, 2008), we define the *fractional count* of the occurrence of a *subtree* in a parse tree t_i as

$$c(subtree, t_i) = \begin{cases} 0 & if\ subtree \notin t_i \\ P(subtree, t_i|f,s) & otherwise \end{cases}$$
$$= \begin{cases} 0 & if\ subtree \notin t_i \\ P(t_i|f,s) & otherwise \end{cases}$$

where we have $P(subtree, t_i|f,s) = P(t_i|f,s)$ if $subtree \in t_i$. Then we define the fractional count of the occurrence of a subtree in a forest *f* as

$$\begin{aligned} c(subtree, f) &= P(subtree|f,s) \\ &= \textstyle\sum_{t_i} P(subtree, t_i|f,s) \\ &= \textstyle\sum_{t_i} I_{subtree}\ (t_i) \cdot P(t_i|f,s) \end{aligned} \quad (2)$$

where $I_{subtree}\ (t_i)$ is a binary function that is 1 iif the $subtree \in t_i$ and zero otherwise. Obviously, it needs exponential time to compute the above fractional counts. However, due to the property of forest that compactly represents all the parse trees, the posterior probability of a subtree in a forest, $P(subtree|f,s)$, can be easily computed in an Inside-Outside fashion as the product of three parts: the outside probability of its root node, the probabilities of parse hyperedges involved in the subtree, and the inside probabilities of its leaf nodes (Lari and Young, 1990; Mi and Huang, 2008).

$$\begin{aligned} c(subtree, f) &= P(subtree|f,s) \\ &= \frac{\alpha\beta(subtree)}{\alpha\beta(root(f))} \end{aligned} \quad (3)$$

where

$$\begin{aligned} \alpha\beta(subtree) &= \alpha\big(root(subtree)\big) \\ &\cdot \prod_{e \in subtree} P(e) \\ &\cdot \prod_{v \in leaf\ (subtree\ )} \beta(v) \end{aligned} \quad (4)$$

and

$$\begin{aligned} \alpha\beta\big(root(f)\big) &= \alpha\big(root(f)\big) \cdot \beta\big(root(f)\big) \\ &= \beta\big(root(f)\big) \end{aligned}$$

where $\alpha(.)$ and $\beta(.)$ denote the outside and inside probabilities. They can be easily obtained using the equations introduced at section 3.1.

Given a subtree, we can easily compute its fractional count (i.e. its feature value) directly using eq. (3) and (4) without the need of enumerating each parse trees as shown at eq. (2)[1]. Nonetheless, it is still computationally infeasible to directly use the feature vector $\phi(F)$ (see eq. (1)) by explicitly enumerating all subtrees although its fractional count is easily calculated. In the next subsection, we present the forest kernel that implicitly calculates the dot-product between two $\phi(F)$s in a polynomial time.

3.2.2 Convolution forest kernel

The forest kernel counts the *fractional numbers* of common subtrees as the syntactic similarity between two forests. We define the forest kernel function $K_f(f_1, f_2)$ in the following way.

$$\begin{aligned} K_f(f_1, f_2) &= <\phi(f_1), \phi(f_2)> \\ &= \sum_i \#subtreetype_i(f_1).\#subtreetype_i(f_2) \\ &= \sum_{\substack{subtree\ 1 \in f_1 \\ subtree\ 2 \in f_2}} \Big(I_{eq}(subtree1, subtree2) \\ &\qquad \cdot c(subtree1, f_1) \\ &\qquad \cdot c(subtree2, f_2) \Big) \\ &= \textstyle\sum_{v_1 \in N_1} \sum_{v_2 \in N_2} \Delta'(v_1, v_2) \end{aligned} \quad (5)$$

where

- $I_{eq}(\cdot,\cdot)$ is a binary function that is 1 iif the input two subtrees are identical (i.e. they have the same typology and node labels) and zero otherwise;
- $c(\cdot,\cdot)$ is the fractional count defined at eq. (3);
- N_1 and N_2 are the sets of nodes in forests f_1 and f_2;
- $\Delta'(v_1, v_2)$ returns the accumulated value of products between each two fractional counts of the common subtrees rooted at v_1 and v_2, i.e.,

$$\begin{aligned} &\Delta'(v_1, v_2) \\ &= \sum_{\substack{root\ (subtree\ 1)=v_1 \\ root\ (subtree\ 2)=v_2}} \Big(I_{eq}(subtree1, subtree2) \\ &\qquad \cdot c(subtree1, f_1) \\ &\qquad \cdot c(subtree2, f_2) \Big) \end{aligned}$$

[1] It has been proven in parsing literatures (Baker, 1979; Lari and Young, 1990) that eq. (3) defined by Inside-Outside probabilities is exactly to compute the sum of those parse tree probabilities that cover the subtree of being considered as defined at eq. (2).

We next show that $\Delta'(v_1, v_2)$ can be computed recursively in a polynomial time as illustrated at Algorithm 1. To facilitate discussion, we temporarily ignore all fractional counts in Algorithm 1. Indeed, Algorithm 1 can be viewed as a natural extension of convolution kernel from over tree to over forest. In forest[2], a node can root multiple hyper-edges and each hyper-edge is independent to each other. Therefore, Algorithm 1 iterates each hyper-edge pairs with roots at v_1 and v_2 (line 3-4), and sums over (eq. (7) at line 9) each recursively-accumulated sub-kernel scores of subtree pairs extended from the hyper-edge pair (e_1, e_2) (eq. (6) at line 8). Eq. (7) holds because the hyper-edges attached to the same node are independent to each other. Eq. (6) is very similar to the **Rule 3** of tree kernel (see section 2) except its inputs are hyper-edges and its further expansion is based on forest nodes. Similar to tree kernel (Collins and Duffy, 2002), eq. (6) holds because a common subtree by extending from (e_1, e_2) can be formed by taking the hyper-edge (e_1, e_2), together with a choice at each of their leaf nodes of simply taking the non-terminal at the leaf node, or any one of the common subtrees with root at the leaf node. Thus there are $\left(1 + \Delta'\left(leaf(e_1, j), leaf(e_2, j)\right)\right)$ possible choices at the j^{th} leaf node. In total, there are $\Delta''(e_1, e_2)$ (eq. (6)) common subtrees by extending from (e_1, e_2) and $\Delta'(v_1, v_2)$ (eq. (7)) common subtrees with root at (v_1, v_2).

Obviously $\Delta'(v_1, v_2)$ calculated by Algorithm 1 is a proper convolution kernel since it simply counts the number of common subtrees under the root (v_1, v_2). Therefore, $K_f(f_1, f_2)$ defined at eq. (5) and calculated through $\Delta'(v_1, v_2)$ is also a proper convolution kernel. From eq. (5) and Algorithm 1, we can see that each hyper-edge pair (e_1, e_2) is only visited at most one time in computing the forest kernel. Thus the time complexity for computing $K_f(f_1, f_2)$ is $O(|E_1| \cdot |E_2|)$, where E_1 and E_2 are the set of hyper-edges in forests f_1 and f_2, respectively. Given a forest and the best parse trees, the number of hyper-edges is only several times (normally <=3 after pruning) than that of tree nodes in the parse tree[3].

[2] Tree can be viewed as a special case of forest with only one hyper-edge attached to each tree node.

[3] Suppose there are *K* forest nodes in a forest, each node has *M* associated hyper-edges fan out and each hyper-edge has *N* children. Then the forest is capable of encoding $M^{\frac{K-1}{N-1}}$ parse trees at most (Zhang et al., 2009b).

Algorithm 1.

Input:

f_1, f_2: *two packed forests*

v_1, v_2: *any two nodes of* f_1 *and* f_2

Notation:

$I_{eq}(\cdot,\cdot)$: *defined at* eq. (5)

$nl(e_1)$: *number of leaf node of* e_1

$leaf(e_1, j)$: *the* j^{th} *leaf node of* e_1

Output: $\Delta'(v_1, v_2)$

1. $\Delta'(v_1, v_2) = 0$
2. **if** $v_1.label \neq v_2.label$ **exit**
3. **for** each hyper-edge e_1 attached to v_1 **do**
4. **for** each hyper-edge e_2 attached to v_2 **do**
5. **if** $I_{eq}(e_1, e_2) == 0$ **do**
6. **goto** line 3
7. **else do**
8. $\Delta''(e_1, e_2) = \prod_{j=1}^{nl(e_1)}\left(1 + \Delta'\left(leaf(e_1, j), leaf(e_2, j)\right)\right)$ (6)
9. $\Delta'(v_1, v_2) \mathrel{+}= \Delta''(e_1, e_2)$ (7)
10. **end if**
11. **end for**
12. **end for**

Same as tree kernel, forest kernel is running more efficiently in practice since only two nodes with the same label needs to be further processed (line 2 of Algorithm 1).

Now let us see how to integrate fractional counts into forest kernel. According to Algorithm 1 (eq. (7)), we have (e_1/e_2 are attached to v_1/v_2, respectively)

$$\Delta'(v_1, v_2) = \sum_{e_1=e_2} \Delta''(e_1, e_2)$$

Recall eq. (4), a fractional count consists of outside, inside and subtree probabilities. It is more straightforward to incorporate the outside and subtree probabilities since all the subtrees with roots at (v_1, v_2) share the same outside probability and each hyper-edge pair is only visited one time. Thus we can integrate the two probabilities into $\Delta'(v_1, v_2)$ as follows.

$$\Delta'(v_1, v_2) = \lambda \cdot \alpha(v_1) \cdot \alpha(v_2) \cdot \sum_{e_1=e_2}\left(P(e_1) \cdot P(e_2) \cdot \Delta''(e_1, e_2)\right) \quad (8)$$

where, following tree kernel, a decay factor $\lambda(0 < \lambda \leq 1)$ is also introduced in order to make the kernel value less variable with respect to the subtree sizes (Collins and Duffy, 2002). It functions like multiplying each feature value by λ^{size_i}, where $size_i$ is the number of hyper-edges in $subtree_i$.

The inside probability is only involved when a node does not need to be further expanded. The integer 1 at eq. (6) represents such case. So the inside probability is integrated into eq. (6) by replacing the integer 1 as follows.

$$\Delta''(e_1, e_2) = \prod_{j=1}^{nl(e_1)} \left(\beta\big(leaf(e_1, j)\big) \cdot \beta\big(leaf(e_2, j)\big) + \frac{\Delta'\big(leaf(e_1, j), leaf(e_2, j)\big)}{\alpha\big(leaf(e_1, j)\big) \cdot \alpha\big(leaf(e_2, j)\big)} \right) \quad (9)$$

where in the last expression the two outside probabilities $\alpha\big(leaf(e_1, j)\big)$ and $\alpha\big(leaf(e_2, j)\big)$ are removed. This is because $leaf(e_1, j)$ and $leaf(e_2, j)$ are not roots of the subtrees of being explored (only outside probabilities of the root of a subtree should be counted in its *fractional count*), and $\Delta'\big(leaf(e_1, j), leaf(e_2, j)\big)$ already contains the two outside probabilities of $leaf(e_1, j)$ and $leaf(e_2, j)$.

Referring to eq. (3), each fractional count needs to be normalized by $\alpha\beta(root(f))$. Since $\alpha\beta(root(f))$ is independent to each individual fractional count, we do the normalization outside the recursive function $\Delta''(e_1, e_2)$. Then we can re-formulize eq. (5) as

$$K_f(f_1, f_2) = < \phi(f_1), \phi(f_2) > = \frac{\left(\sum_{v_1 \in N_1} \sum_{v_2 \in N_2} \Delta'(v_1, v_2)\right)}{\alpha\beta\big(root(f_1)\big) \cdot \alpha\beta\big(root(f_2)\big)} \quad (10)$$

Finally, since the size of input forests is not constant, the forest kernel value is normalized using the following equation.

$$\widehat{K}_f(f_1, f_2) = \frac{K_f(f_1, f_2)}{\sqrt{K_f(f_1, f_1) \cdot K_f(f_2, f_2)}} \quad (11)$$

From the above discussion, we can see that the proposed forest kernel is defined together by eqs. (11), (10), (9) and (8). Thanks to the compact representation of trees in forest and the recursive nature of the kernel function, the introduction of fractional counts and normalization do not change the convolution property and the time complexity of the forest kernel. Therefore, the forest kernel $\widehat{K}_f(f_1, f_2)$ is still a proper convolution kernel with quadratic time complexity.

3.3 Comparison with previous work

To the best of our knowledge, this is the first work to address convolution kernel over packed parse forest.

Convolution tree kernel is a special case of the proposed forest kernel. From feature exploration viewpoint, although theoretically they explore the same subtree feature spaces (defined recursively by CFG parsing rules), their feature values are different. Forest encodes exponential number of trees. So the number of subtree instances extracted from a forest is exponential number of times greater than that from its corresponding parse tree. The significant difference of the amount of subtree instances makes the parameters learned from forests more reliable and also can help to address the data sparseness issue. To some degree, forest kernel can be viewed as a tree kernel with very powerful *back-off* mechanism. In addition, forest kernel is much more robust against parsing errors than tree kernel.

Aiolli *et al.* (2006; 2007) propose using Direct Acyclic Graphs (DAG) as a compact representation of tree kernel-based models. This can largely reduce the computational burden and storage requirements by sharing the common structures and feature vectors in the kernel-based model. There are a few other previous works done by generalizing convolution tree kernels (Kashima and Koyanagi, 2003; Moschitti, 2006; Zhang et al., 2007). However, all of these works limit themselves to single tree structure from modeling viewpoint in nature.

From a broad viewpoint, as suggested by one reviewer of the paper, we can consider the forest kernel as an alternative solution proposed for the general problem of noisy inference pipelines (eg. speech translation by composition of FSTs, machine translation by translating over 'lattices' of segmentations (Dyer *et al*., 2008) or using parse tree info for downstream applications in our cases) . Following this line, Bunescu (2008) and Finkel et al. (2006) are two typical related works done in reducing cascading noisy. However, our works are not overlapped with each other as there are two totally different solutions for the same general problem. In addition, the main motivation of this paper is also different from theirs.

4 Experiments

Forest kernel has a broad application potential in NLP. In this section, we verify the effectiveness of the forest kernel on two NLP applications, semantic role labeling (SRL) (Gildea, 2002) and relation extraction (RE) (ACE, 2002-2006).

In our experiments, SVM (Vapnik, 1998) is selected as our classifier and the *one vs. others* strategy is adopted to select the one with the

largest margin as the final answer. In our implementation, we use the binary SVMLight (Joachims, 1998) and borrow the framework of the Tree Kernel Tools (Moschitti, 2004) to integrate our forest kernel into the SVMLight. We modify Charniak parser (Charniak, 2001) to output a packed forest. Following previous forest-based studies (Charniak and Johnson, 2005), we use the marginal probabilities of hyper-edges (i.e., the Viterbi-style inside-outside probabilities and set the pruning threshold as 8) for forest pruning.

4.1 Semantic role labeling

Given a sentence and each predicate (either a target verb or a noun), SRL recognizes and maps all the constituents in the sentence into their corresponding semantic arguments (roles, e.g., A0 for *Agent*, A1 for *Patient* …) of the predicate or *non*-argument. We use the CoNLL-2005 shared task on Semantic Role Labeling (Carreras and Màrquez, 2005) for the evaluation of our forest kernel method. To speed up the evaluation process, the same as Che *et al.* (2008), we use a subset of the entire training corpus (WSJ sections 02-05 of the entire sections 02-21) for training, section 24 for development and section 23 for test, where there are 35 roles including 7 Core (A0–A5, AA), 14 Adjunct (AM-) and 14 Reference (R-) arguments.

The state-of-the-art SRL methods (Carreras and Màrquez, 2005) use constituents as the labeling units to form the labeled arguments. Due to the errors from automatic parsing, it is impossible for all arguments to find their matching constituents in the single 1-best parse trees. Statistics on the training data shows that 9.78% of arguments have no matching constituents using the Charniak parser (Charniak, 2001), and the number increases to 11.76% when using the Collins parser (Collins, 1999). In our method, we break the limitation of 1-best parse tree and regard each span rooted by a single forest node (i.e., a *sub-forest* with one or more roots) as a candidate argument. This largely reduces the unmatched arguments from 9.78% to 1.31% after forest pruning. However, it also results in a very large amount of argument candidates that is 5.6 times as many as that from 1-best tree. Fortunately, after the pre-processing stage of argument pruning (Xue and Palmer, 2004)[4], although the amount of unmatched argument increases a little bit to 3.1%, its generated total candidate amount decreases substantially to only 1.31 times of that from 1-best parse tree. This clearly shows the advantages of the forest-based method over tree-based in SRL.

The best-reported tree kernel method for SRL $K_{hybrid} = \theta \cdot K_{path} + (1-\theta) \cdot K_{cs}$ $(0 \le \theta \le 1)$, proposed by Che et al. (2006)[5], is adopted as our baseline kernel. We implemented the K_{hybrid} in tree case ($K_{T-hybrid}$, using tree kernel to compute K_{path} and K_{cs}) and in forest case ($K_{F-hybrid}$, using tree kernel to compute K_{path} and K_{cs}).

	Precision	**Recall**	**F-Score**
$K_{T-hybrid}$ (Tree)	76.02	67.38	71.44
$K_{F-hybrid}$ (Forest)	79.06	69.12	73.76

Table 1: Performance comparison of SRL (%)

Table 1 shows that the forest kernel significantly outperforms (χ^2 test with p=0.01) the tree kernel with an absolute improvement of 2.32 (73.76-71.42) percentage in F-Score, representing a relative error rate reduction of 8.19% (2.32/(100-71.64)). This convincingly demonstrates the advantage of the forest kernel over the tree kernel. It suggests that the structured features represented by subtree are very useful to SRL. The performance improvement is mainly due to the fact that forest encodes much more such structured features and the forest kernel is able to more effectively capture such structured features than the tree kernel. Besides F-Score, both precision and recall also show significantly improvement (χ^2 test with p=0.01). The reason for recall improvement is mainly due to the lower rate of unmatched argument (3.1% only) with only a little bit overhead (1.31 times) (see the previous discussion in this section). The precision improvement is mainly attributed to fact that we use *sub-forest* to represent argument instances, rather than sub-tree used in tree kernel, where the sub-tree is only one tree encoded in the *sub-forest*.

[4] We extend (Xue and Palmer, 2004)'s argument pruning algorithm from tree-based to forest-based. The algorithm is very effective. It can prune out around 90% argument candidates in parse tree-based SRL and thus makes the amounts of positive and negative training instances (arguments) more balanced. We apply the same pruning strategies to forest plus our heuristic rules to prune out some of the arguments with span overlapped with each other and those arguments with very small inside probabilities, depending on the numbers of candidates in the span.

[5] K_{path} and K_{cs} are two standard convolution tree kernels to describe predicate-argument path substructures and argument syntactic substructures, respectively.

4.2 Relation extraction

As a subtask of information extraction, relation extraction is to extract various semantic relations between entity pairs from text. For example, the sentence "Bill Gates is chairman and chief software architect of Microsoft Corporation" conveys the semantic relation "EMPLOYMENT.executive" between the entities "Bill Gates" (person) and "Microsoft Corporation" (company). We adopt the method reported in Zhang et al. (2006) as our baseline method as it reports the state-of-the-art performance using tree kernel-based composite kernel method for RE. We replace their tree kernels with our forest kernels and use the same experimental settings as theirs. We carry out the same five-fold cross validation experiment on the same subset of ACE 2004 data (LDC2005T09, ACE 2002-2004) as that in Zhang et al. (2006). The data contain 348 documents and 4400 relation instances.

In SRL, constituents are used as the labeling units to form the labeled arguments. However, previous work (Zhang et al., 2006) shows that if we use complete constituent (MCT) as done in SRL to represent relation instance, there is a large performance drop compared with using the path-enclosed tree (PT)[6]. By simulating PT, we use the minimal fragment of a forest covering the two entities and their internal words to represent a relation instance by only parsing the span covering the two entities and their internal words.

	Precision	Recall	F-Score
Zhang et al. (2006):Tree	68.6	59.3	63.6
Ours: Forest	70.3	60.0	64.7

Table 2: Performance Comparison of RE (%) over 23 subtypes on the ACE 2004 data

Table 2 compares the performance of the forest kernel and the tree kernel on relation extraction. We can see that the forest kernel significantly outperforms (χ^2 test with p=0.05) the tree kernel by 1.1 point of F-score. This further verifies the effectiveness of the forest kernel method for modeling NLP structured data. In summary, we further observe the high precision improvement that is consistent with the SRL experiments. However, the recall improvement is not as significant as observed in SRL. This is because unlike SRL, RE has no un-matching issues in generating relation instances. Moreover, we find that the performance improvement in RE is not as good as that in SRL. Although we know that performance is task-dependent, one of the possible reasons is that SRL tends to be long-distance grammatical structure-related while RE is local and semantic-related as observed from the two experimental benchmark data.

[6] MCT is the minimal constituent rooted by the nearest common ancestor of the two entities under consideration while PT is the minimal portion of the parse tree (may not be a complete subtree) containing the two entities and their internal lexical words. Since in many cases, the two entities and their internal words cannot form a grammatical constituent, MCT may introduce too many noisy context features and thus lead to the performance drop.

5 Conclusions and Future Work

Many NLP applications have benefited from the success of convolution kernel over parse tree. Since a packed parse forest contains much richer structured features than a parse tree, we are motivated to develop a technology to measure the syntactic similarity between two forests.

To achieve this goal, in this paper, we design a convolution kernel over packed forest by generalizing the tree kernel. We analyze the object space of the forest kernel, the fractional count for feature value computing and design a dynamic programming algorithm to realize the forest kernel with quadratic time complexity. Compared with the tree kernel, the forest kernel is more robust against parsing errors and data sparseness issues. Among the broad potential NLP applications, the problems in SRL and RE provide two pointed scenarios to verify our forest kernel. Experimental results demonstrate the effectiveness of the proposed kernel in structured NLP data modeling and the advantages over tree kernel.

In the future, we would like to verify the forest kernel in more NLP applications. In addition, as suggested by one reviewer, we may consider rescaling the probabilities (exponentiating them by a constant value) that are used to compute the fractional counts. We can sharpen or flatten the distributions. This basically says "how seriously do we want to take the very best derivation" compared to the rest. However, the challenge is that we compute the fractional counts together with the forest kernel recursively by using the Inside-Outside probabilities. We cannot differentiate the individual parse tree's contribution to a fractional count on the fly. One possible solution is to do the probability rescaling off-line before kernel calculation. This would be a very interesting research topic of our future work.

Estimating Strictly Piecewise Distributions

Jeffrey Heinz

Richmond, Indiana, USA
jrogers@quark.cs.earlham.edu

Abstract

Strictly Piecewise (SP) languages are a subclass of regular languages which encode certain kinds of long-distance dependencies that are found in natural languages. Like the classes in the Chomsky and Subregular hierarchies, there are many independently converging characterizations of the SP class (Rogers et al., to appear). Here we define SP distributions and show that they can be efficiently estimated from positive data.

1 Introduction

Long-distance dependencies in natural language are of considerable interest. Although much attention has focused on long-distance dependencies which are beyond the expressive power of models with finitely many states (Chomsky, 1956; Joshi, 1985; Shieber, 1985; Kobele, 2006), there are some long-distance dependencies in natural language which permit finite-state characterizations. For example, although it is well-known that vowel and consonantal harmony applies across any arbitrary number of intervening segments (Ringen, 1988; Baković, 2000; Hansson, 2001; Rose and Walker, 2004) and that phonological patterns are regular (Johnson, 1972; Kaplan and Kay, 1994), it is less well-known that harmony patterns are largely characterizable by the Strictly Piecewise languages, a subregular class of languages with independently-motivated, converging characterizations (see Heinz (2007, to appear) and especially Rogers et al. (2009)).

As shown by Rogers et al. (to appear), the Strictly Piecewise (SP) languages, which make distinctions on the basis of (potentially) discontiguous subsequences, are precisely analogous to the Strictly Local (SL) languages (McNaughton and Papert, 1971; Rogers and Pullum, to appear), which make distinctions on the basis of contiguous subsequences. The Strictly Local languages are the formal-language theoretic foundation for n-gram models (Garcia et al., 1990), which are widely used in natural language processing (NLP) in part because such distributions can be estimated from positive data (i.e. a corpus) (Jurafsky and Martin, 2008). N-gram models describe probability distributions over all strings on the basis of the Markov assumption (Markov, 1913): that the probability of the next symbol only depends on the previous contiguous sequence of length $n-1$. From the perspective of formal language theory, these distributions are perhaps properly called Strictly k-Local distributions (SL_k) where $k = n$. It is well-known that one limitation of the Markov assumption is its inability to express any kind of long-distance dependency.

This paper defines Strictly k-Piecewise (SP_k) distributions and shows how they too can be efficiently estimated from positive data. In contrast with the Markov assumption, our assumption is that the probability of the next symbol is conditioned on the previous set of discontiguous subsequences of length $k-1$ in the string. While this suggests the model has too many parameters (one for each subset of all possible subsequences), in fact the model has on the order of $|\Sigma|^{k+1}$ parameters because of an independence assumption: there is no interaction between different subsequences. As a result, SP distributions are efficiently computable even though they condition the probability of the next symbol on the occurrences of earlier (possibly very distant) discontiguous subsequences. Essentially, these SP distributions reflect a kind of long-term memory.

On the other hand, SP models have no short-term memory and are unable to make distinctions on the basis of contiguous subsequences. We do not intend SP models to replace n-gram models, but instead expect them to be used alongside of

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 886–896,
Uppsala, Sweden, 11-16 July 2010.

them. Exactly how this is to be done is beyond the scope of this paper and is left for future research.

Since SP languages are the analogue of SL languages, which are the formal-language theoretical foundation for n-gram models, which are widely used in NLP, it is expected that SP distributions and their estimation will also find wide application. Apart from their interest to problems in theoretical phonology such as phonotactic learning (Coleman and Pierrehumbert, 1997; Hayes and Wilson, 2008; Heinz, to appear), it is expected that their use will have application, in conjunction with n-gram models, in areas that currently use them; e.g. augmentative communication (Newell et al., 1998), part of speech tagging (Brill, 1995), and speech recognition (Jelenik, 1997).

§2 provides basic mathematical notation. §3 provides relevant background on the subregular hierarchy. §4 describes automata-theoretic characterizations of SP languages. §5 defines SP distributions. §6 shows how these distributions can be efficiently estimated from positive data and provides a demonstration. §7 concludes the paper.

2 Preliminaries

We start with some mostly standard notation. Σ denotes a finite set of symbols and a string over Σ is a finite sequence of symbols drawn from that set. Σ^k, $\Sigma^{\leq k}$, $\Sigma^{\geq k}$, and Σ^* denote all strings over this alphabet of length k, of length less than or equal to k, of length greater than or equal to k, and of any finite length, respectively. ϵ denotes the empty string. $|w|$ denotes the length of string w. The prefixes of a string w are $\text{Pfx}(w) = \{v : \exists u \in \Sigma^* \text{ such that } vu = w\}$. When discussing partial functions, the notation $\uparrow$ and $\downarrow$ indicates that the function is undefined, respectively is defined, for particular arguments.

A *language* L is a subset of Σ^*. A *stochastic language* $\mathcal{D}$ is a probability distribution over Σ^*. The probability p of word w with respect to $\mathcal{D}$ is written $Pr_{\mathcal{D}}(w) = p$. Recall that all distributions $\mathcal{D}$ must satisfy $\sum_{w \in \Sigma^*} Pr_{\mathcal{D}}(w) = 1$. If L is language then $Pr_{\mathcal{D}}(L) = \sum_{w \in L} Pr_{\mathcal{D}}(w)$.

A *Deterministic Finite-state Automaton* (DFA) is a tuple $\mathcal{M} = \langle Q, \Sigma, q_0, \delta, F \rangle$ where Q is the state set, Σ is the alphabet, q_0 is the start state, δ is a deterministic transition function with domain $Q \times \Sigma$ and codomain Q, F is the set of accepting states. Let $\hat{d} : Q \times \Sigma^* \rightarrow Q$ be the (partial) path function of $\mathcal{M}$, i.e., $\hat{d}(q, w)$ is the (unique) state reachable from state q via the sequence w, if any, or $\hat{d}(q, w)\uparrow$ otherwise. The language recognized by a DFA $\mathcal{M}$ is $L(\mathcal{M}) \stackrel{\text{def}}{=} \{w \in \Sigma^* \mid \hat{d}(q_0, w)\downarrow \in F\}$.

A state is *useful* iff for all $q \in Q$, there exists $w \in \Sigma^*$ such that $\delta(q_0, w) = q$ and there exists $w \in \Sigma^*$ such that $\delta(q, w) \in F$. *Useless* states are not useful. DFAs without useless states are *trimmed*.

Two strings w and v over Σ are *distinguished* by a DFA $\mathcal{M}$ iff $\hat{d}(q_0, w) \neq \hat{d}(q_0, v)$. They are *Nerode equivalent* with respect to a language L if and only if $wu \in L \iff vu \in L$ for all $u \in \Sigma^*$. All DFAs which recognize L must distinguish strings which are inequivalent in this sense, but no DFA recognizing L necessarily distinguishes any strings which are equivalent. Hence the number of equivalence classes of strings over Σ modulo Nerode equivalence with respect to L gives a (tight) lower bound on the number of states required to recognize L.

A DFA is *minimal* if the size of its state set is minimal among DFAs accepting the same language. The *product* of n DFAs $\mathcal{M}_1 \ldots \mathcal{M}_n$ is given by the standard construction over the state space $Q_1 \times \ldots \times Q_n$ (Hopcroft et al., 2001).

A *Probabilistic Deterministic Finite-state Automaton* (PDFA) is a tuple $\mathcal{M} = \langle Q, \Sigma, q_0, \delta, F, T \rangle$ where Q is the state set, Σ is the alphabet, q_0 is the start state, δ is a deterministic transition function, F and T are the final-state and transition probabilities. In particular, $T : Q \times \Sigma \rightarrow \mathbb{R}^+$ and $F : Q \rightarrow \mathbb{R}^+$ such that

$$\text{for all } q \in Q,\ F(q) + \sum_{a \in \Sigma} T(q, a) = 1. \quad (1)$$

Like DFAs, for all $w \in \Sigma^*$, there is at most one state reachable from q_0. PDFAs are typically represented as labeled directed graphs as in Figure 1.

A PDFA $\mathcal{M}$ generates a stochastic language $\mathcal{D}_{\mathcal{M}}$. If it exists, the (unique) *path* for a word $w = a_0 \ldots a_k$ belonging to Σ^* through a PDFA is a sequence $\langle (q_0, a_0), (q_1, a_1), \ldots, (q_k, a_k) \rangle$, where $q_{i+1} = \delta(q_i, a_i)$. The probability a PDFA assigns to w is obtained by multiplying the transition probabilities with the final probability along w's path if

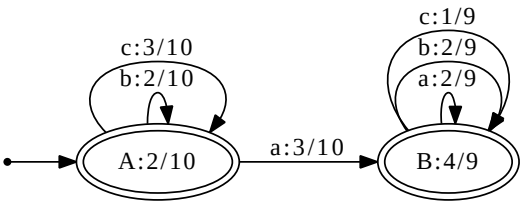

Figure 1: A picture of a PDFA with states labeled A and B. The probabilities of T and F are located to the right of the colon.

it exists, and zero otherwise.

$$Pr_{\mathcal{D}_\mathcal{M}}(w) = \left(\prod_{i=1}^{k} T(q_{i-1}, a_{i-1})\right) \cdot F(q_{k+1}) \quad (2)$$

if $\hat{d}(q_0, w)\downarrow$ and 0 otherwise

A probability distribution is *regular deterministic* iff there is a PDFA which generates it.

The *structural components* of a PDFA $\mathcal{M}$ are its states Q, its alphabet Σ, its transitions δ, and its initial state q_0. By *structure* of a PDFA, we mean its structural components. Each PDFA $\mathcal{M}$ defines a family of distributions given by the possible instantiations of T and F satisfying Equation 1. These distributions have $|Q| \cdot (|\Sigma| + 1)$ independent parameters (since for each state there are $|\Sigma|$ possible transitions plus the possibility of finality.)

We define the product of PDFA in terms of *co-emission probabilities* (Vidal et al., 2005a).

Definition 1 *Let $\mathcal{A}$ be a vector of PDFAs and let $|\mathcal{A}| = n$. For each $1 \leq i \leq n$ let $\mathcal{M}_i = \langle Q_i, \Sigma, q_{0i}, \delta_i, F_i, T_i \rangle$ be the ith PDFA in $\mathcal{A}$. The probability that σ is co-emitted from $q_1, \ldots, q_n$ in $Q_1, \ldots, Q_n$, respectively, is*

$$CT(\langle \sigma, q_1 \ \ldots \ q_n \rangle) = \prod_{i=1}^{n} T_i(q_i, \sigma).$$

Similarly, the probability that a word simultaneously ends at $q_1 \in Q_1 \ \ldots \ q_n \in Q_n$ is

$$CF(\langle q_1 \ \ldots \ q_n \rangle) = \prod_{i=1}^{n} F_i(q_i).$$

Then $\bigotimes \mathcal{A} = \langle Q, \Sigma, q_0, \delta, F, T \rangle$ where

1. *Q, q_0, and δ are defined as with DFA product.*
2. *For all $\langle q_1 \ \ldots \ q_n \rangle \in Q$, let $Z(\langle q_1 \ \ldots \ q_n \rangle) =$*

$$CF(\langle q_1 \ \ldots \ q_n \rangle) + \sum_{\sigma \in \Sigma} CT(\langle \sigma, q_1 \ \ldots \ q_n \rangle)$$

be the normalization term*; and*

   (a) *let $F(\langle q_1 \ \ldots \ q_n \rangle) = \frac{CF(\langle q_1 \ \ldots \ q_n \rangle)}{Z(\langle q_1 \ \ldots \ q_n \rangle)}$; and*

   (b) *for all $\sigma \in \Sigma$, let $T(\langle q_1 \ \ldots \ q_n \rangle, \sigma) = \frac{CT(\langle \sigma, q_1 \ \ldots \ q_n \rangle)}{Z(\langle q_1 \ \ldots \ q_n \rangle)}$*

In other words, the numerators of T and F are defined to be the co-emission probabilities (Vidal et al., 2005a), and division by Z ensures that $\mathcal{M}$ defines a well-formed probability distribution. Statistically speaking, the co-emission product makes an independence assumption: the probability of σ being co-emitted from $q_1, \ldots, q_n$ is exactly what one expects if there is no interaction between the individual factors; that is, between the probabilities of σ being emitted from any q_i. Also note order of product is irrelevant up to renaming of the states, and so therefore we also speak of taking the product of a set of PDFAs (as opposed to an ordered vector).

Estimating regular deterministic distributions is well-studied problem (Vidal et al., 2005a; Vidal et al., 2005b; de la Higuera, in press). We limit discussion to cases when the structure of the PDFA is known. Let S be a finite sample of words drawn from a regular deterministic distribution $\mathcal{D}$. The problem is to estimate parameters T and F of $\mathcal{M}$ so that $\mathcal{D}_\mathcal{M}$ approaches $\mathcal{D}$. We employ the widely-adopted maximum likelihood (ML) criterion for this estimation.

$$(\hat{T}, \hat{F}) = \underset{T,F}{\operatorname{argmax}} \left(\prod_{w \in S} Pr_\mathcal{M}(w)\right) \quad (3)$$

It is well-known that if $\mathcal{D}$ is generated by some PDFA $\mathcal{M}'$ with the same structural components as $\mathcal{M}$, then optimizing the ML estimate guarantees that $\mathcal{D}_\mathcal{M}$ approaches $\mathcal{D}$ as the size of S goes to infinity (Vidal et al., 2005a; Vidal et al., 2005b; de la Higuera, in press).

The optimization problem (3) is simple for deterministic automata with known structural components. Informally, the corpus is passed through the PDFA, and the paths of each word through the corpus are tracked to obtain counts, which are then normalized by state. Let $\mathcal{M} = \langle Q, \Sigma, \delta, q_0, F, T \rangle$ be the PDFA whose parameters F and T are to be estimated. For all states $q \in Q$ and symbols $a \in \Sigma$, The ML estimation of the probability of $T(q, a)$ is obtained by dividing the number of times this transition is used in parsing the sample S by the

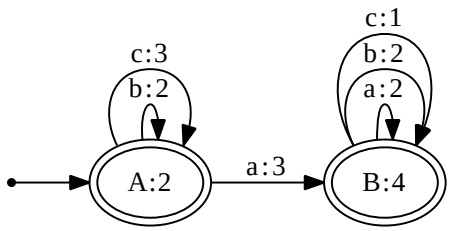

Figure 2: The automata shows the counts obtained by parsing $\mathcal{M}$ with sample $S = \{ab, bba, \epsilon, cab, acb, cc\}$.

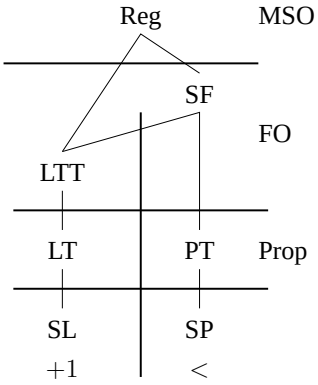

Figure 3: Parallel Sub-regular Hierarchies.

number of times state q is encountered in the parsing of S. Similarly, the ML estimation of $F(q)$ is obtained by calculating the relative frequency of state q being final with state q being encountered in the parsing of S. For both cases, the division is *normalizing*; i.e. it guarantees that there is a well-formed probability distribution at each state. Figure 2 illustrates the counts obtained for a machine $\mathcal{M}$ with sample $S = \{ab, bba, \epsilon, cab, acb, cc\}$.[1] Figure 1 shows the PDFA obtained after normalizing these counts.

3 Subregular Hierarchies

Within the class of regular languages there are dual hierarchies of language classes (Figure 3), one in which languages are defined in terms of their *contiguous substrings* (up to some length k, known as k*-factors*), starting with the languages that are *Locally Testable in the Strict Sense* (SL), and one in which languages are defined in terms of their not necessarily contiguous *subsequences*, starting with the languages that are *Piecewise Testable in the Strict Sense* (SP). Each language class in these hierarchies has independently motivated, converging characterizations and each has been claimed to correspond to specific, fundamental cognitive capabilities (McNaughton and Papert, 1971; Brzozowski and Simon, 1973; Simon, 1975; Thomas, 1982; Perrin and Pin, 1986; García and Ruiz, 1990; Beauquier and Pin, 1991; Straubing, 1994; García and Ruiz, 1996; Rogers and Pullum, to appear; Kontorovich et al., 2008; Rogers et al., to appear).

Languages in the weakest of these classes are defined only in terms of the set of factors (SL) or subsequences (SP) which are licensed to occur in the string (equivalently the complement of that set with respect to $\Sigma^{\leq k}$, the *forbidden factors* or *forbidden subsequences*). For example, the set containing the forbidden 2-factors $\{ab, ba\}$ defines a Strictly 2-Local language which includes all strings except those with contiguous substrings $\{ab, ba\}$. Similarly since the parameters of n-gram models (Jurafsky and Martin, 2008) assign probabilities to symbols given the preceding contiguous substrings up to length $n-1$, we say they describe Strictly n-Local distributions.

These hierarchies have a very attractive model-theoretic characterization. The *Locally Testable* (LT) and *Piecewise Testable* languages are exactly those that are definable by propositional formulae in which the atomic formulae are blocks of symbols interpreted factors (LT) or subsequences (PT) of the string. The languages that are testable in the strict sense (SL and SP) are exactly those that are definable by formulae of this sort restricted to conjunctions of negative literals. Going the other way, the languages that are definable by First-Order formulae with adjacency (successor) but not precedence (less-than) are exactly the *Locally Threshold Testable* (LTT) languages. The *Star-Free* languages are those that are First-Order definable with precedence alone (adjacency being FO definable from precedence). Finally, by extending to Monadic Second-Order formulae (with either signature, since they are MSO definable from each other), one obtains the full class of Regular languages (McNaughton and Papert, 1971; Thomas, 1982; Rogers and Pullum, to appear; Rogers et al., to appear).

The relation between strings which is fundamental along the Piecewise branch is the *subse-*

[1] Technically, this acceptor is neither a simple DFA or PDFA; rather, it has been called a Frequency DFA. We do not formally define them here, see (de la Higuera, in press).

quence relation, which is a partial order on Σ^*:

$$w \sqsubseteq v \overset{\text{def}}{\iff} w = \varepsilon \text{ or } w = \sigma_1 \cdots \sigma_n \text{ and}$$
$$(\exists w_0, \ldots, w_n \in \Sigma^*)[v = w_0\sigma_1 w_1 \cdots \sigma_n w_n].$$

in which case we say w is a *subsequence* of v.

For $w \in \Sigma^*$, let

$$\mathrm{P}_k(w) \overset{\text{def}}{=} \{v \in \Sigma^k \mid v \sqsubseteq w\} \text{ and}$$
$$\mathrm{P}_{\leq k}(w) \overset{\text{def}}{=} \{v \in \Sigma^{\leq k} \mid v \sqsubseteq w\},$$

the set of subsequences of length k, respectively length no greater than k, of w. Let $\mathrm{P}_k(L)$ and $\mathrm{P}_{\leq k}(L)$ be the natural extensions of these to sets of strings. Note that $\mathrm{P}_0(w) = \{\varepsilon\}$, for all $w \in \Sigma^*$, that $\mathrm{P}_1(w)$ is the set of symbols occurring in w and that $\mathrm{P}_{\leq k}(L)$ is finite, for all $L \subseteq \Sigma^*$.

Similar to the Strictly Local languages, Strictly Piecewise languages are defined only in terms of the set of subsequences (up to some length k) which are licensed to occur in the string.

Definition 2 (SP_k **Grammar,** SP**)** *A* SP_k *grammar is a pair* $\mathcal{G} = \langle \Sigma, G \rangle$ *where* $G \subseteq \Sigma^k$. *The language licensed by a* SP_k *grammar is*

$$L(\mathcal{G}) \overset{\text{def}}{=} \{w \in \Sigma^* \mid P_{\leq k}(w) \subseteq P_{\leq k}(G)\}.$$

A language is SP_k iff it is $L(\mathcal{G})$ for some SP_k grammar $\mathcal{G}$. It is SP iff it is SP_k for some k.

This paper is primarily concerned with estimating Strictly Piecewise distributions, but first we examine in greater detail properties of SP languages, in particular DFA representations.

4 DFA representations of SP Languages

Following Sakarovitch and Simon (1983), Lothaire (1997) and Kontorovich, et al. (2008), we call the set of strings that contain w as a subsequence the *principal shuffle ideal*[2] of w:

$$\mathrm{SI}(w) = \{v \in \Sigma^* \mid w \sqsubseteq v\}.$$

The *shuffle ideal* of a set of strings is defined as

$$\mathrm{SI}(S) = \cup_{w \in S} \mathrm{SI}(w)$$

Rogers et al. (to appear) establish that the SP languages have a variety of characteristic properties.

Theorem 1 *The following are equivalent:*[3]

[2]Properly $\mathrm{SI}(w)$ is the principal ideal generated by $\{w\}$ wrt the inverse of $\sqsubseteq$.

[3]For a complete proof, see Rogers et al. (to appear). We only note that 5 implies 1 by DeMorgan's theorem and the fact that every shuffle ideal is finitely generated (see also Lothaire (1997)).

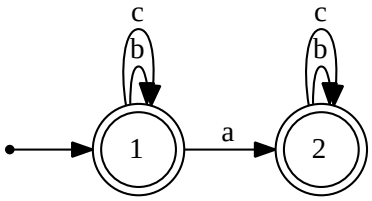

Figure 4: The DFA representation of $\overline{\mathrm{SI}(aa)}$.

1. $L = \bigcap_{w \in S} [\overline{\mathrm{SI}(w)}],\ S$ *finite,*
2. $L \in$ SP
3. $(\exists k)[P_{\leq k}(w) \subseteq P_{\leq k}(L) \Rightarrow w \in L]$,
4. $w \in L$ *and* $v \sqsubseteq w \Rightarrow v \in L$ *(*L *is* subsequence closed*),*
5. $L = \overline{\mathrm{SI}(X)},\ X \subseteq \Sigma^*$ *(*L *is the complement of a shuffle ideal).*

The DFA representation of the complement of a shuffle ideal is especially important.

Lemma 1 *Let* $w \in \Sigma^k$, $w = \sigma_1 \cdots \sigma_k$, *and* $\mathcal{M}_{\overline{\mathrm{SI}(w)}} = \langle Q, \Sigma, q_0, \delta, F \rangle$, *where* $Q = \{i \mid 1 \leq i \leq k\}$, $q_0 = 1$, $F = Q$ *and for all* $q_i \in Q, \sigma \in \Sigma$*:*

$$\delta(q_i, \sigma) = \begin{cases} q_{i+1} & \text{if } \sigma = \sigma_i \text{ and } i < k, \\ \uparrow & \text{if } \sigma = \sigma_i \text{ and } i = k, \\ q_i & \text{otherwise.} \end{cases}$$

Then $\mathcal{M}_{\overline{\mathrm{SI}(w)}}$ *is a minimal, trimmed DFA that recognizes the complement of* $\mathrm{SI}(w)$*, i.e.,* $\overline{\mathrm{SI}(w)} = L(\mathcal{M}_{\overline{\mathrm{SI}(w)}})$.

Figure 4 illustrates the DFA representation of the complement of $\mathrm{SI}(aa)$ with $\Sigma = \{a, b, c\}$. It is easy to verify that the machine in Figure 4 accepts all and only those words which do not contain an aa subsequence.

For any SP_k language $L = L(\langle \Sigma, G \rangle) \neq \Sigma^*$, the first characterization (1) in Theorem 1 above yields a non-deterministic finite-state representation of L, which is a set $\mathcal{A}$ of DFA representations of complements of principal shuffle ideals of the elements of G. The trimmed automata product of this set yields a DFA, with the properties below (Rogers et al., to appear).

Lemma 2 *Let* $\mathcal{M}$ *be a trimmed DFA recognizing a* SP_k *language constructed as described above. Then:*

1. *All states of* $\mathcal{M}$ *are accepting states:* $F = Q$.

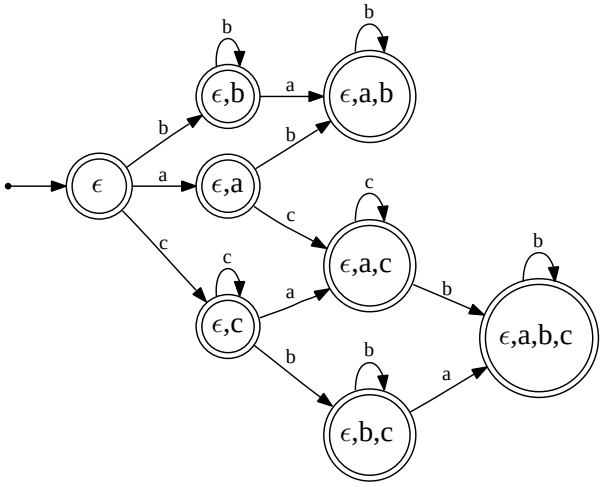

Figure 5: The DFA representation of the of the SP language given by $\mathcal{G} = \langle\{a, b, c\}, \overline{\{aa, bc\}}\rangle$. Names of the states reflect subsets of subsequences up to length 1 of prefixes of the language. Note this DFA is trimmed, but not minimal.

2. *For all $q_1, q_2 \in Q$ and $\sigma \in \Sigma$, if $\hat{d}(q_1, \sigma)\uparrow$ and $\hat{d}(q_1, w) = q_2$ for some $w \in \Sigma^*$ then $\hat{d}(q_2, \sigma)\uparrow$. (Missing edges propagate down.)*

Figure 5 illustrates with the DFA representation of the of the SP_2 language given by $\mathcal{G} = \langle\{a, b, c\}, \overline{\{aa, bc\}}\rangle$. It is straightforward to verify that this DFA is identical (modulo relabeling of state names) to one obtained by the trimmed product of the DFA representations of the complement of the principal shuffle ideals of aa and bc, which are the prohibited subsequences.

States in the DFA in Figure 5 correspond to the subsequences up to length 1 of the prefixes of the language. With this in mind, it follows that the DFA of $\Sigma^* = L(\Sigma, \Sigma^k)$ has states which correspond to the subsequences up to length $k-1$ of the prefixes of Σ^*. Figure 6 illustrates such a DFA when $k = 2$ and $\Sigma = \{a, b, c\}$.

In fact, these DFAs reveal the differences between SP languages and PT languages: they are exactly those expressed in Lemma 2. Within the state space defined by the subsequences up to length $k-1$ of the prefixes of the language, if the conditions in Lemma 2 are violated, then the DFAs describe languages that are PT but not SP. Pictorially, PT_2 languages are obtained by arbitrarily removing arcs, states, and the finality of states from the DFA in Figure 6, and SP_2 ones are obtained by non-arbitrarily removing them in accordance with Lemma 2. The same applies straightforwardly for any k (see Definition 3 below).

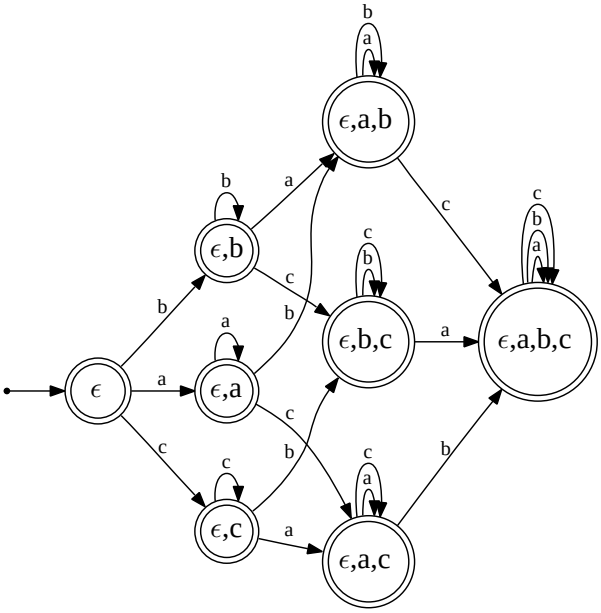

Figure 6: A DFA representation of the of the SP_2 language given by $\mathcal{G} = \langle\{a, b, c\}, \Sigma^2\rangle$. Names of the states reflect subsets of subsequences up to length 1 of prefixes of the language. Note this DFA is trimmed, but not minimal.

5 SP Distributions

In the same way that SL distributions (n-gram models) generalize SL languages, SP distributions generalize SP languages. Recall that SP languages are characterizable by the intersection of the complements of principal shuffle ideals. SP distributions are similarly characterized.

We begin with Piecewise-Testable distributions.

Definition 3 *A distribution $\mathcal{D}$ is k-Piecewise Testable (written $\mathcal{D} \in \text{PTD}_k$) $\overset{def}{\iff}$ $\mathcal{D}$ can be described by a PDFA $\mathcal{M} = \langle Q, \Sigma, q_0, \delta, F, T\rangle$ with*

1. $Q = \{P_{\leq k-1}(w) : w \in \Sigma^*\}$
2. $q_0 = P_{\leq k-1}(\epsilon)$
3. *For all $w \in \Sigma^*$ and all $\sigma \in \Sigma$, $\delta(P_{\leq k-1}(w), a) = P_{\leq k-1}(wa)$*
4. *F and T satisfy Equation 1.*

In other words, a distribution is k-Piecewise Testable provided it can be represented by a PDFA whose structural components are the same (modulo renaming of states) as those of the DFA discussed earlier where states corresponded to the subsequences up to length $k-1$ of the prefixes of the language. The DFA in Figure 6 shows the

structure of a PDFA which describes a PT_2 distribution as long as the assigned probabilities satisfy Equation 1.

The following lemma follows directly from the finite-state representation of PT_k distributions.

Lemma 3 *Let $\mathcal{D}$ belong to PTD_k and let $\mathcal{M} = \langle Q, \Sigma, q_0, \delta, F, T\rangle$ be a PDFA representing $\mathcal{D}$ defined according to Definition 3.*

$$Pr_D(\sigma_1 \dots \sigma_n) = T(P_{\leq k-1}(\epsilon), \sigma_1) \cdot \left(\prod_{2 \leq i \leq n} T(P_{\leq k-1}(\sigma_1 \dots \sigma_{i-1}), \sigma_i) \right) \cdot F(P_{\leq k-1}(w)) \quad (4)$$

PT_k distributions have $2^{|\Sigma|^{k-1}}(|\Sigma|+1)$ parameters (since there are $2^{|\Sigma|^{k-1}}$ states and $|\Sigma|+1$ possible events, i.e. transitions and finality).

Let $Pr(\sigma \mid \#)$ and $Pr(\# \mid P_{\leq k}(w))$ denote the probability (according to some $\mathcal{D} \in \text{PTD}_k$) that a word begins with σ and ends after observing $P_{\leq k}(w)$. Then Equation 4 can be rewritten in terms of conditional probability as

$$Pr_D(\sigma_1 \dots \sigma_n) = Pr(\sigma_1 \mid \#) \cdot \left(\prod_{2 \leq i \leq n} Pr(\sigma_i \mid P_{\leq k-1}(\sigma_1 \dots \sigma_{i-1})) \right) \cdot Pr(\# \mid P_{\leq k-1}(w)) \quad (5)$$

Thus, the probability assigned to a word depends not on the observed contiguous sequences as in a Markov model, but on observed subsequences.

Like SP languages, SP distributions can be defined in terms of the product of machines very similar to the complement of principal shuffle ideals.

Definition 4 *Let $w \in \Sigma^{k-1}$ and $w = \sigma_1 \cdots \sigma_{k-1}$. $\mathcal{M}_w = \langle Q, \Sigma, q_0, \delta, F, T\rangle$ is a* w-subsequence-distinguishing PDFA *(w-SD-PDFA) iff $Q = \text{Pfx}(w)$, $q_0 = \epsilon$, for all $u \in \text{Pfx}(w)$ and each $\sigma \in \Sigma$,*

$$\delta(u, \sigma) = \begin{array}{l} u\sigma \text{ iff } u\sigma \in \text{Pfx}(w) \text{ and} \\ u \text{ otherwise} \end{array}$$

and F and T satisfy Equation 1.

Figure 7 shows the structure of $\mathcal{M}_a$ which is almost the same as the complement of the principal shuffle ideal in Figure 4. The only difference is the additional self-loop labeled a on the rightmost state labeled a. $\mathcal{M}_a$ defines a family of distributions over Σ^*, and its states distinguish those

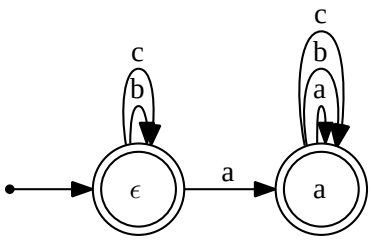

Figure 7: The structure of PDFA $\mathcal{M}_a$. It is the same (modulo state names) as the DFA in Figure 4 except for the self-loop labeled a on state a.

strings which contain a (state a) from those that do not (state ϵ). A set of PDFAs is *a k-set of SD-PDFAs* iff, for each $w \in \Sigma^{\leq k-1}$, it contains exactly one w-SD-PDFA.

In the same way that missing edges propagate down in DFA representations of SP languages (Lemma 2), the final and transitional probabilities must propagate down in PDFA representations of SP_k distributions. In other words, the final and transitional probabilities at states further along paths beginning at the start state must be determined by final and transitional probabilities at earlier states non-increasingly. This is captured by defining SP distributions as a product of k-sets of SD-PDFAs (see Definition 5 below).

While the standard product based on co-emission probability could be used for this purpose, we adopt a modified version of it defined for k-sets of SD-PDFAs: the *positive co-emission probability*. The automata product based on the positive co-emission probability not only ensures that the probabilities propagate as necessary, but also that such probabilities are made on the basis of observed subsequences, and not unobserved ones. This idea is familiar from n-gram models: the probability of σ_n given the immediately preceding sequence $\sigma_1 \dots \sigma_{n-1}$ does not depend on the probability of σ_n given the other $(n-1)$-long sequences which do not immediately precede it, though this is a logical possibility.

Let $\mathcal{A}$ be a k-set of SD-PDFAs. For each $w \in \Sigma^{\leq k-1}$, let $\mathcal{M}_w = \langle Q_w, \Sigma, q_{0w}, \delta_w, F_w, T_w\rangle$ be the w-subsequence-distinguishing PDFA in $\mathcal{A}$. The positive co-emission probability that σ is simultaneously emitted from states $q_\epsilon, \dots, q_u$ from the statesets $Q_\epsilon, \dots Q_u$, respectively, of each SD-

PDFA in $\mathcal{A}$ is

$$PCT(\langle \sigma, q_\epsilon \ \ldots \ q_u \rangle) = \prod_{\substack{q_w \in \langle q_\epsilon \ldots q_u \rangle \\ q_w = w}} T_w(q_w, \sigma) \quad (6)$$

Similarly, the probability that a word simultaneously ends at n states $q_\epsilon \in Q_\epsilon, \ldots, \ q_u \in Q_u$ is

$$PCF(\langle q_\epsilon \ \ldots \ q_u \rangle) = \prod_{\substack{q_w \in \langle q_\epsilon \ldots q_u \rangle \\ q_w = w}} F_w(q_w) \quad (7)$$

In other words, the positive co-emission probability is the product of the probabilities restricted to those assigned to the maximal states in each $\mathcal{M}_w$. For example, consider a 2-set of SD-PDFAs $\mathcal{A}$ with $\Sigma = \{a, b, c\}$. $\mathcal{A}$ contains four PDFAs $\mathcal{M}_\epsilon, \mathcal{M}_a, \mathcal{M}_b, \mathcal{M}_c$. Consider state $q = \langle \epsilon, \epsilon, b, c \rangle \in \bigotimes \mathcal{A}$ (this is the state labeled ϵ, b, c in Figure 6). Then

$$CT(a, q) = T_\epsilon(\epsilon, a) \cdot \ T_a(\epsilon, a) \cdot \ T_b(b, a) \cdot \ T_c(c, a)$$

but

$$PCT(a, q) = T_\epsilon(\epsilon, a) \cdot \ T_b(b, a) \cdot \ T_c(c, a)$$

since in PDFA $\mathcal{M}_a$, the state ϵ is not the maximal state.

The positive co-emission product ($\otimes^+$) is defined just as with co-emission probabilities, substituting PCT and PCF for CT and CF, respectively, in Definition 1. The definition of $\otimes^+$ ensures that the probabilities propagate on the basis of observed subsequences, and not on the basis of unobserved ones.

Lemma 4 *Let $k \geq 1$ and let $\mathcal{A}$ be a k-set of SD-PDFAs. Then $\otimes^+ S$ defines a well-formed probability distribution over Σ^*.*

Proof Since $\mathcal{M}_\epsilon$ belongs to $\mathcal{A}$, it is always the case that PCT and PCF are defined. Well-formedness follows from the normalization term as in Definition 1. ⊣

Definition 5 *A distribution $\mathcal{D}$ is k-Strictly Piecewise (written $\mathcal{D} \in \text{SPD}_k$) $\stackrel{def}{\Longleftrightarrow}$ $\mathcal{D}$ can be described by a PDFA which is the positive co-emission product of a k-set of subsequence-distinguishing PDFAs.*

By Lemma 4, SP distributions are well-formed. Unlike PDFAs for PT distributions, which distinguish $2^{|\Sigma|^{k-1}}$ states, the number of states in a k-set of SD-PDFAs is $\sum_{i<k}(i+1)|\Sigma|^i$, which is $\Theta(|\Sigma|^{k+1})$. Furthermore, since each SD-PDFA only has one state contributing $|\Sigma|+1$ probabilities to the product, and since there are $|\Sigma^{\leq k}| = \frac{|\Sigma|^k - 1}{|\Sigma| - 1}$ many SD-PDFAs in a k-set, there are

$$\frac{|\Sigma|^k - 1}{|\Sigma| - 1} \cdot (|\Sigma| + 1) = \frac{|\Sigma|^{k+1} + |\Sigma|^k - |\Sigma| - 1}{|\Sigma| - 1}$$

parameters, which is $\Theta(|\Sigma|^k)$.

Lemma 5 *Let $\mathcal{D} \in \text{SPD}_k$. Then $\mathcal{D} \in \text{PTD}_k$.*

Proof Since $\mathcal{D} \in \text{SPD}_k$, there is a k-set of subsequence-distinguishing PDFAs. The product of this set has the same structure as the PDFA given in Definition 3. ⊣

Theorem 2 *A distribution $\mathcal{D} \in \text{SPD}_k$ if $\mathcal{D}$ can be described by a PDFA $\mathcal{M} = \langle Q, \Sigma, q_0, \delta, F, T \rangle$ satisfying Definition 3 and the following.*

For all $w \in \Sigma^*$ and all $\sigma \in \Sigma$, let

$$Z(w) = \prod_{s \in P_{\leq k-1}(w)} F(P_{\leq k-1}(s)) + \sum_{\sigma' \in \Sigma} \left(\prod_{s \in P_{\leq k-1}(w)} T(P_{\leq k-1}(s), \sigma') \right) \quad (8)$$

(This is the normalization term.) Then T must satisfy: $T(P_{\leq k-1}(w), \sigma) =$

$$\frac{\prod_{s \in P_{\leq k-1}(w)} T(P_{\leq k-1}(s), \sigma)}{Z(w)} \quad (9)$$

and F must satisfy: $F(P_{\leq k-1}(w)) =$

$$\frac{\prod_{s \in P_{\leq k-1}(w)} F(P_{\leq k-1}(s))}{Z(w)} \quad (10)$$

Proof That SPD_k satisfies Definition 3 Follows directly from Lemma 5. Equations 8-10 follow from the definition of positive co-emission probability. ⊣

The way in which final and transitional probabilities propagate down in SP distributions is reflected in the conditional probability as defined by Equations 9 and 10. In terms of conditional probability, Equations 9 and 10 mean that the probability that σ_i follows a sequence $\sigma_1 \ldots \sigma_{i-1}$ is not only a function of $P_{\leq k-1}(\sigma_1 \ldots \sigma_{i-1})$ (Equation 4) but further that it is a function of each subsequence in $\sigma_1 \ldots \sigma_{i-1}$ up to length $k-1$.

In particular, $Pr(\sigma_i \mid P_{\leq k-1}(\sigma_1 \ldots \sigma_{i-1}))$ is obtained by substituting $Pr(\sigma_i \mid P_{\leq\, k-1}(s))$ for $T(P_{\leq\, k-1}(s), \sigma)$ and $Pr(\# \mid P_{\leq\, k-1}(s))$ for $F(P_{\leq k-1}(s))$ in Equations 8, 9 and 10. For example, for a SP_2 distribution, the probability of a given $P_{\leq 1}(bc)$ (state ϵ, b, c in Figure 6) is the normalized product of the probabilities of a given $P_{\leq 1}(\epsilon)$, a given $P_{\leq 1}(b)$, and a given $P_{\leq 1}(c)$.

To summarize, SP and PT distributions are regular deterministic. Unlike PT distributions, however, SP distributions can be modeled with only $\Theta(|\Sigma|^k)$ parameters and $\Theta(|\Sigma|^{k+1})$ states. This is true even though SP distributions distinguish $2^{|\Sigma|^{k-1}}$ states! Since SP distributions can be represented by a single PDFA, computing $Pr(w)$ occurs in only $\Theta(|w|)$ for such PDFA. While such PDFA might be too large to be practical, $Pr(w)$ can also be computed from the k-set of SD-PDFAs in $\Theta(|w|^k)$ (essentially building the path in the product machine on the fly using Equations 4, 8, 9 and 10).

6 Estimating SP Distributions

The problem of ML estimation of SP_k distributions is reduced to estimating the parameters of the SD-PDFAs. Training (counting and normalization) occurs over each of these machines (i.e. each machine parses the entire corpus), which gives the ML estimates of the parameters of the distribution. It trivially follows that this training successfully estimates any $\mathcal{D} \in \text{SPD}_k$.

Theorem 3 *For any $\mathcal{D} \in \text{SPD}_k$, let $\mathcal{D}$ generate sample S. Let $\mathcal{A}$ be the k-set of SD-PDFAs which describes exactly $\mathcal{D}$. Then optimizing the MLE of S with respect to each $\mathcal{M} \in \mathcal{A}$ guarantees that the distribution described by the positive co-emission product of $\bigotimes^+ \mathcal{A}$ approaches $\mathcal{D}$ as $|S|$ increases.*

Proof The MLE estimate of S with respect to SPD_k returns the parameter values that maximize the likelihood of S. The parameters of $\mathcal{D} \in \text{SPD}_k$ are found on the maximal states of each $\mathcal{M} \in \mathcal{A}$. By definition, each $\mathcal{M} \in \mathcal{A}$ describes a probability distribution over Σ^*, and similarly defines a family of distributions. Therefore finding the MLE of S with respect to SPD_k means finding the MLE estimate of S with respect to each of the family of distributions which each $\mathcal{M} \in \mathcal{A}$ defines, respectively.

Optimizing the ML estimate of S for each $\mathcal{M} \in \mathcal{A}$ means that as $|S|$ increases, the estimates $\hat{T}_{\mathcal{M}}$ and $\hat{F}_{\mathcal{M}}$ approach the true values $T_{\mathcal{M}}$ and $F_{\mathcal{M}}$. It follows that as $|S|$ increases, $\hat{T}_{\bigotimes^+ \mathcal{A}}$ and $\hat{F}_{\bigotimes^+ \mathcal{A}}$ approach the true values of $T_{\bigotimes^+ \mathcal{A}}$ and $F_{\bigotimes^+ \mathcal{A}}$ and consequently $\mathcal{D}_{\bigotimes^+ \mathcal{A}}$ approaches $\mathcal{D}$. ⊣

We demonstrate learning long-distance dependencies by estimating SP_2 distributions given a corpus from Samala (Chumash), a language with sibilant harmony.[4] There are two classes of sibilants in Samala: [-anterior] sibilants like [s] and [t͡s] and [+anterior] sibilants like [ʃ] and [t͡ʃ].[5] Samala words are subject to a phonological process wherein the last sibilant requires earlier sibilants to have the same value for the feature [anterior], no matter how many sounds intervene (Applegate, 1972). As a consequence of this rule, there are generally no words in Samala where [-anterior] sibilants follow [+anterior]. E.g. [ʃtojonowonowaʃ] 'it stood upright' (Applegate 1972:72) is licit but not *[ʃtojonowonowas].

The results of estimating $\mathcal{D} \in \text{SPD}_2$ with the corpus is shown in Table 6. The results clearly demonstrate the effectiveness of the model: the probability of a [α anterior] sibilant given $P_{\leq 1}$([-α anterior]) sounds is orders of magnitude less than given $P_{\leq 1}(\alpha$ anterior]) sounds.

$Pr(x \mid P_{\leq 1}(y))$		x			
		s	t͡s	ʃ	t͡ʃ
y	s	0.0335	0.0051	0.0011	0.0002
	t͡s	0.0218	0.0113	0.0009	0.
	ʃ	0.0009	0.	0.0671	0.0353
	t͡ʃ	0.0006	0.	0.0455	0.0313

Table 1: Results of SP_2 estimation on the Samala corpus. Only sibilants are shown.

7 Conclusion

SP distributions are the stochastic version of SP languages, which model long-distance dependencies. Although SP distributions distinguish $2^{|\Sigma|^{k-1}}$ states, they do so with tractably many parameters and states because of an assumption that distinct subsequences do not interact. As shown, these distributions are efficiently estimable from positive data. As previously mentioned, we anticipate these models to find wide application in NLP.

[4] The corpus was kindly provided by Dr. Richard Applegate and drawn from his 2007 dictionary of Samala.

[5] Samala actually contrasts glottalized, aspirated, and plain variants of these sounds (Applegate, 1972). These laryngeal distinctions are collapsed here for easier exposition.

String Extension Learning

Jeffrey Heinz
University of Delaware
Newark, Delaware, USA
heinz@udel.edu

Abstract

This paper provides a unified, learning-theoretic analysis of several learnable classes of languages discussed previously in the literature. The analysis shows that for these classes an incremental, globally consistent, locally conservative, set-driven learner always exists. Additionally, the analysis provides a recipe for constructing new learnable classes. Potential applications include learnable models for aspects of natural language and cognition.

1 Introduction

The problem of generalizing from examples to patterns is an important one in linguistics and computer science. This paper shows that many disparate language classes, many previously discussed in the literature, have a simple, natural and interesting (because non-enumerative) learner which exactly identifies the class in the limit from distribution-free, positive evidence in the sense of Gold (Gold, 1967).[1] These learners are called String Extension Learners because each string in the language can be mapped (extended) to an element of the grammar, which in every case, is conceived as a finite set of elements. These learners have desirable properties: they are incremental, globally consistent, and locally conservative.

Classes previously discussed in the literature which are string extension learnable include the Locally Testable (LT) languages, the Locally Testable Languages in the Strict Sense (Strictly Local, SL) (McNaughton and Papert, 1971; Rogers and Pullum, to appear), the Piecewise Testable (PT) languages (Simon, 1975), the Piecewise Testable languages in the Strict Sense (Strictly Piecewise, SP) (Rogers et al., 2009), the Strongly Testable languages (Beauquier and Pin, 1991), the Definite languages (Brzozowski, 1962), and the Finite languages, among others. To our knowledge, this is the first analysis which identifies the common structural elements of these language classes which allows them to be identifiable in the limit from positive data: each language class induces a natural partition over all logically possible strings and each language in the class is the union of finitely many blocks of this partition.

One consequence of this analysis is a recipe for constructing new learnable classes. One notable case is the Strictly Piecewise (SP) languages, which was originally motivated for two reasons: the learnability properties discussed here and its ability to describe long-distance dependencies in natural language phonology (Heinz, 2007; Heinz, to appear). Later this class was discovered to have several independent characterizations and form the basis of another subregular hierarchy (Rogers et al., 2009).

It is expected string extension learning will have applications in linguistic and cognitive models. As mentioned, the SP languages already provide a novel hypothesis of how long-distance dependencies in sound patterns are learned. Another example is the Strictly Local (SL) languages which are the categorical, symbolic version of n-gram models, which are widely used in natural language processing (Jurafsky and Martin, 2008). Since the SP languages also admit a probabilistic variant which describe an efficiently estimable class of distributions (Heinz and Rogers, 2010), it is plausible to expect the other classes will as well, though this is left for future research.

String extension learners are also simple, mak-

[1] The allowance of negative evidence (Gold, 1967) or restricting the kinds of texts the learner is required to succeed on (i.e. non-distribution-free evidence) (Gold, 1967; Horning, 1969; Angluin, 1988) admits the learnability of the class of recursively enumerable languages. Classes of languages learnable in the harder, distribution-free, positive-evidence-only settings are due to structural properties of the language classes that permit generalization (Angluin, 1980b; Blumer et al., 1989). That is the central interest here.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 897–906,
Uppsala, Sweden, 11-16 July 2010.

ing them accessible to linguists without a rigorous mathematical background.

This paper is organized as follow. §2 goes over basic notation and definitions. §3 defines string extension grammars, languages, and language classes and proves some of their fundamental properties. §4 defines string extension learners and proves their behavior. §5 shows how important subregular classes are string extension language classes. §6 gives examples of nonregular and infinite language classes which are string extension learnable. §7 summarizes the results, and discusses lines of inquiry for future research.

2 Preliminaries

This section establishes notation and recalls basic definitions for formal languages, the paradigm of identification in the limit from positive data (Gold, 1967). Familiarity with the basic concepts of sets, functions, and sequences is assumed.

For some set A, $\mathcal{P}(A)$ denotes the set of all subsets of A and $\mathcal{P}_{fin}(A)$ denotes the set of all finite subsets of A. If f is a function such that $f : A \rightarrow B$ then let $f^{\diamond}(a) = \{f(a)\}$. Thus, $f^{\diamond} : A \rightarrow \mathcal{P}(B)$ (note $f^{\diamond}$ is not surjective). A set π of nonempty subsets of S is a *partition* of S iff the elements of π (called *blocks*) are pairwise disjoint and their union equals S.

Σ denotes a fixed finite set of symbols, the *alphabet*. Let Σ^n, $\Sigma^{\leq n}$, Σ^*, Σ^+ denote all strings formed over this alphabet of length n, of length less than or equal to n, of any finite length, and of any finite length strictly greater than zero, respectively. The term *word* is used interchangeably with *string*. The *range* of a string w is the set of symbols which are in w. The empty string is the unique string of length zero denoted λ. Thus $range(\lambda) = \emptyset$. The length of a string u is denoted by $|u|$, e.g. $|\lambda| = 0$. A language L is some subset of Σ^*. The reverse of a language $L^r = \{w^r : w \in L\}$.

Gold (1967) establishes a learning paradigm known as identification in the limit from positive data. A *text* is an infinite sequence whose elements are drawn from $\Sigma^* \cup \{\#\}$ where $\#$ represents a non-expression. The ith element of t is denoted $t(i)$, and $t[i]$ denotes the finite sequence $t(0), t(1), \ldots t(i)$. Following Jain et al. (1999), let SEQ denote the set of all possible finite sequences:

$$SEQ = \{t[i] : t \text{ is a text and } i \in \mathbb{N}\}$$

The *content* of a text is defined below.

$$content(t) = \{w \in \Sigma^* : \exists n \in \mathbb{N} \text{ such that } t(n) = w\}$$

A text t is a *positive text for a language* L iff $content(t) = L$. Thus there is only one text t for the empty language: for all i, $t(i) = \#$.

A *learner* is a function ϕ which maps initial finite sequences of texts to grammars, i.e. $\phi : SEQ \rightarrow \mathcal{G}$. The elements of $\mathcal{G}$ (the grammars) generate languages in some well-defined way. A learner *converges on a text* t iff there exists $i \in \mathbb{N}$ and a grammar G such that for all $j > i$, $\phi(t[j]) = G$.

For any grammar G, the language it generates is denoted $L(G)$. A learner ϕ *identifies a language* L *in the limit* iff for any positive text t for L, ϕ converges on t to grammar G and $L(G) = L$. Finally, a learner ϕ *identifies a class of languages* $\mathcal{L}$ *in the limit* iff for any $L \in \mathcal{L}$, ϕ identifies L in the limit. Angluin (1980b) provides necessary and sufficient properties of language classes which are identifiable in the limit from positive data.

A learner ϕ of language class $\mathcal{L}$ is *globally consistent* iff for each i and for all texts t for some $L \in \mathcal{L}$, $content(t[i]) \subseteq L(\phi(t[i]))$. A learner ϕ is *locally conservative* iff for each i and for all texts t for some $L \in \mathcal{L}$, whenever $\phi(t[i]) \neq \phi(t[i-1])$, it is the case that $t(i) \notin L(\phi([i-1]))$. These terms are from Jain et al. (2007). Also, learners which do not depend on the order of the text are called *set-driven* (Jain et al., 1999, p. 99).

3 Grammars and Languages

Consider some set A. A string extension function is a total function $f : \Sigma^* \rightarrow \mathcal{P}_{fin}(A)$. It is not required that f be onto. Denote the class of functions which have this general form $\mathcal{SEF}$.

Each string extension function is naturally associated with some formal class of grammars and languages. These functions, grammars, and languages are called *string extension functions*, *grammars*, and *languages*, respectively.

Definition 1 Let $f \in \mathcal{SEF}$.

1. A *grammar* is a finite subset of A.
2. The *language of grammar* G is

$$L_f(G) = \{w \in \Sigma^* : f(w) \subseteq G\}$$

3. The *class of languages* obtained by all possible grammars is

$$\mathcal{L}_f = \{L_f(G) : G \in \mathcal{P}_{fin}(A)\}$$

The subscript f is omitted when it is understood from context.

A function $f \in \mathcal{SEF}$ naturally induces a partition π_f over Σ^*. Strings u and v are equivalent ($u \sim_f v$) iff $f(u) = f(v)$.

Theorem 1 Every language $L \in \mathcal{L}_f$ is a finite union of blocks of π_f.

Proof: Follows directly from the definition of $\sim_f$ and the finiteness of string extension grammars. □

We return to this result in §6.

Theorem 2 $\mathcal{L}_f$ is closed under intersection.

Proof: We show $L_1 \cap L_2 = L(G_1 \cap G_2)$. Consider any word w belonging to L_1 and L_2. Then $f(w)$ is a subset of G_1 and of G_2. Thus $f(w) \subseteq G_1 \cap G_2$, and therefore $w \in L(G_1 \cap G_2)$. The other inclusion follows similarly. □

String extension language classes are not in general closed under union or reversal (counterexamples to union closure are given in §5.1 and to reversal closure in §6.)

It is useful to extend the domain of the function f from strings to languages.

$$f(L) = \bigcup_{w \in L} f(w) \tag{1}$$

An element g of grammar G for language $L = L_f(G)$ is *useful* iff $g \in f(L)$. An element is *useless* if it is not useful. A grammar with no useless elements is called *canonical*.

Remark 1 *Fix a function $f \in \mathcal{SEF}$. For every $L \in \mathcal{L}_f$, there is a canonical grammar, namely $f(L)$. In other words, $L = L(f(L))$.*

Lemma 1 Let $L, L' \in \mathcal{L}_f$. $L \subseteq L'$ iff $f(L) \subseteq f(L')$

Proof: ($\Rightarrow$) Suppose $L \subseteq L'$ and consider any $g \in f(L)$. Since g is useful, there is a $w \in L$ such that $g \in f(w)$. But $f(w) \subseteq f(L')$ since $w \in L'$.

($\Leftarrow$) Suppose $f(L) \subseteq f(L')$ and consider any $w \in L$. Then $f(w) \subseteq f(L)$ so by transitivity, $f(w) \subseteq f(L')$. Therefore $w \in L'$. □

The significance of this result is that as the grammar G monotonically increases, the language $L(G)$ monotonically increases too. The following result can now be proved, used in the next section on learning.[2]

Theorem 3 For any finite $L_0 \subseteq \Sigma^*$, $L = L(f(L_0))$ is the smallest language in $\mathcal{L}_f$ containing L_0.

Proof: Clearly $L_0 \subseteq L$. Suppose $L' \in \mathcal{L}_f$ and $L_0 \subseteq L'$. It follows directly from Lemma 1 that $L \subseteq L'$ (since $f(L) = f(L_0) \subseteq f(L')$). □

4 String Extension Learning

Learning string extension classes is simple. The initial hypothesis of the learner is the empty grammar. The learner's next hypothesis is obtained by applying function f to the current observation and taking the union of that set with the previous one.

Definition 2 For all $f \in \mathcal{SEF}$ and for all $t \in SEQ$, define ϕ_f as follows:

$$\phi_f(t[i]) = \begin{cases} \emptyset & \text{if } i = -1 \\ \phi_f(t[i-1]) & \text{if } t(i) = \# \\ \phi_f(t[i-1]) \cup f(t(i)) & \text{otherwise} \end{cases}$$

By convention, the initial state of the grammar is given by $\phi(t[-1]) = \emptyset$. The learner ϕ_f exemplifies *string extension learning*. Each individual string in the text reveals, by extension with f, aspects of the canonical grammar for $L \in \mathcal{L}_f$.

Theorem 4 ϕ_f is globally consistent, locally conservative, and set-driven.

Proof: Global consistness and local conservativeness follow immediately from Definition 2. For set-drivenness, witness (by Definition 2) it is the case that for any text t and any $i \in \mathbb{N}$, $\phi(t[i]) = f(content(t[i]))$. □

The key to the proof that ϕ_f identifies $\mathcal{L}_f$ in the limit from positive data is the finiteness of G for all $L(G) \in \mathcal{L}$. The idea is that there is a point in the text in which every element of the grammar has been seen because (1) there are only finitely many useful elements of G, and (2) the learner is guaranteed to see a word in L which yields (via f) each element of G at some point (since the learner receives a positive text for L). Thus at this point

[2]The requirement in Theorem 3 that L_0 be finite can be dropped if the qualifier "in $\mathcal{L}_f$" be dropped as well. This can be seen when one considers the identity function and the class of finite languages. (The identity function is a string extension function, see §6.) In this case, $id(\Sigma^*) = \Sigma^*$, but Σ^* is not a member of $\mathcal{L}_{fin}$. However since the interest here is learners which generalize on the basis of finite experience, Theorem 3 is sufficient as is.

the learner ϕ is guaranteed to have converged to the target G as no additional words will add any more elements to the learner's grammar.

Lemma 2 For all $L \in \mathcal{L}_f$, there is a finite sample S such that L is the smallest language in $\mathcal{L}_f$ containing S. S is called a *characteristic sample* of L in $\mathcal{L}_f$ (S is also called a *tell-tale*).

Proof: For $L \in \mathcal{L}_f$, construct the sample S as follows. For each $g \in f(L)$, choose some word $w \in L$ such that $g \in f(w)$. Since $f(L)$ is finite (Remark 1), S is finite. Clearly $f(S) = f(L)$ and thus $L = L(f(S))$. Therefore, by Theorem 3, L is the smallest language in $\mathcal{L}_f$ containing S. □

Theorem 5 Fix $f \in \mathcal{SEF}$. Then ϕ_f identifies $\mathcal{L}_f$ in the limit.

Proof: For any $L \in \mathcal{L}_f$, there is a characteristic finite sample S for L (Lemma 2). Thus for any text t for L, there is i such that $S \subseteq content(t[i])$. Thus for any $j > i$, $\phi(t(j))$ is the smallest language in $\mathcal{L}_f$ containing S by Theorem 3 and Lemma 2. Thus, $\phi(t(j)) = f(S) = f(L)$. □

An immediate corollary is the efficiency of ϕ_f in the length of the sample, provided f is efficient in the length of the string (de la Higuera, 1997).

Corollary 1 ϕ_f is efficient in the length of the sample iff f is efficiently computable in the length of a string.

To summarize: string extension grammars are finite subsets of some set A. The class of languages they generate are determined by a function f which maps strings to finite subsets of A (chunks of grammars). Since the size of the canonical grammars is finite, a learner which develops a grammar on the basis of the observed words and the function f identifies this class exactly in the limit from positive data. It also follows that if f is efficient in the length of the string then ϕ_f is efficient in the length of the sample and that ϕ_f is globally consistent, locally conservative, and set-driven. It is striking that such a natural and general framework for generalization exists and that, as will be shown, a variety of language classes can be expressed given the choice of f.

5 Subregular examples

This section shows how classes which make up the subregular hierarchies (McNaughton and Papert, 1971) are string extension language classes. Readers are referred to Rogers and Pullum (2007) and Rogers et al. (2009) for an introduction to the subregular hierarchies, as well as their relevance to linguistics and cognition.

5.1 K-factor languages

The k-factors of a word are the contiguous subsequences of length k in w. Consider the following string extension function.

Definition 3 For some $k \in \mathbb{N}$, let

$$fac_k(w) = \{x \in \Sigma^k : \exists u, v \in \Sigma^* \text{ such that } w = uxv\} \text{ when } k \leq |w| \text{ and } \{w\} \text{ otherwise}$$

Following the earlier definitions, for some k, a grammar G is a subset of $\Sigma^{\leq k}$ and a word w belongs to the language of G iff $fac_k(w) \subseteq G$.

Example 1 Let $\Sigma = \{a, b\}$ and consider grammars $G = \{\lambda, a, aa, ab, ba\}$. Then $L(G) = \{\lambda, a\} \cup \{w : |w| \geq 2 \text{ and } w \notin \Sigma^* bb \Sigma^*\}$. The 2-factor bb is a *prohibited* 2-factor for $L(G)$. Clearly, $L(G) \in \mathcal{L}_{fac_2}$.

Languages in $\mathcal{L}_{fac_k}$ make distinctions based on which k-factors are permitted or prohibited. Since $fac_k \in \mathcal{SEF}$, it follows immediately from the results in §§3-4 that the k-factor languages are closed under intersection, and each has a characteristic sample. For example, a characteristic sample for the 2-factor language in Example 1 is $\{\lambda, a, ab, ba, aa\}$; i.e. the canonical grammar itself. It follows from Theorem 5 that the class of k-factor languages is identifiable in the limit by ϕ_{fac_k}. The learner ϕ_{fac_2} with a text from the language in Example 1 is illustrated in Table 1.

The class $\mathcal{L}_{fac_k}$ is not closed under union. For example for $k = 2$, consider $L_1 = L(\{\lambda, a, b, aa, bb, ba\})$ and $L_2 = L(\{\lambda, a, b, aa, ab, bb\})$. Then $L_1 \cup L_2$ excludes string aba, but includes ab and ba, which is not possible for any $L \in \mathcal{L}_{fac_k}$.

K-factors are used to define other language classes, such as the Strictly Local and Locally Testable languages (McNaughton and Papert, 1971), discussed in §5.4 and §5.5.

5.2 Strictly k-Piecewise languages

The Strictly k-Piecewise (SP_k) languages (Rogers et al., 2009) can be defined with a function whose co-domain is $\mathcal{P}(\Sigma^{\leq k})$. However unlike the function fac_k, the function SP_k, does not require that the k-length subsequences be contiguous.

i	$t(i)$	$fac_2(t(i))$	Grammar G	$L(G)$
-1			$\emptyset$	$\emptyset$
0	$aaaa$	$\{aa\}$	$\{\mathbf{aa}\}$	aaa^*
1	aab	$\{aa,\ ab\}$	$\{aa,\ \mathbf{ab}\}$	$aaa^* \cup aaa^*b$
2	a	$\{a\}$	$\{\mathbf{a},\ aa,\ ab\}$	$aa^* \cup aa^*b$
...				

Table 1: The learner ϕ_{fac_2} with a text from the language in Example 1. Boldtype indicates newly added elements to the grammar.

A string $u = a_1 \dots a_k$ is a *subsequence* of string w iff $\exists\ v_0, v_1, \dots\ v_k \in \Sigma^*$ such that $w = v_0 a_1 v_1 \dots a_k v_k$. The empty string λ is a subsequence of every string. When u is a subsequence of w we write $u \sqsubseteq w$.

Definition 4 For some $k \in \mathbb{N}$,

$$SP_k(w) = \{u \in \Sigma^{\leq k} : u \sqsubseteq w\}$$

In other words, $SP_k(w)$ returns all subsequences, contiguous or not, in w up to length k. Thus, for some k, a grammar G is a subset of $\Sigma^{\leq k}$. Following Definition 1, a word w belongs to the language of G only if $SP_2(w) \subseteq G$.[3]

Example 2 Let $\Sigma = \{a, b\}$ and consider the grammar $G = \{\lambda, a, b, aa, ab, ba\}$. Then $L(G) = \Sigma^* \backslash (\Sigma^* b \Sigma^* b \Sigma^*)$.

As seen from Example 2, SP languages encode long-distance dependencies. In Example 2, L prohibits a b from following another b in a word, no matter how distant. Table 2 illustrates ϕ_{SP_2} learning the language in Example 2.

Heinz (2007,2009a) shows that consonantal harmony patterns in natural language are describable by such SP_2 languages and hypothesizes that humans learn them in the way suggested by ϕ_{SP_2}. Strictly 2-Piecewise languages have also been used in models of reading comprehension (Whitney, 2001; Grainger and Whitney, 2004; Whitney and Cornelissen, 2008) as well as text classification(Lodhi et al., 2002; Cancedda et al., 2003) (see also (Shawe-Taylor and Christianini, 2005, chap. 11)).

5.3 K-Piecewise Testable languages

A language L is k-Piecewise Testable iff whenever strings u and v have the same subsequences of length at most k and u is in L, then v is in L as well (Simon, 1975; Simon, 1993; Lothaire, 2005).

A language L is said to be Piecewise-Testable (PT) if it is k-Piecewise Testable for some $k \in \mathbb{N}$. If k is fixed, the k-Piecewise Testable languages are identifiable in the limit from positive data (García and Ruiz, 1996; García and Ruiz, 2004). More recently, the Piecewise Testable languages has been shown to be linearly separable with a subsequence kernel (Kontorovich et al., 2008).

The k-Piecewise Testable languages can also be described with the function $SP_k^\diamond$. Recall that $f^\diamond(a) = \{f(a)\}$. Thus functions $SP_k^\diamond$ define grammars as a finite list of *sets of subsequences* up to length k that may occur in words in the language. This reflects the fact that the k-Piecewise Testable languages are the boolean closure of the Strictly k-Piecewise languages.[4]

5.4 Strictly k-Local languages

To define the Strictly k-Local languages, it is necessary to make a pointwise extension to the definitions in §3.

Definition 5 For sets $A_1, \dots, A_n$, suppose for each i, $f_i : \Sigma^* \to \mathcal{P}_{fin}(A_i)$, and let $f = (f_1, \dots, f_n)$.

1. A *grammar* G is a tuple $(G_1, \dots, G_n)$ where $G_1 \in \mathcal{P}_{fin}(A_1), \dots, G_n \in \mathcal{P}_{fin}(A_n)$.
2. If for any $w \in \Sigma^*$, each $f_i(w) \subseteq G_i$ for all $1 \leq i \leq n$, then $f(w)$ is a *pointwise subset* of G, written $f(w) \subseteq G$.
3. The *language of grammar* G is
$$L_f(G) = \{w : f(w) \subseteq G\}$$
4. The *class of languages* obtained by all such possible grammars G is $\mathcal{L}_f$.

[3] In earlier work, the function SP_2 has been described as returning the set of precedence relations in w, and the language class $\mathcal{L}_{SP_2}$ was called the precedence languages (Heinz, 2007; Heinz, to appear).

[4] More generally, it is not hard to show that $\mathcal{L}_{f^\diamond}$ is the boolean closure of $\mathcal{L}_f$.

i	$t(i)$	$SP_2(t(i))$	Grammar G	Language of G
-1			$\emptyset$	$\emptyset$
0	$aaaa$	$\{\lambda, a, aa\}$	$\{\lambda$**, a, aa**$\}$	a^*
1	aab	$\{\lambda, a, b, aa, ab\}$	$\{\lambda$, a, aa, **b, ab**$\}$	$a^* \cup a^*b$
2	baa	$\{\lambda, a, b, aa, ba\}$	$\{\lambda$, a, b, aa, ab, **ba**$\}$	$\Sigma^* \backslash (\Sigma^* b \Sigma^* b \Sigma^*)$
3	aba	$\{\lambda, a, b, ab, ba\}$	$\{\lambda$, a, b, aa, ab, ba$\}$	$\Sigma^* \backslash (\Sigma^* b \Sigma^* b \Sigma^*)$
...				

Table 2: The learner ϕ_{SP_2} with a text from the language in Example 2. Boldtype indicates newly added elements to the grammar.

These definitions preserve the learning results of §4. Note that the characteristic sample of $L \in \mathcal{L}_f$ will be the union of the characteristic samples of each f_i and the language $L_f(G)$ is the intersection of $L_{f_i}(G_i)$.

Locally k-Testable Languages in the Strict Sense (Strictly k-Local) have been studied by several researchers (McNaughton and Papert, 1971; Garcia et al., 1990; Caron, 2000; Rogers and Pullum, to appear), among others. We follow the definitions from (McNaughton and Papert, 1971, p. 14), effectively encoded in the following functions.

Definition 6 Fix $k \in \mathbb{N}$. Then the (left-edge) prefix of length k, the (right-edge) suffix of length k, and the interior k-factors of a word w are

$$L_k(w) = \{u \in \Sigma^k : \exists v \in \Sigma^* \text{ such that } w = uv\}$$

$$R_k(w) = \{u \in \Sigma^k : \exists v \in \Sigma^* \text{ such that } w = vu\}$$

$$I_k(w) = fac_k(w) \backslash (L_k(w) \cup R_k(w))$$

Example 3 Suppose $w = abcba$. Then $L_2(w) = \{ab\}$, $R_2(w) = \{ba\}$ and $I_2(w) = \{bc,\ cb\}$.

Example 4 Suppose $|w| = k$. Then $L_k(w) = R_k(w) = \{w\}$ and $I_k(w) = \emptyset$.

Example 5 Suppose $|w|$ is less than k. Then $L_k(w) = R_k(w) = \emptyset$ and $I_k(w) = \{w\}$.

A language L is *k-Strictly Local* (k-SL) iff for all $w \in L$, there exist sets $L, R,$ and I such that $w \in L$ iff $L_k(w) \subseteq L$, $R_k(w) \subseteq R$, and $I_k(w) \subseteq I$. McNaughton and Papert note that if w is of length less than k than L may be perfectly arbitrary about w.

This can now be expressed as the string extension function:

$$LRI_k(w) = (L_k(w), R_k(w), I_k(w))$$

Thus for some k, a grammar G is triple formed by taking subsets of Σ^k, Σ^k, and $\Sigma^{\leq k}$, respectively. A word w belongs to the language of G only if $LRI_k(w) \subseteq G$. Clearly, $\mathcal{L}_{LRI_k} = k$-SL, and henceforth we refer to this class as k-SL. Since, for fixed k, $LRI_k \in \mathcal{SEF}$, all of the learning results in §4 apply.

5.5 Locally k-Testable languages

The Locally k-testable languages (k-LT) are originally defined in McNaughton and Papert (1971) and are the subject of several studies (Brzozowski and Simon, 1973; McNaughton, 1974; Kim et al., 1991; Caron, 2000; García and Ruiz, 2004; Rogers and Pullum, to appear).

A language L is k-testable iff for all $w_1, w_2 \in \Sigma^*$ such that $|w_1| \geq k$ and $|w_2| \geq k$, and $LRI_k(w_1) = LRI_k(w_2)$ then either both w_1, w_2 belong to L or neither do. Clearly, every language in k-SL belongs to k-LT. However k-LT properly include k-SL because a k-testable language only distinguishes words whenever $LRI_k(w_1) \neq LRI_k(w_2)$. It is known that the k-LT languages are the boolean closure of the k-SL (McNaughton and Papert, 1971).

The function $LRI_k^\diamond$ exactly expresses k-testable languages. Informally, each word w is mapped to a set containing a single element, this element is the triple $LRI_k(w)$. Thus a grammar G is a subset of the triples used to define k-SL. Clearly, $\mathcal{L}_{LRI_k^\diamond} = k$-LT since it is the boolean closure of $\mathcal{L}_{LRI_k}$. Henceforth we refer to $\mathcal{L}_{LRI_k^\diamond}$ as the k-Locally Testable (k-LT) languages.

5.6 Generalized subsequence languages

Here we introduce generalized subsequence functions, a general class of functions to which the SP_k and fac_k functions belong. Like those functions, generalized subsequence functions map words to a set of subsequences found within the words. These functions are instantiated by a vector whose number of coordinates determine how many times a subsequence may be discontiguous

and whose coordinate values determine the length of each contiguous part of the subsequence.

Definition 7 For some $n \in \mathbb{N}$, let $\vec{v} = \langle v_0, v_1, \ldots, v_n \rangle$, where each $v_i \in \mathbb{N}$. Let k be the length of the subsequences; i.e. $k = \sum_0^n v_i$.

$$f_{\vec{v}}(w) = \{u \in \Sigma^k : \exists x_0, \ldots, x_n, u_0, \ldots, u_{n+1} \in \Sigma^* \text{ such that } w = u_0 x_0 u_1 x_1, \ldots, u_n x_n u_{n+1} \text{ and } |x_i| = v_i \text{ for all } 0 \leq i \leq n\} \text{ when } k \leq |w|, \text{ and} \{w\} \text{ otherwise}$$

The following examples help make the generalized subsequence functions clear.

Example 6 Let $\vec{v} = \langle 2 \rangle$. Then $f_{\langle 2 \rangle} = fac_2$. Generally, $f_{\langle k \rangle} = fac_k$.

Example 7 Let $\vec{v} = \langle 1, 1 \rangle$. Then $f_{\langle 1,1 \rangle} = SP_2$. Generally, if $\vec{v} = \langle 1, \ldots 1 \rangle$ with $|\vec{v}| = k$. Then $f_{\vec{v}} = SP_k$.

Example 8 Let $\vec{v} = \langle 3, 2, 1 \rangle$ and *a, b, c, d, e, f*$\in \Sigma$. Then $\mathcal{L}_{f_{\langle 3,2,1 \rangle}}$ includes languages which prohibit strings w which contain subsequences $abcdef$ where abc and de must be contiguous in w and $abcdef$ is a subsequence of w.

Generalized subsequence languages make different kinds of distinctions to be made than PT and LT languages. For example, the language in Example 8 is neither k-LT nor k'-PT for any values k, k'. Generalized subsequence languages properly include the k-SP and k-SL classes (Examples 6 and 7), and the boolean closure of the subsequence languages ($f^{\diamond}_{\vec{v}}$) properly includes the LT and PT classes.

Since for any $\vec{v}$, $f_{\vec{v}}$ and $f^{\diamond}_{\vec{v}}$ are string extension functions the learning results in §4 apply. Note that $f_{\vec{v}}(w)$ is computable in time $O(|w|^k)$ where k is the length of the maximal subsequences determined by $\vec{v}$.

6 Other examples

This section provides examples of infinite and nonregular language classes that are string extension learnable. Recall from Theorem 1 that string extension languages are finite unions of blocks of the partition of Σ^* induced by f. Assuming the blocks of this partition can be enumerated, the range of f can be construed as $\mathcal{P}_{fin}(\mathbb{N})$.

grammar G	Language of G
$\emptyset$	$\emptyset$
$\{0\}$	$a^n b^n$
$\{1\}$	$\Sigma^* \backslash a^n b^n$
$\{0,\ 1\}$	Σ^*

Table 3: The language class $\mathcal{L}_f$ from Example 9

In the examples considered so far, the enumeration of the blocks is essentially encoded in particular substrings (or tuples of substrings). However, much less clever enumerations are available.

Example 9 Let A = {0,1} and consider the following function:

$$f(w) = \begin{cases} 0 & \text{iff } w \in a^n b^n \\ 1 & \text{otherwise} \end{cases}$$

The function f belongs to $\mathcal{SEF}$ because it is maps strings to a finite co-domain. $\mathcal{L}_f$ has four languages shown in Table 3.

The language class in Example 9 is not regular because it includes the well-known context-free language $a^n b^n$. This collection of languages is also not closed under reversal.

There are also infinite language classes that are string extension language classes. Arguably the simplest example is the class of finite languages, denoted $\mathcal{L}_{fin}$.

Example 10 Consider the function id which maps words in Σ^* to their singleton sets, i.e. $id(w) = \{w\}$.[5] A grammar G is then a finite subset of Σ^*, and so $L(G)$ is just a finite set of words in Σ^*; in fact, $L(G) = G$. It follows that $\mathcal{L}_{id} = \mathcal{L}_{fin}$.

It can be easily seen that the function id induces the trivial partition over Σ^*, and languages are just finite unions of these blocks. The learner ϕ_{id} makes no generalizations at all, and only remembers what it has observed.

There are other more interesting infinite string extension classes. Here is one relating to the Parikh map (Parikh, 1966). For all $a \in \Sigma$, let $f_a(w)$ be the set containing n where n is the number of times the letter a occurs in the string w. For

[5] Strictly speaking, this is not the identity function per se, but it is as close to the identity function as one can get since string extension functions are defined as mappings from strings to sets. However, once the domain of the function is extended (Equation 1), then it follows that id is the identity function when its argument is a set of strings.

example $f_a(babab) = \{2\}$. Thus f_a is a total function mapping strings to singleton sets of natural numbers, so it is a string extension function. This function induces an infinite partition of Σ^*, where the words in any particular block have the same number of letters a. It is convenient to enumerate the blocks according to how many occurrences of the letter a may occur in words within the block. Hence, B_0 is the block whose words have no occurrences of a, B_1 is the block whose words have one occurrence of a, and so on.

In this case, a grammar G is a finite subset of $\mathbb{N}$, e.g. $\{2, 3, 4\}$. $L(G)$ is simply those words which have either 2, 3, or 4, occurrences of the letter a. Thus $\mathcal{L}_{f_a}$ is an infinite class, which contains languages of infinite size, which is easily identified in the limit from positive data by ϕ_{f_a}.

This section gave examples of nonregular and nonfinite string extension classes by pursuing the implications of Theorem 1, which established that $f \in \mathcal{SEF}$ partition Σ^* into blocks of which languages are finite unions thereof. The string extension function f provides an effective way of encoding all languages L in $\mathcal{L}_f$ because $f(L)$ encodes a finite set, the grammar.

7 Conclusion and open questions

One contribution of this paper is a unified way of thinking about many formal language classes, all of which have been shown to be identifiable in the limit from positive data by a string extension learner. Another contribution is a recipe for defining classes of languages identifiable in the limit from positive data by this kind of learner.

As shown, these learners have many desirable properties. In particular, they are globally consistent, locally conservative, and set-driven. Additionally, the learner is guaranteed to be efficient in the size of the sample, provided the function f itself is efficient in the length of the string.

Several additional questions of interest remain open for theoretical linguistics, theoretical computer science, and computational linguistics.

For theoretical linguistics, it appears that the string extension function $f = (LRI_3, P_2)$, which defines a class of languages which obey restrictions on both contiguous subsequences of length 3 and on discontiguous subsequences of length 2, provides a good first approximation to the segmental phonotactic patterns in natural languages (Heinz, 2007). The string extension learner for this class is essentially two learners: ϕ_{LRI_3} and ϕ_{P_2}, operating simultaneously.[6] The learners make predictions about generalizations, which can be tested in artificial language learning experiments on adults and infants (Rogers and Pullum, to appear; Chambers et al., 2002; Onishi et al., 2003; Cristiá and Seidl, 2008).[7]

For theoretical computer science, it remains an open question what property holds of functions f in $\mathcal{SEF}$ to ensure that $\mathcal{L}_f$ is regular, context-free, or context-sensitive. For known subregular classes, there are constructions that provide deterministic automata that suggest the relevant properties. (See, for example, Garcia et al. (1990) and Garica and Ruiz (1996).)

Also, Timo Kötzing and Samuel Moelius (p.c.) suggest that the results here may be generalized along the following lines. Instead of defining the function f as a map from strings to finite subsets, let f be a function from strings to elements of a lattice. A grammar G is an element of the lattice and the language of the G are all strings w such that f maps w to a grammar less than G. Learners ϕ_f are defined as the least upper bound of its current hypothesis and the grammar to which f maps the current word.[8] Kasprzik and Kötzing (2010) develop this idea and demonstrate additional properties of string extension classes and learning, and show that the pattern languages (Angluin, 1980a) form a string extension class.[9]

Also, hyperplane learning (Clark et al., 2006a; Clark et al., 2006b) and function-distinguishable learning (Fernau, 2003) similarly associate language classes with functions. How those analyses relate to the current one remains open.

Finally, since the stochastic counterpart of k-SL class is the n-gram model, it is plausible that probabilistic string extension language classes can form the basis of new natural language processing techniques. (Heinz and Rogers, 2010) show

[6] This learner resembles what learning theorists call *parallel learning* (Case and Moelius, 2007) and what cognitive scientists call *modular learning* (Gallistel and King, 2009).

[7] I conjecture that morphological and syntactic patterns are generally not amenable to a string extension learning analysis because these patterns appear to require a paradigm, i.e. a set of data points, before any conclusion can be confidently drawn about the generating grammar. Stress patterns also do not appear to be amenable to a string extension learning (Heinz, 2007; Edlefsen et al., 2008; Heinz, 2009).

[8] See also Lange et al. (2008, Theorem 15) and Case et al. (1999, pp.101-103).

[9] The basic idea is to consider the lattice $\mathbb{L} = \langle \mathcal{L}_{fin}, \supseteq \rangle$. Each element of $\mathbb{L}$ is a finite set of strings representing the intersection of all pattern languages consistent with this set.

how to efficiently estimate k-SP distributions, and it is conjectured that the other string extension language classes can be recast as classes of distributions, which can also be successfully estimated from positive evidence.

Acknowledgments

This work was supported by a University of Delaware Research Fund grant during the 2008-2009 academic year. I would like to thank John Case, Alexander Clark, Timo Kötzing, Samuel Moelius, James Rogers, and Edward Stabler for valuable discussion. I would also like to thank Timo Kötzing for careful reading of an earlier draft and for catching some errors. Remaining errors are my responsibility.

Compositional Matrix-Space Models of Language

Abstract

We propose CMSMs, a novel type of generic compositional models for syntactic and semantic aspects of natural language, based on matrix multiplication. We argue for the structural and cognitive plausibility of this model and show that it is able to cover and combine various common compositional NLP approaches ranging from statistical word space models to symbolic grammar formalisms.

1 Introduction

In computational linguistics and information retrieval, Vector Space Models (Salton et al., 1975) and its variations – such as Word Space Models (Schütze, 1993), Hyperspace Analogue to Language (Lund and Burgess, 1996), or Latent Semantic Analysis (Deerwester et al., 1990) – have become a mainstream paradigm for text representation. Vector Space Models (VSMs) have been empirically justified by results from cognitive science (Gärdenfors, 2000). They embody the distributional hypothesis of meaning (Firth, 1957), according to which the meaning of words is defined by contexts in which they (co-)occur. Depending on the specific model employed, these contexts can be either local (the co-occurring words), or global (a sentence or a paragraph or the whole document). Indeed, VSMs proved to perform well in a number of tasks requiring computation of *semantic relatedness* between words, such as synonymy identification (Landauer and Dumais, 1997), automatic thesaurus construction (Grefenstette, 1994), semantic priming, and word sense disambiguation (Padó and Lapata, 2007).

Until recently, little attention has been paid to the task of modeling more complex conceptual structures with such models, which constitutes a crucial barrier for semantic vector models on the way to model language (Widdows, 2008). An emerging area of research receiving more and more attention among the advocates of distributional models addresses the methods, algorithms, and evaluation strategies for representing *compositional* aspects of language within a VSM framework. This requires novel modeling paradigms, as most VSMs have been predominantly used for meaning representation of single words and the key problem of common bag-of-words-based VSMs is that word order information and thereby the structure of the language is lost.

There are approaches under way to work out a combined framework for meaning representation using both the advantages of symbolic and distributional methods. Clark and Pulman (2007) suggest a conceptual model which unites symbolic and distributional representations by means of traversing the parse tree of a sentence and applying a tensor product for combining vectors of the meanings of words with the vectors of their roles. The model is further elaborated by Clark et al. (2008).

To overcome the aforementioned difficulties with VSMs and work towards a tight integration of symbolic and distributional approaches, we propose a *Compositional Matrix-Space Model* (CMSM) which employs matrices instead of vectors and makes use of matrix multiplication as the one and only composition operation.

The paper is structured as follows: We start by providing the necessary basic notions in linear algebra in Section 2. In Section 3, we give a formal account of the concept of compositionality, introduce our model, and argue for the plausibility of CMSMs in the light of structural and cognitive considerations. Section 4 shows how common VSM approaches to compositionality can be captured by CMSMs while Section 5 illustrates the capabilities of our model to likewise cover symbolic approaches. In Section 6, we demonstrate

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 907–916,
Uppsala, Sweden, 11-16 July 2010.

how several CMSMs can be combined into one model. We provide an overview of related work in Section 7 before we conclude and point out avenues for further research in Section 8.

2 Preliminaries

In this section, we recap some aspects of linear algebra to the extent needed for our considerations about CMSMs. For a more thorough treatise we refer the reader to a linear algebra textbook (such as Strang (1993)).

Vectors. Given a natural number n, an n-dimensional vector $\mathbf{v}$ over the reals can be seen as a list (or tuple) containing n real numbers $r_1, \ldots, r_n \in \mathbb{R}$, written $\mathbf{v} = (r_1 \quad r_2 \quad \cdots \quad r_n)$. Vectors will be denoted by lowercase bold font letters and we will use the notation $\mathbf{v}(i)$ to refer to the ith entry of vector $\mathbf{v}$. As usual, we write $\mathbb{R}^n$ to denote the set of all n-dimensional vectors with real entries. Vectors can be added entry-wise, i.e., $(r_1 \quad \cdots \quad r_n) + (r'_1 \quad \cdots \quad r'_n) = (r_1 + r'_1 \quad \cdots \quad r_n + r'_n)$. Likewise, the entry-wise product (also known as Hadamard product) is defined by $(r_1 \quad \cdots \quad r_n) \odot (r'_1 \quad \cdots \quad r'_n) = (r_1 \cdot r'_1 \quad \cdots \quad r_n \cdot r'_n)$.

Matrices. Given two real numbers n, m, an $n \times m$ matrix over the reals is an array of real numbers with n rows and m columns. We will use capital letters to denote matrices and, given a matrix M we will write $M(i, j)$ to refer to the entry in the ith row and the jth column:

$$M = \begin{pmatrix} M(1,1) & M(1,2) & \cdots & M(1,j) & \cdots & M(1,m) \\ M(2,1) & M(2,2) & & & & \vdots \\ \vdots & & & & & \vdots \\ M(i,1) & & & M(i,j) & & \vdots \\ \vdots & & & & & \vdots \\ M(n,1) & M(1,2) & \cdots & \cdots & \cdots & M(n,m) \end{pmatrix}$$

The set of all $n \times m$ matrices with real number entries is denoted by $\mathbb{R}^{n \times m}$. Obviously, m-dimensional vectors can be seen as $1 \times m$ matrices. A matrix can be *transposed* by exchanging columns and rows: given the $n \times m$ matrix M, its transposed version M^T is a $m \times n$ matrix defined by $M^T(i, j) = M(j, i)$.

Linear Mappings. Beyond being merely array-like data structures, matrices correspond to certain type of functions, so-called *linear mappings*, having vectors as in- and output. More precisely, an $n \times m$ matrix M applied to an m-dimensional vector $\mathbf{v}$ yields an n-dimensional vector $\mathbf{v}'$ (written: $\mathbf{v}M = \mathbf{v}'$) according to

$$\mathbf{v}'(i) = \sum_{j=1}^{m} \mathbf{v}(j) \cdot M(i, j)$$

Linear mappings can be concatenated, giving rise to the notion of standard matrix multiplication: we write $M_1 M_2$ to denote the matrix that corresponds to the linear mapping defined by applying first M_1 and then M_2. Formally, the matrix product of the $n \times l$ matrix M_1 and the $l \times m$ matrix M_2 is an $n \times m$ matrix $M = M_1 M_2$ defined by

$$M(i, j) = \sum_{k=1}^{l} M_1(i, k) \cdot M_2(k, j)$$

Note that the matrix product is associative (i.e., $(M_1 M_2)M_3 = M_1(M_2 M_3)$ always holds, thus parentheses can be omitted) but not commutative ($M_1 M_2 = M_2 M_1$ does not hold in general, i.e., the order matters).

Permutations. Given a natural number n, a *permutation* on $\{1 \ldots n\}$ is a bijection (i.e., a mapping that is one-to-one and onto) $\Phi : \{1 \ldots n\} \to \{1 \ldots n\}$. A permutation can be seen as a "reordering scheme" on a list with n elements: the element at position i will get the new position $\Phi(i)$ in the reordered list. Likewise, a permutation can be applied to a vector resulting in a rearrangement of the entries. We write Φ^n to denote the permutation corresponding to the n-fold application of Φ and Φ^{-1} to denote the permutation that "undoes" Φ.

Given a permutation Φ, the corresponding *permutation matrix* M_Φ is defined by

$$M_\Phi(i, j) = \begin{cases} 1 \text{ if } \Phi(j) = i, \\ 0 \text{ otherwise.} \end{cases}$$

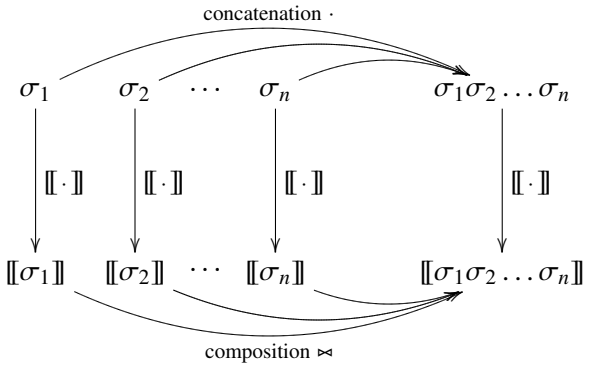
Then, obviously permuting a vector according to Φ can be expressed in terms of matrix multiplication as well as we obtain for any vector $\mathbf{v} \in \mathbb{R}^n$:

$$\Phi(\mathbf{v}) = \mathbf{v} M_\Phi$$

Likewise, iterated application (Φ^n) and the inverses Φ^{-n} carry over naturally to the corresponding notions in matrices.

3 Compositionality and Matrices

The underlying principle of compositional semantics is that the meaning of a sentence (or a word phrase) can be derived from the meaning of its constituent tokens by applying a composition operation. More formally, the underlying idea can be described as follows: given a mapping $[\![\cdot]\!] : \Sigma \to \mathbb{S}$ from a set of tokens (words) Σ into some semantical space $\mathbb{S}$ (the elements of which we will simply call "meanings"), we find a semantic composition operation $\bowtie$: $\mathbb{S}^* \to \mathbb{S}$ mapping sequences of meanings to meanings such that the meaning of a sequence of tokens $\sigma_1\sigma_2 \ldots \sigma_n$ can be obtained by applying $\bowtie$ to the sequence $[\![\sigma_1]\!][\![\sigma_2]\!] \ldots [\![\sigma_n]\!]$. This situation qualifies $[\![\cdot]\!]$ as a homomorphism between $(\Sigma^*, \cdot)$ and $(\mathbb{S}, \bowtie)$ and can be displayed as follows:



A great variety of linguistic models are subsumed by this general idea ranging from purely symbolic approaches (like type systems and categorial grammars) to rather statistical models (like vector space and word space models). At the first glance, the underlying encodings of word semantics as well as the composition operations differ significantly. However, we argue that a great variety of them can be incorporated – and even freely inter-combined – into a unified model where the semantics of simple tokens and complex phrases is expressed by matrices and the composition operation is standard matrix multiplication.

More precisely, in Compositional Marix-Space Models, we have $\mathbb{S} = \mathbb{R}^{n \times n}$, i.e. the semantical space consists of quadratic matrices, and the composition operator $\bowtie$ coincides with matrix multiplication as introduced in Section 2. In the following, we will provide diverse arguments illustrating that CMSMs are intuitive and natural.

3.1 Algebraic Plausibility – Structural Operation Properties

Most linear-algebra-based operations that have been proposed to model composition in language models are associative and commutative. Thereby, they realize a multiset (or bag-of-words) semantics that makes them insensitive to structural differences of phrases conveyed through word order.

While associativity seems somewhat acceptable and could be defended by pointing to the stream-like, sequential nature of language, commutativity seems way less justifiable, arguably.

As mentioned before, matrix multiplication is associative but non-commutative, whence we propose it as more adequate for modeling compositional semantics of language.

3.2 Neurological Plausibility – Progression of Mental States

From a very abstract and simplified perspective, CMSMs can also be justified neurologically.

Suppose the mental state of a person at one specific moment in time can be encoded by a vector $\mathbf{v}$ of numerical values; one might, e.g., think of the level of excitation of neurons. Then, an external stimulus or signal, such as a perceived word, will result in a change of the mental state. Thus, the external stimulus can be seen as a function being applied to $\mathbf{v}$ yielding as result the vector $\mathbf{v}'$ that corresponds to the persons mental state after receiving the signal. Therefore, it seems sensible to associate with every signal (in our case: token σ) a respective function (a linear mapping, represented by a matrix $M = [\![\sigma]\!]$ that maps mental states to mental states (i.e. vectors $\mathbf{v}$ to vectors $\mathbf{v}' = \mathbf{v}M$).

Consequently, the subsequent reception of inputs σ, σ' associated to matrices M and M' will transform a mental vector $\mathbf{v}$ into the vector $(\mathbf{v}M)M'$ which by associativity equals $\mathbf{v}(MM')$. Therefore, MM' represents the mental state transition triggered by the signal sequence $\sigma\sigma'$. Naturally, this consideration carries over to sequences of arbitrary length. This way, abstracting from specific initial mental state vectors, our semantic space $\mathbb{S}$ can be seen as a function space of mental transformations represented by matrices, whereby matrix multiplication realizes subsequent execution of those transformations triggered by the input token sequence.

3.3 Psychological Plausibility – Operations on Working Memory

A structurally very similar argument can be provided on another cognitive explanatory level. There have been extensive studies about human language processing justifying the hypothesis of a *working memory* (Baddeley, 2003). The mental state vector can be seen as representation of a person's working memory which gets transformed by external input. Note that matrices can perform standard memory operations such as storing, deleting, copying etc. For instance, the matrix $M_{\text{copy(k,l)}}$ defined by

$$M_{\text{copy(k,l)}}(i,j) = \begin{cases} 1 \text{ if } i = j \neq l \text{ or } i = k,\ j = l, \\ 0 \text{ otherwise.} \end{cases}$$

applied to a vector $\mathbf{v}$, will copy its kth entry to the lth position. This mechanism of storage and insertion can, e.g., be used to simulate simple forms of anaphora resolution.

4 CMSMs Encode Vector Space Models

In VSMs numerous vector operations have been used to model composition (Widdows, 2008), some of the more advanced ones being related to quantum mechanics. We show how these common composition operators can be modeled by CMSMs.[1] Given a vector composition operation $\bowtie\colon \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^n$, we provide a surjective function $\psi_\bowtie : \mathbb{R}^n \to \mathbb{R}^{n' \times n'}$ that translates the vector representation into a matrix representation in a way such that for all $\mathbf{v}_1, \ldots \mathbf{v}_k \in \mathbb{R}^n$ holds

$$\mathbf{v}_1 \bowtie \ldots \bowtie \mathbf{v}_k = \psi_\bowtie^{-1}(\psi_\bowtie(\mathbf{v}_1) \ldots \psi_\bowtie(\mathbf{v}_k))$$

where $\psi_\bowtie(\mathbf{v}_i)\psi_\bowtie(\mathbf{v}_j)$ denotes matrix multiplication of the matrices assigned to $\mathbf{v}_i$ and $\mathbf{v}_j$.

4.1 Vector Addition

As a simple basic model for semantic composition, vector addition has been proposed. Thereby, tokens σ get assigned (usually high-dimensional) vectors $\mathbf{v}_\sigma$ and to obtain a representation of the meaning of a phrase or a sentence $w = \sigma_1 \ldots \sigma_k$, the vector sum of the vectors associated to the constituent tokens is calculated: $\mathbf{v}_w = \sum_{i=1}^k \mathbf{v}_{\sigma_i}$.

[1] In our investigations we will focus on VSM composition operations which preserve the format (i.e. which yield a vector of the same dimensionality), as our notion of compositionality requires models that allow for iterated composition. In particular, this rules out dot product and tensor product. However the convolution product can be seen as a condensed version of the tensor product.

This kind of composition operation is subsumed by CMSMs; suppose in the original model, a token σ gets assigned the vector $\mathbf{v}_\sigma$, then by defining

$$\psi_+(\mathbf{v}_\sigma) = \left(\begin{array}{ccc|c} 1 & \cdots & 0 & 0 \\ \vdots & \ddots & & \vdots \\ 0 & & 1 & 0 \\ \hline & \mathbf{v}_\sigma & & 1 \end{array}\right)$$

(mapping n-dimensional vectors to $(n+1)\times(n+1)$ matrices), we obtain for a phrase $w = \sigma_1 \ldots \sigma_k$

$$\psi_+^{-1}(\psi_+(\mathbf{v}_{\sigma_1}) \ldots \psi_+(\mathbf{v}_{\sigma_k})) = \mathbf{v}_{\sigma_1} + \ldots + \mathbf{v}_{\sigma_k} = \mathbf{v}_w.$$

Proof. By induction on k. For $k = 1$, we have $\mathbf{v}_w = \mathbf{v}_\sigma = \psi_+^{-1}(\psi_+(\mathbf{v}_{\sigma_1}))$. For $k > 1$, we have

$$\begin{aligned} & \psi_+^{-1}(\psi_+(\mathbf{v}_{\sigma_1}) \ldots \psi_+(\mathbf{v}_{\sigma_{k-1}})\psi_+(\mathbf{v}_{\sigma_k})) \\ = \ & \psi_+^{-1}(\psi_+(\psi_+^{-1}(\psi_+(\mathbf{v}_{\sigma_1}) \ldots \psi_+(\mathbf{v}_{\sigma_{k-1}})))\psi_+(\mathbf{v}_{\sigma_k})) \\ \overset{i.h.}{=} \ & \psi_+^{-1}(\psi_+(\textstyle\sum_{i=1}^{k-1} \mathbf{v}_{\sigma_i})\psi_+(\mathbf{v}_{\sigma_k})) \end{aligned}$$

$$= \psi_+^{-1}\left(\left(\begin{array}{ccc|c} 1 & \cdots & 0 & 0 \\ \vdots & \ddots & & \vdots \\ 0 & & 1 & 0 \\ \hline \sum_{i=1}^{k-1}\mathbf{v}_{\sigma_i}(1) & \cdots & \sum_{i=1}^{k-1}\mathbf{v}_{\sigma_i}(n) & 1 \end{array}\right)\left(\begin{array}{ccc|c} 1 & \cdots & 0 & 0 \\ \vdots & \ddots & & \vdots \\ 0 & & 1 & 0 \\ \hline \mathbf{v}_{\sigma_k}(1) & \cdots & \mathbf{v}_{\sigma_k}(n) & 1 \end{array}\right)\right)$$

$$= \psi_+^{-1}\left(\begin{array}{ccc|c} 1 & \cdots & 0 & 0 \\ \vdots & \ddots & & \vdots \\ 0 & & 1 & 0 \\ \hline \sum_{i=1}^{k}\mathbf{v}_{\sigma_i}(1) & \cdots & \sum_{i=1}^{k}\mathbf{v}_{\sigma_i}(n) & 1 \end{array}\right) = \sum_{i=1}^{k}\mathbf{v}_{\sigma_i} \qquad q.e.d.[2]$$

4.2 Component-wise Multiplication

On the other hand, the Hadamard product (also called entry-wise product, denoted by $\odot$) has been proposed as an alternative way of semantically composing token vectors.

By using a different encoding into matrices, CMSMs can simulate this type of composition operation as well. By letting

$$\psi_\odot(\mathbf{v}_\sigma) = \begin{pmatrix} \mathbf{v}_\sigma(1) & 0 & \cdots & 0 \\ 0 & \mathbf{v}_\sigma(2) & & \\ \vdots & & \ddots & 0 \\ 0 & \cdots & 0 & \mathbf{v}_\sigma(n) \end{pmatrix},$$

we obtain an $n \times n$ matrix representation for which $\psi_\odot^{-1}(\psi_\odot(\mathbf{v}_{\sigma_1}) \ldots \psi_\odot(\mathbf{v}_{\sigma_k})) = \mathbf{v}_{\sigma_1} \odot \ldots \odot \mathbf{v}_{\sigma_k} = \mathbf{v}_w$.

4.3 Holographic Reduced Representations

Holographic reduced representations as introduced by Plate (1995) can be seen as a refinement

[2] The proofs for the respective correspondences for $\odot$ and $\circledast$ as well as the permutation-based approach in the following sections are structurally analog, hence, we will omit them for space reasons.

of convolution products with the benefit of preserving dimensionality: given two vectors $\mathbf{v}_1, \mathbf{v}_2 \in \mathbb{R}^n$, their *circular convolution product* $\mathbf{v}_1 \circledast \mathbf{v}_2$ is again an n-dimensional vector $\mathbf{v}_3$ defined by

$$\mathbf{v}_3(i+1) = \sum_{k=0}^{n-1} \mathbf{v}_1(k+1) \cdot \mathbf{v}_2((i-k \mod n)+1)$$

for $0 \leq i \leq n-1$. Now let $\psi_{\circledast}(\mathbf{v})$ be the $n \times n$ matrix M with

$$M(i,j) = \mathbf{v}((j-i \mod n)+1).$$

In the 3-dimensional case, this would result in

$$\psi_{\circledast}(\mathbf{v}(1) \quad \mathbf{v}(2) \quad \mathbf{v}(3)) = \begin{pmatrix} \mathbf{v}(1) & \mathbf{v}(2) & \mathbf{v}(3) \\ \mathbf{v}(3) & \mathbf{v}(1) & \mathbf{v}(2) \\ \mathbf{v}(2) & \mathbf{v}(3) & \mathbf{v}(1) \end{pmatrix}$$

Then, it can be readily checked that

$$\psi_{\circledast}^{-1}(\psi_{\circledast}(\mathbf{v}_{\sigma_1}) \ldots \psi_{\circledast}(\mathbf{v}_{\sigma_k})) = \mathbf{v}_{\sigma_1} \circledast \ldots \circledast \mathbf{v}_{\sigma_k} = \mathbf{v}_w.$$

4.4 Permutation-based Approaches

Sahlgren et al. (2008) use permutations on vectors to account for word order. In this approach, given a token σ_m occurring in a sentence $w = \sigma_1 \ldots \sigma_k$ with predefined "uncontextualized" vectors $\mathbf{v}_{\sigma_1} \ldots \mathbf{v}_{\sigma_k}$, we compute the contextualized vector $\mathbf{v}_{w,m}$ for σ_m by

$$\mathbf{v}_{w,m} = \Phi^{1-m}(\mathbf{v}_{\sigma_1}) + \ldots + \Phi^{k-m}(\mathbf{v}_{\sigma_k}),$$

which can be equivalently transformed into

$$\Phi^{1-m}(\mathbf{v}_{\sigma_1} + \Phi(\ldots + \Phi(\mathbf{v}_{\sigma_{k-1}} + (\Phi(\mathbf{v}_{\sigma_k}))) \ldots)).$$

Note that the approach is still token-centered, i.e., a vector representation of a token is endowed with contextual representations of surrounding tokens. Nevertheless, this setting can be transferred to a CMSM setting by recording the position of the focused token as an additional parameter. Now, by assigning every $\mathbf{v}_\sigma$ the matrix

$$\psi_\Phi(\mathbf{v}_\sigma) = \left(\begin{array}{c|c} M_\Phi & \begin{matrix} 0 \\ \vdots \\ 0 \end{matrix} \\ \hline \mathbf{v}_\sigma & 1 \end{array}\right)$$

we observe that for

$$M_{w,m} := (M_\Phi^-)^{m-1} \psi_\Phi(\mathbf{v}_{\sigma_1}) \ldots \psi_\Phi(\mathbf{v}_{\sigma_k})$$

we have

$$M_{w,m} = \left(\begin{array}{c|c} M_\Phi^{k-m} & \begin{matrix} 0 \\ \vdots \\ 0 \end{matrix} \\ \hline \mathbf{v}_{w,m} & 1 \end{array}\right),$$

whence $\psi_\Phi^{-1}((M_\Phi^-)^{m-1} \psi_\Phi(\mathbf{v}_{\sigma_1}) \ldots \psi_\Phi(\mathbf{v}_{\sigma_k})) = \mathbf{v}_{w,m}$.

5 CMSMs Encode Symbolic Approaches

Now we will elaborate on symbolic approaches to language, i.e., discrete grammar formalisms, and show how they can conveniently be embedded into CMSMs. This might come as a surprise, as the apparent likeness of CMSMs to vector-space models may suggest incompatibility to discrete settings.

5.1 Group Theory

Group theory and grammar formalisms based on groups and pre-groups play an important role in computational linguistics (Dymetman, 1998; Lambek, 1958). From the perspective of our compositionality framework, those approaches employ a group (or pre-group) $(G, \cdot)$ as semantical space $\mathbb{S}$ where the group operation (often written as multiplication) is used as composition operation $\bowtie$.

According Cayley's Theorem (Cayley, 1854), every group G is isomorphic to a permutation group on some set S. Hence, assuming finiteness of G and consequently S, we can encode group-based grammar formalisms into CMSMs in a straightforward way by using permutation matrices of size $|S| \times |S|$.

5.2 Regular Languages

Regular languages constitute a basic type of languages characterized by a symbolic formalism. We will show how to select the assignment $[\![\cdot]\!]$ for a CMSM such that the matrix associated to a token sequence exhibits whether this sequence belongs to a given regular language, that is if it is accepted by a given finite state automaton. As usual (cf. e.g., Hopcroft and Ullman (1979)) we define a nondeterministic finite automaton $\mathcal{A} = (Q, \Sigma, \Delta, Q_\mathrm{I}, Q_\mathrm{F})$ with $Q = \{q_0, \ldots, q_{n-1}\}$ being the set of states, Σ the input alphabet, $\Delta \subseteq Q \times \Sigma \times Q$ the transition relation, and Q_I and Q_F being the sets of initial and final states, respectively.

Then we assign to every token $\sigma \in \Sigma$ the $n \times n$ matrix $[\![\sigma]\!] = M$ with

$$M(i,j) = \begin{cases} 1 \text{ if } (q_i, \sigma, q_j) \in \Delta, \\ 0 \text{ otherwise.} \end{cases}$$

Hence essentially, the matrix M encodes all state transitions which can be caused by the input σ. Likewise, for a word $w = \sigma_1 \dots \sigma_k \in \Sigma^*$, the matrix $M_w := [\![\sigma_1]\!] \dots [\![\sigma_k]\!]$ will encode all state transitions mediated by w. Finally, if we define vectors $\mathbf{v}_\mathrm{I}$ and $\mathbf{v}_\mathrm{F}$ by

$$\mathbf{v}_\mathrm{I}(i) = \begin{cases} 1 \text{ if } q_i \in Q_\mathrm{I}, \\ 0 \text{ otherwise,} \end{cases} \qquad \mathbf{v}_\mathrm{F}(i) = \begin{cases} 1 \text{ if } q_i \in Q_\mathrm{F}, \\ 0 \text{ otherwise,} \end{cases}$$

then we find that w is accepted by $\mathcal{A}$ exactly if $\mathbf{v}_\mathrm{I} M_w \mathbf{v}_\mathrm{F}^T \geq 1$.

5.3 The General Case: Matrix Grammars

Motivated by the above findings, we now define a general notion of matrix grammars as follows:

Definition 1 *Let Σ be an alphabet. A* matrix grammar *$\mathcal{M}$ of degree n is defined as the pair $\langle [\![\cdot]\!], AC\rangle$ where $[\![\cdot]\!]$ is a mapping from Σ to $n \times n$ matrices and $AC = \{\langle \mathbf{v}'_1, \mathbf{v}_1, r_1\rangle, \dots, \langle \mathbf{v}'_m, \mathbf{v}_m, r_m\rangle\}$ with $\mathbf{v}'_1, \mathbf{v}_1, \dots, \mathbf{v}'_m, \mathbf{v}_m \in \mathbb{R}^n$ and $r_1, \dots, r_m \in \mathbb{R}$ is a finite set of* acceptance conditions. *The language generated by $\mathcal{M}$ (denoted by $L(\mathcal{M})$) contains a token sequence $\sigma_1 \dots \sigma_k \in \Sigma^*$ exactly if $\mathbf{v}'_i [\![\sigma_1]\!] \dots [\![\sigma_k]\!] \mathbf{v}_i^T \geq r_i$ for all $i \in \{1, \dots, m\}$. We will call a language L* matricible *if $L = L(\mathcal{M})$ for some matrix grammar $\mathcal{M}$.*

Then, the following proposition is a direct consequence from the preceding section.

Proposition 1 *Regular languages are matricible.*

However, as demonstrated by the subsequent examples, also many non-regular and even non-context-free languages are matricible, hinting at the expressivity of our grammar model.

Example 1 *We define $\mathcal{M}\langle [\![\cdot]\!], AC\rangle$ with*

$$\Sigma = \{a, b, c\} \qquad [\![a]\!] = \begin{pmatrix} 3 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 3 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

$$[\![b]\!] = \begin{pmatrix} 3 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 1 & 3 & 0 \\ 1 & 0 & 0 & 1 \end{pmatrix} \quad [\![c]\!] = \begin{pmatrix} 3 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 2 & 3 & 0 \\ 2 & 0 & 0 & 1 \end{pmatrix}$$

$$\begin{aligned} AC = \{ &\langle (0 \quad 0 \quad 1 \quad 1), (1 \quad -1 \quad 0 \quad 0), 0\rangle, \\ &\langle (0 \quad 0 \quad 1 \quad 1), (-1 \quad 1 \quad 0 \quad 0), 0\rangle\} \end{aligned}$$

Then $L(\mathcal{M})$ contains exactly all palindromes from $\{a, b, c\}^*$, i.e., the words $d_1 d_2 \dots d_{n-1} d_n$ for which $d_1 d_2 \dots d_{n-1} d_n = d_n d_{n-1} \dots d_2 d_1$.

Example 2 *We define $\mathcal{M} = \langle [\![\cdot]\!], AC\rangle$ with*

$$\Sigma = \{a, b, c\} \qquad [\![a]\!] = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

$$[\![b]\!] = \begin{pmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix} \quad [\![c]\!] = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 2 \end{pmatrix}$$

$$\begin{aligned} AC = \{ &\langle (1 \ 0 \ 0 \ 0 \ 0 \ 0), (0 \ 0 \ 1 \ 0 \ 0 \ 0), 1\rangle, \\ &\langle (0 \ 0 \ 0 \ 1 \ 1 \ 0), (0 \ 0 \ 0 \ 1 \ -1 \ 0), 0\rangle, \\ &\langle (0 \ 0 \ 0 \ 0 \ 1 \ 1), (0 \ 0 \ 0 \ 0 \ 1 \ -1), 0\rangle, \\ &\langle (0 \ 0 \ 0 \ 1 \ 1 \ 0), (0 \ 0 \ 0 \ -1 \ 0 \ 1), 0\rangle\} \end{aligned}$$

Then $L(\mathcal{M})$ is the (non-context-free) language $\{a^m b^m c^m \mid m > 0\}$.

The following properties of matrix grammars and matricible language are straightforward.

Proposition 2 *All languages characterized by a set of linear equations on the letter counts are matricible.*

Proof. Suppose $\Sigma = \{a_1, \dots a_n\}$. Given a word w, let x_i denote the number of occurrences of a_i in w. A linear equation on the letter counts has the form

$$k_1 x_1 + \dots + k_n x_n = k \qquad (k, k_1, \dots, k_n \in \mathbb{R})$$

Now define $[\![a_i]\!] = \psi_+(\mathbf{e}_i)$, where $\mathbf{e}_i$ is the ith unit vector, i.e. it contains a 1 at he ith position and 0 in all other positions. Then, it is easy to see that w will be mapped to $M = \psi_+(x_1 \quad \cdots \quad x_n)$. Due to the fact that $\mathbf{e}_{n+1} M = (x_1 \quad \cdots \quad x_n \quad 1)$ we can enforce the above linear equation by defining the acceptance conditions

$$\begin{aligned} AC = \{ &\langle \mathbf{e}_{n+1}, (k_1 \quad \dots \quad k_n \quad -k), 0\rangle, \\ &\langle -\mathbf{e}_{n+1}, (k_1 \quad \dots \quad k_n \quad -k), 0\rangle\}. \end{aligned}$$

q.e.d.

Proposition 3 *The intersection of two matricible languages is again a matricible language.*

Proof. This is a direct consequence of the considerations in Section 6 together with the observation, that the new set of acceptance conditions is trivially obtained from the old ones with adapted dimensionalities. *q.e.d.*

Note that the fact that the language $\{a^m b^m c^m \mid m > 0\}$ is matricible, as demonstrated in Example 2 is a straightforward consequence of the Propositions 1, 2, and 3, since the language in question can be described as the intersection of the regular language $a^+b^+c^+$ with the language characterized by the equations $x_a - x_b = 0$ and $x_b - x_c = 0$. We proceed by giving another account of the expressivity of matrix grammars by showing undecidability of the emptiness problem.

Proposition 4 *The problem whether there is a word which is accepted by a given matrix grammar is undecidable.*

Proof. The undecidable *Post correspondence problem* (Post, 1946) is described as follows: given two lists of words $u_1, \ldots, u_n$ and $v_1, \ldots, v_n$ over some alphabet Σ', is there a sequence of numbers $h_1, \ldots, h_m$ $(1 \leq h_j \leq n)$ such that $u_{h_1} \ldots u_{h_m} = v_{h_1} \ldots v_{h_m}$?

We now reduce this problem to the emptiness problem of a matrix grammar. W.l.o.g., let $\Sigma' = \{a_1, \ldots, a_k\}$. We define a bijection # from Σ'^* to $\mathbb{N}$ by

$$\#(a_{n_1} a_{n_2} \ldots a_{n_l}) = \sum_{i=1}^{l} (n_i - 1) \cdot k^{(l-i)}$$

Note that this is indeed a bijection and that for $w_1, w_2 \in \Sigma'^*$, we have

$$\#(w_1 w_2) = \#(w_1) \cdot k^{|w_2|} + \#(w_2).$$

Now, we define $\mathcal{M}$ as follows:

$$\Sigma = \{b_1, \ldots b_n\} \qquad [\![b_i]\!] = \begin{pmatrix} k^{|u_i|} & 0 & 0 \\ 0 & k^{|v_i|} & 0 \\ \#(u_i) & \#(v_i) & 1 \end{pmatrix}$$

$$AC = \{ \langle (0 \quad 0 \quad 1), (1 \quad -1 \quad 0), 0 \rangle, \\ \langle (0 \quad 0 \quad 1), (-1 \quad 1 \quad 0), 0 \rangle \}$$

Using the above fact about # and a simple induction on m, we find that

$$[\![a_{h_1}]\!] \ldots [\![a_{h_m}]\!] = \begin{pmatrix} k^{|u_{h_1} .. u_{h_m}|} & 0 & 0 \\ 0 & k^{|v_{h_1} .. v_{h_m}|} & 0 \\ \#(u_{h_1} \ldots u_{h_m}) & \#(v_{h_1} \ldots v_{h_m}) & 1 \end{pmatrix}$$

Evaluating the two acceptance conditions, we find them satisfied exactly if $\#(u_{h_1} \ldots u_{h_m}) = \#(v_{h_1} \ldots v_{h_m})$. Since # is a bijection, this is the case if and only if $u_{h_1} \ldots u_{h_m} = v_{h_1} \ldots v_{h_m}$. Therefore $\mathcal{M}$ accepts $b_{h_1} \ldots b_{h_m}$ exactly if the sequence $h_1, \ldots, h_m$ is a solution to the given Post Correspondence Problem. Consequently, the question whether such a solution exists is equivalent to the question whether the language $L(\mathcal{M})$ is non-empty. *q.e.d.*

These results demonstrate that matrix grammars cover a wide range of formal languages. Nevertheless some important questions remain open and need to be clarified next:

Are all context-free languages matricible? We conjecture that this is not the case.[3] Note that this question is directly related to the question whether Lambek calculus can be modeled by matrix grammars.

Are matricible languages closed under concatenation? That is: given two arbitrary matricible languages L_1, L_2, is the language $L = \{w_1 w_2 \mid w_1 \in L_1, w_2 \in L_2\}$ again matricible? Being a property common to all language types from the Chomsky hierarchy, answering this question is surprisingly non-trivial for matrix grammars.

In case of a negative answer to one of the above questions it might be worthwhile to introduce an extended notion of context grammars to accommodate those desirable properties. For example, allowing for some nondeterminism by associating several matrices to one token would ensure closure under concatenation.

How do the theoretical properties of matrix grammars depend on the underlying algebraic structure? Remember that we considered matrices containing real numbers as entries. In general, matrices can be defined on top of any mathematical structure that is (at least) a semiring (Golan, 1992). Examples for semirings are the natural numbers, boolean algebras, or polynomials with natural number coefficients. Therefore, it would be interesting to investigate the influence of the choice of the underlying semiring on the properties of the matrix grammars – possibly non-standard structures turn out to be more appropriate for capturing certain compositional language properties.

6 Combination of Different Approaches

Another central advantage of the proposed matrix-based models for word meaning is that several matrix models can be easily combined into one.

[3] For instance, we have not been able to find a matrix grammar that recognizes the language of all well-formed parenthesis expressions.

Again assume a sequence $w = \sigma_1 \dots \sigma_k$ of tokens with associated matrices $[\![\sigma_1]\!], \dots, [\![\sigma_k]\!]$ according to one specific model and matrices $(\!|\sigma_1|\!), \dots, (\!|\sigma_k|\!)$ according to another.

Then we can combine the two models into one $\{\!|\ \cdot\ |\!\}$ by assigning to σ_i the matrix

$$\{\!|\sigma_i|\!\} = \left(\begin{array}{ccc|ccc} & & & 0 & \cdots & 0 \\ & [\![\sigma_i]\!] & & \vdots & \ddots & \\ & & & 0 & & 0 \\ \hline 0 & \cdots & 0 & & & \\ \vdots & \ddots & & & (\!|\sigma_i|\!) & \\ 0 & & 0 & & & \end{array}\right)$$

By doing so, we obtain the correspondence

$$\{\!|\sigma_1|\!\} \dots \{\!|\sigma_k|\!\} = \left(\begin{array}{ccc|ccc} & & & 0 & \cdots & 0 \\ & [\![\sigma_1]\!] \dots [\![\sigma_k]\!] & & \vdots & \ddots & \\ & & & 0 & & 0 \\ \hline 0 & \cdots & 0 & & & \\ \vdots & \ddots & & & (\!|\sigma_1|\!) \dots (\!|\sigma_k|\!) & \\ 0 & & 0 & & & \end{array}\right)$$

In other words, the semantic compositions belonging to two CMSMs can be executed "in parallel." Mark that by providing non-zero entries for the upper right and lower left matrix part, information exchange between the two models can be easily realized.

7 Related Work

We are not the first to suggest an extension of classical VSMs to matrices. Distributional models based on matrices or even higher-dimensional arrays have been proposed in information retrieval (Gao et al., 2004; Antonellis and Gallopoulos, 2006). However, to the best of our knowledge, the approach of realizing compositionality via matrix multiplication seems to be entirely original.

Among the early attempts to provide more compelling combinatory functions to capture word order information and the non-commutativity of linguistic compositional operation in VSMs is the work of Kintsch (2001) who is using a more sophisticated addition function to model predicate-argument structures in VSMs.

Mitchell and Lapata (2008) formulate semantic composition as a function $m = f(w_1, w_2, R, K)$ where R is a relation between w_1 and w_2 and K is additional knowledge. They evaluate the model with a number of addition and multiplication operations for vector combination on a sentence similarity task proposed by Kintsch (2001). Widdows (2008) proposes a number of more advanced vector operations well-known from quantum mechanics, such as tensor product and convolution, to model composition in vector spaces. He shows the ability of VSMs to reflect the relational and phrasal meanings on a simplified analogy task. Giesbrecht (2009) evaluates four vector composition operations (+, $\odot$, tensor product, convolution) on the task of identifying multi-word units. The evaluation results of the three studies are not conclusive in terms of which vector operation performs best; the different outcomes might be attributed to the underlying word space models; e.g., the models of Widdows (2008) and Giesbrecht (2009) feature dimensionality reduction while that of Mitchell and Lapata (2008) does not. In the light of these findings, our CMSMs provide the benefit of just one composition operation that is able to mimic all the others as well as combinations thereof.

8 Conclusion and Future Work

We have introduced a generic model for compositionality in language where matrices are associated with tokens and the matrix representation of a token sequence is obtained by iterated matrix multiplication. We have given algebraic, neurological, and psychological plausibility indications in favor of this choice. We have shown that the proposed model is expressive enough to cover and combine a variety of distributional and symbolic aspects of natural language. This nourishes the hope that matrix models can serve as a kind of *lingua franca* for compositional models.

This having said, some crucial questions remain before CMSMs can be applied in practice:
How to acquire CMSMs for large token sets and specific purposes? We have shown the value and expressivity of CMSMs by providing carefully hand-crafted encodings. In practical cases, however, the number of token-to-matrix assignments will be too large for this manual approach. Therefore, methods to (semi-)automatically acquire those assignments from available data are required. To this end, machine learning techniques need to be investigated with respect to their applicability to this task. Presumably, hybrid approaches have to be considered, where parts of

the matrix representation are learned whereas others are stipulated in advance guided by external sources (such as lexical information).

In this setting, data sparsity may be overcome through tensor methods: given a set T of tokens together with the matrix assignment $[\![]\!] : T \rightarrow \mathbb{R}^{n \times n}$, this datastructure can be conceived as a 3-dimensional array (also known as tensor) of size $n \times n \times |T|$ wherein the single token-matrices can be found as slices. Then tensor decomposition techniques can be applied in order to find a compact representation, reduce noise, and cluster together similar tokens (Tucker, 1966; Rendle et al., 2009). First evaluation results employing this approach to the task of free associations are reported by Giesbrecht (2010).

How does linearity limit the applicability of CMSMs? In Section 3, we justified our model by taking the perspective of tokens being functions which realize mental state transitions. Yet, using matrices to represent those functions restricts them to linear mappings. Although this restriction brings about benefits in terms of computability and theoretical accessibility, the limitations introduced by this assumption need to be investigated. Clearly, certain linguistic effects (like a-posteriori disambiguation) cannot be modeled via linear mappings. Instead, we might need some in-between application of simple nonlinear functions in the spirit of quantum-collapsing of a "superposed" mental state (such as the winner takes it all, survival of the top-k vector entries, and so forth). Thus, another avenue of further research is to generalize from the linear approach.

Abstract

Cross-language document summarization is a task of producing a summary in one language for a document set in a different language. Existing methods simply use machine translation for document translation or summary translation. However, current machine translation services are far from satisfactory, which results in that the quality of the cross-language summary is usually very poor, both in readability and content. In this paper, we propose to consider the translation quality of each sentence in the English-to-Chinese cross-language summarization process. First, the translation quality of each English sentence in the document set is predicted with the SVM regression method, and then the quality score of each sentence is incorporated into the summarization process. Finally, the English sentences with high translation quality and high informativeness are selected and translated to form the Chinese summary. Experimental results demonstrate the effectiveness and usefulness of the proposed approach.

1 Introduction

Given a document or document set in one source language, cross-language document summarization aims to produce a summary in a different target language. In this study, we focus on English-to-Chinese document summarization for the purpose of helping Chinese readers to quickly understand the major content of an English document or document set. This task is very important in the field of multilingual information access.

Till now, most previous work focuses on monolingual document summarization, but cross-language document summarization has received little attention in the past years. A straightforward way for cross-language document summarization is to translate the summary from the source language to the target language by using machine translation services. However, though machine translation techniques have been advanced a lot, the machine translation quality is far from satisfactory, and in many cases, the translated texts are hard to understand. Therefore, the translated summary is likely to be hard to understand by readers, i.e., the summary quality is likely to be very poor. For example, the translated Chinese sentence for an ordinary English sentence ("It is also Mr Baker who is making the most of presidential powers to dispense largesse.") by using Google Translate is "同时，也是贝克是谁提出了对总统权力免除最慷慨。". The translated sentence is hard to understand because it contains incorrect translations and it is very disfluent. If such sentences are selected into the summary, the quality of the summary would be very poor.

In order to address the above problem, we propose to consider the translation quality of the English sentences in the summarization process. In particular, the translation quality of each English sentence is predicted by using the SVM regression method, and then the predicted MT quality score of each sentence is incorporated into the sentence evaluation process, and finally both informative and easy-to-translate sentences are selected and translated to form the Chinese summary.

An empirical evaluation is conducted to evaluate the performance of machine translation quality prediction, and a user study is performed to evaluate the cross-language summary quality. The results demonstrate the effectiveness of the proposed approach.

The rest of this paper is organized as follows: Section 2 introduces related work. The system is overviewed in Section 3. In Sections 4 and 5, we present the detailed algorithms and evaluation

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 917–926,
Uppsala, Sweden, 11-16 July 2010.

results of machine translation quality prediction and cross-language summarization, respectively. We discuss in Section 6 and conclude this paper in Section 7.

2 Related Work

2.1 Machine Translation Quality Prediction

Machine translation evaluation aims to assess the correctness and quality of the translation. Usually, the human reference translation is provided, and various methods and metrics have been developed for comparing the system-translated text and the human reference text. For example, the BLEU metric, the NIST metric and their relatives are all based on the idea that the more shared substrings the system-translated text has with the human reference translation, the better the translation is. Blatz et al. (2003) investigate training sentence-level confidence measures using a variety of fuzzy match scores. Albrecht and Hwa (2007) rely on regression algorithms and reference-based features to measure the quality of sentences.

Transition evaluation without using reference translations has also been investigated. Quirk (2004) presents a supervised method for training a sentence level confidence measure on translation output using a human-annotated corpus. Features derived from the source sentence and the target sentence (e.g. sentence length, perplexity, etc.) and features about the translation process are leveraged. Gamon et al. (2005) investigate the possibility of evaluating MT quality and fluency at the sentence level in the absence of reference translations, and they can improve on the correlation between language model perplexity scores and human judgment by combing these perplexity scores with class probabilities from a machine-learned classifier. Specia et al. (2009) use the ICM theory to identify the threshold to map a continuous predicted score into "good" or "bad" categories. Chae and Nenkova (2009) use surface syntactic features to assess the fluency of machine translation results.

In this study, we further predict the translation quality of an English sentence before the machine translation process, i.e., we do not leverage reference translation and the target sentence.

2.2 Document Summarization

Document summarization methods can be generally categorized into extraction-based methods and abstraction-based methods. In this paper, we focus on extraction-based methods. Extraction-based summarization methods usually assign each sentence a saliency score and then rank the sentences in a document or document set.

For single document summarization, the sentence score is usually computed by empirical combination of a number of statistical and linguistic feature values, such as term frequency, sentence position, cue words, stigma words, topic signature (Luhn 1969; Lin and Hovy, 2000). The summary sentences can also be selected by using machine learning methods (Kupiec et al., 1995; Amini and Gallinari, 2002) or graph-based methods (ErKan and Radev, 2004; Mihalcea and Tarau, 2004). Other methods include mutual reinforcement principle (Zha 2002; Wan et al., 2007).

For multi-document summarization, the centroid-based method (Radev et al., 2004) is a typical method, and it scores sentences based on cluster centroids, position and TFIDF features. NeATS (Lin and Hovy, 2002) makes use of new features such as topic signature to select important sentences. Machine Learning based approaches have also been proposed for combining various sentence features (Wong et al., 2008). The influences of input difficulty on summarization performance have been investigated in (Nenkova and Louis, 2008). Graph-based methods have also been used to rank sentences in a document set. For example, Mihalcea and Tarau (2005) extend the TextRank algorithm to compute sentence importance in a document set. Cluster-level information has been incorporated in the graph model to better evaluate sentences (Wan and Yang, 2008). Topic-focused or query biased multi-document summarization has also been investigated (Wan et al., 2006). Wan et al. (2010) propose the EUSUM system for extracting easy-to-understand English summaries for non-native readers.

Several pilot studies have been performed for the cross-language summarization task by simply using document translation or summary translation. Leuski et al. (2003) use machine translation for English headline generation for Hindi documents. Lim et al. (2004) propose to generate a Japanese summary without using a Japanese summarization system, by first translating Japanese documents into Korean documents, and then extracting summary sentences by using Korean summarizer, and finally mapping Korean summary sentences to Japanese summary sentences. Chalendar et al. (2005) focuses on semantic analysis and sentence generation techniques for cross-language summarization. Orasan

and Chiorean (2008) propose to produce summaries with the MMR method from Romanian news articles and then automatically translate the summaries into English. Cross language query based summarization has been investigated in (Pingali et al., 2007), where the query and the documents are in different languages. Other related work includes multilingual summarization (Lin et al., 2005), which aims to create summaries from multiple sources in multiple languages. Siddharthan and McKeown (2005) use the information redundancy in multilingual input to correct errors in machine translation and thus improve the quality of multilingual summaries.

3 The Proposed Approach

Previous methods for cross-language summarization usually consist of two steps: one step for summarization and one step for translation. Different order of the two steps can lead to the following two basic English-to-Chinese summarization methods:

Late Translation (LateTrans): Firstly, an English summary is produced for the English document set by using existing summarization methods. Then, the English summary is automatically translated into the corresponding Chinese summary by using machine translation services.

Early Translation (EarlyTrans): Firstly, the English documents are translated into Chinese documents by using machine translation services. Then, a Chinese summary is produced for the translated Chinese documents.

Generally speaking, the LateTrans method has a few advantages over the EarlyTrans method:

1) The LateTrans method is much more efficient than the EarlyTrans method, because only a very few summary sentences are required to be translated in the LateTrans method, whereas all the sentences in the documents are required to be translated in the EarlyTrans method.

2) The LateTrans method is deemed to be more effective than the EarlyTrans method, because the translation errors of the sentences have great influences on the summary sentence extraction in the EarlyTrans method.

Thus in this study, we adopt the LateTrans method as our baseline method. We also adopt the late translation strategy for our proposed approach.

In the baseline method, a translated Chinese sentence is selected into the summary because the original English sentence is informative. However, an informative and fluent English sentence is likely to be translated into an uninformative and disfluent Chinese sentence, and therefore, this sentence cannot be selected into the summary.

In order to address the above problem of existing methods, our proposed approach takes into account a novel factor of each sentence for cross-language summary extraction. Each English sentence is associated with a score indicating its translation quality. An English sentence with high translation quality score is more likely to be selected into the original English summary, and such English summary can be translated into a better Chinese summary. Figure 1 gives the architecture of our proposed approach.

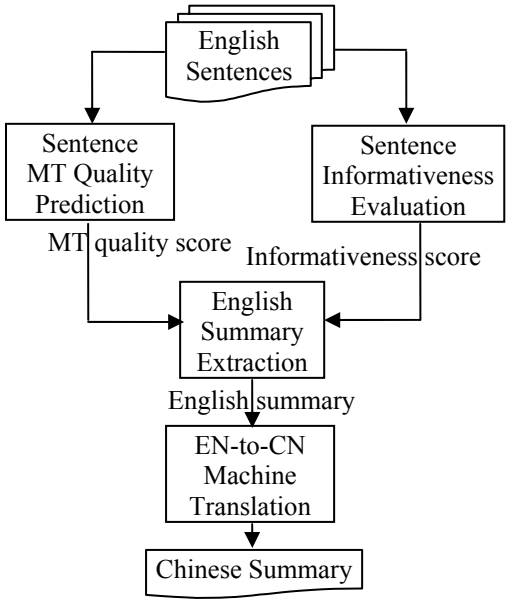

Figure 1: Architecture of our proposed approach

Seen from the figure, our proposed approach consists of four main steps: 1) The machine translation quality score of each English sentence is predicted by using regression methods; 2) The informativeness score of each English sentence is computed by using existing methods; 3) The English summary is produced by making use of both the machine translation quality score and the informativeness score; 4) The extracted English summary is translated into Chinese summary by using machine translation services.

In this study, we adopt *Google Translate*[1] for English-to-Chinese translation. *Google Translate* is one of the state-of-the-art commercial machine translation systems used today. It applies statistical learning techniques to build a translation

[1] http://translate.google.com/translate_t

model based on both monolingual text in the target language and aligned text consisting of examples of human translations between the languages.

The first step and the evaluation results will be described in Section 4, and the other steps and the evaluation results will be described together in Section 5.

4 Machine Translation Quality Prediction

4.1 Methodology

In this study, machine translation (MT) quality reflects both the translation accuracy and the fluency of the translated sentence. An English sentence with high MT quality score is likely to be translated into an accurate and fluent Chinese sentence, which can be easily read and understand by Chinese readers. The MT quality prediction is a task of mapping an English sentence to a numerical value corresponding to a quality level. The larger the value is, the more accurately and fluently the sentence can be translated into Chinese sentence.

As introduced in Section 2.1, several related work has used regression and classification methods for MT quality prediction without reference translations. In our approach, the MT quality of each sentence in the documents is also predicted without reference translations. The difference between our task and previous work is that previous work can make use of both features in source sentence and features in target sentence, while our task only leverages features in source sentence, because in the late translation strategy, the English sentences in the documents have not been translated yet at this step.

In this study, we adopt the ε-support vector regression (ε-SVR) method (Vapnik 1995) for the sentence-level MT quality prediction task. The SVR algorithm is firmly grounded in the framework of statistical learning theory (VC theory). The goal of a regression algorithm is to fit a flat function to the given training data points.

Formally, given a set of training data points $D=\{(x_i,y_i)|\ i=1,2,\ldots,n\} \subset R^d \times R$, where x_i is input feature vector and y_i is associated score, the goal is to fit a function f which approximates the relation inherited between the data set points. The standard form is:

$$\min_{w,b,\xi,\xi^*} \frac{1}{2} w^T w + C\sum_{i=1}^{n} \xi_i + C\sum_{i=1}^{n} \xi_i^*$$

Subject to

$$w^T f(x_i) + b - y_i \le \varepsilon + \xi_i$$
$$y_i - w^T f(x_i) - b \le \varepsilon + \xi_i^*$$
$$\varepsilon, \xi_i, \xi_i^* \ge 0,\ i = 1,\ldots,n.$$

The constant $C>0$ is a parameter for determining the trade-off between the flatness of f and the amount up to which deviations larger than ε are tolerated.

In the experiments, we use the LIBSVM tool (Chang and Lin, 2001) with the RBF kernel for the task, and we use the parameter selection tool of 10-fold cross validation via grid search to find the best parameters on the training set with respect to mean squared error (MSE), and then use the best parameters to train on the whole training set.

We use the following two groups of features for each sentence: the first group includes several basic features, and the second group includes several parse based features[2]. They are all derived based on the source English sentence.

The basic features are as follows:

1) **Sentence length**: It refers to the number of words in the sentence.
2) **Sub-sentence number**: It refers to the number of sub-sentences in the sentence. We simply use the punctuation marks as indicators of sub-sentences.
3) **Average sub-sentence length**: It refers to the average number of words in the sub-sentences within the sentence.
4) **Percentage of nouns and adjectives**: It refers to the percentage of noun words or adjective words in the in the sentence.
5) **Number of question words**: It refers to the number of question words (who, whom, whose, when, where, which, how, why, what) in the sentence.

We use the Stanford Lexicalized Parser (Klein and Manning, 2002) with the provided English PCFG model to parse a sentence into a parse tree. The output tree is a context-free phrase structure grammar representation of the sentence. The parse features are then selected as follows:

1) **Depth of the parse tree**: It refers to the depth of the generated parse tree.
2) **Number of SBARs in the parse tree**: SBAR is defined as a clause introduced by a (possibly empty) subordinating conjunction. It is an indictor of sentence complexity.

[2] Other features, including n-gram frequency, perplexity features, etc., are not useful in our study. MT features are not used because *Google Translate* is used as a black box.

3) **Number of NPs in the parse tree**: It refers to the number of noun phrases in the parse tree.
4) **Number of VPs in the parse tree**: It refers to the number of verb phrases in the parse tree.

All the above feature values are scaled by using the provided svm-scale program.

At this step, each English sentence s_i can be associated with a MT quality score *TransScore*(s_i) predicted by the ε-SVR method. The score is finally normalized by dividing by the maximum score.

4.2 Evaluation

4.2.1 Evaluation Setup

In the experiments, we first constructed the gold-standard dataset in the following way:

DUC2001 provided 309 English news articles for document summarization tasks, and the articles were grouped into 30 document sets. The news articles were selected from TREC-9. We chose five document sets (d04, d05, d06, d08, d11) with 54 news articles out of the DUC2001 document sets. The documents were then split into sentences and we used 1736 sentences for evaluation. All the sentences were automatically translated into Chinese sentences by using the *Google Translate* service.

Two Chinese college students were employed for data annotation. They read the original English sentence and the translated Chinese sentence, and then manually labeled the overall translation quality score for each sentence, separately. The translation quality is an overall measure for both the translation accuracy and the readability of the translated sentence. The score ranges between 1 and 5, and 1 means "very bad", and 5 means "very good", and 3 means "normal". The correlation between the two sets of labeled scores is 0.646. The final translation quality score was the average of the scores provided by the two annotators.

After annotation, we randomly separated the labeled sentence set into a training set of 1428 sentences and a test set of 308 sentences. We then used the LIBSVM tool for training and testing.

Two metrics were used for evaluating the prediction results. The two metrics are as follows:

Mean Square Error (MSE): This metric is a measure of how correct each of the prediction values is on average, penalizing more severe errors more heavily. Given the set of prediction scores for the test sentences: $\hat{Y} = \{\hat{y}_i \mid i = 1,...n\}$, and the manually assigned scores for the sentences: $Y = \{y_i \mid i = 1,...n\}$, the MSE of the prediction result is defined as

$$MSE(\hat{Y}) = \frac{1}{n}\sum_{i=1}^{n}(\hat{y}_i - y_i)^2$$

Pearson's Correlation Coefficient (ρ): This metric is a measure of whether the trends of prediction values matched the trends for human-labeled data. The coefficient between Y and $\hat{Y}$ is defined as

$$\rho = \frac{\sum_{i=1}^{n}(y_i - \bar{y})(\hat{y}_i - \bar{\hat{y}})}{n s_y s_{\hat{y}}}$$

where $\bar{y}$ and $\bar{\hat{y}}$ are the sample means of Y and $\hat{Y}$, s_y and $s_{\hat{y}}$ are the sample standard deviations of Y and $\hat{Y}$.

4.2.2 Evaluation Results

Table 1 shows the prediction results. We can see that the overall results are promising. And the correlation is moderately high. The results are acceptable because we only make use of the features derived from the source sentence. The results guarantee that the use of MT quality scores in the summarization process is feasible.

We can also see that both the basic features and the parse features are beneficial to the overall prediction results.

Feature Set	MSE	ρ
Basic features	0.709	0.399
Parse features	0.702	0.395
All features	**0.683**	**0.433**

Table 1: Prediction results

5 Cross-Language Document Summarization

5.1 Methodology

In this section, we first compute the informativeness score for each sentence. The score reflect how the sentence expresses the major topic in the documents. Various existing methods can be used for computing the score. In this study, we adopt the centroid-based method.

The centroid-based method is the algorithm used in the MEAD system. The method uses a heuristic and simple way to sum the sentence scores computed based on different features. The score for each sentence is a linear combination of

the weights computed based on the following three features:

Centroid-based Weight. The sentences close to the centroid of the document set are usually more important than the sentences farther away. And the centroid weight $C(s_i)$ of a sentence s_i is calculated as the cosine similarity between the sentence text and the concatenated text for the whole document set D. The weight is then normalized by dividing the maximal weight.

Sentence Position. The leading several sentences of a document are usually important. So we calculate for each sentence a weight to reflect its position priority as $P(s_i)=1-(i-1)/n$, where i is the sequence of the sentence s_i and n is the total number of sentences in the document. Obviously, i ranges from 1 to n.

First Sentence Similarity. Because the first sentence of a document is very important, a sentence similar to the first sentence is also important. Thus we use the cosine similarity value between a sentence and the corresponding first sentence in the same document as the weight $F(s_i)$ for sentence s_i.

After all the above weights are calculated for each sentence, we sum all the weights and get the overall score for the sentence as follows:

$$InfoScore(s_i) = \alpha \cdot C(s_i) + \beta \cdot P(s_i) + \gamma \cdot F(s_i)$$

where α, β and γ are parameters reflecting the importance of different features. We empirically set $\alpha=\beta=\gamma=1$.

After the informativeness scores for all sentences are computed, the score of each sentence is normalized by dividing by the maximum score.

After we obtain the MT quality score and the informativeness score of each sentence in the document set, we linearly combine the two scores to get the overall score of each sentence.

Formally, let $TransScore(s_i) \in [0,1]$ and $InfoScore(s_i) \in [0,1]$ denote the MT quality score and the informativeness score of sentence s_i, the overall score of the sentence is:

$$OverallScore(s_i) = (1-\lambda) \times InfoScore(s_i) + \lambda \times TransScore(s_i)$$

where $\lambda \in [0,1]$ is a parameter controlling the influences of the two factors. If λ is set to 0, the summary is extracted without considering the MT quality factor. In the experiments, we empirically set the parameter to 0.3 in order to balance the two factors of content informativeness and translation quality.

For multi-document summarization, some sentences are highly overlapping with each other, and thus we apply the same greedy algorithm in (Wan et al., 2006) to penalize the sentences highly overlapping with other highly scored sentences, and finally the informative, novel, and easy-to-translate sentences are chosen into the English summary.

Finally, the sentences in the English summary are translated into the corresponding Chinese sentences by using *Google Translate*, and the Chinese summary is formed.

5.2 Evaluation

5.2.1 Evaluation Setup

In this experiment, we used the document sets provided by DUC2001 for evaluation. As mentioned in Section 4.2.1, DUC2001 provided 30 English document sets for generic multi-document summarization. The average document number per document set was 10. The sentences in each article have been separated and the sentence information has been stored into files. Generic reference English summaries were provided by NIST annotators for evaluation. In our study, we aimed to produce Chinese summaries for the English document sets. The summary length was limited to five sentences, i.e. each summary consisted of five sentences.

The DUC2001 dataset was divided into the following two datasets:

Ideal Dataset: We have manually labeled the MT quality scores for the sentences in five document sets (d04-d11), and we directly used the manually labeled scores in the summarization process. The ideal dataset contained these five document sets.

Real Dataset: The MT quality scores for the sentences in the remaining 25 document sets were automatically predicted by using the learned SVM regression model. And we used the automatically predicted scores in the summarization process. The real dataset contained these 25 document sets.

We performed two evaluation procedures: one based on the ideal dataset to validate the feasibility of the proposed approach, and the other based on the real dataset to demonstrate the effectiveness of the proposed approach in real applications.

To date, various methods and metrics have been developed for English summary evaluation by comparing system summary with reference summary, such as the pyramid method (Nenkova et al., 2007) and the ROUGE metrics (Lin and Hovy, 2003). However, such methods or metrics cannot be directly used for evaluating Chinese summary without reference Chinese summary.

Instead, we developed an evaluation protocol as follows:

The evaluation was based on human scoring. Four Chinese college students participated in the evaluation as subjects. We have developed a friendly tool for helping the subjects to evaluate each Chinese summary from the following three aspects:

Content: This aspect indicates how much a summary reflects the major content of the document set. After reading a summary, each user can select a score between 1 and 5 for the summary. 1 means "very uninformative" and 5 means "very informative".

Readability: This aspect indicates the readability level of the whole summary. After reading a summary, each user can select a score between 1 and 5 for the summary. 1 means "hard to read", and 5 means "easy to read".

Overall: This aspect indicates the overall quality of a summary. After reading a summary, each user can select a score between 1 and 5 for the summary. 1 means "very bad", and 5 means "very good".

We performed the evaluation procedures on the ideal dataset and the read dataset, separately. During each evaluation procedure, we compared our proposed approach (λ=0.3) with the baseline approach without considering the MT quality factor (λ=0). And the two summaries produced by the two systems for the same document set were presented in the same interface, and then the four subjects assigned scores to each summary after they read and compared the two summaries. And the assigned scores were finally averaged across the documents sets and across the subjects.

5.2.2 Evaluation Results

Table 2 shows the evaluation results on the ideal dataset with 5 document sets. We can see that based on the manually labeled MT quality scores, the Chinese summaries produced by our proposed approach are significantly better than that produced by the baseline approach over all three aspects. All subjects agree that our proposed approach can produce more informative and easy-to-read Chinese summaries than the baseline approach.

Table 3 shows the evaluation results on the real dataset with 25 document sets. We can see that based on the automatically predicted MT quality scores, the Chinese summaries produced by our proposed approach are significantly better than that produced by the baseline approach over the readability aspect and the overall aspect. Almost all subjects agree that our proposed approach can produce more easy-to-read and high-quality Chinese summaries than the baseline approach.

Comparing the evaluation results in the two tables, we can find that the performance difference between the two approaches on the ideal dataset is bigger than that on the real dataset, especially on the content aspect. The results demonstrate that the more accurate the MT quality scores are, the more significant the performance improvement is.

Overall, the proposed approach is effective to produce good-quality Chinese summaries for English document sets.

	Baseline Approach			**Proposed Approach**		
	content	**readability**	**overall**	**content**	**readability**	**overall**

5.2.3 *Example Analysis*

In this section, we give two running examples to better show the effectiveness of our proposed approach. The Chinese sentences and the original English sentences in the summary are presented together. The normalized MT quality score for each sentence is also given at the end of the Chinese sentence.

Document set 1: D04 from the ideal dataset

Summary by baseline approach:

s1: 预计美国的保险公司支付，估计在佛罗里达州的73亿美元（37亿英镑），作为安德鲁飓风的结果-迄今为止最昂贵的灾难曾经面临产业。(0.56)
(US INSURERS expect to pay out an estimated Dollars 7.3bn (Pounds 3.7bn) in Florida as a result of Hurricane Andrew - by far the costliest disaster the industry has ever faced.)
s2: 有越来越多的迹象表明安德鲁飓风，不受欢迎的，因为它的佛罗里达和路易斯安那州的受灾居民，最后可能不伤害到连任的布什总统竞选。(0.67)
(THERE are growing signs that Hurricane Andrew, unwelcome as it was for the devastated inhabitants of Florida and Louisiana, may in the end do no harm to the re-election campaign of President George Bush.)
s3: 一般事故发生后，英国著名保险公司昨日表示，保险索赔的安德鲁飓风所引发的成本也高达4000万美元'。 (0.44)
(GENERAL ACCIDENT said yesterday that insurance claims arising from Hurricane Andrew could 'cost it as much as Dollars 40m'.)
s4: 在巴哈马，政府发言人麦库里说，4人死亡已离岛东部群岛报告。 (0.56)
(In the Bahamas, government spokesman Mr Jimmy Curry said four deaths had been reported on outlying eastern islands.)
s5: 新奥尔良的和1.6万人，是特别脆弱，因为该市位于海平面以下，有密西西比河通过其中心的运行和一个大型湖泊立即向北方。(0.44)
(New Orleans, with a population of 1.6m, is particularly vulnerable because the city lies below sea level, has the Mississippi River running through its centre and a large lake immediately to the north.)

Summary by proposed approach:

s1: 预计美国的保险公司支付，估计在佛罗里达州的73亿美元（37亿英镑），作为安德鲁飓风的结果-迄今为止最昂贵的灾难曾经面临产业。(0.56)
(US INSURERS expect to pay out an estimated Dollars 7.3bn (Pounds 3.7bn) in Florida as a result of Hurricane Andrew - by far the costliest disaster the industry has ever faced.)

s4: 有两个国会任期限制，经济学家，至少公共选择那些劝说，要充分理解充分的理由。(0.39)
(There are two solid reasons for congressional term limitation that economists, at least those of the public-choice persuasion, should fully appreciate.)
s5: 与国会的问题的根源是，除非有重大丑闻，几乎是不可能战胜现任。(0.47)
(The root of the problems with Congress is that, barring major scandal, it is almost impossible to defeat an incumbent.)

6 Discussion

In this study, we adopt the late translation strategy for cross-document summarization. As mentioned earlier, the late translation strategy has some advantages over the early translation strategy. However, in the early translation strategy, we can use the features derived from both the source English sentence and the target Chinese sentence to improve the MT quality prediction results.

Overall, the framework of our proposed approach can be easily adapted for cross-document summarization with the early translation strategy.

And an empirical comparison between the two strategies is left as our future work.

Though this study focuses on English-to-Chinese document summarization, cross-language summarization tasks for other languages can also be solved by using our proposed approach.

7 Conclusion and Future Work

In this study we propose a novel approach to address the cross-language document summarization task. Our proposed approach predicts the MT quality score of each English sentence and then incorporates the score into the summarization process. The user study results verify the effectiveness of the approach.

In future work, we will manually translate English reference summaries into Chinese reference summaries, and then adopt the ROUGE metrics to perform automatic evaluation of the extracted Chinese summaries by comparing them with the Chinese reference summaries. Moreover, we will further improve the sentence's MT quality by using sentence compression or sentence reduction techniques.

Abstract

Automated summarization methods can be defined as "language-independent," if they are not based on any language-specific knowledge. Such methods can be used for multilingual summarization defined by Mani (2001) as "processing several languages, with summary in the same language as input." In this paper, we introduce MUSE, a language-independent approach for extractive summarization based on the linear optimization of several sentence ranking measures using a genetic algorithm. We tested our methodology on two languages—English and Hebrew—and evaluated its performance with ROUGE-1 Recall vs. state-of-the-art extractive summarization approaches. Our results show that MUSE performs better than the best known multilingual approach (TextRank[1]) in both languages. Moreover, our experimental results on a bilingual (English and Hebrew) document collection suggest that MUSE does not need to be retrained on each language and the same model can be used across at least two different languages.

1 Introduction

Document summaries should use a minimum number of words to express a document's main ideas. As such, high quality summaries can significantly reduce the information overload many professionals in a variety of fields must contend with on a daily basis (Filippova et al., 2009), assist in the automated classification and filtering of documents, and increase search engines precision.

Automated summarization methods can use different levels of linguistic analysis: *morphological*, *syntactic*, *semantic* and *discourse/pragmatic* (Mani, 2001). Although the summary quality is expected to improve when a summarization technique includes language specific knowledge, the inclusion of that knowledge impedes the use of the summarizer on multiple languages. Only systems that perform equally well on different languages without language-specific knowledge (including linguistic analysis) can be considered language-independent summarizers.

The publication of information on the Internet in an ever-increasing variety of languages [2] dictates the importance of developing multilingual summarization approaches. There is a particular need for language-independent statistical techniques that can be readily applied to text in any language without depending on language-specific linguistic tools. In the absence of such techniques, the only alternative to language-independent summarization would be the labor-intensive translation of the entire document into a common language.

Here we introduce MUSE (MUltilingual Sentence Extractor), a new approach to multilingual single-document extractive summarization where summarization is considered as an optimization or a search problem. We use a Genetic Algorithm (GA) to find an optimal weighted linear combination of 31 statistical sentence scoring methods that are all language-independent and are based on either a vector or a graph representation of a document, where both representations are based on a

[1] We evaluated several summarizers—SUMMA, MEAD, Microsoft Word Autosummarize and TextRank—on the DUC 2002 corpus. Our results show that TextRank performed best. In addition, TextRank can be considered language-independent as long as it does not perform any morphological analysis.

[2] Gulli and Signorini (2005) used Web searches in 75 different languages to estimate the size of the Web as of the end of January 2005.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 927–936,
Uppsala, Sweden, 11-16 July 2010.

word segmentation.

We have evaluated our approach on two monolingual corpora of English and Hebrew documents and, additionally, on one bilingual corpora comprising English and Hebrew documents. Our evaluation experiments sought to
- Compare the GA-based approach for single-document extractive summarization (MUSE) to the best known sentence scoring methods.
- Determine whether the same weighting model is applicable across two different languages.

This paper is organized as follows. The next section describes the related work in statistical extractive summarization. Section 3 introduces MUSE, the GA-based approach to multilingual single-document extractive summarization. Section 4 presents our experimental results on monolingual and bilingual corpora. Our conclusions and suggestions for future work comprise the final section.

2 Related Work

Extractive summarization is aimed at the selection of a subset of the most relevant fragments from a source text into the summary. The fragments can be paragraphs (Salton et al., 1997), sentences (Luhn, 1958), keyphrases (Turney, 2000) or keywords (Litvak and Last, 2008). Statistical methods for calculating the relevance score of each fragment can be categorized into several classes: *cue*-based (Edmundson, 1969), *keyword*- or *frequency*-based (Luhn, 1958; Edmundson, 1969; Neto et al., 2000; Steinberger and Jezek, 2004; Kallel et al., 2004; Vanderwende et al., 2007), *title*-based (Edmundson, 1969; Teufel and Moens, 1997), *position*-based (Baxendale, 1958; Edmundson, 1969; Lin and Hovy, 1997; Satoshi et al., 2001) and *length*-based (Satoshi et al., 2001).

Considered the first work on sentence scoring for automated text summarization, Luhn (1958) based the significance factor of a sentence on the frequency and the relative positions of significant words within a sentence. Edmundson (1969) tested different linear combinations of four sentence ranking scoring methods—*cue*, *key*, *title* and *position*—to identify that which performed best on a training corpus. Linear combinations of several statistical sentence ranking methods were also applied in the MEAD (Radev et al., 2001) and SUMMA (Saggion et al., 2003) approaches, both of which use the vector space model for text representation and a set of predefined or user-specified weights for a combination of *position*, *frequency*, *title*, and *centroid*-based (MEAD) features. Goldstein et al. (1999) integrated linguistic and statistical features. In none of these works, however, did the researchers attempt to find the optimal weights for the best linear combination.

Information retrieval and machine learning techniques were integrated to determine sentence importance (Kupiec et al., 1995; Wong et al., 2008). Gong and Liu (2001) and Steinberger and Jezek (2004) used singular value decomposition (SVD) to generate extracts. Ishikawa et al. (2002) combined conventional sentence extraction and a trainable classifier based on support vector machines.

Some authors reduced the summarization process to an optimization or a search problem. Hassel and Sjobergh (2006) used a standard hill-climbing algorithm to build summaries that maximize the score for the total impact of the summary. A summary consists of first sentences from the document was used as a starting point for the search, and all neighbours (summaries that can be created by simply removing one sentence and adding another) were examined, looking for a better summary.

Kallel et al. (2004) and Liu et al. (2006b) used genetic algorithms (GAs), which are known as prominent search and optimization methods (Goldberg, 1989), to find sets of sentences that maximize summary quality metrics, starting from a random selection of sentences as the initial population. In this capacity, however, the high computational complexity of GAs is a disadvantage. To choose the best summary, multiple candidates should be generated and evaluated for each document (or document cluster).

Following a different approach, Turney (2000) used a GA to learn an optimized set of parameters for a keyword extractor embedded in the Extractor tool.[3] Orăsan et al. (2000) enhanced the preference-based anaphora resolution algorithms by using a GA to find an optimal set of values for the outcomes of 14 indicators and apply the optimal combination of values from data on one text to a different text. With such approach, training may be the only time-consuming phase in the operation.

[3] `http://www.extractor.com/`

Today, graph-based text representations are becoming increasingly popular, due to their ability to enrich the document model with syntactic and semantic relations. Salton et al. (1997) were among the first to make an attempt at using graph-based ranking methods in single document extractive summarization, generating similarity links between document paragraphs and using degree scores in order to extract the important paragraphs from the text. Erkan and Radev (2004) and Mihalcea (2005) introduced algorithms for unsupervised extractive summarization that rely on the application of iterative graph-based ranking algorithms, such as PageRank (Brin and Page, 1998) and HITS (Kleinberg, 1999). Their methods represent a document as a graph of sentences interconnected by similarity relations. Various similarity functions can be applied: cosine similarity as in (Erkan and Radev, 2004), simple overlap as in (Mihalcea, 2005), or other functions. Edges representing the similarity relations can be weighted (Mihalcea, 2005) or unweighted (Erkan and Radev, 2004): two sentences are connected if their similarity is above some predefined threshold value.

3 MUSE – MUltilingual Sentence Extractor

In this paper we propose a learning approach to language-independent extractive summarization where the best set of weights for a linear combination of sentence scoring methods is found by a genetic algorithm trained on a collection of document summaries. The weighting vector thus obtained is used for sentence scoring in future summarizations. Since most sentence scoring methods have a linear computational complexity, only the training phase of our approach is time-consuming.

3.1 Sentence scoring methods

Our work is aimed at identifying the best linear combination of the 31 sentence scoring methods listed in Table 1. Each method description includes a reference to the original work where the method was proposed for extractive summarization. Methods proposed in this paper are denoted by **new**. Formulas incorporate the following notation: a sentence is denoted by S, a text document by D, the total number of words in S by N, the total number of sentences in D by n, the sequential number of S in D by i, and the in-document term frequency of the term t by $tf(t)$. In the *LUHN* method, W_i and N_i are the number of keywords and the total number of words in the i^{th} cluster, respectively, such that clusters are portions of a sentence bracketed by keywords, i.e., frequent, non-common words.[4]

Figure 1 demonstrates the taxonomy of the methods listed in Table 1. Methods that require pre-defined threshold values are marked with a cross and listed in Table 2 together with the average threshold values obtained after method evaluation on English and Hebrew corpora. Each method was evaluated on both corpora, with different threshold $t \in [0, 1]$ (only numbers with one decimal digit were considered). Threshold values resulted in the best ROUGE-1 scores, were selected. A threshold of 1 means that all terms are considered, while a value of 0 means that only terms with the highest rank (*tf*, *degree*, or *pagerank*) are considered. The methods are divided into three main categories—*structure-*, *vector-*, and *graph*-based—according to the text representation model, and each category is divided into sub-categories.

Section 3.3 describes our application of a GA to the summarization task.

Table 2: Selected thresholds for threshold-based scoring methods

Method	Threshold
LUHN	0.9
LUHN_DEG	0.9
LUHN_PR	0.0
KEY	[0.8, 1.0]
KEY_DEG	[0.8, 1.0]
KEY_PR	[0.1, 1.0]
COV	0.9
COV_DEG	[0.7, 0.9]
COV_PR	0.1

3.2 Text representation models

The vector-based scoring methods listed in Table 1 use *tf* or *tf-idf* term weights to evaluate sentence importance. In contrast, representation used by the graph-based methods (except for TextRank) is based on the word-based graph representation models described in (Schenker et al., 2004). Schenker et al. (2005) showed that such graph representations can outperform the vector space model on several document categorization tasks. In the graph representation used by us in this work

[4] Luhn's experiments suggest an optimal limit of 4 or 5 non-significant words between keywords.

Table 1: Sentence scoring metrics

Name	Description	Source
POS_F	Closeness to the beginning of the document: $\frac{1}{i}$	(Edmundson, 1969)
POS_L	Closeness to the end of the document: i	(Baxendale, 1958)
POS_B	Closeness to the borders of the document: $max(\frac{1}{i}, \frac{1}{n-i+1})$	(Lin and Hovy, 1997)
LEN_W	Number of *words* in the sentence	(Satoshi et al., 2001)
LEN_CH	Number of *characters* in the sentence[5]	
LUHN	$max_{i \in \{clusters(S)\}}\{CS_i\}, CS_i = \frac{W_i^2}{N_i}$	(Luhn, 1958)
KEY	Sum of the keywords frequencies: $\sum_{t \in \{Keywords(S)\}} tf(t)$	(Edmundson, 1969)
COV	Ratio of keywords number (Coverage): $\frac{\lvert Keywords(S)\rvert}{\lvert Keywords(D)\rvert}$	(Liu et al., 2006a)
TF	Average term frequency for all sentence words: $\frac{\sum_{t \in S} tf(t)}{N}$	(Vanderwende et al., 2007)
TFISF	$\sum_{t \in S} tf(t) \times isf(t), isf(t) = 1 - \frac{log(n(t))}{log(n)}$, $n(t)$ is the number of sentences containing t	(Neto et al., 2000)
SVD	Length of a sentence vector in $\Sigma^2 \cdot V^T$ after computing Singular Value Decomposition of a term by sentences matrix $A = U\Sigma V^T$	(Steinberger and Jezek, 2004)
TITLE_O	Overlap similarity[6] to the title: $sim(S,T) = \frac{\lvert S \cap T\rvert}{min\{\lvert S\rvert,\lvert T\rvert\}}$	(Edmundson, 1969)
TITLE_J	Jaccard similarity to the title: $sim(S,T) = \frac{\lvert S \cap T\rvert}{\lvert S \cup T\rvert}$	
TITLE_C	Cosine similarity to the title: $sim(\vec{S},\vec{T}) = cos(\vec{S},\vec{T}) = \frac{\vec{S} \bullet \vec{T}}{\lvert\vec{S}\rvert \bullet \lvert\vec{T}\rvert}$	
D_COV_O	Overlap similarity to the document complement $sim(S, D-S) = \frac{\lvert S \cap T\rvert}{min\{\lvert S\rvert,\lvert D-S\rvert\}}$	**new**
D_COV_J	Jaccard similarity to the document complement $sim(S, D-S) = \frac{\lvert S \cap T\rvert}{\lvert S \cup D-S\rvert}$	
D_COV_C	Cosine similarity to the document complement $cos(\vec{S}, \vec{D-S}) = \frac{\vec{S} \bullet \vec{D-S}}{\lvert\vec{S}\rvert \bullet \lvert\vec{D-S}\rvert}$	
LUHN_DEG	Graph-based extensions of LUHN, KEY and COV measures respectively.	
KEY_DEG	Node degree is used instead of a word frequency: words are considered	
COV_DEG	significant if they are represented by nodes having a degree higher than a predefined threshold	
DEG	Average degree for all sentence nodes: $\frac{\sum_{i \in \{words(S)\}} Deg_i}{N}$	
GRASE	Frequent sentences from *bushy* paths are selected. Each sentence in the *bushy* path gets a domination score that is the number of edges with its label in the path normalized by the sentence length. The relevance score for a sentence is calculated as a sum of its domination scores over all paths.	
LUHN_PR	Graph-based extensions of LUHN, KEY and COV measures respectively.	
KEY_PR	Node PageRank score is used instead of a word frequency: words are considered	
COV_PR	significant if they are represented by nodes having a PageRank score higher than a predefined threshold	
PR	Average PageRank for all sentence nodes: $\frac{\sum_{t \in S} PR(t)}{N}$	
TITLE_E_O	Overlap-based edge matching between title and sentence graphs	
TITLE_E_J	Jaccard-based edge matching between title and sentence graphs	
D_COV_E_O	Overlap-based edge matching between sentence and a document complement graphs	
D_COV_E_J	Jaccard-based edge matching between sentence and a document complement graphs	
ML_TR	Multilingual version of TextRank without morphological analysis: Sentence score equals to PageRank (Brin and Page, 1998) rank of its node: $WS(V_i) = (1-d) + d * \sum_{V_j \in In(V_i)} \frac{w_{ji}}{\sum_{V_k \in Out(V_j)} w_{jk}} WS(V_j)$	(Mihalcea, 2005)

nodes represent unique terms (distinct words) and edges represent order-relationships between two terms. There is a directed edge from A to B if an A term immediately precedes the B term in any sentence of the document. We label each edge with the IDs of sentences that contain both words in the specified order.

3.3 Optimization—learning the best linear combination

We found the best linear combination of the methods listed in Table 1 using a Genetic Algorithm (GA). GAs are categorized as global search heuristics. Figure 2 shows a simplified GA flowchart. A typical genetic algorithm requires (1) a genetic representation of the solution domain, and (2) a fitness function to evaluate the solution domain.

We represent the solution as a vector of weights

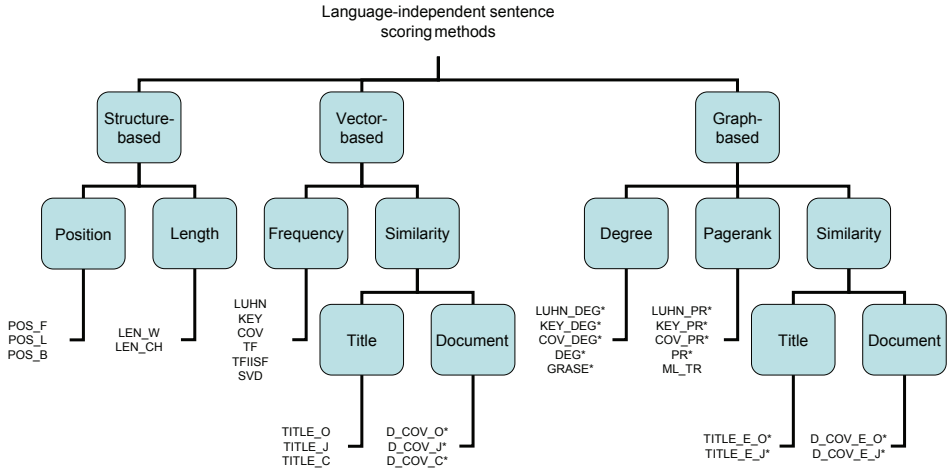

Figure 1: Taxonomy of language-independent sentence scoring methods

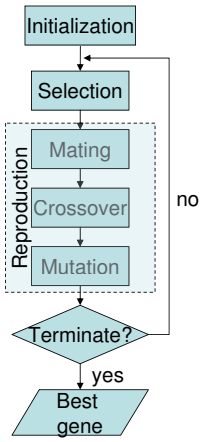

Figure 2: Simplified flowchart of a Genetic Algorithm

for a linear combination of sentence scoring methods—real-valued numbers in the unlimited range normalized in such a way that they sum up to 1. The vector size is fixed and it equals to the number of methods used in the combination.

Defined over the genetic representation, the fitness function measures the quality of the represented solution. We use ROUGE-1 Recall (Lin and Hovy, 2003) as a fitness function for measuring summarization quality, which is maximized during the optimization procedure.

Below we describe each phase of the optimization procedure in detail.

Initialization GA will explore only a small part of the search space, if the population is too small, whereas it slows down if there are too many solutions. We start from $N = 500$ randomly generated genes/solutions as an initial population, that empirically was proven as a good choice. Each gene is represented by a weighting vector $v_i = w_1, \ldots, w_D$ having a fixed number of $D \leq 31$ elements. All elements are generated from a standard normal distribution, with $\mu = 0$ and $\sigma^2 = 1$, and normalized to sum up to 1. For this solution representation, a negative weight, if it occurs, can be considered as a "penalty" for the associated metric.

Selection During each successive generation, a proportion of the existing population is selected to breed a new generation. We use a truncation selection method that rates the fitness of each solution and selects the best fifth (100 out of 500) of the individual solutions, i.e., getting the maximal ROUGE value. In such manner, we discard "bad" solutions and prevent them from reproduction. Also, we use *elitism*—method that prevents losing the best found solution in the population by copying it to the next generation.

Reproduction In this stage, new genes/solutions are introduced into the population, i.e., new points in the search space are explored. These new solutions are generated from those selected through the following genetic operators: *mating*, *crossover*, and *mutation*.

In *mating*, a pair of "parent" solutions is randomly selected, and a new solution is created using *crossover* and *mutation*, that are the most important part of a genetic algorithm. The GA performance is influenced mainly by these two operators. New parents are selected for each new child, and the process continues until a new population of solutions of appropriate size N is generated.

Crossover is performed under the assumption

that new solutions can be improved by re-using the good parts of old solutions. However it is good to keep some part of population from one generation to the next. Our *crossover* operator includes a probability (80%) that a new and different offspring solution will be generated by calculating the weighted average of two "parent" vectors according to (Vignaux and Michalewicz, 1991). Formally, a new vector v will be created from two vectors v_1 and v_2 according to the formula $v = \lambda * v_1 + (1 - \lambda) * v_2$ (we set $\lambda = 0.5$). There is a probability of 20% that the offspring will be a duplicate of one of its parents.

Mutation in GAs functions both to preserve the existing diversity and to introduce new variation. It is aimed at preventing GA from falling into local extreme, but it should not be applied too often, because then GA will in fact change to random search. Our mutation operator includes a probability (3%) that an arbitrary weight in a vector will be changed by a uniformly randomized factor in the range of $[-0.3, 0.3]$ from its original value.

Termination The generational process is repeated until a termination condition—a plateau of solution/combination fitness such that successive iterations no longer produce better results—has been reached. The minimal improvement in our experiments was set to $\epsilon = 1.0E - 21$.

4 Experiments

4.1 Overview

The MUSE summarization approach was evaluated using a comparative experiment on two monolingual corpora of English and Hebrew texts and on a bilingual corpus of texts in both languages. We intentionally chose English and Hebrew, which belong to distinct language families (Indo-European and Semitic languages, respectfully), to ensure that the results of our evaluation would be widely generalizable. The specific goals of the experiment are to:

- Evaluate the optimal sentence scoring models induced from the corpora of summarized documents in two different languages.
- Compare the performance of the GA-based multilingual summarization method proposed in this work to the state-of-the-art approaches.
- Compare method performance on both languages.
- Determine whether the same sentence scoring model can be efficiently used for extractive summarization across two different languages.

4.2 Text preprocessing

Crucial to extractive summarization, proper sentence segmentation contributes to the quality of summarization results. For English sentences, we used the sentence splitter provided with the MEAD summarizer (Radev et al., 2001). A simple splitter that can split the text at periods, exclamation points, or question marks was used for the Hebrew text.[7]

4.3 Experiment design

The English text material we used in our experiments comprised the corpus of summarized documents available to the single document summarization task at the Document Understanding Conference, 2002 (DUC, 2002). This benchmark dataset contains 533 news articles, each accompanied by two to three human-generated abstracts of approximately 100 words each.

For the Hebrew language, however, to the best of our knowledge, no summarization benchmarks exist. To generate a corpus of summarized Hebrew texts, therefore, we set up an experiment where human assessors were given 50 news articles of 250 to 830 words each from the Website of the *Haaretz* newspaper.[8] All assessors were provided with the *Tool Assisting Human Assessors* (TAHA) software tool[9] that enables sentences to be easily selected and stored for later inclusion in the document extract. In total, 70 undergraduate students from the Department of Information Systems Engineering, Ben Gurion University of the Negev participated in the experiment. Each student participant was randomly assigned ten different documents and instructed to (1) spend at least five minutes on each document, (2) ignore dialogs and quotations, (3) read the whole document before beginning sentence extraction, (4) ignore redundant, repetitive, and overly detailed information, and (5) remain within the minimal and maximal summary length constraints (95 and 100 words, respectively). Summaries were assessed for quality by comparing each student's summary to those of all the other students using the ROUGE evalua-

[7] Although the same set of splitting rules may be used for many different languages, separate splitters were used for English and Hebrew because the MEAD splitter tool is restricted to European languages.

[8] `http://www.haaretz.co.il`

[9] TAHA can be provided upon request

tion toolkit adapted to Hebrew[10] and the ROUGE-1 metric (Lin and Hovy, 2003). We filtered all the summaries produced by assessors that received average ROUGE score below 0.5, i. e. agreed with the rest of assessors in less than 50% of cases. Finally, our corpus of summarized Hebrew texts was compiled from the summaries of about 60% of the most consistent assessors, with an average of seven extracts per single document[11]. The ROUGE scores of the selected assessors are distributed between 50 and 57 percents.

The third, bilingual, experimental corpus was assembled from documents in both languages.

4.4 Experimental Results

We evaluated English and Hebrew summaries using ROUGE-$1, 2, 3, 4, L, SU$ and W metrics, described in (2004). In agreement with Lin's (2004) conclusion, our results for the different metrics were not statistically distinguishable. However, ROUGE-1 showed the largest variation across the methods. In the following comparisons, all results are presented in terms of the ROUGE-1 Recall metric.

We estimated the ROUGE metric using 10-fold cross validation. The results of training and testing comprise the average ROUGE values obtained for English, Hebrew, and bilingual corpora (Table 3). Since we experimented with a different number of English and Hebrew documents (533 and 50, respectively), we have created 10 balanced bilingual corpora, each with the same number of English and Hebrew documents, by combining approximately 50 randomly selected English documents with all 50 Hebrew documents. Each corpus was then subjected to 10-fold cross validation, and the average results for training and testing were calculated.

We compared our approach (1) with a multilingual version of TextRank (denoted by ML_TR) (Mihalcea, 2005) as the best known multilingual summarizer, (2) with Microsoft Word's Autosummarize function[12] (denoted by MS_SUM) as a widely used commercial summarizer, and (3) with the best single scoring method in each corpus. As a baseline, we compiled summaries created from the initial sentences (denoted by POS_F). Table 4 shows the comparative results (ROUGE mean values) for English, Hebrew, and bilingual corpora, with the best summarizers on top. Pairwise comparisons between summarizers indicated that all methods (except POS_F and ML_TR in the English and bilingual corpora and D_COV_J and POS_F in the Hebrew corpus) were significantly different at the 95% confidence level. MUSE performed significantly better than TextRank in all three corpora and better than the best single methods COV_DEG in English and D_COV_J in Hebrew corpora respectively.

Two sets of features—the full set of 31 sentence scoring metrics and the 10 best bilingual metrics determined in our previous work[13] using a clustering analysis of the methods results on both corpora—were tested on the bilingual corpus. The experimental results show that the optimized combination of the 10 best metrics is not significantly distinguishable from the best single metric in the multilingual corpus – COV_DEG. The difference between the combination of all 31 metrics and COV_DEG is significant only with a one-tailed p-value of 0.0798 (considered not very significant). Both combinations significantly outperformed all the other summarizers that were compared. Table 4 contains the results of MUSE-trained weights for all 31 metrics.

Our experiments showed that the removal of highly-correlated metrics (the metric with the lower ROUGE value out of each pair of highly-correlated metrics) from the linear combination slightly improved summarization quality, but the improvement was not statistically significant. Discarding bottom ranked features (up to 50%), also, did not affect the results significantly.

Table 5 shows the best vectors generated from training MUSE on all the documents in the English, Hebrew, and multilingual (one of 10 balanced) corpora and their ROUGE training scores and number of GA iterations.

While the optimal values of the weights are expected to be nonnegative, among the actual results are some negative values. Although there is no simple explanation for this outcome, it may be related to a well-known phenomenon from Numerical Analysis called *over-relaxation* (Friedman

[10]The regular expressions specifying "word" were adapted to Hebrew alphabet. The same toolkit was used for summaries evaluation on Hebrew corpus.

[13]submitted to publication

and Kandel, 1994). For example, Laplace equation $\phi_{xx} + \phi_{yy} = 0$ is iteratively solved over a grid of points as follows: At each grid point let $\phi^{(n)}, \overline{\phi}^{(n)}$ denote the n^{th} iteration as calculated from the differential equation and its *modified* final value, respectively. The final value is chosen as $\omega\phi^{(n)} + (1-\omega)\overline{\phi}^{(n-1)}$. While the sum of the two weights is obviously 1, the *optimal* value of ω, which minimizes the number of iterations needed for convergence, usually satisfies $1 < \omega < 2$ (i.e., the second weight $1-\omega$ is negative) and approaches 2 the finer the grid gets. Though somewhat unexpected, this surprising result can be rigorously proved (Varga, 1962).

Assuming efficient implementation, most metrics have a linear computational complexity relative to the total number of words in a document - $O(n)$. As a result, MUSE total computation time, given a trained model, is also linear (at factor of the number of metrics in a combination). The training time is proportional to the number of GA iterations multiplied by the number of individuals in a population times the fitness evaluation (ROUGE) time. On average, in our experiments the GA performed $5-6$ iterations—selection and reproduction—before reaching convergence.

5 Conclusions and future work

In this paper we introduced MUSE, a new, GA-based approach to multilingual extractive summarization. We evaluated the proposed methodology on two languages from different language families: English and Hebrew. The experimental results showed that MUSE significantly outperformed TextRank, the best known language-independent approach, in both Hebrew and English using either monolingual or bilingual corpora. Moreover, our results suggest that the same weighting model is applicable across multiple languages. In future work, one may:

- Evaluate MUSE on additional languages and language families.
- Incorporate threshold values for threshold-based methods (Table 2) into the GA-based optimization procedure.
- Improve performance of similarity-based metrics in the multilingual domain.
- Apply additional optimization techniques like Evolution Strategy (Beyer and Schwefel, 2002), which is known to perform well in a real-valued search space.
- Extend the search for the best summary to the problem of multi-object optimization, combining several summary quality metrics.

Bayesian Synchronous Tree-Substitution Grammar Induction and its Application to Sentence Compression

Elif Yamangil and **Stuart M. Shieber**
Harvard University
Cambridge, Massachusetts, USA
{elif, shieber}@seas.harvard.edu

Abstract

We describe our experiments with training algorithms for tree-to-tree synchronous tree-substitution grammar (STSG) for monolingual translation tasks such as sentence compression and paraphrasing. These translation tasks are characterized by the relative ability to commit to parallel parse trees and availability of word alignments, yet the unavailability of large-scale data, calling for a Bayesian tree-to-tree formalism. We formalize nonparametric Bayesian STSG with epsilon alignment in full generality, and provide a Gibbs sampling algorithm for posterior inference tailored to the task of *extractive sentence compression*. We achieve improvements against a number of baselines, including expectation maximization and variational Bayes training, illustrating the merits of nonparametric inference over the space of grammars as opposed to sparse parametric inference with a fixed grammar.

1 Introduction

Given an aligned corpus of tree pairs, we might want to learn a mapping between the paired trees. Such induction of tree mappings has application in a variety of natural-language-processing tasks including machine translation, paraphrase, and sentence compression. The induced tree mappings can be expressed by synchronous grammars. Where the tree pairs are isomorphic, synchronous context-free grammars (SCFG) may suffice, but in general, non-isomorphism can make the problem of rule extraction difficult (Galley and McKeown, 2007). More expressive formalisms such as synchronous tree-substitution (Eisner, 2003) or tree-adjoining grammars may better capture the pairings.

In this work, we explore techniques for inducing synchronous tree-substitution grammars (STSG) using as a testbed application extractive sentence compression. Learning an STSG from aligned trees is tantamount to determining a segmentation of the trees into elementary trees of the grammar along with an alignment of the elementary trees (see Figure 1 for an example of such a segmentation), followed by estimation of the weights for the extracted tree pairs.[1] These elementary tree pairs serve as the *rules* of the extracted grammar. For SCFG, segmentation is trivial — each parent with its immediate children is an elementary tree — but the formalism then restricts us to deriving isomorphic tree pairs. STSG is much more expressive, especially if we allow some elementary trees on the source or target side to be unsynchronized, so that insertions and deletions can be modeled, but the segmentation and alignment problems become nontrivial.

Previous approaches to this problem have treated the two steps — grammar extraction and weight estimation — with a variety of methods. One approach is to use word alignments (where these can be reliably estimated, as in our testbed application) to align subtrees and extract rules (Och and Ney, 2004; Galley et al., 2004) but this leaves open the question of finding the right level of generality of the rules — how deep the rules should be and how much lexicalization they should involve — necessitating resorting to heuristics such as *minimality* of rules, and leading to

[1] Throughout the paper we will use the word STSG to refer to the tree-to-tree version of the formalism, although the string-to-tree version is also commonly used.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 937–947,
Uppsala, Sweden, 11-16 July 2010.

large grammars. Once a given set of rules is extracted, weights can be imputed using a discriminative approach to maximize the (joint or conditional) likelihood or the classification margin in the training data (taking or not taking into account the derivational ambiguity). This option leverages a large amount of manual domain knowledge engineering and is not in general amenable to latent variable problems.

A simpler alternative to this two step approach is to use a generative model of synchronous derivation and simultaneously segment and weight the elementary tree pairs to maximize the probability of the training data under that model; the simplest exemplar of this approach uses expectation maximization (EM) (Dempster et al., 1977). This approach has two frailties. First, EM search over the space of all possible rules is computationally impractical. Second, even if such a search were practical, the method is degenerate, pushing the probability mass towards larger rules in order to better approximate the empirical distribution of the data (Goldwater et al., 2006; DeNero et al., 2006). Indeed, the optimal grammar would be one in which each tree pair in the training data is its own rule. Therefore, proposals for using EM for this task start with a precomputed subset of rules, and with EM used just to assign weights within this grammar. In summary, previous methods suffer from problems of *narrowness* of search, having to restrict the space of possible rules, and *overfitting* in preferring overly specific grammars.

We pursue the use of hierarchical probabilistic models incorporating sparse priors to simultaneously solve both the narrowness and overfitting problems. Such models have been used as generative solutions to several other segmentation problems, ranging from word segmentation (Goldwater et al., 2006), to parsing (Cohn et al., 2009; Post and Gildea, 2009) and machine translation (DeNero et al., 2008; Cohn and Blunsom, 2009; Liu and Gildea, 2009). Segmentation is achieved by introducing a prior bias towards grammars that are compact representations of the data, namely by enforcing *simplicity* and *sparsity*: preferring simple rules (smaller segments) unless the use of a complex rule is evidenced by the data (through repetition), and thus mitigating the overfitting problem. A Dirichlet process (DP) prior is typically used to achieve this interplay. Interestingly, sampling-based nonparametric inference further allows the possibility of searching over the infinite space of grammars (and, in machine translation, possible word alignments), thus side-stepping the narrowness problem outlined above as well.

In this work, we use an extension of the aforementioned models of generative segmentation for STSG induction, and describe an algorithm for posterior inference under this model that is tailored to the task of extractive sentence compression. This task is characterized by the availability of word alignments, providing a clean testbed for investigating the effects of grammar extraction. We achieve substantial improvements against a number of baselines including EM, support vector machine (SVM) based discriminative training, and variational Bayes (VB). By comparing our method to a range of other methods that are subject differentially to the two problems, we can show that both play an important role in performance limitations, and that our method helps address both as well. Our results are thus not only encouraging for grammar estimation using sparse priors but also illustrate the merits of nonparametric inference over the space of grammars as opposed to sparse parametric inference with a fixed grammar.

In the following, we define the task of extractive sentence compression and the Bayesian STSG model, and algorithms we used for inference and prediction. We then describe the experiments in extractive sentence compression and present our results in contrast with alternative algorithms. We conclude by giving examples of compression patterns learned by the Bayesian method.

2 Sentence compression

Sentence compression is the task of summarizing a sentence while retaining most of the informational content and remaining grammatical (Jing, 2000). In *extractive* sentence compression, which we focus on in this paper, an order-preserving subset of the words in the sentence are selected to form the summary, that is, we summarize by deleting words (Knight and Marcu, 2002). An example sentence pair, which we use as a running example, is the following:

- Like FaceLift, much of ATM's screen performance depends on the underlying application.
- ATM's screen performance depends on the underlying application.

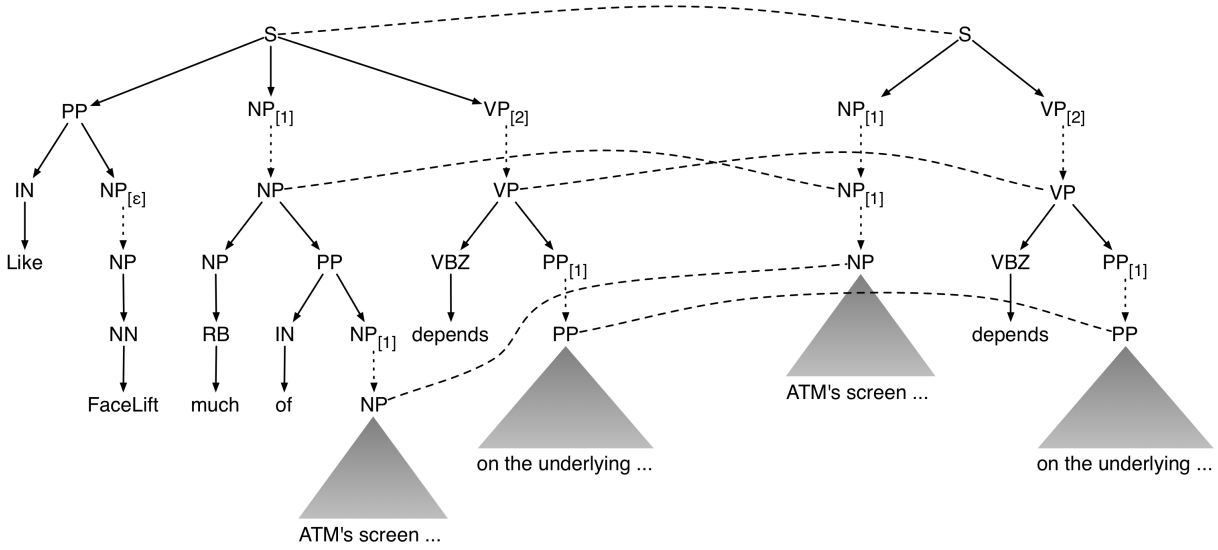

Figure 1: A portion of an STSG derivation of the example sentence and its extractive compression.

where the underlined words were deleted. In *supervised* sentence compression, the goal is to generalize from a parallel training corpus of sentences (source) and their compressions (target) to unseen sentences in a test set to predict their compressions. An *unsupervised* setup also exists; methods for the unsupervised problem typically rely on language models and linguistic/discourse constraints (Clarke and Lapata, 2006a; Turner and Charniak, 2005). Because these methods rely on dynamic programming to efficiently consider hypotheses over the space of all possible compressions of a sentence, they may be harder to extend to general paraphrasing.

3 The STSG Model

Synchronous tree-substitution grammar is a formalism for synchronously generating a pair of non-isomorphic source and target trees (Eisner, 2003). Every grammar rule is a pair of elementary trees aligned at the leaf level at their frontier nodes, which we will denote using the form

$$c_s/c_t \rightarrow e_s/e_t, \quad \gamma$$

(indices s for source, t for target) where c_s, c_t are root nonterminals of the elementary trees e_s, e_t respectively and γ is a 1-to-1 correspondence between the frontier nodes in e_s and e_t. For example, the rule

$$\text{S / S} \rightarrow \text{(S (PP (IN Like) NP}_{[\epsilon]}\text{) NP}_{[1]}\ \text{VP}_{[2]}\text{) / (S NP}_{[1]}\ \text{VP}_{[2]}\text{)}$$

can be used to delete a subtree rooted at PP. We use square bracketed indices to represent the alignment γ of frontier nodes — $\text{NP}_{[1]}$ aligns with $\text{NP}_{[1]}$, $\text{VP}_{[2]}$ aligns with $\text{VP}_{[2]}$, $\text{NP}_{[\epsilon]}$ aligns with the special symbol ϵ denoting a deletion from the source tree. Symmetrically ϵ-aligned target nodes are used to represent insertions into the target tree. Similarly, the rule

$$\text{NP / } \epsilon \rightarrow \text{(NP (NN FaceLift)) / } \epsilon$$

can be used to continue deriving the deleted subtree. See Figure 1 for an example of how an STSG with these rules would operate in synchronously generating our example sentence pair.

STSG is a convenient choice of formalism for a number of reasons. First, it eliminates the isomorphism and strong independence assumptions of SCFGs. Second, the ability to have rules deeper than one level provides a principled way of modeling lexicalization, whose importance has been emphasized (Galley and McKeown, 2007; Yamangil and Nelken, 2008). Third, we may have our STSG operate on trees instead of sentences, which allows for efficient parsing algorithms, as well as providing syntactic analyses for our predictions, which is desirable for automatic evaluation purposes.

A straightforward extension of the popular EM algorithm for probabilistic context free grammars (PCFG), the inside-outside algorithm (Lari and Young, 1990), can be used to estimate the rule weights of a given unweighted STSG based on a corpus of parallel parse trees $\mathbf{t} = t_1, \ldots, t_N$ where $t_n = t_{n,s}/t_{n,t}$ for $n = 1, \ldots, N$. Similarly, an

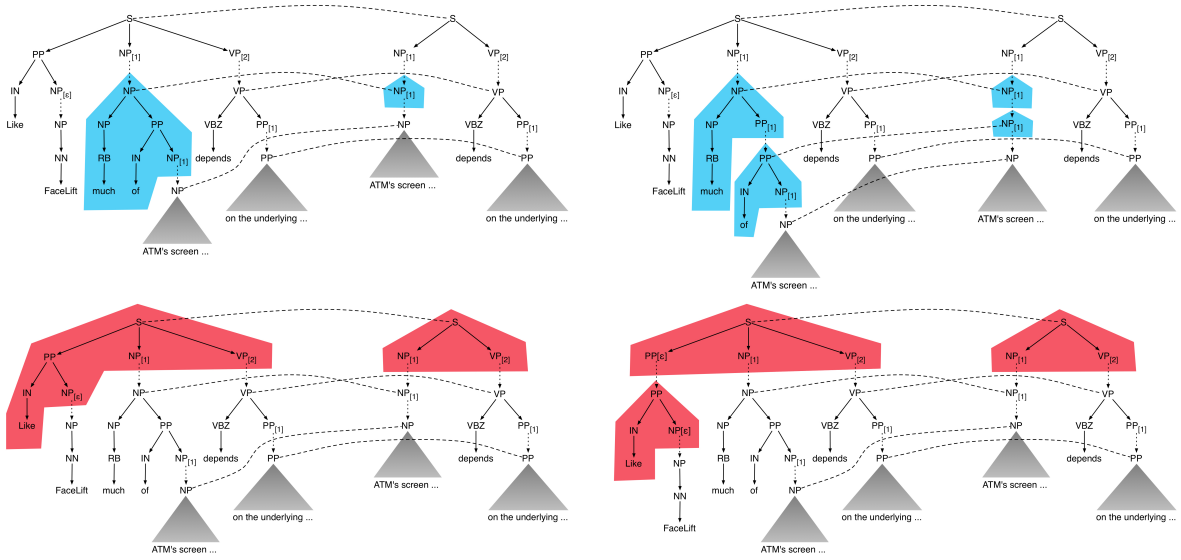

Figure 2: Gibbs sampling updates. We illustrate a sampler move to align/unalign a source node with a target node (top row in blue), and split/merge a deletion rule via aligning with ϵ (bottom row in red).

extension of the Viterbi algorithm is available for finding the maximum probability derivation, useful for predicting the target analysis $t_{N+1,t}$ for a test instance $t_{N+1,s}$. (Eisner, 2003) However, as noted earlier, EM is subject to the narrowness and overfitting problems.

3.1 The Bayesian generative process

Both of these issues can be addressed by taking a nonparametric Bayesian approach, namely, assuming that the elementary tree pairs are sampled from an independent collection of Dirichlet process (DP) priors. We describe such a process for sampling a corpus of tree pairs $\mathbf{t}$.

For all pairs of root labels $c = c_s/c_t$ that we consider, where up to one of c_s or c_t can be ϵ (e.g., S / S, NP / ϵ), we sample a sparse discrete distribution G_c over infinitely many elementary tree pairs $e = e_s/e_t$ sharing the common root c from a DP

$$G_c \sim \mathrm{DP}(\alpha_c, P_0(\cdot \mid c)) \quad (1)$$

where the DP has the concentration parameter α_c controlling the sparsity of G_c, and the base distribution $P_0(\cdot \mid c)$ is a distribution over novel elementary tree pairs that we describe more fully shortly.

We then sample a sequence of elementary tree pairs to serve as a derivation for each observed derived tree pair. For each $n = 1, \ldots, N$, we sample elementary tree pairs $e_n = e_{n,1}, \ldots, e_{n,d_n}$ in a derivation sequence (where d_n is the number of rules used in the derivation), consulting G_c whenever an elementary tree pair with root c is to be sampled.

$$e \overset{\text{iid}}{\sim} G_c, \quad \text{for all } e \text{ whose root label is } c$$

Given the derivation sequence e_n, a tree pair t_n is determined, that is,

$$p(t_n \mid e_n) = \begin{cases} 1 & e_{n,1}, \ldots, e_{n,d_n} \text{ derives } t_n \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

The hyperparameters α_c can be incorporated into the generative model as random variables; however, we opt to fix these at various constants to investigate different levels of sparsity.

For the base distribution $P_0(\cdot \mid c)$ there are a variety of choices; we used the following simple scenario. (We take $c = c_s/c_t$.)

Synchronous rules For the case where neither c_s nor c_t are the special symbol ϵ, the base distribution first generates e_s and e_t independently, and then samples an alignment between the frontier nodes. Given a nonterminal, an elementary tree is generated by first making a decision to expand the nonterminal (with probability β_c) or to leave it as a frontier node ($1 - \beta_c$). If the decision to expand was made, we sample an appropriate rule from a PCFG which we estimate ahead

of time from the training corpus. We expand the nonterminal using this rule, and then repeat the same procedure for every child generated that is a nonterminal until there are no generated nonterminal children left. This is done independently for both e_s and e_t. Finally, we sample an alignment between the frontier nodes uniformly at random out of all possible alingments.

Deletion/insertion rules If $c_t = \epsilon$, that is, we have a deletion rule, we need to generate $e = e_s/\epsilon$. (The insertion rule case is symmetric.) The base distribution generates e_s using the same process described for synchronous rules above. Then with probability 1 we align all frontier nodes in e_s with ϵ. In essence, this process generates TSG rules, rather than STSG rules, which are used to cover deleted (or inserted) subtrees.

This simple base distribution does nothing to enforce an alignment between the internal nodes of e_s and e_t. One may come up with more sophisticated base distributions. However the main point of the base distribution is to encode a controllable preference towards simpler rules; we therefore make the simplest possible assumption.

3.2 Posterior inference via Gibbs sampling

Assuming fixed hyperparameters $\boldsymbol{\alpha} = \{\alpha_c\}$ and $\boldsymbol{\beta} = \{\beta_c\}$, our inference problem is to find the posterior distribution of the derivation sequences $\mathbf{e} = e_1, \ldots, e_N$ given the observations $\mathbf{t} = t_1, \ldots, t_N$. Applying Bayes' rule, we have

$$p(\mathbf{e} \mid \mathbf{t}) \quad \propto \quad p(\mathbf{t} \mid \mathbf{e}) p(\mathbf{e}) \tag{3}$$

where $p(\mathbf{t} \mid \mathbf{e})$ is a $0/1$ distribution (2) which does not depend on G_c, and $p(\mathbf{e})$ can be obtained by collapsing G_c for all c.

Consider repeatedly generating elementary tree pairs $e_1, \ldots, e_i$, all with the same root c, iid from G_c. Integrating over G_c, the e_i become dependent. The conditional prior of the i-th elementary tree pair given previously generated ones $e_{<i} = e_1, \ldots, e_{i-1}$ is given by

$$p(e_i \mid e_{<i}) \quad = \quad \frac{n_{e_i} + \alpha_c P_0(e_i \mid c)}{i - 1 + \alpha_c} \tag{4}$$

where n_{e_i} denotes the number of times e_i occurs in $e_{<i}$. Since the collapsed model is exchangeable in the e_i, this formula forms the backbone of the inference procedure that we describe next. It also makes clear DP's inductive bias to reuse elementary tree pairs.

We use Gibbs sampling (Geman and Geman, 1984), a Markov chain Monte Carlo (MCMC) method, to sample from the posterior (3). A derivation $\mathbf{e}$ of the corpus $\mathbf{t}$ is completely specified by an alignment between the source nodes and the corresponding target nodes (as well as ϵ on either side), which we take to be the state of the sampler. We start at a random derivation of the corpus, and at every iteration resample a derivation by amending the current one through local changes made at the node level, in the style of Goldwater et al. (2006).

Our sampling updates are extensions of those used by Cohn and Blunsom (2009) in MT, but are tailored to our task of extractive sentence compression. In our task, no target node can align with ϵ (which would indicate a subtree insertion), and barring unary branches no source node i can align with two different target nodes j and j' at the same time (indicating a tree expansion). Rather, the configurations of interest are those in which only source nodes i can align with ϵ, and two source nodes i and i' can align with the same target node j. Thus, the alignments of interest are not arbitrary relations, but (partial) functions from nodes in e_s to nodes in e_t or ϵ. We therefore sample in the direction from source to target. In particular, we visit every tree pair and each of its source nodes i, and update its alignment by selecting between and within two choices: (a) unaligned, (b) aligned with some target node j or ϵ. The number of possibilities j in (b) is significantly limited, firstly by the word alignment (for instance, a source node dominating a deleted subspan cannot be aligned with a target node), and secondly by the current alignment of other nearby aligned source nodes. (See Cohn and Blunsom (2009) for details of matching spans under tree constraints.)[2]

[2] One reviewer was concerned that since we explicitly disallow insertion rules in our sampling procedure, our model that generates such rules wastes probability mass and is therefore "deficient". However, we regard sampling as a separate step from the data generation process, in which we can formulate more effective algorithms by using our domain knowledge that our data set was created by annotators who were instructed to delete words only. Also, disallowing insertion rules in the base distribution unnecessarily complicates the definition of the model, whereas it is straightforward to define the joint distribution of all (potentially useful) rules and then use domain knowledge to constrain the support of that distribution during inference, as we do here. In fact, it is pos-

More formally, let e_M be the elementary tree pair rooted at the closest aligned ancestor i' of node i when it is unaligned; and let e_A and e_B be the elementary tree pairs rooted at i' and i respectively when i is aligned with some target node j or ϵ. Then, by exchangeability of the elementary trees sharing the same root label, and using (4), we have

$$p(\text{unalign}) = \frac{n_{e_M} + \alpha_{c_M} P_0(e_M \mid c_M)}{n_{c_M} + \alpha_{c_M}} \quad (5)$$

$$p(\text{align with } j) = \frac{n_{e_A} + \alpha_{c_A} P_0(e_A \mid c_A)}{n_{c_A} + \alpha_{c_A}} \quad (6)$$

$$\times \frac{n_{e_B} + \alpha_{c_B} P_0(e_B \mid c_B)}{n_{c_B} + \alpha_{c_B}} \quad (7)$$

where the counts $n_{e.}, n_{c.}$ are with respect to the current derivation of the rest of the corpus; except for n_{e_B}, n_{c_B} we also make sure to account for having generated e_A. See Figure 2 for an illustration of the sampling updates.

It is important to note that the sampler described can move from any derivation to any other derivation with positive probability (if only, for example, by virtue of fully merging and then resegmenting), which guarantees convergence to the posterior (3). However some of these transition probabilities can be extremely small due to passing through low probability states with large elementary trees; in turn, the sampling procedure is prone to local modes. In order to counteract this and to improve mixing we used simulated annealing. The probability mass function (5-7) was raised to the power $1/T$ with T dropping linearly from $T = 5$ to $T = 0$. Furthermore, using a final temperature of zero, we recover a maximum a posteriori (MAP) estimate which we denote $\mathbf{e}_{\text{MAP}}$.

3.3 Prediction

We discuss the problem of predicting a target tree $t_{N+1,t}$ that corresponds to a source tree $t_{N+1,s}$ unseen in the observed corpus $\mathbf{t}$. The maximum probability tree (MPT) can be found by considering all possible ways to derive it. However a much simpler alternative is to choose the target tree implied by the maximum probability derivation (MPD), which we define as

$$\begin{aligned} e^* &= \operatorname*{argmax}_e p(e \mid t_s, \mathbf{t}) \\ &= \operatorname*{argmax}_e \sum_{\mathbf{e}} p(e \mid t_s, \mathbf{e}) p(\mathbf{e} \mid \mathbf{t}) \end{aligned}$$

where e denotes a derivation for $t = t_s/t_t$. (We suppress the $N+1$ subscripts for brevity.) We approximate this objective first by substituting $\delta_{\mathbf{e}_{\text{MAP}}}(\mathbf{e})$ for $p(\mathbf{e} \mid \mathbf{t})$ and secondly using a finite STSG model for the infinite $p(e \mid t_s, \mathbf{e}_{\text{MAP}})$, which we obtain simply by normalizing the rule counts in $\mathbf{e}_{\text{MAP}}$. We use dynamic programming for parsing under this finite model (Eisner, 2003).[3]

Unfortunately, this approach does not ensure that the test instances are parsable, since t_s may include unseen structure or novel words. A workaround is to include all zero-count context free copy rules such as

NP / NP → (NP NP$_{[1]}$ PP$_{[2]}$) / (NP NP$_{[1]}$ PP$_{[2]}$)
NP / ϵ → (NP NP$_{[\epsilon]}$ PP$_{[\epsilon]}$) / ϵ

in order to smooth our finite model. We used Laplace smoothing (adding 1 to all counts) as it gave us interpretable results.

4 Evaluation

We compared the Gibbs sampling compressor (GS) against a version of maximum a posteriori EM (with Dirichlet parameter greater than 1) and a discriminative STSG based on SVM training (Cohn and Lapata, 2008) (SVM). EM is a natural benchmark, while SVM is also appropriate since it can be taken as the state of the art for our task.[4]

We used a publicly available extractive sentence compression corpus: the Broadcast News compressions corpus (BNC) of Clarke and Lapata (2006a). This corpus consists of 1370 sentence pairs that were manually created from transcribed Broadcast News stories. We split the pairs into training, development, and testing sets of 1000,

sible to prove that our approach is equivalent up to a rescaling of the concentration parameters. Since we fit these parameters to the data, our approach is equivalent.

[3] We experimented with MPT using Monte Carlo integration over possible derivations; the results were not significantly different from those using MPD.

[4] The comparison system described by Cohn and Lapata (2008) attempts to solve a more general problem than ours, abstractive sentence compression. However, given the nature of the data that we provided, it can only learn to compress by deleting words. Since the system is less specialized to the task, their model requires additional heuristics in decoding not needed for extractive compression, which might cause a reduction in performance. Nonetheless, because the comparison system is a generalization of the extractive SVM compressor of Cohn and Lapata (2007), we do not expect that the results would differ qualitatively.

	SVM	EM	GS
Precision	55.60	58.80	58.94
Recall	53.37	56.58	64.59
Relational F1	54.46	57.67	61.64
Compression rate	59.72	64.11	65.52

	SVM	EM	GS	Gold
Grammar	$2.75^{\dagger}$	2.85^{*}	3.69	4.25
Importance	2.85	2.67^{*}	3.41	3.82
Comp. rate	68.18	64.07	67.97	62.34

Table 2: Average grammar and importance scores for various systems on the 20-sentence subsample. Scores marked with $*$ are significantly different than the corresponding GS score at $\alpha < .05$ and with † at $\alpha < .01$ according to post-hoc Tukey tests. ANOVA was significant at $p < .01$ both for grammar and importance.

170, and 200 pairs, respectively. The corpus was parsed using the Stanford parser (Klein and Manning, 2003).

In our experiments with the publicly available SVM system we used all except paraphrasal rules extracted from bilingual corpora (Cohn and Lapata, 2008). The model chosen for testing had parameter for trade-off between training error and margin set to $C = 0.001$, used margin rescaling, and Hamming distance over bags of tokens with brevity penalty for loss function. EM used a subset of the rules extracted by SVM, namely all rules except non-head deleting compression rules, and was initialized uniformly. Each EM instance was characterized by two parameters: α, the smoothing parameter for MAP-EM, and δ, the smoothing parameter for augmenting the learned grammar with rules extracted from unseen data (add-$(\delta - 1)$ smoothing was used), both of which were fit to the development set using grid-search over $(1, 2]$. The model chosen for testing was $(\alpha, \delta) = (1.0001, 1.01)$.

GS was initialized at a random derivation. We sampled the alignments of the source nodes in random order. The sampler was run for 5000 iterations with annealing. All hyperparameters α_c, β_c were held constant at α, β for simplicity and were fit using grid-search over $\alpha \in [10^{-6}, 10^{6}], \beta \in [10^{-3}, 0.5]$. The model chosen for testing was $(\alpha, \beta) = (100, 0.1)$.

As an automated metric of quality, we compute F-score based on grammatical relations (relational F1, or RelF1) (Riezler et al., 2003), by which the consistency between the set of predicted grammatical relations and those from the gold standard is measured, which has been shown by Clarke and Lapata (2006b) to correlate reliably with human judgments. We also conducted a small human subjective evaluation of the grammaticality and informativeness of the compressions generated by the various methods.

4.1 Automated evaluation

For all three systems we obtained predictions for the test set and used the Stanford parser to extract grammatical relations from predicted trees and the gold standard. We computed precision, recall, RelF1 (all based on grammatical relations), and compression rate (percentage of the words that are *retained*), which we report in Table 1. The results for GS are averages over five independent runs. EM gives a strong baseline since it already uses rules that are limited in depth and number of frontier nodes by stipulation, helping with the overfitting we have mentioned, surprisingly outperforming its discriminative counterpart in both precision and recall (and consequently RelF1). GS however maintains the same level of precision as EM while improving recall, bringing an overall improvement in RelF1.

4.2 Human evaluation

We randomly subsampled our 200-sentence test set for 20 sentences to be evaluated by human judges through Amazon Mechanical Turk. We asked 15 self-reported native English speakers for their judgments of GS, EM, and SVM output sentences and the gold standard in terms of *grammaticality* (how fluent the compression is) and *importance* (how much of the meaning of and important information from the original sentence is retained) on a scale of 1 (worst) to 5 (best). We report in Table 2 the average scores. EM and SVM perform at very similar levels, which we attribute to using the same set of rules, while GS performs at a level substantially better than both, and much closer to human performance in both criteria. The

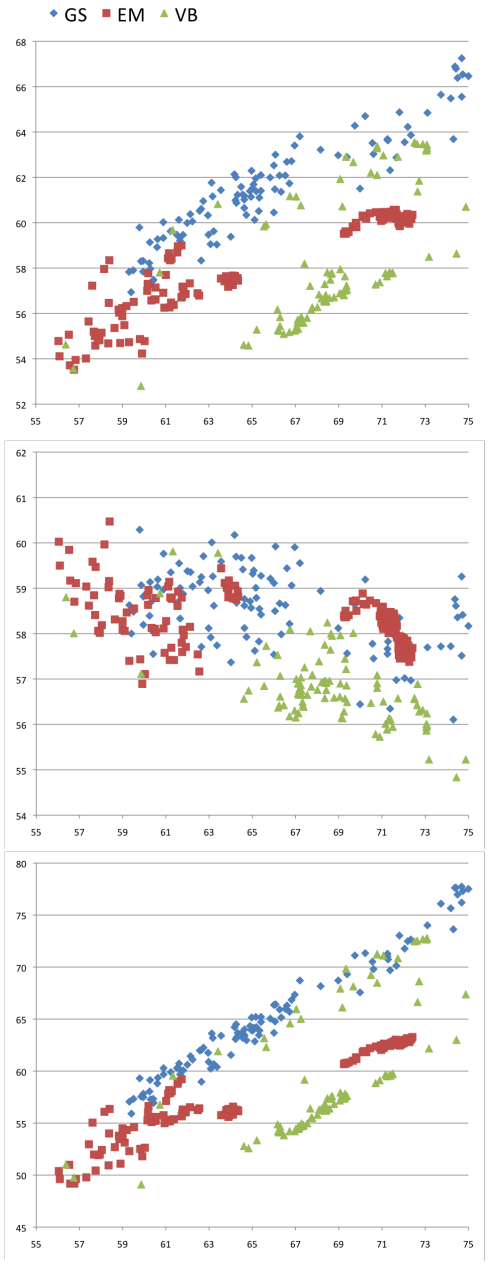

Figure 3: RelF1, precision, recall plotted against compression rate for GS, EM, VB.

human evaluation indicates that the superiority of the Bayesian nonparametric method is underappreciated by the automated evaluation metric.

4.3 Discussion

The fact that GS performs better than EM can be attributed to two reasons: (1) GS uses a sparse prior and selects a compact representation of the data (grammar sizes ranged from 4K-7K for GS compared to a grammar of about 35K rules for EM). (2) GS does not commit to a precomputed grammar and searches over the space of all grammars to find one that bests represents the corpus. It is possible to introduce DP-like sparsity in EM using variational Bayes (VB) training. We experiment with this next in order to understand how dominant the two factors are. The VB algorithm requires a simple update to the M-step formulas for EM where the expected rule counts are normalized, such that instead of updating the rule weight in the t-th iteration as in the following

$$\theta_{c,e}^{t+1} = \frac{n_{c,e} + \alpha - 1}{n_{c,\cdot} + K\alpha - K}$$

where $n_{c,e}$ represents the expected count of rule $c \rightarrow e$, and K is the total number of ways to rewrite c, we now take into account our DP$(\alpha_c, P_0(\cdot \mid c))$ prior in (1), which, when truncated to a finite grammar, reduces to a K-dimensional Dirichlet prior with parameter $\alpha_c P_0(\cdot \mid c)$. Thus in VB we perform a *variational* E-step with the subprobabilities given by

$$\theta_{c,e}^{t+1} = \frac{\exp\left(\Psi(n_{c,e} + \alpha_c P_0(e \mid c))\right)}{\exp\left(\Psi(n_{c,\cdot} + \alpha_c)\right)}$$

where Ψ denotes the digamma function. (Liu and Gildea, 2009) (See MacKay (1997) for details.) Hyperparameters were handled the same way as for GS.

Instead of selecting a single model on the development set, here we provide the whole spectrum of models and their performances in order to better understand their comparative behavior. In Figure 3 we plot RelF1 on the test set versus compression rate and compare GS, EM, and VB ($\beta = 0.1$ fixed, (α, δ) ranging in $[10^{-6}, 10^{6}] \times (1, 2]$). Overall, we see that GS maintains roughly the same level of precision as EM (despite its larger compression rates) while achieving an improvement in recall, consequently performing at a higher RelF1 level. We note that VB somewhat bridges the gap between GS and EM, without quite reaching GS performance. We conclude that the mitigation of the two factors (narrowness and overfitting) both contribute to the performance gain of GS.[5]

4.4 Example rules learned

In order to provide some insight into the grammar extracted by GS, we list in Tables (3) and (4) high

[5]We have also experimented with VB with parametric independent symmetric Dirichlet priors. The results were similar to EM with the exception of sparse priors resulting in smaller grammars and slightly improving performance.

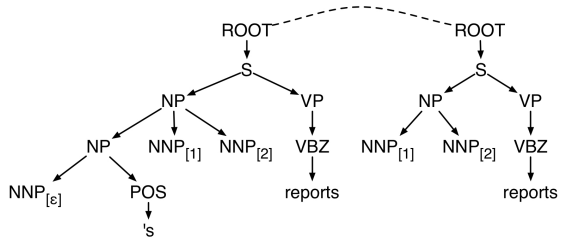
probability subtree-deletion rules expanding categories ROOT / ROOT and S / S, respectively. Of especial interest are deep lexicalized rules such as



a pattern of compression used many times in the BNC in sentence pairs such as "NPR's Anne Garrels reports" / "Anne Garrels reports". Such an informative rule with nontrivial collocation (between the possessive marker and the word "reports") would be hard to extract heuristically and can only be extracted by reasoning across the training examples.

5 Conclusion

We explored nonparametric Bayesian learning of non-isomorphic tree mappings using Dirichlet process priors. We used the task of extractive sentence compression as a testbed to investigate the effects of sparse priors and nonparametric inference over the space of grammars. We showed that, despite its degeneracy, expectation maximization is a strong baseline when given a reasonable grammar. However, Gibbs-sampling–based nonparametric inference achieves improvements against this baseline. Our investigation with variational Bayes showed that the improvement is due both to finding sparse grammars (mitigating overfitting) and to searching over the space of all grammars (mitigating narrowness). Overall, we take these results as being encouraging for STSG induction via Bayesian nonparametrics for monolingual translation tasks. The future for this work would involve natural extensions such as mixing over the space of word alignments; this would allow application to MT-like tasks where flexible word reordering is allowed, such as abstractive sentence compression and paraphrasing.

Contextualizing Semantic Representations Using Syntactically Enriched Vector Models

Abstract

We present a syntactically enriched vector model that supports the computation of contextualized semantic representations in a quasi compositional fashion. It employs a systematic combination of first- and second-order context vectors. We apply our model to two different tasks and show that (i) it substantially outperforms previous work on a paraphrase ranking task, and (ii) achieves promising results on a word-sense similarity task; to our knowledge, it is the first time that an unsupervised method has been applied to this task.

1 Introduction

In the logical paradigm of natural-language semantics originating from Montague (1973), semantic structure, composition and entailment have been modelled to an impressive degree of detail and formal consistency. These approaches, however, lack coverage and robustness, and their impact on realistic natural-language applications is limited: The logical framework suffers from over-specificity, and is inappropriate to model the pervasive vagueness, ambivalence, and uncertainty of natural-language semantics. Also, the handcrafting of resources covering the huge amounts of content which are required for deep semantic processing is highly inefficient and expensive.

Co-occurrence-based semantic vector models offer an attractive alternative. In the standard approach, word meaning is represented by feature vectors, with large sets of context words as dimensions, and their co-occurrence frequencies as values. Semantic similarity information can be acquired using unsupervised methods at virtually no cost, and the information gained is soft and gradual. Many NLP tasks have been modelled successfully using vector-based models. Examples include information retrieval (Manning et al., 2008), word-sense discrimination (Schütze, 1998) and disambiguation (McCarthy and Carroll, 2003), to name but a few.

Standard vector-space models have serious limitations, however: While semantic information is typically encoded in phrases and sentences, distributional semantics, in sharp contrast to logic-based semantics, does not offer any natural concept of compositionality that would allow the semantics of a complex expression to be computed from the meaning of its parts. A different, but related problem is caused by word-sense ambiguity and contextual variation of usage. Frequency counts of context words for a given target word provide invariant representations averaging over all different usages of the target word. There is no obvious way to distinguish the different senses of e.g. *acquire* in different contexts, such as *acquire knowledge* or *acquire shares*.

Several approaches for word-sense disambiguation in the framework of distributional semantics have been proposed in the literature (Schütze, 1998; McCarthy and Carroll, 2003). In contrast to these approaches, we present a method to model the mutual contextualization of words in a phrase in a compositional way, guided by syntactic structure. To some extent, our method resembles the approaches proposed by Mitchell and Lapata (2008) and Erk and Padó (2008). We go one step further, however, in that we employ *syntactically enriched vector models* as the basic meaning representations, assuming a vector space spanned by combinations of dependency relations and words (Lin, 1998). This allows us to model the semantic interaction between the meaning of a head word and its dependent at the micro-level of relation-specific co-occurrence frequencies. It turns out that the benefit to precision is considerable.

Using syntactically enriched vector models raises problems of different kinds: First, the use

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 948–957,
Uppsala, Sweden, 11-16 July 2010.

of syntax increases dimensionality and thus may cause data sparseness (Padó and Lapata, 2007). Second, the vectors of two syntactically related words, e.g., a target verb *acquire* and its direct object *knowledge*, typically have different syntactic environments, which implies that their vector representations encode complementary information and there is no direct way of combining the information encoded in the respective vectors.

To solve these problems, we build upon previous work (Thater et al., 2009) and propose to use *syntactic second-order vector representations*. Second-order vector representations in a bag-of-words setting were first used by Schütze (1998); in a syntactic setting, they also feature in Dligach and Palmer (2008). For the problem at hand, the use of second-order vectors alleviates the sparseness problem, and enables the definition of vector space transformations that make the distributional information attached to words in different syntactic positions compatible. Thus, it allows vectors for a predicate and its arguments to be combined in a compositional way.

We conduct two experiments to assess the suitability of our method. Our first experiment is carried out on the SemEval 2007 lexical substitution task dataset (McCarthy and Navigli, 2007). It will show that our method significantly outperforms other unsupervised methods that have been proposed in the literature to rank words with respect to their semantic similarity in a given linguistic context. In a second experiment, we apply our model to the "word sense similarity task" recently proposed by Erk and McCarthy (2009), which is a refined variant of a word-sense disambiguation task. The results show a substantial positive effect.

Plan of the paper. We will first review related work in Section 2, before presenting our model in Section 3. In Sections 4 and 5 we evaluate our model on the two different tasks. Section 6 concludes.

2 Related Work

Several approaches to contextualize vector representations of word meaning have been proposed. One common approach is to represent the meaning of a word a in context b simply as the sum, or centroid of a and b (Landauer and Dumais, 1997).

Kintsch (2001) considers a variant of this simple model. By using vector representations of a predicate p and an argument a, Kintsch identifies words that are similar to p and a, and takes the centroid of these words' vectors to be the representation of the complex expression $p(a)$.

Mitchell and Lapata (2008), henceforth M&L, propose a general framework in which meaning representations for complex expressions are computed compositionally by combining the vector representations of the individual words of the complex expression. They focus on the assessment of different operations combining the vectors of the subexpressions. An important finding is that component-wise multiplication outperforms the more common addition method. Although their composition method is guided by syntactic structure, the actual instantiations of M&L's framework are insensitive to syntactic relations and word-order, assigning identical representation to *dog bites man* and *man bites dog* (see Erk and Padó (2008) for a discussion). Also, they use syntax-free bag-of-words-based vectors as basic representations of word meaning.

Erk and Padó (2008), henceforth E&P, represent the meaning of a word w through a collection of vectors instead of a single vector: They assume selectional preferences and inverse selectional preferences to be constitutive parts of the meaning in addition to the meaning proper. The interpretation of a word p in context a is a combination of p's meaning with the (inverse) selectional preference of a. Thus, a verb meaning does not combine directly with the meaning of its object noun, as on the M&L account, but with the centroid of the vectors of the verbs to which the noun can stand in an object relation. Clearly, their approach is sensitive to syntactic structure. Their evaluation shows that their model outperforms the one proposed by M&L on a lexical substitution task (see Section 4). The basic vectors, however, are constructed in a word space similar to the one of the M&L approach.

In Thater et al. (2009), henceforth TDP, we took up the basic idea from E&P of exploiting selectional preference information for contextualization. Instead of using collections of different vectors, we incorporated syntactic information by assuming a richer internal structure of the vector representations. In a small case study, moderate improvements over E&P on a lexical substitution task could be shown. In the present paper, we formulate a general model of syntactically informed contextualization and show how to apply it to a number a of representative lexical substitution tasks. Evaluation shows significant improvements over TDP

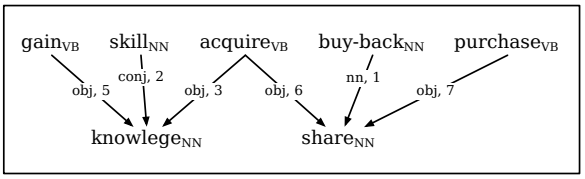

Figure 1: Co-occurrence graph of a small sample corpus of dependency trees.

and E&P.

3 The model

In this section, we present our method of contextualizing semantic vector representations. We first give an overview of the main ideas, which is followed by a technical description of first-order and second-order vectors (Section 3.2) and the contextualization operation (Section 3.3).

3.1 Overview

Our model employs vector representations for words and expressions containing syntax-specific first and second order co-occurrences information.

The basis for the construction of both kinds of vector representations are co-occurrence graphs. Figure 1 shows the co-occurrence graph of a small sample corpus of dependency trees: Words are represented as nodes in the graph, possible dependency relations between them are drawn as labeled edges, with weights corresponding to the observed frequencies. From this graph, we can directly read off the first-order vector for every word w: the vector's dimensions correspond to pairs (r, w') of a grammatical relation and a neighboring word, and are assigned the frequency count of (w, r, w').

The noun *knowledge*, for instance, would be represented by the following vector:

$$\langle 5_{(\text{OBJ}^{-1},\text{gain})}, 2_{(\text{CONJ}^{-1},\text{skill})}, 3_{(\text{OBJ}^{-1},\text{acquire})}, \ldots \rangle$$

This vector talks about the possible dependency heads of *knowledge* and thus can be seen as the (inverse) selectional preference of *knowledge* (see Erk and Padó (2008)).

As soon as we want to compute a meaning representation for a phrase like *acquire knowledge* from the verb *acquire* together with its direct object *knowledge*, we are facing the problem that verbs have different syntactic neighbors than nouns, hence their first-order vectors are not easily comparable. To solve this problem we additionally introduce another kind of vectors capturing informations about all words that can be reached with two steps in the co-occurrence graph. Such a path is characterized by two dependency relations and two words, i.e., a quadruple (r, w', r', w''), whose weight is the product of the weights of the two edges used in the path. To avoid overly sparse vectors we generalize over the "middle word" w' and build our second-order vectors on the dimensions corresponding to triples (r, r', w'') of two dependency relations and one word at the end of the two-step path. For instance, the second-order vector for *acquire* is

$$\langle 15_{(\text{OBJ},\text{OBJ}^{-1},\text{gain})}, 6_{(\text{OBJ},\text{CONJ}^{-1},\text{skill})}, 6_{(\text{OBJ},\text{OBJ}^{-1},\text{buy-back})}, 42_{(\text{OBJ},\text{OBJ}^{-1},\text{purchase})}, \ldots \rangle$$

In this simple example, the values are the products of the edge weights on each of the paths. The method of computation is detailed in Section 3.2. Note that second order vectors in particular contain paths of the form (r, r^{-1}, w'), relating a verb w to other verbs w' which are possible substitution candidates.

With first- and second-order vectors we can now model the interaction of semantic information within complex expressions. Given a pair of words in a particular grammatical relation like *acquire knowledge*, we contextualize the second-order vector of *acquire* with the first-order vector of *knowledge*. We let the first-order vector with its selectional preference information act as a kind of weighting filter on the second-order vector, and thus refine the meaning representation of the verb. The actual operation we will use is pointwise multiplication, which turned out to be the best-performing one for our purpose. Interestingly, Mitchell and Lapata (2008) came to the same result in a different setting.

In our example, we obtain a new second-order vector for *acquire* in the context of *knowledge*:

$$\langle 75_{(\text{OBJ},\text{OBJ}^{-1},\text{gain})}, 12_{(\text{OBJ},\text{CONJ}^{-1},\text{skill})}, 0_{(\text{OBJ},\text{OBJ}^{-1},\text{buy-back})}, 0_{(\text{OBJ},\text{OBJ}^{-1},\text{purchase})}, \ldots \rangle$$

Note that all dimensions that are not "licensed" by the argument *knowledge* are filtered out as they are multiplied with 0. Also, contextualisation of *acquire* with the argument *share* instead of *knowledge*

would have led to a very different vector, which reflects the fact that the two argument nouns induce different readings of the inherently ambiguous *acquire*.

3.2 First and second-order vectors

Assuming a set W of words and a set R of dependency relation labels, we consider a Euclidean vector space V_1 spanned by the set of orthonormal basis vectors $\{\vec{e}_{r,w'} \mid r \in R, w' \in W\}$, i.e., a vector space whose dimensions correspond to pairs of a relation and a word. Recall that any vector of V_1 can be represented as a finite sum of the form $\sum a_i \vec{e}_{r,w'}$ with appropriate scalar factors a_i. In this vector space we define the *first-order vector* $[w]$ of a word w as follows:

$$[w] = \sum_{\substack{r \in R \\ w' \in W}} \omega(w, r, w') \cdot \vec{e}_{r,w'}$$

where ω is a function that assigns the dependency triple (w, r, w') a corresponding weight. In the simplest case, ω would denote the frequency in a corpus of dependency trees of w occurring together with w' in relation r. In the experiments reported below, we use *pointwise mutual information* (Church and Hanks, 1990) instead as it proved superior to raw frequency counts:

$$pmi(w, r, w') = \log \frac{p(w, w' \mid r)}{p(w \mid r)p(w' \mid r)}$$

We further consider a similarly defined vector space V_2, spanned by an orthonormal basis $\{\vec{e}_{r,r',w'} \mid r, r' \in R, w' \in W\}$. Its dimensions therefore correspond to triples of two relations and a word. Evidently this is a higher dimensional space than V_1, which therefore can be embedded into V_2 by the "lifting maps" $L_r : V_1 \hookrightarrow V_2$ defined by $L_r(\vec{e}_{r',w'}) := \vec{e}_{r,r',w'}$ (and by linear extension therefore on all vectors of V_1). Using these lifting maps we define the *second-order vector* $[\![w]\!]$ of a word w as

$$[\![w]\!] = \sum_{\substack{r \in R \\ w' \in W}} \omega(w, r, w') \cdot L_r\left([w']\right)$$

Substituting the definitions of L_r and $[w']$, this yields

$$[\![w]\!] = \sum_{\substack{r, r' \in R \\ w'' \in W}} \left(\sum_{w' \in W} \omega(w, r, w')\omega(w', r', w'') \right) \vec{e}_{r,r',w''}$$

which shows the generalization over w' in form of the inner sum.

For example, if w is a verb, $r = \textsc{Obj}$ and $r' = \textsc{Obj}^{-1}$ (i.e., the inverse object relation), then the coefficients of $\vec{e}_{r,r',w''}$ in $[\![w]\!]$ would characterize the distribution of verbs w'' which share objects with w.

3.3 Composition

Both first and second-order vectors are defined for lexical expressions only. In order to represent the meaning of complex expressions we need to combine the vectors for grammatically related words in a given sentence. Given two words w and w' in relation r we contextualize the second-order vector of w with the r-lifted first-order vector of w':

$$[\![w_{r:w'}]\!] = [\![w]\!] \times L_r([w'])$$
