Preface: From the General Chair

Welcome back to Europe at ACL 2010! After three years, the ACL crowd is meeting again in Europe, this time at the very north, to escape from the Central European heat it experienced in 2007.

This year, some significant changes can be found under the hood. The call for papers was formulated much more broadly than usual, and this idea brought up by the ACL membership and the Exec and then developed in detail by this year's program chairs, Sandra Carberry and Stephen Clark, really caught on - the number of submissions has been the highest of all times, forcing us to put some activities, such as the SRW, as the fifth track on Tuesday morning. The number of reviewers is hard to compute exactly - but a glimpse into their lists in this year's and previous years' proceedings reveals that we almost certainly set a new record here, too (thank you all!). Also, the proceedings have switched to electronic-only for all events, and adaptation of the START conference automation software has begun towards a fully automated workflow from submission to the production of the final proceedings in pdf format. It has been made possible thanks to Philipp Koehn's and Jing-Shin Chang's willingness to serve as Publication Chairs two years in a row in order to ensure a smooth transition from the semi-manual process employed in the past. However, there was one thing that overshadowed it all: the enthusiastic, meticulously precise and absolutely professional yet in every situation very polite approach of the local arrangements committee headed by Joakim Nivre. His efforts have made my job, as the General Chair, a piece of cake, limited essentially to watching the tons of emails exchanged between the local and other committees and to answering emails like "why wasn't I asked to be an invited speaker?" (obviously, from people no one would consider for this honor anyway).

Joakim has been helped by Beáta Megyesi, Rolf Carlson, Mats Dahllöf, Marco Kuhlmann, Mattias Nilsson, Markus Saers, Anna Sågvall Hein, Per Starbäck, Oscar Täckström, Jörg Tiedemann, Reut Tsarfaty and by the Akademikonferens team affiliated to Uppsala University headed by Ulla Conti; from her team, I would like to thank specifically Maria Carlson, Maria Bäckström and Johanna Thyselius Nilsson for taking care of the website.

There are traditional ACL conference features as well - the workshops (with CoNLL-2010 as the big one), tutorials and the Student Research Workshop, the banquet (at the Uppsala Castle), the invited talks (albeit not-so-traditional this year, please come and see yourself), the Lifetime Achievement award, the business meeting and the closing session where the "conference torch" will be handed over to the Americas, as planned.

The Workshop Chairs (Pushpak Bhattacharyya and David Weir) had a hard time deciding which workshops to turn down, and tutorials had to be kept to a reasonable number, too: quite an uneasy job for the Tutorials Chairs, Lluís Màrquez and Haifeng Wang. Demos have been selected by Sandra Kübler, and exhibitions handled by Jörg Tiedemann. Publicity has been the responsibility of Koenraad de Smedt and Beata Megyesi, the local ararngements vice-chair. Students had again the opportunity to submit papers to the Student Research Workshop, organized by the SRW Chairs Nils Reiter, Seniz Demir, and Jan Raab, helped by their Faculty Advisor Tomek Strzalkowski, who also handled the application for the usual NSF grant supporting the SRW. Markéta Lopatková, the other Faculty Advisor, then centrally handled the student travel grants. Mentoring was the responsibility of Björn Gambäck and Diana McCarthy. Taking about money and the budget, the sponsoring committee has been quite successful this year by securing grants both locally and internationally: Mats Wirén, Hercules Dalianis, Christy Doran, Srinivas Bangalore, Frédérique Segond, and Steven Pulman assembled and impressive lineup of sponsors. Thanks to them, all of you can benefit from low registration fees, subsidized banquet, the conference bag, and student scholarships and prizes.

No thank-you would be complete without mentioning Priscilla Rasmussen - her experience, insight, and ability to predict the numbers and other things was extremely helpful, to say the least. The secretary-

treasurer, Graeme Hirst, has helped to reassure us whenever there was doubt or an open budgetary question. And Steven Bird, who chaired the coordinating committee (a subcommittee of the ACL and EACL executive boards) which selected the conference venue and appointed the general chair and program chairs, has been with us throughout almost two years of preparations, helping to make sure we all (read and) follow the Conference organization handbook, and address all possible problems.

Finally, a conference without your contributions (and you as participants, of course) would not happen at all. Thank you for working hard, for submitting solid work and for preparing interesting talks and posters!

Enjoy the conference.

Jan Hajič
ACL 2010 General Chair
July 2010

Preface: Program Committee Co-Chairs

Our goal this year has been to provide a broad conference program that acknowledges the very diverse field of computational linguistics and that recognizes the importance of both theoretical and empirical, data-driven research. In addition, we explicitly sought non-traditional conference papers such as surveys of important topics or emerging areas and papers that pose a challenge to the research community. A novel feature of the review process was the construction of different review forms for long and short papers and for the different types of papers, leading to a total of 20 different review forms. Not only were the review criteria for survey and challenge papers very different from the review criteria for research papers, but also the review criteria for theoretical research papers differed significantly from the review criteria for empirical research papers. Consequently, the program for the ACL 2010 conference includes a diverse set of papers, including papers in areas such as psycholinguistics and multimodal communication, as well as three survey papers and three challenge papers.

Both the number of paper submissions and attendance at ACL conferences continues to grow. Once again, the number of paper submissions to ACL 2010 broke the record set by the preceding year's conference. Discounting papers that were withdrawn or not reviewed due to failure to adhere to the specifications in the Call for Papers, there were 638 long paper submissions and 318 short paper submissions. Each submission was categorized according to topic and assigned to one of our paper tracks which were overseen by our 27 Area Chairs who selected expert reviewers to evaluate the submissions. Long paper submissions received at least three reviews and short paper submissions received at least two reviews. If there was a lack of consensus among the reviews for a paper, the reviewers then engaged in a discussion period in order to resolve disagreements. 25% of the long paper submissions and 22% of the short paper submissions were accepted for presentation at the conference. Unfortunately, even with adding a fifth parallel session, space prevented many very good papers from being accepted. As an experiment this year, authors were allowed to add an extra page of content to their final paper in order to enable them to address the comments and suggestions of their reviewers.

The conference program consists of three kinds of presentations: long 25 minute oral presentations, short 10 minute oral talks along with a subsequent poster presentation, and solely poster presentations. While the conference proceedings differentiates papers according to whether they are long or short papers, there is no distinction in the proceedings with respect to the mode of presentation.

We are delighted to have two invited speakers who will give what promise to be exciting plenary lectures. Andrei Broder (Vice-president, Yahoo! Research) will discuss the emerging field of computational advertising. Zenzi Griffin (Professor, University of Texas) will discuss language processing in interpersonal interactions. In addition, the recipient of the ACL Lifetime Achievement Award will present a plenary lecture on the second day of the conference.

As is traditional, there will be an award for the best long paper, the best long paper by a student, and the best short paper. Reviewers were asked to indicate whether a paper might merit a best paper prize. Area chairs then reviewed suggested papers and nominated deserving papers for further consideration. Two Best Paper Prize Committees were formed, one for long papers and one for short papers; each committee consisted of 5-6 senior researchers. The committees, along with the Program Chairs, then selected the award recipients. The Best Long Paper Prize will be presented at the plenary final session of the conference on Wednesday afternoon, and the recipient will present his or her paper during this session. The prize for Best Long Paper by a Student and the prize for the Best Short Paper will be presented at the oral talks given by the recipients during one of the regular paper sessions.

As usual, there are many individuals to thank for their contributions to the conference program. Most notably, we thank our 27 Area Chairs who did a superb job of overseeing the review of papers in their domain, the members of the Best Paper Committees, and the over 600 reviewers who in almost all cases

provided detailed, comprehensive reviews. We also owe a tremendous debt of gratitude to Rich Gerber; his START system made the review and scheduling process manageable. Moreover, his quick response to questions and requested modifications were very much appreciated. We want to thank Jason Eisner for his web site that provides invaluable advice on "How to Serve as a Program Chair of a Conference". We were very fortunate to work with wonderful organizers: Jan Hajic as General Chair, Joakim Nivre as Local Arrangements Chair, Jing-Shin Chang and Philipp Koehn as Publications Co-Chairs, and the ACL 2010 Coordinating Committee. We also thank last year's program chairs, Jian Su and Jan Wiebe, for their advice and responses to our questions.

But the ACL conference is more than just the main technical presentations. We would like to acknowledge the efforts of Seniz Demir, Jan Raab, and Nils Reiter, along with the faculty advisers Marketa Lopatkova and Tomek Strzalkowski, for organizing the Student Research Workshop. We would also like to acknowledge the work of Lluis Marquez and Haifeng Wang for soliciting an excellent set of pre-conference tutorials, Pushpak Bhattacharyia and David Weir for compiling a set of very interesting post-conference workshops, Sandra Kubler for assembling informative system demonstrations, and Jörg Tiedemann for handling exhibits.

We hope that you enjoy the conference!

ACL 2010 Program Co-Chairs
Sandra Carberry, University of Delaware
Stephen Clark, University of Cambridge

Organizing Committee

General Chair:

Jan Hajič, Charles University in Prague, Czech Republic

Local Arrangements Chair:

Joakim Nivre, Uppsala University, Sweden

Program Chairs:

Sandra Carberry, University of Delaware, USA
Stephen Clark, University of Cambridge, United Kingdom

Local Arrangements Committee:

Beata Megyesi, Uppsala University, Sweden (vice-chair)
Anna Sågvall Hein, Uppsala University, Sweden
Rolf Carlson, KTH, Stockholm, Sweden
Mats Dahllöf, Uppsala University, Sweden
Marco Kuhlmann, Uppsala University, Sweden
Mattias Nilsson, Uppsala University, Sweden
Markus Saers, Uppsala University, Sweden
Per Starbäck, Uppsala University, Sweden
Oscar Täckström, Uppsala University, Sweden
Jörg Tiedemann, Uppsala University, Sweden
Reut Tsarfaty, Uppsala University, Sweden

Local Organizing Secretariat (Akademikonferens, Uppsala, Sweden):

Ulla Conti (head)
Maria Carlson, Maria Bäckström, Johanna Tyselius Nilsson (webmasters)

Publicity Chairs:

Koenraad de Smedt, University of Bergen, Norway
Beata Megyesi, Uppsala University, Sweden

Exhibits Chair:

Jörg Tiedemann, Uppsala University, Sweden

Sponsorship Chairs:

Stephen Pulman, University of Oxford, United Kingdom
Frédérique Segond, Xerox Research Centre Europe, France
Srinivas Bangalore, AT&T Labs-Research, USA
Christy Doran, MITRE, USA
Hercules Dalianis, Stockholm University, Sweden

Mats Wirén, Stockholm University, Sweden

Workshop Chairs:

David Weir, University of Sussex, United Kingdom
Pushpak Bhattacharyya, IIT Mumbai, India

Tutorial Chairs:

Lluís Màrquez, Technical University of Catalonia, Spain
Haifeng Wang, Baidu, China

Publications Chairs:

Jing-Shin Chang, National Chi Nan University, Taiwan
Philipp Koehn, University of Edinburgh, United Kingdom

System Demonstrations Chair:

Sandra Kübler, Indiana University, USA

Student Research Workshop Chairs:

Nils Reiter, University of Heidelberg, Germany
Seniz Demir, University of Delaware, USA
Jan Raab, Charles University in Prague, Czech Republic
Tomek Strzalkowski, University at Albany – SUNY, USA (Faculty advisor)
Markéta Lopatková, Charles University in Prague (Faculty advisor)

Mentoring Service Chairs:

Björn Gambäck, SICS, Sweden
Diana McCarthy, Lexical Computing Ltd., United Kingdom

Registration:

Priscilla Rasmussen, Association for Computational Linguistics (ACL), USA

ACL Conference Coordinating Committee Chair for 2010:

Steven Bird, University of Melbourne, Australia

Mentoring Service Chairs:

Björn Gambäck, SICS, Sweden
Diana McCarthy, Lexical Computing Ltd., United Kingdom

Mentoring Committee:

Efficient Third-order Dependency Parsers

Terry Koo and Michael Collins
MIT CSAIL, Cambridge, MA, 02139, USA
{maestro,mcollins}@csail.mit.edu

Abstract

We present algorithms for higher-order dependency parsing that are "third-order" in the sense that they can evaluate substructures containing three dependencies, and "efficient" in the sense that they require only $O(n^4)$ time. Importantly, our new parsers can utilize both sibling-style and grandchild-style interactions. We evaluate our parsers on the Penn Treebank and Prague Dependency Treebank, achieving unlabeled attachment scores of 93.04% and 87.38%, respectively.

1 Introduction

Dependency grammar has proven to be a very useful syntactic formalism, due in no small part to the development of efficient parsing algorithms (Eisner, 2000; McDonald et al., 2005b; McDonald and Pereira, 2006; Carreras, 2007), which can be leveraged for a wide variety of learning methods, such as feature-rich discriminative models (Lafferty et al., 2001; Collins, 2002; Taskar et al., 2003). These parsing algorithms share an important characteristic: they *factor* dependency trees into sets of *parts* that have limited interactions. By exploiting the additional constraints arising from the factorization, maximizations or summations over the set of possible dependency trees can be performed efficiently and exactly.

A crucial limitation of factored parsing algorithms is that the associated parts are typically quite small, losing much of the contextual information within the dependency tree. For the purposes of improving parsing performance, it is desirable to increase the size and variety of the parts used by the factorization.[1] At the same time, the need for more expressive factorizations must be balanced against any resulting increase in the computational cost of the parsing algorithm. Consequently, recent work in dependency parsing has been restricted to applications of second-order parsers, the most powerful of which (Carreras, 2007) requires $O(n^4)$ time and $O(n^3)$ space, while being limited to second-order parts.

In this paper, we present new third-order parsing algorithms that increase both the size and variety of the parts participating in the factorization, while simultaneously maintaining computational requirements of $O(n^4)$ time and $O(n^3)$ space. We evaluate our parsers on the Penn WSJ Treebank (Marcus et al., 1993) and Prague Dependency Treebank (Hajič et al., 2001), achieving unlabeled attachment scores of 93.04% and 87.38%. In summary, we make three main contributions:

1. Efficient new third-order parsing algorithms.
2. Empirical evaluations of these parsers.
3. A free distribution of our implementation.[2]

The remainder of this paper is divided as follows: Sections 2 and 3 give background, Sections 4 and 5 describe our new parsing algorithms, Section 6 discusses related work, Section 7 presents our experimental results, and Section 8 concludes.

2 Dependency parsing

In dependency grammar, syntactic relationships are represented as head-modifier dependencies: directed arcs between a *head*, which is the more "essential" word in the relationship, and a *modifier*, which supplements the meaning of the head. For example, Figure 1 contains a dependency between the verb "report" (the head) and its object "sales" (the modifier). A complete analysis of a sentence is given by a dependency tree: a set of dependencies that forms a rooted, directed tree spanning the words of the sentence. Every dependency tree is rooted at a special "*" token, allowing the

[1] For examples of how performance varies with the degree of the parser's factorization see, e.g., McDonald and Pereira (2006, Tables 1 and 2), Carreras (2007, Table 2), Koo et al. (2008, Tables 2 and 4), or Suzuki et al. (2009, Tables 3–6).

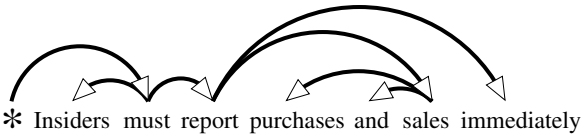

Figure 1: An example dependency structure.

selection of the sentential head to be modeled as if it were a dependency.

For a sentence $\boldsymbol{x}$, we define dependency parsing as a search for the highest-scoring analysis of $\boldsymbol{x}$:

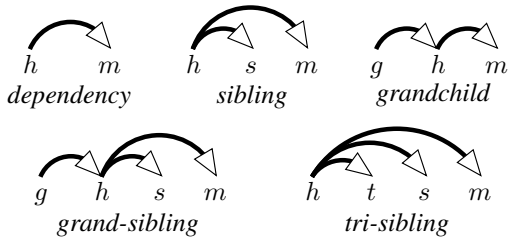
$$y^*(\boldsymbol{x}) = \operatorname*{argmax}_{y \in \mathcal{Y}(\boldsymbol{x})} \textsc{Score}(\boldsymbol{x}, y) \quad (1)$$

Here, $\mathcal{Y}(\boldsymbol{x})$ is the set of all trees compatible with $\boldsymbol{x}$ and $\textsc{Score}(\boldsymbol{x}, y)$ evaluates the event that tree y is the analysis of sentence $\boldsymbol{x}$. Since the cardinality of $\mathcal{Y}(\boldsymbol{x})$ grows exponentially with the length of the sentence, directly solving Eq. 1 is impractical. A common strategy, and one which forms the focus of this paper, is to *factor* each dependency tree into small *parts*, which can be scored in isolation. Factored parsing can be formalized as follows:

$$\textsc{Score}(\boldsymbol{x}, y) = \sum_{p \in y} \textsc{ScorePart}(\boldsymbol{x}, p)$$

That is, we treat the dependency tree y as a set of parts p, each of which makes a separate contribution to the score of y. For certain factorizations, efficient parsing algorithms exist for solving Eq. 1.

We define the *order* of a part according to the number of dependencies it contains, with analogous terminology for factorizations and parsing algorithms. In the remainder of this paper, we focus on factorizations utilizing the following parts:



Specifically, Sections 4.1, 4.2, and 4.3 describe parsers that, respectively, factor trees into grandchild parts, grand-sibling parts, and a mixture of grand-sibling and tri-sibling parts.

3 Existing parsing algorithms

Our new third-order dependency parsers build on ideas from existing parsing algorithms. In this section, we provide background on two relevant parsers from previous work.

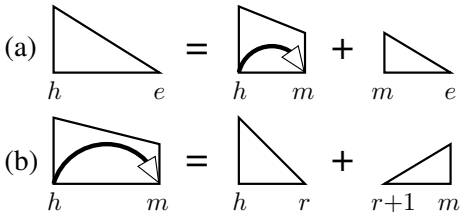


Figure 2: The dynamic-programming structures and derivations of the Eisner (2000) algorithm. Complete spans are depicted as triangles and incomplete spans as trapezoids. For brevity, we elide the symmetric right-headed versions.

3.1 First-order factorization

The first type of parser we describe uses a "first-order" factorization, which decomposes a dependency tree into its individual dependencies. Eisner (2000) introduced a widely-used dynamic-programming algorithm for first-order parsing; as it is the basis for many parsers, including our new algorithms, we summarize its design here.

The Eisner (2000) algorithm is based on two interrelated types of dynamic-programming structures: *complete* spans, which consist of a head-word and its descendents on one side, and *incomplete* spans, which consist of a dependency and the region between the head and modifier.

Formally, we denote a complete span as $C_{h,e}$ where h and e are the indices of the span's head-word and endpoint. An incomplete span is denoted as $I_{h,m}$ where h and m are the index of the head and modifier of a dependency. Intuitively, a complete span represents a "half-constituent" headed by h, whereas an incomplete span is only a partial half-constituent, since the constituent can be extended by adding more modifiers to m.

Each type of span is created by recursively combining two smaller, adjacent spans; the constructions are specified graphically in Figure 2. An incomplete span is constructed from a pair of complete spans, indicating the division of the range $[h, m]$ into constituents headed by h and m. A complete span is created by "completing" an incomplete span with the other half of m's constituent. The point of concatenation in each construction—m in Figure 2(a) or r in Figure 2(b)—is the *split point*, a free index that must be enumerated to find the optimal construction.

In order to parse a sentence $\boldsymbol{x}$, it suffices to find optimal constructions for all complete and incomplete spans defined on $\boldsymbol{x}$. This can be

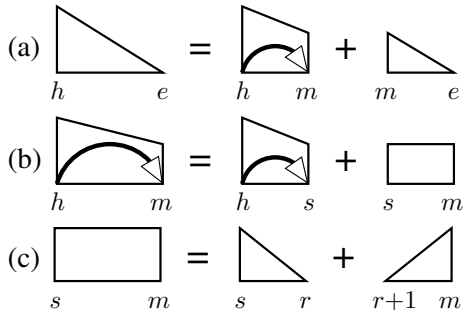

Figure 3: The dynamic-programming structures and derivations of the second-order sibling parser; sibling spans are depicted as boxes. For brevity, we elide the right-headed versions.

accomplished by adapting standard chart-parsing techniques (Cocke and Schwartz, 1970; Younger, 1967; Kasami, 1965) to the recursive derivations defined in Figure 2. Since each derivation is defined by two fixed indices (the boundaries of the span) and a third free index (the split point), the parsing algorithm requires $O(n^3)$ time and $O(n^2)$ space (Eisner, 1996; McAllester, 1999).

3.2 Second-order sibling factorization

As remarked by Eisner (1996) and McDonald and Pereira (2006), it is possible to rearrange the dynamic-programming structures to conform to an improved factorization that decomposes each tree into *sibling* parts—pairs of dependencies with a shared head. Specifically, a sibling part consists of a triple of indices (h, m, s) where (h, m) and (h, s) are dependencies, and where s and m are successive modifiers to the same side of h.

In order to parse this factorization, the second-order parser introduces a third type of dynamic-programming structure: *sibling* spans, which represent the region between successive modifiers of some head. Formally, we denote a sibling span as $S_{s,m}$ where s and m are a pair of modifiers involved in a sibling relationship. Modified versions of sibling spans will play an important role in the new parsing algorithms described in Section 4.

Figure 3 provides a graphical specification of the second-order parsing algorithm. Note that incomplete spans are constructed in a new way: the second-order parser combines a smaller incomplete span, representing the next-innermost dependency, with a sibling span that covers the region between the two modifiers. Sibling parts (h, m, s) can thus be obtained from Figure 3(b). Despite the use of second-order parts, each derivation is still defined by a span and split point, so the parser requires $O(n^3)$ time and $O(n^2)$ space.

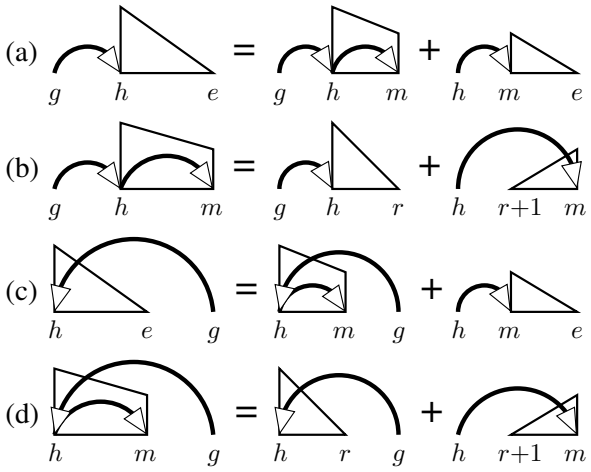

Figure 4: The dynamic-programming structures and derivations of Model 0. For brevity, we elide the right-headed versions. Note that (c) and (d) differ from (a) and (b) only in the position of g.

4 New third-order parsing algorithms

In this section we describe our new third-order dependency parsing algorithms. Our overall method is characterized by the augmentation of each span with a "grandparent" index: an index external to the span whose role will be made clear below. This section presents three parsing algorithms based on this idea: Model 0, a second-order parser, and Models 1 and 2, which are third-order parsers.

4.1 Model 0: all grandchildren

The first parser, Model 0, factors each dependency tree into a set of *grandchild* parts—pairs of dependencies connected head-to-tail. Specifically, a grandchild part is a triple of indices (g, h, m) where (g, h) and (h, m) are dependencies.[3]

In order to parse this factorization, we augment both complete and incomplete spans with grandparent indices; for brevity, we refer to these augmented structures as *g-spans*. Formally, we denote a complete g-span as $C^g_{h,e}$, where $C_{h,e}$ is a normal complete span and g is an index lying outside the range $[h, e]$, with the implication that (g, h) is a dependency. Incomplete g-spans are defined analogously and are denoted as $I^g_{h,m}$.

Figure 4 depicts complete and incomplete g-spans and provides a graphical specification of the

[3]The Carreras (2007) parser also uses grandchild parts but only in restricted cases; see Section 6 for details.

OPTIMIZEALLSPANS($\boldsymbol{x}$)

1. $\forall g, i \quad C^g_{i,i} = 0$ ◁ *base case*
2. **for** $w = 1 \ldots (n-1)$ ◁ *span width*
3. **for** $i = 1 \ldots (n-w)$ ◁ *span start index*
4. $j = i + w$ ◁ *span end index*
5. **for** $g < i$ **or** $g > j$ ◁ *grandparent index*
6. $I^g_{i,j} = \max_{i \le r < j} \{C^g_{i,r} + C^i_{j,r+1}\} +$ SCOREG($\boldsymbol{x}, g, i, j$)
7. $I^g_{j,i} = \max_{i \le r < j} \{C^g_{j,r+1} + C^j_{i,r}\} +$ SCOREG($\boldsymbol{x}, g, j, i$)
8. $C^g_{i,j} = \max_{i < m \le j} \{I^g_{i,m} + C^i_{m,j}\}$
9. $C^g_{j,i} = \max_{i \le m < j} \{I^g_{j,m} + C^j_{m,i}\}$
10. **endfor**
11. **endfor**
12. **endfor**

Figure 5: A bottom-up chart parser for Model 0. SCOREG is the scoring function for grandchild parts. We use the g-span identities as shorthand for their chart entries (e.g., $I^g_{i,j}$ refers to the entry containing the maximum score of that g-span).

Model 0 dynamic-programming algorithm. The algorithm resembles the first-order parser, except that every recursive construction must also set the grandparent indices of the smaller g-spans; fortunately, this can be done deterministically in all cases. For example, Figure 4(a) depicts the decomposition of $C^g_{h,e}$ into an incomplete half and a complete half. The grandparent of the incomplete half is copied from $C^g_{h,e}$ while the grandparent of the complete half is set to h, the head of m as defined by the construction. Clearly, grandchild parts (g, h, m) can be read off of the incomplete g-spans in Figure 4(b,d). Moreover, since each derivation copies the grandparent index g into successively smaller g-spans, grandchild parts will be produced for *all* grandchildren of g.

Model 0 can be parsed by adapting standard top-down or bottom-up chart parsing techniques. For concreteness, Figure 5 provides a pseudocode sketch of a bottom-up chart parser for Model 0; although the sketch omits many details, it suffices for the purposes of illustration. The algorithm progresses from small widths to large in the usual manner, but after defining the endpoints (i, j) there is an additional loop that enumerates all possible grandparents. Since each derivation is defined by three fixed indices (the g-span) and one free index (the split point), the complexity of the algorithm is $O(n^4)$ time and $O(n^3)$ space.

Note that the grandparent indices cause each g-span to have non-contiguous structure. For example, in Figure 4(a) the words between g and h will be controlled by some other g-span. Due to these discontinuities, the correctness of the Model 0 dynamic-programming algorithm may not be immediately obvious. While a full proof of correctness is beyond the scope of this paper, we note that each structure on the right-hand side of Figure 4 lies completely within the structure on the left-hand side. This nesting of structures implies, in turn, that the usual properties required to ensure the correctness of dynamic programming hold.

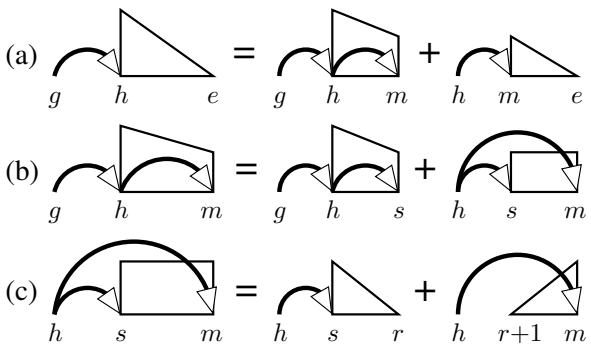

Figure 6: The dynamic-programming structures and derivations of Model 1. Right-headed and right-grandparented versions are omitted.

4.2 Model 1: all grand-siblings

We now describe our first third-order parsing algorithm. Model 1 decomposes each tree into a set of *grand-sibling* parts—combinations of sibling parts and grandchild parts. Specifically, a grand-sibling is a 4-tuple of indices (g, h, m, s) where (h, m, s) is a sibling part and (g, h, m) and (g, h, s) are grandchild parts. For example, in Figure 1, the words "must," "report," "sales," and "immediately" form a grand-sibling part.

In order to parse this factorization, we introduce sibling g-spans $S^h_{m,s}$, which are composed of a normal sibling span $S_{m,s}$ and an external index h, with the implication that (h, m, s) forms a valid sibling part. Figure 6 provides a graphical specification of the dynamic-programming algorithm for Model 1. The overall structure of the algorithm resembles the second-order sibling parser, with the addition of grandparent indices; as in Model 0, the grandparent indices can be set deterministically in all cases. Note that the sibling g-spans are crucial: they allow grand-sibling parts (g, h, m, s) to be read off of Figure 6(b), while simultaneously propagating grandparent indices to smaller g-spans.

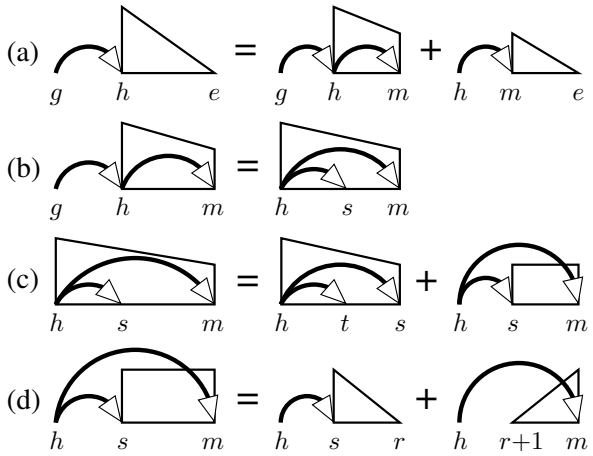

Figure 7: The dynamic-programming structures and derivations of Model 2. Right-headed and right-grandparented versions are omitted.

Like Model 0, Model 1 can be parsed via adaptations of standard chart-parsing techniques; we omit the details for brevity. Despite the move to third-order parts, each derivation is still defined by a g-span and a split point, so that parsing requires only $O(n^4)$ time and $O(n^3)$ space.

4.3 Model 2: grand-siblings and tri-siblings

Higher-order parsing algorithms have been proposed which extend the second-order sibling factorization to parts containing multiple siblings (McDonald and Pereira, 2006, also see Section 6 for discussion). In this section, we show how our g-span-based techniques can be combined with a third-order sibling parser, resulting in a parser that captures both grand-sibling parts and *tri-sibling* parts—4-tuples of indices (h, m, s, t) such that both (h, m, s) and (h, s, t) are sibling parts.

In order to parse this factorization, we introduce a new type of dynamic-programming structure: sibling-augmented spans, or *s-spans*. Formally, we denote an incomplete s-span as $I_{h,m,s}$ where $I_{h,m}$ is a normal incomplete span and s is an index lying in the strict interior of the range $[h, m]$, such that (h, m, s) forms a valid sibling part.

Figure 7 provides a graphical specification of the Model 2 parsing algorithm. An incomplete s-span is constructed by combining a smaller incomplete s-span, representing the next-innermost pair of modifiers, with a sibling g-span, covering the region between the outer two modifiers. As in Model 1, sibling g-spans are crucial for propagating grandparent indices, while allowing the recovery of tri-sibling parts (h, m, s, t). Figure 7(b) shows how an incomplete s-span can be converted into an incomplete g-span by exchanging the internal sibling index for an external grandparent index; in the process, grand-sibling parts (g, h, m, s) are enumerated. Since every derivation is defined by an augmented span and a split point, Model 2 can be parsed in $O(n^4)$ time and $O(n^3)$ space.

It should be noted that unlike Model 1, Model 2 produces grand-sibling parts only for the outermost pair of grandchildren,[4] similar to the behavior of the Carreras (2007) parser. In fact, the resemblance is more than passing, as Model 2 can *emulate* the Carreras (2007) algorithm by "demoting" each third-order part into a second-order part:

$$\textsc{ScoreGS}(\boldsymbol{x}, g, h, m, s) = \textsc{ScoreG}(\boldsymbol{x}, g, h, m)$$
$$\textsc{ScoreTS}(\boldsymbol{x}, h, m, s, t) = \textsc{ScoreS}(\boldsymbol{x}, h, m, s)$$

where ScoreG, ScoreS, ScoreGS and ScoreTS are the scoring functions for grandchildren, siblings, grand-siblings and tri-siblings, respectively. The emulated version has the same computational complexity as the original, so there is no practical reason to prefer it over the original. Nevertheless, the relationship illustrated above highlights the efficiency of our approach: we are able to recover third-order parts in place of second-order parts, at no additional cost.

4.4 Discussion

The technique of grandparent-index augmentation has proven fruitful, as it allows us to parse expressive third-order factorizations while retaining an efficient $O(n^4)$ runtime. In fact, our third-order parsing algorithms are "optimally" efficient in an asymptotic sense. Since each third-order part is composed of four separate indices, there are $\Theta(n^4)$ distinct parts. Any third-order parsing algorithm must at least consider the score of each part, hence third-order parsing is $\Omega(n^4)$ and it follows that the asymptotic complexity of Models 1 and 2 cannot be improved.

The key to the efficiency of our approach is a fundamental asymmetry in the structure of a directed tree: a head can have any number of modifiers, while a modifier always has exactly one head. Factorizations like that of Carreras (2007) obtain grandchild parts by augmenting spans with the indices of modifiers, leading to limitations on

[4] The reason for the restriction is that in Model 2, grand-siblings can only be derived via Figure 7(b), which does not recursively copy the grandparent index for reuse in smaller g-spans as Model 1 does in Figure 6(b).

the grandchildren that can participate in the factorization. Our method, by "inverting" the modifier indices into grandparent indices, exploits the structural asymmetry.

As a final note, the parsing algorithms described in this section fall into the category of *projective* dependency parsers, which forbid crossing dependencies. If crossing dependencies are allowed, it is possible to parse a first-order factorization by finding the maximum directed spanning tree (Chu and Liu, 1965; Edmonds, 1967; McDonald et al., 2005b). Unfortunately, designing efficient higher-order non-projective parsers is likely to be challenging, based on recent hardness results (McDonald and Pereira, 2006; McDonald and Satta, 2007).

5 Extensions

We briefly outline a few extensions to our algorithms; we hope to explore these in future work.

5.1 Probabilistic inference

Many statistical modeling techniques are based on partition functions and marginals—summations over the set of possible trees $\mathcal{Y}(\boldsymbol{x})$. Straightforward adaptations of the inside-outside algorithm (Baker, 1979) to our dynamic-programming structures would suffice to compute these quantities.

5.2 Labeled parsing

Our parsers are easily extended to labeled dependencies. Direct integration of labels into Models 1 and 2 would result in third-order parts composed of three labeled dependencies, at the cost of increasing the time and space complexities by factors of $O(L^3)$ and $O(L^2)$, respectively, where L bounds the number of labels per dependency.

5.3 Word senses

If each word in $\boldsymbol{x}$ has a set of possible "senses," our parsers can be modified to recover the best joint assignment of syntax and senses for $\boldsymbol{x}$, by adapting methods in Eisner (2000). Complexity would increase by factors of $O(S^4)$ time and $O(S^3)$ space, where S bounds the number of senses per word.

5.4 Increased context

If more vertical context is desired, the dynamic-programming structures can be extended with additional ancestor indices, resulting in a "spine" of ancestors above each span. Each additional ancestor lengthens the vertical scope of the factorization (e.g., from grand-siblings to "great-grand-siblings"), while increasing complexity by a factor of $O(n)$. Horizontal context can also be increased by adding internal sibling indices; each additional sibling widens the scope of the factorization (e.g., from grand-siblings to "grand-tri-siblings"), while increasing complexity by a factor of $O(n)$.

6 Related work

Our method augments each span with the index of the head that governs that span, in a manner superficially similar to parent annotation in CFGs (Johnson, 1998). However, parent annotation is a *grammar* transformation that is independent of any particular sentence, whereas our method annotates spans with *indices* into the current sentence. These indices allow the use of arbitrary features predicated on the position of the grandparent (e.g., word identity, POS tag, contextual POS tags) without affecting the asymptotic complexity of the parsing algorithm. Efficiently encoding this kind of information into a sentence-independent grammar transformation would be challenging at best.

Eisner (2000) defines dependency parsing models where each word has a set of possible "senses" and the parser recovers the best joint assignment of syntax and senses. Our new parsing algorithms could be implemented by defining the "sense" of each word as the index of its head. However, when parsing with senses, the complexity of the Eisner (2000) parser increases by factors of $O(S^3)$ time and $O(S^2)$ space (ibid., Section 4.2). Since each word has n potential heads, a direct application of the word-sense parser leads to time and space complexities of $O(n^6)$ and $O(n^4)$, respectively, in contrast to our $O(n^4)$ and $O(n^3)$.[5]

Eisner (2000) also uses head automata to score or recognize the dependents of each head. An interesting question is whether these automata could be coerced into modeling the grandparent indices used in our parsing algorithms. However, note that the head automata are defined in a sentence-independent manner, with two automata per word in the vocabulary (ibid., Section 2). The automata are thus analogous to the rules of a CFG and at-

[5] In brief, the reason for the inefficiency is that the word-sense parser is unable to exploit certain constraints, such as the fact that the endpoints of a sibling g-span must have the same head. The word-sense parser would needlessly enumerate all possible pairs of heads in this case.

tempts to use them to model grandparent indices would face difficulties similar to those already described for grammar transformations in CFGs.

It should be noted that third-order parsers have previously been proposed by McDonald and Pereira (2006), who remarked that their second-order sibling parser (see Figure 3) could easily be extended to capture $m > 1$ successive modifiers in $O(n^{m+1})$ time (ibid., Section 2.2). To our knowledge, however, Models 1 and 2 are the first third-order parsing algorithms capable of modeling grandchild parts. In our experiments, we find that grandchild interactions make important contributions to parsing performance (see Table 3).

Carreras (2007) presents a second-order parser that can score both sibling and grandchild parts, with complexities of $O(n^4)$ time and $O(n^3)$ space. An important limitation of the parser's factorization is that it only defines grandchild parts for outermost grandchildren: (g, h, m) is scored only when m is the outermost modifier of h in some direction. Note that Models 1 and 2 have the same complexity as Carreras (2007), but strictly greater expressiveness: for each sibling or grandchild part used in the Carreras (2007) factorization, Model 1 defines an enclosing grand-sibling, while Model 2 defines an enclosing tri-sibling or grand-sibling.

The factored parsing approach we focus on is sometimes referred to as "graph-based" parsing; a popular alternative is "transition-based" parsing, in which trees are constructed by making a series of incremental decisions (Yamada and Matsumoto, 2003; Attardi, 2006; Nivre et al., 2006; McDonald and Nivre, 2007). Transition-based parsers do not impose factorizations, so they can define arbitrary features on the tree as it is being built. As a result, however, they rely on greedy or approximate search algorithms to solve Eq. 1.

7 Parsing experiments

In order to evaluate the effectiveness of our parsers in practice, we apply them to the Penn WSJ Treebank (Marcus et al., 1993) and the Prague Dependency Treebank (Hajič et al., 2001; Hajič, 1998).[6] We use standard training, validation, and test splits[7] to facilitate comparisons. Accuracy is measured with unlabeled attachment score (UAS): the percentage of words with the correct head.[8]

7.1 Features for third-order parsing

Our parsing algorithms can be applied to scores originating from any source, but in our experiments we chose to use the framework of structured linear models, deriving our scores as:

$$\textsc{ScorePart}(\boldsymbol{x}, p) \;=\; \boldsymbol{w} \cdot \boldsymbol{f}(\boldsymbol{x}, p)$$

Here, $\boldsymbol{f}$ is a feature-vector mapping and $\boldsymbol{w}$ is a vector of associated parameters. Following standard practice for higher-order dependency parsing (McDonald and Pereira, 2006; Carreras, 2007), Models 1 and 2 evaluate not only the relevant third-order parts, but also the lower-order parts that are implicit in their third-order factorizations. For example, Model 1 defines feature mappings for dependencies, siblings, grandchildren, and grand-siblings, so that the score of a dependency parse is given by:

$$\begin{aligned}\textsc{Model1Score}(\boldsymbol{x}, y) \;=\; & \\ & \sum_{(h,m)\in y} \boldsymbol{w}_{\text{dep}} \cdot \boldsymbol{f}_{\text{dep}}(\boldsymbol{x}, h, m) \\ & \sum_{(h,m,s)\in y} \boldsymbol{w}_{\text{sib}} \cdot \boldsymbol{f}_{\text{sib}}(\boldsymbol{x}, h, m, s) \\ & \sum_{(g,h,m)\in y} \boldsymbol{w}_{\text{gch}} \cdot \boldsymbol{f}_{\text{gch}}(\boldsymbol{x}, g, h, m) \\ & \sum_{(g,h,m,s)\in y} \boldsymbol{w}_{\text{gsib}} \cdot \boldsymbol{f}_{\text{gsib}}(\boldsymbol{x}, g, h, m, s)\end{aligned}$$

Above, y is simultaneously decomposed into several different types of parts; trivial modifications to the Model 1 parser allow it to evaluate all of the necessary parts in an interleaved fashion. A similar treatment of Model 2 yields five feature mappings: the four above plus $\boldsymbol{f}_{\text{tsib}}(\boldsymbol{x}, h, m, s, t)$, which represents tri-sibling parts.

The lower-order feature mappings $\boldsymbol{f}_{\text{dep}}$, $\boldsymbol{f}_{\text{sib}}$, and $\boldsymbol{f}_{\text{gch}}$ are based on feature sets from previous work (McDonald et al., 2005a; McDonald and Pereira, 2006; Carreras, 2007), to which we added lexicalized versions of several features. For example, $\boldsymbol{f}_{\text{dep}}$ contains lexicalized "in-between" features that depend on the head and modifier words as well as a word lying in between the two; in contrast, previous work has generally defined in-between features for POS tags only. As another example, our

[6] For English, we extracted dependencies using Joakim Nivre's Penn2Malt tool with standard head rules (Yamada and Matsumoto, 2003); for Czech, we "projectivized" the training data by finding best-match projective trees.

[7] For Czech, the PDT has a predefined split; for English, we split the Sections as: 2–21 training, 22 validation, 23 test.

[8] As in previous work, English evaluation ignores any token whose gold-standard POS tag is one of {`` '' : , .}.

second-order mappings $\boldsymbol{f}_{\text{sib}}$ and $\boldsymbol{f}_{\text{gch}}$ define lexical trigram features, while previous work has generally used POS trigrams only.

Our third-order feature mappings $\boldsymbol{f}_{\text{gsib}}$ and $\boldsymbol{f}_{\text{tsib}}$ consist of four types of features. First, we define *4-gram features* that characterize the four relevant indices using words and POS tags; examples include POS 4-grams and mixed 4-grams with one word and three POS tags. Second, we define *4-gram context features* consisting of POS 4-grams augmented with adjacent POS tags: for example, $\boldsymbol{f}_{\text{gsib}}(\boldsymbol{x}, g, h, m, s)$ includes POS 7-grams for the tags at positions $(g, h, m, s, g{+}1, h{+}1, m{+}1)$. Third, we define *backed-off features* that track bigram and trigram interactions which are absent in the lower-order feature mappings: for example, $\boldsymbol{f}_{\text{tsib}}(\boldsymbol{x}, h, m, s, t)$ contains features predicated on the trigram (m, s, t) and the bigram (m, t), neither of which exist in any lower-order part. Fourth, noting that coordinations are typically annotated as grand-siblings (e.g., "report purchases and sales" in Figure 1), we define *coordination features* for certain grand-sibling parts. For example, $\boldsymbol{f}_{\text{gsib}}(\boldsymbol{x}, g, h, m, s)$ contains features examining the implicit head-modifier relationship (g, m) that are only activated when the POS tag of s is a coordinating conjunction.

Finally, we make two brief remarks regarding the use of POS tags. First, we assume that input sentences have been automatically tagged in a preprocessing step.[9] Second, for any feature that depends on POS tags, we include *two* copies of the feature: one using normal POS tags and another using coarsened versions[10] of the POS tags.

7.2 Averaged perceptron training

There are a wide variety of parameter estimation methods for structured linear models, such as log-linear models (Lafferty et al., 2001) and max-margin models (Taskar et al., 2003). We chose the averaged structured perceptron (Freund and Schapire, 1999; Collins, 2002) as it combines highly competitive performance with fast training times, typically converging in 5–10 iterations. We train each parser for 10 iterations and select parameters from the iteration that achieves the best score on the validation set.

Beam	Pass	Orac	Acc1	Acc2	Time1	Time2
0.0001	26.5	99.92	93.49	93.49	49.6m	73.5m
0.001	16.7	99.72	93.37	93.29	25.9m	24.2m
0.01	9.1	99.19	93.26	93.16	6.7m	7.9m

Table 1: Effect of the marginal-probability beam on English parsing. For each beam value, parsers were trained on the English training set and evaluated on the English validation set; the same beam value was applied to both training and validation data. **Pass** = %dependencies surviving the beam in training data, **Orac** = maximum achievable UAS on validation data, **Acc1/Acc2** = UAS of Models 1/2 on validation data, and **Time1/Time2** = minutes per perceptron training iteration for Models 1/2, averaged over all 10 iterations. For perspective, the English training set has a total of 39,832 sentences and 950,028 words. A beam of 0.0001 was used in all experiments outside this table.

7.3 Coarse-to-fine pruning

In order to decrease training times, we follow Carreras et al. (2008) and eliminate unlikely dependencies using a form of coarse-to-fine pruning (Charniak and Johnson, 2005; Petrov and Klein, 2007). In brief, we train a log-linear first-order parser[11] and for every sentence $\boldsymbol{x}$ in training, validation, and test data we compute the marginal probability $P(h, m \mid \boldsymbol{x})$ of each dependency. Our parsers are then modified to ignore any dependency (h, m) whose marginal probability is below $0.0001 \times \max_{h'} P(h', m \mid \boldsymbol{x})$. Table 1 provides information on the behavior of the pruning method.

7.4 Main results

Table 2 lists the accuracy of Models 1 and 2 on the English and Czech test sets, together with some relevant results from related work.[12] The models marked "†" are *not* directly comparable to our work as they depend on additional sources of information that our models are trained without—unlabeled data in the case of Koo et al. (2008) and

[9] For Czech, the PDT provides automatic tags; for English, we used MXPOST (Ratnaparkhi, 1996) to tag validation and test data, with 10-fold cross-validation on the training set. Note that the reliance on POS-tagged input can be relaxed slightly by treating POS tags as word senses; see Section 5.3 and McDonald (2006, Table 6.1).

[10] For Czech, we used the first character of the tag; for English, we used the first two characters, except `PRP` and `PRP$`.

[11] For English, we generate marginals using a projective parser (Baker, 1979; Eisner, 2000); for Czech, we generate marginals using a non-projective parser (Smith and Smith, 2007; McDonald and Satta, 2007; Koo et al., 2007). Parameters for these models are obtained by running exponentiated gradient training for 10 iterations (Collins et al., 2008).

[12] Model 0 was not tested as its factorization is a strict subset of the factorization of Model 1.

Suzuki et al. (2009) and phrase-structure annotations in the case of Carreras et al. (2008). All three of the "†" models are based on versions of the Carreras (2007) parser, so modifying these methods to work with our new third-order parsing algorithms would be an interesting topic for future research. For example, Models 1 and 2 obtain results comparable to the semi-supervised parsers of Koo et al. (2008), and additive gains might be realized by applying their cluster-based feature sets to our enriched factorizations.

7.5 Ablation studies

In order to better understand the contributions of the various feature types, we ran additional ablation experiments; the results are listed in Table 3, in addition to the scores of Model 0 and the emulated Carreras (2007) parser (see Section 4.3). Interestingly, grandchild interactions appear to provide important information: for example, when Model 2 is used without grandchild-based features ("Model 2, no-G" in Table 3), its accuracy suffers noticeably. In addition, it seems that grandchild interactions are particularly useful in Czech, while sibling interactions are less important: consider that Model 0, a second-order grandchild parser with no sibling-based features, can easily outperform "Model 2, no-G," a *third*-order sibling parser with no grandchild-based features.

8 Conclusion

We have presented new parsing algorithms that are capable of efficiently parsing third-order factorizations, including both grandchild and sibling interactions. Due to space restrictions, we have been necessarily brief at some points in this paper; some additional details can be found in Koo (2010).

Parser	Eng	Cze
Model 0	93.07	87.39
Carreras (2007) emulation	93.14	87.25
Model 1	93.49	87.64
Model 1, no-3rd	93.17	87.57
Model 2	93.49	87.46
Model 2, no-3rd	93.20	87.43
Model 2, no-G	92.92	86.76

Table 3: UAS for modified versions of our parsers on validation data. The term **no-3rd** indicates a parser that was trained and tested with the third-order feature mappings $\boldsymbol{f}_{\text{gsib}}$ and $\boldsymbol{f}_{\text{tsib}}$ deactivated, though lower-order features were retained; note that "Model 2, no-3rd" is not identical to the Carreras (2007) parser as it defines grandchild parts for the pair of grandchildren. The term **no-G** indicates a parser that was trained and tested with the grandchild-based feature mappings $\boldsymbol{f}_{\text{gch}}$ and $\boldsymbol{f}_{\text{gsib}}$ deactivated; note that "Model 2, no-G" emulates the third-order sibling parser proposed by McDonald and Pereira (2006).

There are several possibilities for further research involving our third-order parsing algorithms. One idea would be to consider extensions and modifications of our parsers, some of which have been suggested in Sections 5 and 7.4. A second area for future work lies in applications of dependency parsing. While we have evaluated our new algorithms on standard parsing benchmarks, there are a wide variety of tasks that may benefit from the extended context offered by our third-order factorizations; for example, the 4-gram substructures enabled by our approach may be useful for dependency-based language modeling in machine translation (Shen et al., 2008). Finally, in the hopes that others in the NLP community may find our parsers useful, we provide a free distribution of our implementation.[2]

Acknowledgments

We would like to thank the anonymous reviewers for their helpful comments and suggestions. We also thank Regina Barzilay and Alexander Rush for their much-appreciated input during the writing process. The authors gratefully acknowledge the following sources of support: Terry Koo and Michael Collins were both funded by a DARPA subcontract under SRI (#27-001343), and Michael Collins was additionally supported by NTT (Agmt. dtd. 06/21/98).

Abstract

In this paper we describe an intuitionistic method for dependency parsing, where a classifier is used to determine whether a pair of words forms a dependency edge. And we also propose an effective strategy for dependency projection, where the dependency relationships of the word pairs in the source language are projected to the word pairs of the target language, leading to a set of classification instances rather than a complete tree. Experiments show that, the classifier trained on the projected classification instances significantly outperforms previous projected dependency parsers. More importantly, when this classifier is integrated into a maximum spanning tree (MST) dependency parser, obvious improvement is obtained over the MST baseline.

1 Introduction

Supervised dependency parsing achieves the state-of-the-art in recent years (McDonald et al., 2005a; McDonald and Pereira, 2006; Nivre et al., 2006). Since it is costly and difficult to build human-annotated treebanks, a lot of works have also been devoted to the utilization of unannotated text. For example, the unsupervised dependency parsing (Klein and Manning, 2004) which is totally based on unannotated data, and the semisupervised dependency parsing (Koo et al., 2008) which is based on both annotated and unannotated data. Considering the higher complexity and lower performance in unsupervised parsing, and the need of reliable priori knowledge in semisupervised parsing, it is a promising strategy to project the dependency structures from a resource-rich language to a resource-scarce one across a bilingual corpus (Hwa et al., 2002; Hwa et al., 2005; Ganchev et al., 2009; Smith and Eisner, 2009; Jiang et al., 2009).

For dependency projection, the relationship between words in the parsed sentences can be simply projected across the word alignment to words in the unparsed sentences, according to the DCA assumption (Hwa et al., 2005). Such a projection procedure suffers much from the word alignment errors and syntactic isomerism between languages, which usually lead to relationship projection conflict and incomplete projected dependency structures. To tackle this problem, Hwa et al. (2005) use some filtering rules to reduce noise, and some hand-designed rules to handle language heterogeneity. Smith and Eisner (2009) perform dependency projection and annotation adaptation with quasi-synchronous grammar features. Jiang and Liu (2009) resort to a dynamic programming procedure to search for a completed projected tree. However, these strategies are all confined to the same category that dependency projection must produce completed projected trees. Because of the free translation, the syntactic isomerism between languages and word alignment errors, it would be strained to completely project the dependency structure from one language to another.

We propose an effective method for dependency projection, which does not have to produce complete projected trees. Given a word-aligned bilingual corpus with source language sentences parsed, the dependency relationships of the word pairs in the source language are projected to the word pairs of the target language. A dependency relationship is a boolean value that represents whether this word pair forms a dependency edge. Thus a set of classification instances are obtained. Meanwhile, we propose an intuitionistic model for dependency parsing, which uses a classifier to determine whether a pair of words form a dependency edge. The classifier can then be trained on the projected classification instance set, so as to build a projected dependency parser without the need of complete projected trees.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 12–20,
Uppsala, Sweden, 11-16 July 2010.

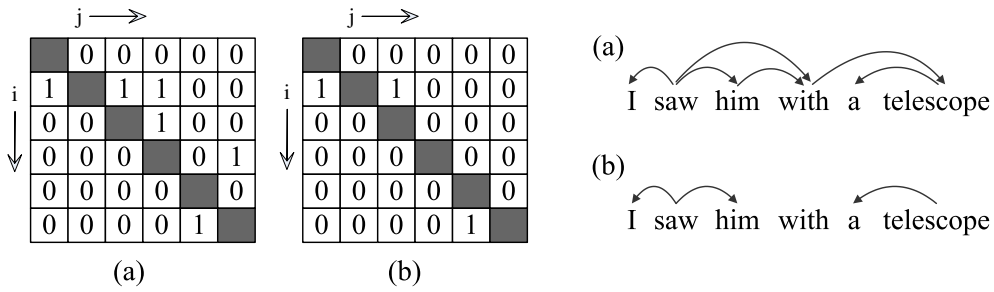

Figure 1: Illegal (a) and incomplete (b) dependency tree produced by the simple-collection method.

Experimental results show that, the classifier trained on the projected classification instances significantly outperforms the projected dependency parsers in previous works. The classifier trained on the Chinese projected classification instances achieves a precision of 58.59% on the CTB standard test set. More importantly, when this classifier is integrated into a 2nd-ordered maximum spanning tree (MST) dependency parser (McDonald and Pereira, 2006) in a weighted average manner, significant improvement is obtained over the MST baselines. For the 2nd-order MST parser trained on Penn Chinese Treebank (CTB) 5.0, the classifier give an precision increment of 0.5 points. Especially for the parser trained on the smaller CTB 1.0, more than 1 points precision increment is obtained.

In the rest of this paper, we first describe the word-pair classification model for dependency parsing (section 2) and the generation method of projected classification instances (section 3). Then we describe an application of the projected parser: boosting a state-of-the-art 2nd-ordered MST parser (section 4). After the comparisons with previous works on dependency parsing and projection, we finally five the experimental results.

2 Word-Pair Classification Model

2.1 Model Definition

Following (McDonald et al., 2005a), $\mathbf{x}$ is used to denote the sentence to be parsed, and x_i to denote the i-th word in the sentence. $\mathbf{y}$ denotes the dependency tree for sentence $\mathbf{x}$, and $(i,j) \in \mathbf{y}$ represents a dependency edge from word x_i to word x_j, where x_i is the parent of x_j.

The task of the word-pair classification model is to determine whether any candidate word pair, x_i and x_j s.t. $1 \leq i,j \leq |\mathbf{x}|$ and $i \neq j$, forms a dependency edge. The classification result $\mathcal{C}(i,j)$ can be a boolean value:

$$\mathcal{C}(i,j) = p \qquad p \in \{0,1\} \tag{1}$$

as produced by a support vector machine (SVM) classifier (Vapnik, 1998). $p = 1$ indicates that the classifier supports the candidate edge (i,j), and $p = 0$ the contrary. $\mathcal{C}(i,j)$ can also be a real-valued probability:

$$\mathcal{C}(i,j) = p \qquad 0 \leq p \leq 1 \tag{2}$$

as produced by an maximum entropy (ME) classifier (Berger et al., 1996). p is a probability which indicates the degree the classifier support the candidate edge (i,j). Ideally, given the classification results for all candidate word pairs, the dependency parse tree can be composed of the candidate edges with higher score (1 for the boolean-valued classifier, and large p for the real-valued classifier). However, more robust strategies should be investigated since the ambiguity of the language syntax and the classification errors usually lead to illegal or incomplete parsing result, as shown in Figure 1.

Follow the edge based factorization method (Eisner, 1996), we factorize the score of a dependency tree $\mathbf{s}(\mathbf{x},\mathbf{y})$ into its dependency edges, and design a dynamic programming algorithm to search for the candidate parse with maximum score. This strategy alleviate the classification errors to some degree and ensure a valid, complete dependency parsing tree. If a boolean-valued classifier is used, the search algorithm can be formalized as:

$$\begin{aligned} \tilde{\mathbf{y}} &= \operatorname*{argmax}_{\mathbf{y}} \mathbf{s}(\mathbf{x},\mathbf{y}) \\ &= \operatorname*{argmax}_{\mathbf{y}} \sum_{(i,j)\in\mathbf{y}} \mathcal{C}(i,j) \end{aligned} \tag{3}$$

And if a probability-valued classifier is used instead, we replace the accumulation with cumula-

Type	Features		
Unigram	$word_i \circ pos_i$	$word_i$	pos_i
	$word_j \circ pos_j$	$word_j$	pos_j
Bigram	$word_i \circ pos_i \circ word_j \circ pos_j$	$pos_i \circ word_j \circ pos_j$	$word_i \circ word_j \circ pos_j$
	$word_i \circ pos_i \circ pos_j$	$word_i \circ pos_i \circ word_j$	$word_i \circ word_j$
	$pos_i \circ pos_j$	$word_i \circ pos_j$	$pos_i \circ word_j$
Surrounding	$pos_i \circ pos_{i+1} \circ pos_{j-1} \circ pos_j$	$pos_{i-1} \circ pos_i \circ pos_{j-1} \circ pos_j$	$pos_i \circ pos_{i+1} \circ pos_j \circ pos_{j+1}$
	$pos_{i-1} \circ pos_i \circ pos_j \circ pos_{j+1}$	$pos_{i-1} \circ pos_i \circ pos_{j-1}$	$pos_{i-1} \circ pos_i \circ pos_{j+1}$
	$pos_i \circ pos_{i+1} \circ pos_{j-1}$	$pos_i \circ pos_{i+1} \circ pos_{j+1}$	$pos_{i-1} \circ pos_{j-1} \circ pos_j$
	$pos_{i-1} \circ pos_j \circ pos_{j+1}$	$pos_{i+1} \circ pos_{j-1} \circ pos_j$	$pos_{i+1} \circ pos_j \circ pos_{j+1}$
	$pos_i \circ pos_{j-1} \circ pos_j$	$pos_i \circ pos_j \circ pos_{j+1}$	$pos_{i-1} \circ pos_i \circ pos_j$
	$pos_i \circ pos_{i+1} \circ pos_j$		

Table 1: Feature templates for the word-pair classification model.

tive product:

$$\begin{aligned} \tilde{\mathbf{y}} &= \operatorname*{argmax}_{\mathbf{y}} \mathbf{s}(\mathbf{x}, \mathbf{y}) \\ &= \operatorname*{argmax}_{\mathbf{y}} \prod_{(i,j)\in\mathbf{y}} \mathcal{C}(i,j) \end{aligned} \tag{4}$$

Where y is searched from the set of well-formed dependency trees.

In our work we choose a real-valued ME classifier. Here we give the calculation of dependency probability $\mathcal{C}(i,j)$. We use $\mathbf{w}$ to denote the parameter vector of the ME model, and $\mathbf{f}(i,j,r)$ to denote the feature vector for the *assumption* that the word pair i and j has a dependency relationship r. The symbol r indicates the supposed classification result, where $r = +$ means we suppose it as a dependency edge and $r = -$ means the contrary. A feature $\mathbf{f}_k(i,j,r) \in \mathbf{f}(i,j,r)$ equals 1 if it is activated by the assumption and equals 0 otherwise. The dependency probability can then be defined as:

$$\begin{aligned} \mathcal{C}(i,j) &= \frac{exp(\mathbf{w}\cdot\mathbf{f}(i,j,+))}{\sum_r exp(\mathbf{w}\cdot\mathbf{f}(i,j,r))} \\ &= \frac{exp(\sum_k \mathbf{w}_k \times \mathbf{f}_k(i,j,+))}{\sum_r exp(\sum_k \mathbf{w}_k \times \mathbf{f}_k(i,j,r))} \end{aligned} \tag{5}$$

2.2 Features for Classification

The feature templates for the classifier are similar to those of 1st-ordered MST model (McDonald et al., 2005a). [1] Each feature is composed of some words and POS tags surrounded word i and/or word j, as well as an optional distance representations between this two words. Table shows the feature templates we use.

Previous graph-based dependency models usually use the index distance of word i and word j to enrich the features with word distance information. However, in order to utilize some syntax information between the pair of words, we adopt the syntactic distance representation of (Collins, 1996), named *Collins distance* for convenience. A Collins distance comprises the answers of 6 questions:

- Does word i precede or follow word j?
- Are word i and word j adjacent?
- Is there a verb between word i and word j?
- Are there 0, 1, 2 or more than 2 commas between word i and word j?
- Is there a comma immediately following the first of word i and word j?
- Is there a comma immediately preceding the second of word i and word j?

Besides the original features generated according to the templates in Table 1, the enhanced features with Collins distance as postfixes are also used in training and decoding of the word-pair classifier.

2.3 Parsing Algorithm

We adopt logarithmic dependency probabilities in decoding, therefore the cumulative product of probabilities in formula 6 can be replaced by accumulation of logarithmic probabilities:

$$\begin{aligned} \tilde{\mathbf{y}} &= \operatorname*{argmax}_{\mathbf{y}} \mathbf{s}(\mathbf{x}, \mathbf{y}) \\ &= \operatorname*{argmax}_{\mathbf{y}} \prod_{(i,j)\in\mathbf{y}} \mathcal{C}(i,j) \\ &= \operatorname*{argmax}_{\mathbf{y}} \sum_{(i,j)\in\mathbf{y}} log(\mathcal{C}(i,j)) \end{aligned} \tag{6}$$

Thus, the decoding algorithm for 1st-ordered MST model, such as the Chu-Liu-Edmonds algorithm

[1] We exclude the *in between* features of McDonald et al. (2005a) since preliminary experiments show that these features bring no improvement to the word-pair classification model.

12: $\quad d \cdot evl \leftarrow$ EVAL(d) ▷ evaluation function
13: $\quad$ **return** d

used in McDonald et al. (2005b), is also applicable here. In this work, however, we still adopt the more general, bottom-up dynamic programming algorithm Algorithm 1 in order to facilitate the possible expansions. Here, $\mathbf{V}[i,j]$ contains the candidate parsing segments of the span $[i,j]$, and the function EVAL(d) accumulates the scores of all the edges in dependency segment d. In practice, the cube-pruning strategy (Huang and Chiang, 2005) is used to speed up the enumeration of derivations (loops started by line 4 and 5).

3 Projected Classification Instance

After the introduction of the word-pair classification model, we now describe the extraction of projected dependency instances. In order to alleviate the effect of word alignment errors, we base the projection on the alignment matrix, a compact representation of multiple GIZA++ (Och and Ney, 2000) results, rather than a single word alignment in previous dependency projection works. Figure 2 shows an example.

Suppose a bilingual sentence pair, composed of a source sentence $\mathbf{e}$ and its target translation $\mathbf{f}$. $\mathbf{y_e}$ is the parse tree of the source sentence. $\mathbf{A}$ is the alignment matrix between them, and each element $\mathbf{A}_{i,j}$ denotes the degree of the alignment between word $\mathbf{e}_i$ and word $\mathbf{f}_j$. We define a boolean-valued function $\delta(\mathbf{y}, i, j, r)$ to investigate the dependency relationship of word i and word j in parse tree $\mathbf{y}$:

$$\delta(\mathbf{y},i,j,r) = \begin{cases} 1 & (i,j) \in \mathbf{y} \textbf{ and } r = + \\ & \quad \textbf{or} \\ & (i,j) \notin \mathbf{y} \textbf{ and } r = - \\ 0 & \textbf{otherwise} \end{cases} \quad (7)$$

Then the score that word i and word j in the target sentence $\mathbf{y}$ forms a projected dependency edge, $\mathbf{s}_+(i,j)$, can be defined as:

$$\mathbf{s}_+(i,j) = \sum_{i',j'} \mathbf{A}_{i,i'} \times \mathbf{A}_{j,j'} \times \delta(\mathbf{y_e}, i', j', +) \quad (8)$$

The score that they do not form a projected dependency edge can be defined similarly:

$$\mathbf{s}_-(i,j) = \sum_{i',j'} \mathbf{A}_{i,i'} \times \mathbf{A}_{j,j'} \times \delta(\mathbf{y_e}, i', j', -) \quad (9)$$

Note that for simplicity, the condition factors $\mathbf{y_e}$ and $\mathbf{A}$ are omitted from these two formulas. We finally define the probability of the supposed projected dependency edge as:

$$\mathcal{C}_p(i,j) = \frac{exp(\mathbf{s}_+(i,j))}{exp(\mathbf{s}_+(i,j)) + exp(\mathbf{s}_-(i,j))} \quad (10)$$

The probability $\mathcal{C}_p(i,j)$ is a real value between 0 and 1. Obviously, $\mathcal{C}_p(i,j) = 0.5$ indicates the most ambiguous case, where we can not distinguish between positive and negative at all. On the other hand, there are as many as $2|\mathbf{f}|(|\mathbf{f}|-1)$ candidate projected dependency instances for the target sentence $\mathbf{f}$. Therefore, we need choose a threshold b for $\mathcal{C}_p(i,j)$ to filter out the ambiguous instances: the instances with $\mathcal{C}_p(i,j) > b$ are selected as the positive, and the instances with $\mathcal{C}_p(i,j) < 1-b$ are selected as the negative.

4 Boosting an MST Parser

The classifier can be used to boost a existing parser trained on human-annotated trees. We first establish a unified framework for the enhanced parser. For a sentence to be parsed, $\mathbf{x}$, the enhanced parser selects the best parse $\tilde{\mathbf{y}}$ according to both the baseline model $\mathbb{B}$ and the projected classifier $\mathbb{C}$.

$$\tilde{\mathbf{y}} = \underset{\mathbf{y}}{\text{argmax}}[\mathbf{s}_{\mathbb{B}}(\mathbf{x},\mathbf{y}) + \lambda \mathbf{s}_{\mathbb{C}}(\mathbf{x},\mathbf{y})] \quad (11)$$

Here, $\mathbf{s}_{\mathbb{B}}$ and $\mathbf{s}_{\mathbb{C}}$ denote the evaluation functions of the baseline model and the projected classifier, respectively. The parameter λ is the relative weight of the projected classifier against the baseline model.

There are several strategies to integrate the two evaluation functions. For example, they can be integrated deeply at each decoding step (Carreras et al., 2008; Zhang and Clark, 2008; Huang, 2008), or can be integrated shallowly in a reranking manner (Collins, 2000; Charniak and Johnson, 2005). As described previously, the score of a dependency tree given by a word-pair classifier can be factored into each candidate dependency edge in this tree. Therefore, the projected classifier can be integrated with a baseline model deeply at each dependency edge, if the evaluation score given by the baseline model can also be factored into dependency edges.

We choose the 2nd-ordered MST model (McDonald and Pereira, 2006) as the baseline. Especially, the effect of the Collins distance in the baseline model is also investigated. The relative weight λ is adjusted to maximize the performance on the development set, using an algorithm similar to minimum error-rate training (Och, 2003).

5.1 Dependency Parsing

Both the graph-based (McDonald et al., 2005a; McDonald and Pereira, 2006; Carreras et al., 2006) and the transition-based (Yamada and Matsumoto, 2003; Nivre et al., 2006) parsing algorithms are related to our word-pair classification model.

Similar to the graph-based method, our model is factored on dependency edges, and its decoding procedure also aims to find a maximum spanning tree in a fully connected directed graph. From this point, our model can be classified into the graph-based category. On the training method, however, our model obviously differs from other graph-based models, that we only need a set of word-pair dependency instances rather than a regular dependency treebank. Therefore, our model is more suitable for the partially bracketed or noisy training corpus.

The most apparent similarity between our model and the transition-based category is that they all need a classifier to perform classification conditioned on a certain configuration. However, they differ from each other in the classification results. The classifier in our model predicates a dependency probability for each pair of words, while the classifier in a transition-based model gives a possible next transition operation such as *shift* or *reduce*. Another difference lies in the factorization strategy. For our method, the evaluation score of a candidate parse is factorized into each dependency edge, while for the transition-based models, the score is factorized into each transition operation.

Thanks to the reminding of the third reviewer of our paper, we find that the pairwise classification schema has also been used in Japanese dependency parsing (Uchimoto et al., 1999; Kudo and Matsumoto, 2000). However, our work shows more advantage in feature engineering, model training and decoding algorithm.

5.2 Dependency Projection

Many works try to learn parsing knowledge from bilingual corpora. Lü et al. (2002) aims to obtain Chinese bracketing knowledge via ITG (Wu, 1997) alignment. Hwa et al. (2005) and Ganchev et al. (2009) induce dependency grammar via projection from aligned bilingual corpora, and use some thresholds to filter out noise and some hand-written rules to handle heterogeneity. Smith and Eisner (2009) perform dependency projection and annotation adaptation with Quasi-Synchronous Grammar features. Jiang and Liu (2009) refer to alignment matrix and a dynamic programming search algorithm to obtain better projected dependency trees.

All previous works for dependency projection (Hwa et al., 2005; Ganchev et al., 2009; Smith and Eisner, 2009; Jiang and Liu, 2009) need complete projected trees to train the projected parsers. Because of the free translation, the word alignment errors, and the heterogeneity between two languages, it is reluctant and less effective to project the dependency tree completely to the target language sentence. On the contrary, our dependency projection strategy prefer to extract a set of dependency instances, which coincides our model's demand for training corpus. An obvious advantage of this strategy is that, we can select an appropriate filtering threshold to obtain dependency instances of good quality.

In addition, our word-pair classification model can be integrated deeply into a state-of-the-art MST dependency model. Since both of them are

Corpus	Train	Dev	Test

factorized into dependency edges, the integration can be conducted at each dependency edge, by weightedly averaging their evaluation scores for this dependency edge. This strategy makes better use of the projected parser while with faster decoding, compared with the cascaded approach of Jiang and Liu (2009).

6 Experiments

In this section, we first validate the word-pair classification model by experimenting on human-annotated treebanks. Then we investigate the effectiveness of the dependency projection by evaluating the projected classifiers trained on the projected classification instances. Finally, we report the performance of the integrated dependency parser which integrates the projected classifier and the 2nd-ordered MST dependency parser. We evaluate the parsing accuracy by the precision of lexical heads, which is the percentage of the words that have found their correct parents.

6.1 Word-Pair Classification Model

We experiment on two popular treebanks, the Wall Street Journal (WSJ) portion of the Penn English Treebank (Marcus et al., 1993), and the Penn Chinese Treebank (CTB) 5.0 (Xue et al., 2005). The constituent trees in the two treebanks are transformed to dependency trees according to the head-finding rules of Yamada and Matsumoto (2003). For English, we use the automatically-assigned POS tags produced by an implementation of the POS tagger of Collins (2002). While for Chinese, we just use the gold-standard POS tags following the tradition. Each treebank is splitted into three partitions, for training, development and testing, respectively, as shown in Table 2.

For a dependency tree with n words, only $n-1$ positive dependency instances can be extracted. They account for only a small proportion of all the dependency instances. As we know, it is important to balance the proportions of the positive and the negative instances for a batched-trained classifier. We define a new parameter r to denote the ratio of the negative instances relative to the positive ones.

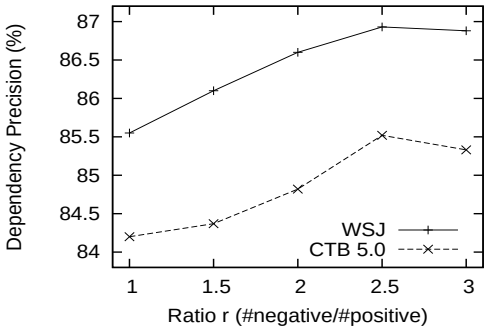

Figure 3: Performance curves of the word-pair classification model on the development sets of WSJ and CTB 5.0, with respect to a series of ratio r.

Corpus	System	P %

	Nivre and Scholz (2004)	87.3
	1st-ordered MST	90.7
	2nd-ordered MST	91.5
	our model	86.8
CTB 5.0	1st-ordered MST	86.53
	2nd-ordered MST	87.15
	our model	82.06

Table 3: Performance of the word-pair classification model on WSJ and CTB 5.0, compared with the current state-of-the-art models.

For example, $r = 2$ means we reserve negative instances two times as many as the positive ones.

The MaxEnt toolkit by Zhang [2] is adopted to train the ME classifier on extracted instances. We set the gaussian prior as 1.0 and the iteration limit as 100, leaving other parameters as default values. We first investigate the impact of the ratio r on the performance of the classifier. Curves in Figure 3 show the performance of the English and Chinese parsers, each of which is trained on an instance set corresponding to a certain r. We find that for both English and Chinese, maximum performance is achieved at about $r = 2.5$. [3] The English and Chinese classifiers trained on the instance sets with $r = 2.5$ are used in the final evaluation phase. Table 3 shows the performances on the test sets of WSJ and CTB 5.0.

We also compare them with previous works on the same test sets. On both English and Chinese, the word-pair classification model falls behind of the state-of-the-art. We think that it is probably

[2] http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html.

[3] We did not investigate more fine-grained ratios, since the performance curves show no dramatic fluctuation along with the alteration of r.

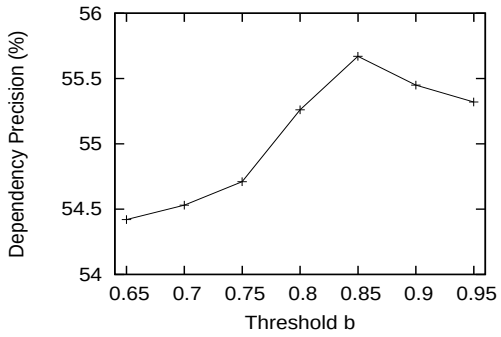

Figure 4: The performance curve of the word-pair classification model on the development set of CTB 5.0, with respect to a series of threshold b.

due to the local optimization of the training procedure. Given complete trees as training data, it is easy for previous models to utilize structural, global and linguistical information in order to obtain more powerful parameters. The main advantage of our model is that it doesn't need complete trees to tune its parameters. Therefore, if trained on instances extracted from human-annotated treebanks, the word-pair classification model would not demonstrate its advantage over existed state-of-the-art dependency parsing methods.

6.2 Dependency Projection

In this work we focus on the dependency projection from English to Chinese. We use the FBIS Chinese-English bitext as the bilingual corpus for dependency projection. It contains 239K sentence pairs with about 6.9M/8.9M words in Chinese/English. Both English and Chinese sentences are tagged by the implementations of the POS tagger of Collins (2002), which trained on WSJ and CTB 5.0 respectively. The English sentences are then parsed by an implementation of 2nd-ordered MST model of McDonald and Pereira (2006), which is trained on dependency trees extracted from WSJ. The alignment matrixes for sentence pairs are generated according to (Liu et al., 2009).

Similar to the ratio r, the threshold b need also be assigned an appropriate value to achieve a better performance. Larger thresholds result in better but less classification instances, the lower coverage of the instances would hurt the performance of the classifier. On the other hand, smaller thresholds lead to worse but more instances, and too much noisy instances will bring down the classifier's discriminating power.

We extract a series of classification instance sets with different thresholds. Then, on each instance set we train a classifier and test it on the development set of CTB 5.0. Figure 4 presents the experimental results. The curve shows that the maximum performance is achieved at the threshold of about 0.85. The classifier corresponding to this threshold is evaluated on the test set of CTB 5.0, and the test set of CTB 2.0 determined by Hwa et al. (2005). Table 4 shows the performance of the projected classifier, as well as the performance of previous works on the corresponding test sets. The projected classifier significantly outperforms previous works on both test sets, which demonstrates that the word-pair classification model, although falling behind of the state-of-the-art on human-annotated treebanks, performs well in projected dependency parsing. We give the credit to its good collaboration with the word-pair classification instance extraction for dependency projection.

6.3 Integrated Dependency Parser

We integrate the word-pair classification model into the state-of-the-art 2nd-ordered MST model. First, we implement a chart-based dynamic programming parser for the 2nd-ordered MST model, and develop a training procedure based on the perceptron algorithm with averaged parameters (Collins, 2002). On the WSJ corpus, this parser achieves the same performance as that of McDonald and Pereira (2006). Then, at each derivation step of this 2nd-ordered MST parser, we weightedly add the evaluation score given by the projected classifier to the original MST evaluation score. Such a weighted summation of two eval-

uation scores provides better evaluation for candidate parses. The weight parameter λ is tuned by a minimum error-rate training algorithm (Och, 2003).

Given a 2nd-ordered MST parser trained on CTB 5.0 as the baseline, the projected classifier brings an accuracy improvement of about 0.5 points. For the baseline trained on the smaller CTB 1.0, whose training set is chapters 1-270 of CTB 5.0, the accuracy improvement is much significant, about 1.5 points over the baseline. It indicates that, the smaller the human-annotated treebank we have, the more significant improvement we can achieve by integrating the projecting classifier. This provides a promising strategy for boosting the parsing performance of resource-scarce languages. Table 5 summarizes the experimental results.

7 Conclusion and Future Works

In this paper, we first describe an intuitionistic method for dependency parsing, which resorts to a classifier to determine whether a word pair forms a dependency edge, and then propose an effective strategy for dependency projection, which produces a set of projected classification instances rather than complete projected trees. Although this parsing method falls behind of previous models, it can collaborate well with the word-pair classification instance extraction strategy for dependency projection, and achieves the state-of-the-art in projected dependency parsing. In addition, when integrated into a 2nd-ordered MST parser, the projected parser brings significant improvement to the baseline, especially for the baseline trained on smaller treebanks. This provides a new strategy for resource-scarce languages to train high-precision dependency parsers. However, considering its lower performance on human-annotated treebanks, the dependency parsing method itself still need a lot of investigations, especially on the training method of the classifier.

Abstract

This paper proposes a dependency parsing method that uses bilingual constraints to improve the accuracy of parsing bilingual texts (bitexts). In our method, a target-side tree fragment that corresponds to a source-side tree fragment is identified via word alignment and mapping rules that are automatically learned. Then it is verified by checking the subtree list that is collected from large scale automatically parsed data on the target side. Our method, thus, requires gold standard trees only on the source side of a bilingual corpus in the training phase, unlike the joint parsing model, which requires gold standard trees on the both sides. Compared to the re-ordering constraint model, which requires the same training data as ours, our method achieved higher accuracy because of richer bilingual constraints. Experiments on the translated portion of the Chinese Treebank show that our system outperforms monolingual parsers by 2.93 points for Chinese and 1.64 points for English.

1 Introduction

Parsing bilingual texts (bitexts) is crucial for training machine translation systems that rely on syntactic structures on either the source side or the target side, or the both (Ding and Palmer, 2005; Nakazawa et al., 2006). Bitexts could provide more information, which is useful in parsing, than a usual monolingual texts that can be called "bilingual constraints", and we expect to obtain more accurate parsing results that can be effectively used in the training of MT systems. With this motivation, there are several studies aiming at highly accurate bitext parsing (Smith and Smith, 2004; Burkett and Klein, 2008; Huang et al., 2009).

This paper proposes a dependency parsing method, which uses the bilingual constraints that we call *bilingual subtree constraints* and statistics concerning the constraints estimated from large unlabeled monolingual corpora. Basically, a (candidate) dependency subtree in a source-language sentence is mapped to a subtree in the corresponding target-language sentence by using word alignment and mapping rules that are automatically learned. The target subtree is verified by checking the subtree list that is collected from unlabeled sentences in the target language parsed by a usual monolingual parser. The result is used as additional features for the source side dependency parser. In this paper, our task is to improve the source side parser with the help of the translations on the target side.

Many researchers have investigated the use of bilingual constraints for parsing (Burkett and Klein, 2008; Zhao et al., 2009; Huang et al., 2009). For example, Burkett and Klein (2008) show that parsing with joint models on bitexts improves performance on either or both sides. However, their methods require that the training data have tree structures on both sides, which are hard to obtain. Our method only requires dependency annotation on the source side and is much simpler and faster. Huang et al. (2009) proposes a method, bilingual-constrained monolingual parsing, in which a source-language parser is extended to use the re-ordering of words between two sides' sentences as additional information. The input of their method is the source trees with their translation on the target side as ours, which is much easier to obtain than trees on both sides. However, their method does not use any tree structures on

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 21–29,
Uppsala, Sweden, 11-16 July 2010.

the target side that might be useful for ambiguity resolution. Our method achieves much greater improvement because it uses the richer subtree constraints.

Our approach takes the same input as Huang et al. (2009) and exploits the subtree structure on the target side to provide the bilingual constraints. The subtrees are extracted from large-scale auto-parsed monolingual data on the target side. The main problem to be addressed is mapping words on the source side to the target subtree because there are many to many mappings and reordering problems that often occur in translation (Koehn et al., 2003). We use an automatic way for generating mapping rules to solve the problems. Based on the mapping rules, we design a set of features for parsing models. The basic idea is as follows: if the words form a subtree on one side, their corresponding words on the another side will also probably form a subtree.

Experiments on the translated portion of the Chinese Treebank (Xue et al., 2002; Bies et al., 2007) show that our system outperforms state-of-the-art monolingual parsers by 2.93 points for Chinese and 1.64 points for English. The results also show that our system provides higher accuracies than the parser of Huang et al. (2009).

The rest of the paper is organized as follows: Section 2 introduces the motivation of our idea. Section 3 introduces the background of dependency parsing. Section 4 proposes an approach of constructing bilingual subtree constraints. Section 5 explains the experimental results. Finally, in Section 6 we draw conclusions and discuss future work.

2 Motivation

In this section, we use an example to show the idea of using the bilingual subtree constraints to improve parsing performance.

Suppose that we have an input sentence pair as shown in Figure 1, where the source sentence is in English, the target is in Chinese, the dashed undirected links are word alignment links, and the directed links between words indicate that they have a (candidate) dependency relation.

In the English side, it is difficult for a parser to determine the head of word "with" because there is a PP-attachment problem. However, in Chinese it is unambiguous. Therefore, we can use the information on the Chinese side to help disambiguation.

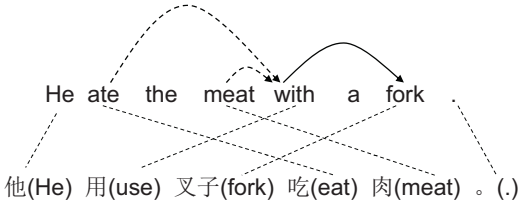

Figure 1: Example for disambiguation

There are two candidates "ate" and "meat" to be the head of "with" as the dashed directed links in Figure 1 show. By adding "fork", we have two possible dependency relations, "meat-with-fork" and "ate-with-fork", to be verified.

First, we check the possible relation of "meat", "with", and "fork". We obtain their corresponding words "肉(meat)", "用(use)", and "叉子(fork)" in Chinese via the word alignment links. We verify that the corresponding words form a subtree by looking up a subtree list in Chinese (described in Section 4.1). But we can not find a subtree for them.

Next, we check the possible relation of "ate", "with", and "fork". We obtain their corresponding words "吃(ate)", "用(use)", and "叉子(fork)". Then we verify that the words form a subtree by looking up the subtree list. This time we can find the subtree as shown in Figure 2.

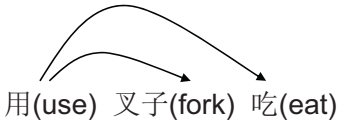

Figure 2: Example for a searched subtree

Finally, the parser may assign "ate" to be the head of "with" based on the verification results. This simple example shows how to use the subtree information on the target side.

3 Dependency parsing

For dependency parsing, there are two main types of parsing models (Nivre and McDonald, 2008; Nivre and Kubler, 2006): transition-based (Nivre, 2003; Yamada and Matsumoto, 2003) and graph-based (McDonald et al., 2005; Carreras, 2007). Our approach can be applied to both parsing models.

In this paper, we employ the graph-based MST parsing model proposed by McDonald and Pereira

(2006), which is an extension of the projective parsing algorithm of Eisner (1996). To use richer second-order information, we also implement parent-child-grandchild features (Carreras, 2007) in the MST parsing algorithm.

3.1 Parsing with monolingual features

Figure 3 shows an example of dependency parsing. In the graph-based parsing model, features are represented for all the possible relations on single edges (two words) or adjacent edges (three words). The parsing algorithm chooses the tree with the highest score in a bottom-up fashion.

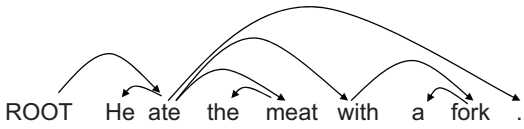

Figure 3: Example of dependency tree

In our systems, the monolingual features include the first- and second- order features presented in (McDonald et al., 2005; McDonald and Pereira, 2006) and the parent-child-grandchild features used in (Carreras, 2007). We call the parser with the monolingual features monolingual parser.

3.2 Parsing with bilingual features

In this paper, we parse source sentences with the help of their translations. A set of bilingual features are designed for the parsing model.

3.2.1 Bilingual subtree features

We design bilingual subtree features, as described in Section 4, based on the constraints between the source subtrees and the target subtrees that are verified by the subtree list on the target side. The source subtrees are from the possible dependency relations.

3.2.2 Bilingual reordering feature

Huang et al. (2009) propose features based on reordering between languages for a shift-reduce parser. They define the features based on word-alignment information to verify that the corresponding words form a contiguous span for resolving shift-reduce conflicts. We also implement similar features in our system.

4 Bilingual subtree constraints

In this section, we propose an approach that uses the bilingual subtree constraints to help parse source sentences that have translations on the target side.

We use large-scale auto-parsed data to obtain subtrees on the target side. Then we generate the mapping rules to map the source subtrees onto the extracted target subtrees. Finally, we design the bilingual subtree features based on the mapping rules for the parsing model. These features indicate the information of the constraints between bilingual subtrees, that are called bilingual subtree constraints.

4.1 Subtree extraction

Chen et al. (2009) propose a simple method to extract subtrees from large-scale monolingual data and use them as features to improve monolingual parsing. Following their method, we parse large unannotated data with a monolingual parser and obtain a set of subtrees (ST_t) in the target language.

We encode the subtrees into string format that is expressed as $st = w : hid(-w : hid)+$[1], where w refers to a word in the subtree and hid refers to the word ID of the word's head (hid=0 means that this word is the root of a subtree). Here, word ID refers to the ID (starting from 1) of a word in the subtree (words are ordered based on the positions of the original sentence). For example, "He" and "ate" have a left dependency arc in the sentence shown in Figure 3. The subtree is encoded as "He:2-ate:0". There is also a parent-child-grandchild relation among "ate", "with", and "fork". So the subtree is encoded as "ate:0-with:1-fork:2". If a subtree contains two nodes, we call it a bigram-subtree. If a subtree contains three nodes, we call it a trigram-subtree.

From the dependency tree of Figure 3, we obtain the subtrees, as shown in Figure 4 and Figure 5. Figure 4 shows the extracted bigram-subtrees and Figure 5 shows the extracted trigram-subtrees. After extraction, we obtain a set of subtrees. We remove the subtrees occurring only once in the data. Following Chen et al. (2009), we also group the subtrees into different sets based on their frequencies.

[1] + refers to matching the preceding element one or more times and is the same as a regular expression in Perl.

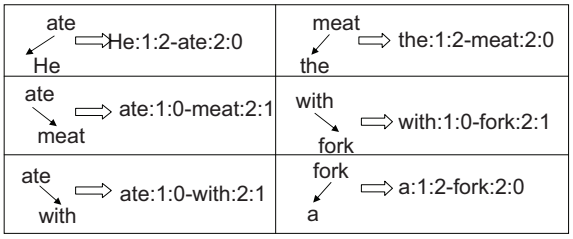

Figure 4: Examples of bigram-subtrees

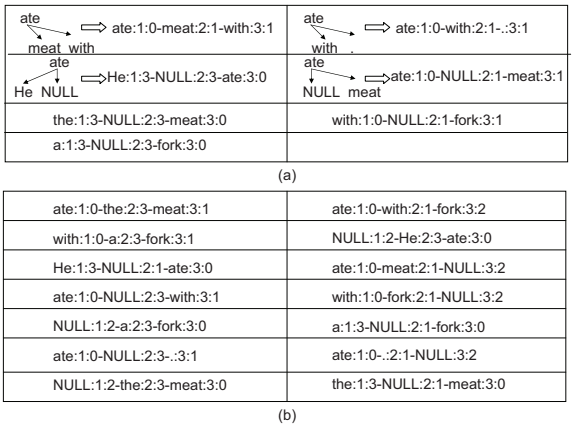

Figure 5: Examples of trigram-subtrees

4.2 Mapping rules

To provide bilingual subtree constraints, we need to find the characteristics of subtree mapping for the two given languages. However, subtree mapping is not easy. There are two main problems: MtoN (words) mapping and reordering, which often occur in translation. MtoN (words) mapping means that a source subtree with M words is mapped onto a target subtree with N words. For example, 2to3 means that a source bigram-subtree is mapped onto a target trigram-subtree.

Due to the limitations of the parsing algorithm (McDonald and Pereira, 2006; Carreras, 2007), we only use bigram- and trigram-subtrees in our approach. We generate the mapping rules for the 2to2, 2to3, 3to3, and 3to2 cases. For trigram-subtrees, we only consider the parent-child-grandchild type. As for the use of other types of trigram-subtrees, we leave it for future work.

We first show the MtoN and reordering problems by using an example in Chinese-English translation. Then we propose a method to automatically generate mapping rules.

4.2.1 Reordering and MtoN mapping in translation

Both Chinese and English are classified as SVO languages because verbs precede objects in simple sentences. However, Chinese has many characteristics of such SOV languages as Japanese. The typical cases are listed below:

1) Prepositional phrases modifying a verb precede the verb. Figure 6 shows an example. In English the prepositional phrase “at the ceremony” follows the verb “said”, while its corresponding prepositional phrase “在(NULL) 仪式(ceremony) 上(at)” precedes the verb “说(say)” in Chinese.

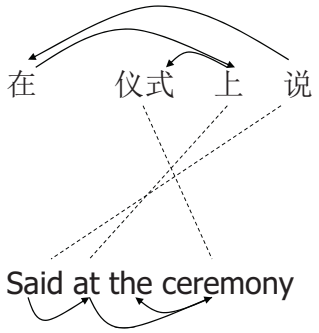

Figure 6: Example for prepositional phrases modifying a verb

2) Relative clauses precede head noun. Figure 7 shows an example. In Chinese the relative clause “今天(today) 签字(signed)” precedes the head noun “项目(project)”, while its corresponding clause “signed today” follows the head noun “projects” in English.

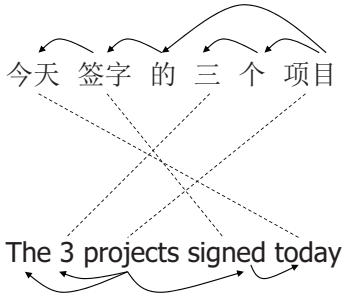

Figure 7: Example for relative clauses preceding the head noun

3) Genitive constructions precede head noun. For example, “汽车(car) 轮子(wheel)” can be translated as “the wheel of the car”.

4) Postposition in many constructions rather than prepositions. For example, “桌子(table) 上(on)” can be translated as “on the table”.

We can find the MtoN mapping problem occurring in the above cases. For example, in Figure 6, trigram-subtree "在(NULL):3-上(at):1-说(say):0" is mapped onto bigram-subtree "said:0-at:1".

Since asking linguists to define the mapping rules is very expensive, we propose a simple method to easily obtain the mapping rules.

4.2.2 Bilingual subtree mapping

To solve the mapping problems, we use a bilingual corpus, which includes sentence pairs, to automatically generate the mapping rules. First, the sentence pairs are parsed by monolingual parsers on both sides. Then we perform word alignment using a word-level aligner (Liang et al., 2006; DeNero and Klein, 2007). Figure 8 shows an example of a processed sentence pair that has tree structures on both sides and word alignment links.

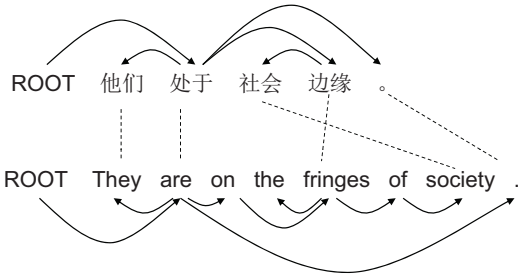

Figure 8: Example of auto-parsed bilingual sentence pair

From these sentence pairs, we obtain subtree pairs. First, we extract a subtree (st_s) from a source sentence. Then through word alignment links, we obtain the corresponding words of the words of st_s. Because of the MtoN problem, some words lack of corresponding words in the target sentence. Here, our approach requires that at least two words of st_s have corresponding words and nouns and verbs need corresponding words. If not, it fails to find a subtree pair for st_s. If the corresponding words form a subtree (st_t) in the target sentence, st_s and st_t are a subtree pair. We also keep the word alignment information in the target subtree. For example, we extract subtree "社会(society):2-边缘(fringe):0" on the Chinese side and get its corresponding subtree "fringes(W_2):0-of:1-society(W_1):2" on the English side, where W_1 means that the target word is aligned to the first word of the source subtree, and W_2 means that the target word is aligned to the second word of the source subtree. That is, we have a subtree pair: "社会(society):2-边缘(fringe):0" and "fringe(W_2):0-of:1-society(W_1):2".

The extracted subtree pairs indicate the translation characteristics between Chinese and English. For example, the pair "社会(society):2-边缘(fringe):0" and "fringes:0-of:1-society:2" is a case where "Genitive constructions precede/follow the head noun".

4.2.3 Generalized mapping rules

To increase the mapping coverage, we generalize the mapping rules from the extracted subtree pairs by using the following procedure. The rules are divided by "=>" into two parts: source (left) and target (right). The source part is from the source subtree and the target part is from the target subtree. For the source part, we replace *nouns* and *verbs* using their POS tags (coarse grained tags). For the target part, we use the word alignment information to represent the target words that have corresponding source words. For example, we have the subtree pair: "社会(society):2-边缘(fringe):0" and "fringes(W_2):0-of:1-society(W_1):2", where "of" does not have a corresponding word, the POS tag of "社会(society)" is N, and the POS tag of "边缘(fringe)" is N. The source part of the rule becomes "N:2-N:0" and the target part becomes "W_2:0-of:1-W_1:2".

Table 1 shows the top five mapping rules of all four types ordered by their frequencies, where W_1 means that the target word is aligned to the first word of the source subtree, W_2 means that the target word is aligned to the second word, and W_3 means that the target word is aligned to the third word. We remove the rules that occur less than three times. Finally, we obtain 9,134 rules for 2to2, 5,335 for 2to3, 7,450 for 3to3, and 1,244 for 3to2 from our data. After experiments with different threshold settings on the development data sets, we use the top 20 rules for each type in our experiments.

The generalized mapping rules might generate incorrect target subtrees. However, as described in Section 4.3.1, the generated subtrees are verified by looking up list ST_t before they are used in the parsing models.

4.3 Bilingual subtree features

Informally, if the words form a subtree on the source side, then the corresponding words on the target side will also probably form a subtree. For

#	rules	freq
2to2 mapping		
1	N:2 N:0 => W_1:2 W_2:0	92776
2	V:0 N:1 => W_1:0 W_2:1	62437
3	V:0 V:1 => W_1:0 W_2:1	49633
4	N:2 V:0 => W_1:2 W_2:0	43999
5	的:2 N:0 => W_2:0 W_1:2	25301
2to3 mapping		
1	N:2-N:0 => W_2:0-of:1-W_1:2	10361
2	V:0-N:1 => W_1:0-of:1-W_2:2	4521
3	V:0-N:1 => W_1:0-to:1-W_2:2	2917
4	N:2-V:0 => W_2:0-of:1-W_1:2	2578
5	N:2-N:0 => W_1:2-':3-W_2:0	2316
3to2 mapping		
1	V:2-的/DEC:3-N:0 => W_1:0-W_3:1	873
2	V:2-的/DEC:3-N:0 => W_3:2-W_1:0	634
3	N:2-的/DEG:3-N:0 => W_1:0-W_3:1	319
4	N:2-的/DEG:3-N:0 => W_3:2-W_1:0	301
5	V:0-的/DEG:3-N:1 => W_3:0-W_1:1	247
3to3 mapping		
1	V:0-V:1-N:2 => W_1:0-W_2:1-W_3:2	9580
2	N:2-的/DEG:3-N:0 => W_3:0-W_2:1-W_1:2	7010
3	V:0-N:3-N:1 => W_1:0-W_2:3-W_3:1	5642
4	V:0-V:1-V:2 => W_1:0-W_2:1-W_3:2	4563
5	N:2-N:3-N:0 => W_1:2-W_2:3-W_3:0	3570

Table 1: Top five mapping rules of 2to3 and 3to2

example, in Figure 8, words "他 们(they)" and "处 于(be_on)" form a subtree , which is mapped onto the words "they" and "are" on the target side. These two target words form a subtree. We now develop this idea as bilingual subtree features.

In the parsing process, we build relations for two or three words on the source side. The conditions of generating bilingual subtree features are that at least two of these source words must have corresponding words on the target side and nouns and verbs must have corresponding words.

At first, we have a possible dependency relation (represented as a source subtree) of words to be verified. Then we obtain the corresponding target subtree based on the mapping rules. Finally, we verify that the target subtree is included in ST_t. If yes, we activate a positive feature to encourage the dependency relation.

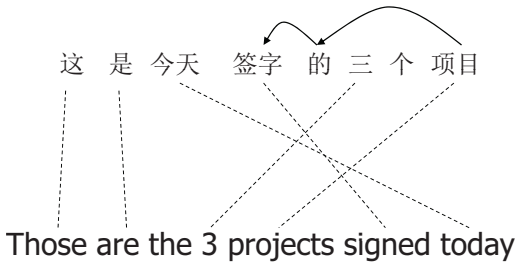

Figure 9: Example of features for parsing

We consider four types of features based on 2to2, 3to3, 3to2, and 2to3 mappings. In the 2to2, 3to3, and 3to2 cases, the target subtrees do not add new words. We represent features in a direct way. For the 2to3 case, we represent features using a different strategy.

4.3.1 Features for 2to2, 3to3, and 3to2

We design the features based on the mapping rules of 2to2, 3to3, and 3to2. For example, we design features for a 3to2 case from Figure 9. The possible relation to be verified forms source subtree "签 字(signed)/VV:2-的(NULL)/DEC:3-项 目(project)/NN:0" in which "项 目(project)" is aligned to "projects" and "签 字(signed)" is aligned to "signed" as shown in Figure 9. The procedure of generating the features is shown in Figure 10. We explain Steps (1), (2), (3), and (4) as follows:

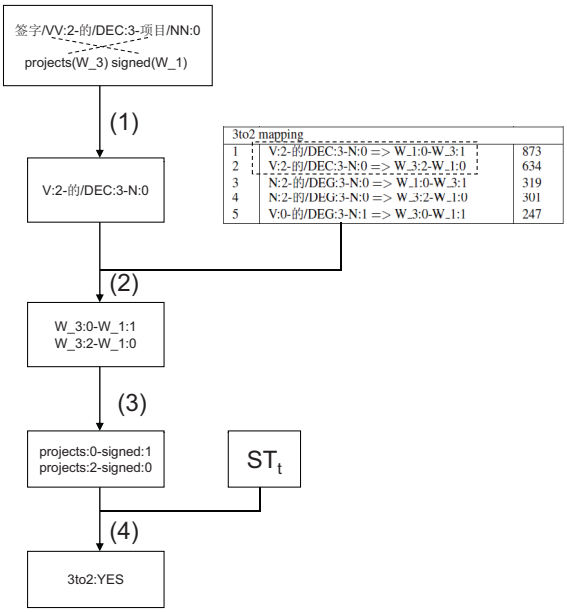

Figure 10: Example of feature generation for 3to2 case

(1) Generate source part from the source subtree. We obtain "V:2-的/DEC:3-N:0" from "签 字(signed)/VV:2-的(NULL)/DEC:3-项 目(project)/NN:0".

(2) Obtain target parts based on the matched mapping rules, whose source parts equal "V:2-的/DEC:3-N:0". The matched rules are "V:2-的/DEC:3-N:0 =>W_3:0-W_1:1" and "V:2-的/DEC:3-N:0 => W_3:2-W_1:0". Thus, we have two target parts "W_3:0-W_1:1" and "W_3:2-W_1:0".

(3) Generate possible subtrees by consider-

ing the dependency relation indicated in the target parts. We generate a possible subtree "projects:0-signed:1" from the target part "W_3:0-W_1:1", where "projects" is aligned to "项目(project)(W_3)" and "signed" is aligned to "签字(signed)(W_1)". We also generate another possible subtree "projects:2-signed:0" from "W_3:2-W_1:0".

(4) Verify that at least one of the generated possible subtrees is a target subtree, which is included in ST_t. If yes, we activate this feature. In the figure, "projects:0-signed:1" is a target subtree in ST_t. So we activate the feature "3to2:YES" to encourage dependency relations among "签字(signed)", "的(NULL)", and "项目(project)".

4.3.2 Features for 2to3

In the 2to3 case, a new word is added on the target side. The first two steps are identical as those in the previous section. For example, a source part "N:2-N:0" is generated from "汽车(car)/NN:2-轮子(wheel)/NN:0". Then we obtain target parts such as "W_2:0-of/IN:1-W_1:2", "W_2:0-in/IN:1-W_1:2", and so on, according to the matched mapping rules.

The third step is different. In the target parts, there is an added word. We first check if the added word is in the span of the corresponding words, which can be obtained through word alignment links. We can find that "of" is in the span "wheel of the car", which is the span of the corresponding words of "汽 车(car)/NN:2-轮 子(wheel)/NN:0". Then we choose the target part "W_2:0-of/IN:1-W_1:2" to generate a possible subtree. Finally, we verify that the subtree is a target subtree included in ST_t. If yes, we say feature "2to3:YES" to encourage a dependency relation between "汽车(car)" and "轮子(wheel)".

4.4 Source subtree features

Chen et al. (2009) shows that the source subtree features (F_{src-st}) significantly improve performance. The subtrees are obtained from the auto-parsed data on the source side. Then they are used to verify the possible dependency relations among source words.

In our approach, we also use the same source subtree features described in Chen et al. (2009). So the possible dependency relations are verified by the source and target subtrees. Combining two types of features together provides strong discrimination power. If both types of features are active, building relations is very likely among source words. If both are inactive, this is a strong negative signal for their relations.

5 Experiments

All the bilingual data were taken from the translated portion of the Chinese Treebank (CTB) (Xue et al., 2002; Bies et al., 2007), articles 1-325 of CTB, which have English translations with gold-standard parse trees. We used the tool "Penn2Malt"[2] to convert the data into dependency structures. Following the study of Huang et al. (2009), we used the same split of this data: 1-270 for training, 301-325 for development, and 271-300 for test. Note that some sentence pairs were removed because they are not one-to-one aligned at the sentence level (Burkett and Klein, 2008; Huang et al., 2009). Word alignments were generated from the Berkeley Aligner (Liang et al., 2006; DeNero and Klein, 2007) trained on a bilingual corpus having approximately 0.8M sentence pairs. We removed notoriously bad links in {a, an, the}×{的(DE), 了(LE)} following the work of Huang et al. (2009).

For Chinese unannotated data, we used the XIN_CMN portion of Chinese Gigaword Version 2.0 (LDC2009T14) (Huang, 2009), which has approximately 311 million words whose segmentation and POS tags are given. To avoid unfair comparison, we excluded the sentences of the CTB data from the Gigaword data. We discarded the annotations because there are differences in annotation policy between CTB and this corpus. We used the MMA system (Kruengkrai et al., 2009) trained on the training data to perform word segmentation and POS tagging and used the Baseline Parser to parse all the sentences in the data. For English unannotated data, we used the BLLIP corpus that contains about 43 million words of WSJ text. The POS tags were assigned by the MXPOST tagger trained on training data. Then we used the Baseline Parser to parse all the sentences in the data.

We reported the parser quality by the unlabeled attachment score (UAS), i.e., the percentage of tokens (excluding all punctuation tokens) with correct HEADs.

5.1 Main results

The results on the Chinese-source side are shown in Table 2, where "Baseline" refers to the systems

[2] http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html

with monolingual features, "Baseline2" refers to adding the reordering features to the Baseline, "F_{BI}" refers to adding all the bilingual subtree features to "Baseline2", "F_{src-st}" refers to the monolingual parsing systems with source subtree features, "Order-1" refers to the first-order models, and "Order-2" refers to the second-order models. The results showed that the reordering features yielded an improvement of 0.53 and 0.58 points (UAS) for the first- and second-order models respectively. Then we added four types of bilingual constraint features one by one to "Baseline2". Note that the features based on 3to2 and 3to3 can not be applied to the first-order models, because they only consider single dependencies (bigram). That is, in the first model, F_{BI} only includes the features based on 2to2 and 2to3. The results showed that the systems performed better and better. In total, we obtained an absolute improvement of 0.88 points (UAS) for the first-order model and 1.36 points for the second-order model by adding all the bilingual subtree features. Finally, the system with all the features (OURS) outperformed the Baseline by an absolute improvement of 3.12 points for the first-order model and 2.93 points for the second-order model. The improvements of the final systems (OURS) were significant in McNemar's Test ($p < 10^{-4}$).

	Order-1	Order-2
Baseline	84.35	87.20
Baseline2	84.88	87.78
+2to2	85.08	88.07
+2to3	85.23	88.14
+3to3	–	88.29
+3to2	–	88.56
F_{BI}	85.23(+0.88)	88.56(+1.36)
F_{src-st}	86.54(+2.19)	89.49(+2.29)
OURS	87.47(+3.12)	90.13(+2.93)

Table 2: Dependency parsing results of Chinese-source case

We also conducted experiments on the English-source side. Table 3 shows the results, where abbreviations are the same as in Table 2. As in the Chinese experiments, the parsers with bilingual subtree features outperformed the Baselines. Finally, the systems (OURS) with all the features outperformed the Baselines by 1.30 points for the first-order model and 1.64 for the second-order model. The improvements of the final systems (OURS) were significant in McNemar's Test ($p < 10^{-3}$).

	Order-1	Order-2
Baseline	86.41	87.37
Baseline2	86.86	87.66
+2to2	87.23	87.87
+2to3	87.35	87.96
+3to3	–	88.25
+3to2	–	88.37
F_{BI}	87.35(+0.94)	88.37(+1.00)
F_{src-st}	87.25(+0.84)	88.57(+1.20)
OURS	87.71(+1.30)	89.01(+1.64)

Table 3: Dependency parsing results of English-source case

5.2 Comparative results

Table 4 shows the performance of the system we compared, where Huang2009 refers to the result of Huang et al. (2009). The results showed that our system performed better than Huang2009. Compared with the approach of Huang et al. (2009), our approach used additional large-scale auto-parsed data. We did not compare our system with the joint model of Burkett and Klein (2008) because they reported the results on phrase structures.

	Chinese	English
Huang2009	86.3	87.5
Baseline	87.20	87.37
OURS	90.13	89.01

Table 4: Comparative results

6 Conclusion

We presented an approach using large automatically parsed monolingual data to provide bilingual subtree constraints to improve bitexts parsing. Our approach remains the efficiency of monolingual parsing and exploits the subtree structure on the target side. The experimental results show that the proposed approach is simple yet still provides significant improvements over the baselines in parsing accuracy. The results also show that our systems outperform the system of previous work on the same data.

There are many ways in which this research could be continued. First, we may attempt to apply the bilingual subtree constraints to transition-

based parsing models (Nivre, 2003; Yamada and Matsumoto, 2003). Here, we may design new features for the models. Second, we may apply the proposed method for other language pairs such as Japanese-English and Chinese-Japanese. Third, larger unannotated data can be used to improve the performance further.

Computing weakest readings

Abstract

We present an efficient algorithm for computing the weakest readings of semantically ambiguous sentences. A corpus-based evaluation with a large-scale grammar shows that our algorithm reduces over 80% of sentences to one or two readings, in negligible runtime, and thus makes it possible to work with semantic representations derived by deep large-scale grammars.

1 Introduction

Over the past few years, there has been considerable progress in the ability of manually created large-scale grammars, such as the English Resource Grammar (ERG, Copestake and Flickinger (2000)) or the ParGram grammars (Butt et al., 2002), to parse wide-coverage text and assign it deep semantic representations. While applications should benefit from these very precise semantic representations, their usefulness is limited by the presence of semantic ambiguity: On the Rondane Treebank (Oepen et al., 2002), the ERG computes an average of several million semantic representations for each sentence, even when the syntactic analysis is fixed. The problem of appropriately selecting one of them to work with would ideally be solved by statistical methods (Higgins and Sadock, 2003) or knowledge-based inferences. However, no such approach has been worked out in sufficient detail to support the disambiguation of treebank sentences.

As an alternative, Bos (2008) proposes to compute the *weakest* reading of each sentence and then use it instead of the "true" reading of the sentence. This is based on the observation that the readings of a semantically ambiguous sentence are partially ordered with respect to logical entailment, and the weakest readings – the minimal (least informative) readings with respect to this order – only express "safe" information that is common to all other readings as well. However, when a sentence has millions of readings, finding the weakest reading is a hard problem. It is of course completely infeasible to compute all readings and compare all pairs for entailment; but even the best known algorithm in the literature (Gabsdil and Striegnitz, 1999) is only an optimization of this basic strategy, and would take months to compute the weakest readings for the sentences in the Rondane Treebank.

In this paper, we propose a new, efficient approach to the problem of computing weakest readings. We follow an *underspecification* approach to managing ambiguity: Rather than deriving all semantic representations from the syntactic analysis, we work with a single, compact underspecified semantic representation, from which the semantic representations can then be extracted by need. We then approximate entailment with a rewrite system that rewrites readings into logically weaker readings; the weakest readings are exactly those readings that cannot be rewritten into some other reading any more (the *relative normal forms*). We present an algorithm that computes the relative normal forms, and evaluate it on the underspecified descriptions that the ERG derives on a 624-sentence subcorpus of the Rondane Treebank. While the mean number of scope readings in the subcorpus is in the millions, our system computes on average 4.5 weakest readings for each sentence, in less than twenty milliseconds; over 80% of all sentences are reduced to at most two weakest readings. In other words, we make it feasible for the first time to build an application that uses the individual (weakest) semantic representations computed by the ERG, both in terms of the remaining ambiguity and in terms of performance. Our technique is not limited to the ERG, but should be applicable to other underspecification-based grammars as well.

Technically, we use underspecified descriptions that are regular tree grammars derived from dominance graphs (Althaus et al., 2003; Koller et al.,

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 30–39,
Uppsala, Sweden, 11-16 July 2010.

2008). We compute the weakest readings by intersecting these grammars with other grammars representing the rewrite rules. This approach can be used much more generally than just for the computation of weakest readings; we illustrate this by showing how a more general version of the redundancy elimination algorithm by Koller et al. (2008) can be seen as a special case of our construction. Thus our system can serve as a general framework for removing unintended readings from an underspecified representation.

The paper is structured as follows. Section 2 starts by reviewing related work. We recall dominance graphs, regular tree grammars, and the basic ideas of underspecification in Section 3, before we show how to compute weakest readings (Section 4) and logical equivalences (Section 5). In Section 6, we define a weakening rewrite system for the ERG and evaluate it on the Rondane Treebank. Section 7 concludes and points to future work.

2 Related work

The idea of deriving a single approximative semantic representation for ambiguous sentences goes back to Hobbs (1983); however, Hobbs only works his algorithm out for a restricted class of quantifiers, and his representations can be weaker than our weakest readings. Rules that weaken one reading into another were popular in the 1990s underspecification literature (Reyle, 1995; Monz and de Rijke, 2001; van Deemter, 1996) because they simplify logical reasoning with underspecified representations. From a linguistic perspective, Kempson and Cormack (1981) even go so far as to claim that the weakest reading should be taken as the "basic" reading of a sentence, and the other readings only seen as pragmatically licensed special cases.

The work presented here is related to other approaches that reduce the set of readings of an underspecified semantic representation (USR). Koller and Niehren (2000) showed how to strengthen a dominance constraint using information about anaphoric accessibility; later, Koller et al. (2008) presented and evaluated an algorithm for redundancy elimination, which removes readings from an USR based on logical equivalence. Our system generalizes the latter approach and applies it to a new inference problem (weakest readings) which they could not solve.

This paper builds closely upon Koller and Thater (2010), which lays the formal groundwork for the work presented here. Here we go beyond that paper by applying a concrete implementation of our RTG construction for weakest readings to a real-world grammar, evaluating the system on practical inputs, and combining weakest readings with redundancy elimination.

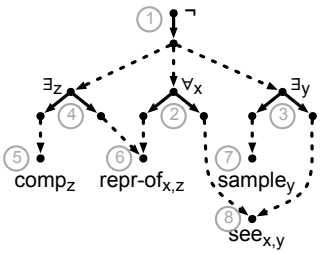

Figure 1: A dominance graph describing the five readings of the sentence "it is not the case that every representative of a company saw a sample."

3 Underspecification

This section briefly reviews two formalisms for specifying sets of trees: dominance graphs and regular tree grammars. Both of these formalisms can be used to model scope ambiguities compactly by regarding the semantic representations of a sentence as trees. Some example trees are shown in Fig. 2. These trees can be read as simplified formulas of predicate logic, or as formulas involving generalized quantifiers (Barwise and Cooper, 1981). Formally, we assume a ranked signature Σ of tree constructors $\{f, g, a, \ldots\}$, each of which is equipped with an arity $\mathsf{ar}(f) \geq 0$. We take a *(finite constructor) tree t* as a finite tree in which each node is labelled with a symbol of Σ, and the number of children of the node is exactly the arity of this symbol. For instance, the signature of the trees in Fig. 1 is $\{\forall_x|2, \exists_y|2, comp_z|0, \ldots\}$. Finite constructor trees can be seen as ground terms over Σ that respect the arities. We write $T(\Sigma)$ for the finite constructor trees over Σ.

3.1 Dominance graphs

A (labelled) dominance graph D (Althaus et al., 2003) is a directed graph that consists of a collection of trees called *fragments*, plus *dominance edges* relating nodes in different fragments. We distinguish the *roots* W_D of the fragments from their *holes*, which are the unlabelled leaves. We write $L_D : W_D \to \Sigma$ for the labeling function of D.

The basic idea behind using dominance graphs to model scope underspecification is to specify

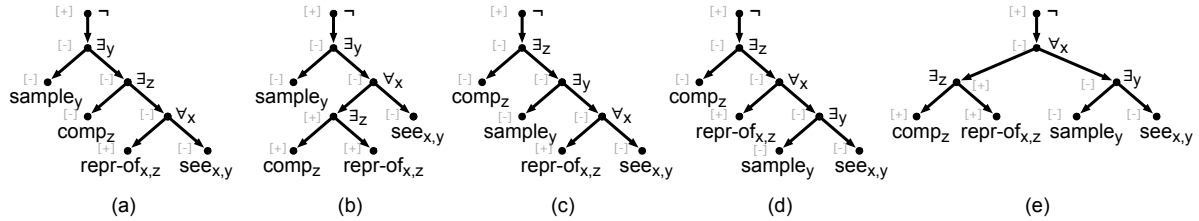

Figure 2: The five configurations of the dominance graph in Fig. 1.

the "semantic material" common to all readings as fragments, plus dominance relations between these fragments. An example dominance graph D is shown in Fig. 1. It represents the five readings of the sentence "it is not the case that every representative of a company saw a sample."

Each reading is encoded as a *(labeled) configuration* of the dominance graph, which can be obtained by "plugging" the tree fragments into each other, in a way that respects the dominance edges: The source node of each dominance edge must dominate (be an ancestor of) the target node in each configuration. The trees in Fig. 2 are the five labeled configurations of the example graph.

3.2 Regular tree grammars

Regular tree grammars (RTGs) are a general grammar formalism for describing languages of trees (Comon et al., 2007). An RTG is a 4-tuple $G = (S, N, \Sigma, P)$, where N and Σ are nonterminal and terminal alphabets, $S \in N$ is the start symbol, and P is a finite set of production rules. Unlike in context-free string grammars (which look superficially the same), the terminal symbols are tree constructors from Σ. The production rules are of the form $A \to t$, where A is a nonterminal and t is a tree from $T(\Sigma \cup N)$; nonterminals count as having arity zero, i.e. they must label leaves. A derivation starts with a tree containing a single node labeled with S. Then in each step of the derivation, some leaf u which is labelled with a nonterminal A is expanded with a rule $A \to t$; this results in a new tree in which u has been replaced by t, and the derivation proceeds with this new tree. The *language* $L(G)$ generated by the grammar is the set of all trees in $T(\Sigma)$ that can be derived in this way.

Fig. 3 shows an RTG as an example. This grammar uses sets of root names from D as nonterminal symbols, and generates exactly the five configurations of the graph in Fig. 1.

The languages that can be accepted by regular tree grammars are called *regular tree languages*

$$
\begin{aligned}
\{1,2,3,4,5,6,7,8\} &\to \neg(\{2,3,4,5,6,7,8\}) \\
\{2,3,4,5,6,7,8\} &\to \forall_x(\{4,5,6\},\{3,7,8\}) \\
\{2,3,4,5,6,7,8\} &\to \exists_y(\{7\},\{2,4,5,6,8\}) \\
\{2,3,4,5,6,7,8\} &\to \exists_z(\{5\},\{2,3,6,7,8\}) \\
\{2,4,5,6,8\} &\to \forall_x(\{4,5,6\},\{8\}) \\
&\quad \mid \exists_z(\{5\},\{2,6,8\}) \\
\{2,3,6,7,8\} &\to \forall_x(\{6\},\{3,7,8\}) \\
&\quad \mid \exists_y(\{7\},\{2,6,8\}) \\
\{2,6,8\} &\to \forall_x(\{6\},\{8\}) \\
\{3,7,8\} &\to \exists_y(\{7\},\{8\}) \\
\{4,5,6\} &\to \exists_z(\{5\},\{6\}) \\
\{5\} \to \mathit{comp}_z \qquad & \{7\} \to \mathit{sample}_y \\
\{6\} \to \mathit{repr\text{-}of}_{x,z} \qquad & \{8\} \to \mathit{see}_{x,y}
\end{aligned}
$$

Figure 3: A regular tree grammar that generates the five trees in Fig. 2.

(RTLs), and regular tree grammars are equivalent to *finite tree automata*, which are defined essentially like the well-known finite string automata, except that they assign states to the nodes in a tree rather than the positions in a string. Regular tree languages enjoy many of the closure properties of regular string languages. In particular, we will later exploit that RTLs are closed under intersection and complement.

3.3 Dominance graphs as RTGs

An important class of dominance graphs are *hypernormally connected (hnc)* dominance graphs (Koller et al., 2003). The precise definition of hnc graphs is not important here, but note that virtually all underspecified descriptions that are produced by current grammars are hypernormally connected (Flickinger et al., 2005), and we will restrict ourselves to hnc graphs for the rest of the paper.

Every hypernormally connected dominance graph D can be automatically translated into an equivalent RTG G_D that generates exactly the same configurations (Koller et al., 2008); the RTG in Fig. 3 is an example. The nonterminals of G_D are

always hnc subgraphs of D. In the worst case, G_D can be exponentially bigger than D, but in practice it turns out that the grammar size remains manageable: even the RTG for the most ambiguous sentence in the Rondane Treebank, which has about 4.5×10^{12} scope readings, has only about 75 000 rules and can be computed in a few seconds.

4 Computing weakest readings

Now we are ready to talk about computing the weakest readings of a hypernormally connected dominance graph. We will first explain how we approximate logical weakening with rewrite systems. We will then discuss how weakest readings can be computed efficiently as the *relative normal forms* of these rewrite systems.

4.1 Weakening rewrite systems

The different readings of a sentence with a scope ambiguity are not a random collection of formulas; they are partially ordered with respect to logical entailment, and are structurally related in a way that allows us to model this entailment relation with simpler technical means.

To illustrate this, consider the five configurations in Fig. 2. The formula represented by (d) logically entails (c); we say that (c) is a *weaker* reading than (d) because it is satisfied by more models. Similar entailment relations hold between (d) and (e), (e) and (b), and so on (see also Fig. 5). We can define the *weakest readings* of the dominance graph as the minimal elements of the entailment order; in the example, these are (b) and (c). Weakest readings capture "safe" information in that whichever reading of the sentence the speaker had in mind, any model of this reading also satisfies at least one weakest reading; in the absence of convincing disambiguation methods, they can therefore serve as a practical approximation of the intended meaning of the sentence.

A naive algorithm for computing weakest readings would explicitly compute the entailment order, by running a theorem prover on each pair of configurations, and then pick out the minimal elements. But this algorithm is quadratic in the number of configurations, and therefore impractically slow for real-life sentences.

Here we develop a fast algorithm for this problem. The fundamental insight we exploit is that entailment among the configurations of a dominance graph can be approximated with rewriting rules (Baader and Nipkow, 1999). Consider the relation between (d) and (c). We can explain that (d) entails (c) by observing that (c) can be built from (d) by exchanging the positions of the adjacent quantifiers $\forall_x$ and $\exists_y$; more precisely, by applying the following rewrite rule:

$$[-]\ \forall_x(Q, \exists_y(P,R)) \to \exists_y(P, \forall_x(Q,R)) \qquad (1)$$

The body of the rule specifies that an occurrence of $\forall_x$ which is the direct parent of an occurrence of $\exists_y$ may change positions with it; the subformulas P, Q, and R must be copied appropriately. The annotation $[-]$ specifies that we must only apply the rule to subformulas in negative logical polarity: If the quantifiers in (d) were not in the scope of a negation, then applying the rule would actually make the formula *stronger*. We say that the rule (1) is logically *sound* because applying it to a subformula with the correct polarity of some configuration t always makes the result t' logically weaker than t.

We formalize these rewrite systems as follows. We assume a finite *annotation alphabet* Ann with a special *starting annotation* $\mathsf{a}_0 \in \mathsf{Ann}$; in the example, we had $\mathsf{Ann} = \{+,-\}$ and $\mathsf{a}_0 = +$. We also assume an *annotator function* $\mathsf{ann} : \mathsf{Ann} \times \Sigma \times \mathbb{N} \to \mathsf{Ann}$. The function ann can be used to traverse a tree top-down and compute the annotation of each node from the annotation of its parent: Its first argument is the annotation and its second argument the node label of the parent, and the third argument is the position of the child among the parent's children. In our example, the annotator ann models logical polarity by mapping, for instance, $\mathsf{ann}(+,\exists_z,1) = \mathsf{ann}(+,\exists_z,2) = \mathsf{ann}(+,\exists_y,2) = +$, $\mathsf{ann}(-,\exists_z,1) = \mathsf{ann}(-,\exists_z,2) = \mathsf{ann}(+,\forall_x,1) = -$, etc. We have labelled each node of the configurations in Fig. 1 with the annotations that are computed in this way.

Now we can define an *annotated rewrite system* R to be a finite set of pairs (a,r) where a is an annotation and r is an ordinary rewrite rule. The rule (1) above is an example of an annotated rewrite rule with $a = -$. A rewrite rule (a,r) can be applied at the node u of a tree t if ann assigns the annotation a to u and r is applicable at u as usual. The rule then rewrites t as described above. In other words, annotated rewrite systems are rewrite systems where rule applications are restricted to subtrees with specific annotations. We write $t \to_R t'$ if some rule of R can be applied at a node of t, and the result of rewriting is t'. The rewrite system R is called *linear*

if every variable that occurs on the left-hand side of a rule occurs on its right-hand side exactly once.

4.2 Relative normal forms

The rewrite steps of a sound weakening rewrite system are related to the entailment order: Because every rewrite step transforms a reading into a weaker reading, an actual weakest readings must be such that there is no other configuration into which it can be rewritten. The converse is not always true, i.e. there can be non-rewritable configurations that are not weakest readings, but we will see in Section 6 that this approximation is good enough for practical use. So one way to solve the problem of computing weakest readings is to find readings that cannot be rewritten further.

One class of configurations that "cannot be rewritten" with a rewrite system R is the set of *normal forms* of R, i.e. those configurations to which no rule in R can be applied. In our example, (b) and (c) are indeed normal forms with respect to a rewrite system that consists only of the rule (1). However, this is not exactly what we need here. Consider a rewrite system that also contains the following annotated rewrite rule, which is also sound for logical entailment:

$$[+]\ \neg(\exists_z(P,Q)) \to \exists_z(P,\neg(Q)), \qquad (2)$$

This rule would allow us to rewrite the configuration (c) into the tree $\exists_z(\mathsf{comp}_z, \neg(\exists_y(\mathsf{sample}_y, \forall_x(\mathsf{repr{-}of}_{x,z}, \mathsf{see}_{x,y}))))$. But this is no longer a configuration of the graph. If we were to equate weakest readings with normal forms, we would erroneously classify (c) as not being a weakest reading. The correct concept for characterizing weakest readings in terms of rewriting is that of a *relative normal form*. We define a configuration t of a dominance graph D to be a R-relative normal form of (the configurations of) D iff there is no other configuration t' of D such that $t \to_R t'$. These are the configurations that can't be weakened further without obtaining a tree that is no longer a configuration of D. In other words, if R approximates entailment, then the R-relative normal forms approximate the weakest readings.

4.3 Computing relative normal forms

We now show how the relative normal forms of a dominance graph can be computed efficiently. For lack of space, we only sketch the construction and omit all proofs. Details can be found in Koller and Thater (2010).

The key idea of the construction is to represent the relation $\to_R$ in terms of a *context tree transducer* M, and characterize the relative normal forms of a tree language L in terms of the pre-image of L under M. Like ordinary regular tree transducers (Comon et al., 2007), context tree transducers read an input tree, assigning states to the nodes, while emitting an output tree. But while ordinary transducers read the input tree symbol by symbol, a context tree transducer can read multiple symbols at once. In this way, they are equivalent to the extended left-hand side transducers of Graehl et al. (2008).

We will now define context tree transducers. Let Σ be a ranked signature, and let X_m be a set of m variables. We write $\mathrm{Con}^{(m)}(\Sigma)$ for the *contexts* with m holes, i.e. those trees in $T(\Sigma \cup X_m)$ in which each element of X_m occurs exactly once, and always as a leaf. If $C \in \mathrm{Con}^{(m)}(\Sigma)$, then $C[t_1,\ldots,t_m] = C[t_1/x_1,\ldots,t_m/x_m]$, where $x_1,\ldots,x_m$ are the variables from left to right.

A *(top-down) context tree transducer* from Σ to Δ is a 5-tuple $M = (Q,\Sigma,\Delta,q_0,\delta)$. Σ and Δ are ranked signatures, Q is a finite set of states, and $q_0 \in Q$ is the start state. δ is a finite set of transition rules of the form $q(C[x_1,\ldots,x_n]) \to D[q_1(x_{i_1}),\ldots,q_m(x_{i_m})]$, where $C \in \mathrm{Con}^{(n)}(\Sigma)$ and $D \in \mathrm{Con}^{(m)}(\Delta)$.

If $t \in T(\Sigma \cup \Delta \cup Q)$, then we say that M derives t' in one step from t, $t \to_M t'$, if t is of the form $C'[q(C[t_1,\ldots,t_n])]$ for some $C' \in \mathrm{Con}^{(1)}(\Sigma)$, t' is of the form $C'[D[q_1(t_{i_1}),\ldots,q_m(t_{i_m})]]$, and there is a rule $q(C[x_1,\ldots,x_n]) \to D[q_1(x_{i_1}),\ldots,q_m(x_{i_m})]$ in δ. The *derivation relation* $\to_M^*$ is the reflexive, transitive closure of $\to_M$. The *translation relation* τ_M of M is

$$\tau_M = \{(t,t') \mid t \in T(\Sigma) \text{ and } t' \in T(\Delta) \text{ and } q_0(t) \to^* t'\}.$$

For each linear annotated rewrite system R, we can now build a context tree transducer M_R such that $t \to_R t'$ iff $(t,t') \in \tau_{M_R}$. The idea is that M_R traverses t from the root to the leaves, keeping track of the current annotation in its state. M_R can nondeterministically choose to either copy the current symbol to the output tree unchanged, or to apply a rewrite rule from R. The rules are built in such a way that in each run, exactly one rewrite rule must be applied.

We achieve this as follows. M_R takes as its states the set $\{\bar{q}\} \cup \{q^a \mid a \in \mathsf{Ann}\}$ and as its start state the state q^{a_0}. If M_R reads a node u in state q^a, this means that the annotator assigns annotation a to u and M_R will rewrite a subtree at or

below u. If M_R reads u in state $\bar{q}$, this means that M_R will copy the subtree below u unchanged because the rewriting has taken place elsewhere. Thus M_R has three types of rewrite rules. First, for any $f \in \Sigma$, we have a rule $\bar{q}(f(x_1,\ldots,x_n)) \to f(\bar{q}(x_1),\ldots,\bar{q}(x_n))$. Second, for any f and $1 \leq i \leq n$, we have a rule $q^a(f(x_1,\ldots,x_n)) \to f(\bar{q}(x_1),\ldots,q^{\mathsf{ann}(a,f,i)}(x_i),\ldots,\bar{q}(x_n))$, which nondeterministically chooses under which child the rewriting should take place, and assigns it the correct annotation. Finally, we have a rule $q^a(C[x_1,\ldots,x_n]) \to C'[\bar{q}(x_{i_1}),\ldots,\bar{q}(x_{i_n})]$ for every rewrite rule $C[x_1,\ldots,x_n] \to C'[x_{i_1},\ldots,x_{i_n}]$ with annotation a in R.

Now let's put the different parts together. We know that for each hnc dominance graph D, there is a regular tree grammar G_D such that $L(G_D)$ is the set of configurations of D. Furthermore, the pre-image $\tau_M^{-1}(L) = \{t \mid \text{exists } t' \in L \text{ with } (t,t') \in \tau_M\}$ of a regular tree language L is also regular (Koller and Thater, 2010) if M is linear, and regular tree languages are closed under intersection and complement (Comon et al., 2007). So we can compute another RTG G' such that

$$L(G') = L(G_D) \cap \overline{\tau_{M_R}^{-1}(L(G_D))}.$$

$L(G')$ consists of the members of $L(G_D)$ which cannot be rewritten by M_R into members of $L(G_D)$; that is, $L(G')$ is exactly the set of R-relative normal forms of D. In general, the complement construction requires exponential time in the size of M_R and G_D. However, it can be shown that if the rules in R have at most depth two and G_D is deterministic, then the entire above construction can be computed in time $O(|G_D| \cdot |R|)$ (Koller and Thater, 2010).

In other words, we have shown how to compute the weakest readings of a hypernormally connected dominance graph D, as approximated by a weakening rewrite system R, in time linear in the size of G_D and linear in the size of R. This is a dramatic improvement over the best previous algorithm, which was quadratic in $|\mathsf{conf}(D)|$.

4.4 An example

Consider an annotated rewrite system that contains rule (1) plus the following rewrite rule:

$$[-]\ \exists_z(P, \forall_x(Q,R)) \to \forall_x(\exists_z(P,Q),R) \qquad (3)$$

This rewrite system translates into a top-down context tree transducer M_R with the following transition rules, omitting most rules of the first two types for lack of space.

$$\begin{aligned}
q^-(\forall_x(x_1,\exists_y(x_2,x_3))) &\to \exists_y(\bar{q}(x_2),\forall_x(\bar{q}(x_1),\bar{q}(x_3)))\\
q^-(\exists_y(x_1,\forall_x(x_2,x_3))) &\to \forall_x(\exists_y(\bar{q}(x_1),\bar{q}(x_2)),\bar{q}(x_3))\\
\bar{q}(\neg(x_1)) &\to \neg(\bar{q}(x_1))\\
q^+(\neg(x_1)) &\to \neg(q^-(x_1))\\
\bar{q}(\forall_x(x_1,x_2)) &\to \forall_x(\bar{q}(x_1),\bar{q}(x_2))\\
q^+(\forall_x(x_1,x_2)) &\to \forall_x(\bar{q}(x_1),q^+(x_2))\\
q^+(\forall_x(x_1,x_2)) &\to \forall_x(q^-(x_1),\bar{q}(x_2)) \quad \ldots
\end{aligned}$$

$$\begin{aligned}
\{1,2,3,4,5,6,7,8\}_F &\to \neg(\{2,3,4,5,6,7,8\}_F)\\
\{2,3,4,5,6,7,8\}_F &\to \exists_y(\{7\}_{\{\bar{q}\}},\{2,4,5,6,8\}_F)\\
&\quad\ \mid \exists_z(\{5\}_{\{\bar{q}\}},\{2,3,6,7,8\}_F)\\
\{2,3,6,7,8\}_F &\to \exists_y(\{7\}_{\{\bar{q}\}},\forall_x(\{6\}_{\{\bar{q}\}},\{8\}_{\{\bar{q}\}}))\\
\{2,4,5,6,8\}_F &\to \forall_x(\{4,5,6\}_{\{\bar{q}\}},\{8\}_{\{\bar{q}\}})\\
\{4,5,6\}_{\{\bar{q}\}} &\to \exists_z(\{5\}_{\{\bar{q}\}},\{6\}_{\{\bar{q}\}})\\
\{5\}_{\{\bar{q}\}} &\to \mathit{comp}_z \qquad \{6\}_{\{\bar{q}\}} \to \mathit{repr\text{-}of}_{x,z}\\
\{7\}_{\{\bar{q}\}} &\to \mathit{sample}_y \quad \{8\}_{\{\bar{q}\}} \to \mathit{see}_{x,y}
\end{aligned}$$

Figure 4: RTG for the weakest readings of Fig. 1.

The grammar G' for the relative normal forms is shown in Fig. 4 (omitting rules that involve unproductive nonterminals). We obtain it by starting with the example grammar G_D in Fig. 3; then computing a deterministic RTG G_R for $\tau_{M_R}^{-1}(L(G_D))$; and then intersecting the complement of G_R with G_D. The nonterminals of G' are subgraphs of D, marked either with a set of states of M_R or the symbol F, indicating that G_R had no production rule for a given left-hand side. The start symbol of G' is marked with F because G' should only generate trees that G_R can*not* generate. As expected, G' generates precisely two trees, namely (b) and (c).

5 Redundancy elimination, revisited

The construction we just carried out – characterize the configurations we find interesting as the relative normal forms of an annotated rewrite system R, translate it into a transducer M_R, and intersect $\mathsf{conf}(D)$ with the complement of the pre-image under M_R – is more generally useful than just for the computation of weakest readings. We illustrate this on the problem of *redundancy elimination* (Vestre, 1991; Chaves, 2003; Koller et al., 2008) by showing how a variant of the algorithm of Koller et al. (2008) falls out of our technique as a special case.

Redundancy elimination is the problem of computing, from a dominance graph D, another dominance graph D' such that $\mathsf{conf}(D') \subseteq \mathsf{conf}(D)$ and

every formula in $\mathsf{conf}(D)$ is *logically equivalent* to some formula in $\mathsf{conf}(D')$. We can approximate logical equivalence using a finite system of equations such as

$$\exists_y(P, \exists_z(Q,R)) = \exists_z(Q, \exists_y(P,R)), \qquad (4)$$

indicating that $\exists_y$ and $\exists_z$ can be permuted without changing the models of the formula.

Following the approach of Section 4, we can solve the redundancy elimination problem by transforming the equation system into a rewrite system R such that $t \to_R t'$ implies that t and t' are equivalent. To this end, we assume an arbitrary linear order $<$ on Σ, and orient all equations into rewrite rules that respect this order. If we assume $\exists_y < \exists_z$, the example rule (4) translates into the annotated rewrite rules

$$[a]\ \exists_z(P, \exists_y(Q,R)) \to \exists_y(Q, \exists_z(P,R)) \qquad (5)$$

for all annotations $a \in \mathsf{Ann}$; logical equivalence is not sensitive to the annotation. Finally, we can compute the relative normal forms of $\mathsf{conf}(D)$ under this rewrite system as above. The result will be an RTG G' describing a subset of $\mathsf{conf}(D)$. Every tree t in $\mathsf{conf}(D)$ that is not in $L(G')$ is equivalent to some tree t' in $L(G')$, because if t could not be rewritten into such a t', then t would be in relative normal form. That is, the algorithm solves the redundancy elimination problem. Furthermore, if the oriented rewrite system is confluent (Baader and Nipkow, 1999), no two trees in $L(G')$ will be equivalent to each other, i.e. we achieve complete reduction in the sense of Koller et al. (2008).

This solution shares much with that of Koller et al. (2008), in that we perform redundancy elimination by intersecting tree grammars. However, the construction we present here is much more general: The algorithmic foundation for redundancy elimination is now exactly the same as that for weakest readings, we only have to use an equivalence-preserving rewrite system instead of a weakening one. This new formal clarity also simplifies the specification of certain equations, as we will see in Section 6.

In addition, we can now combine the weakening rules (1), (3), and (5) into a single rewrite system, and then construct a tree grammar for the relative normal forms of the combined system. This algorithm performs redundancy elimination and computes weakest readings at the same time, and in our example retains only a single configuration, namely

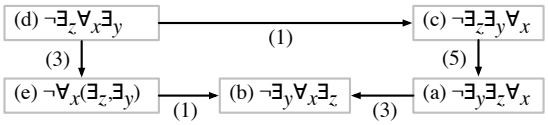

Figure 5: Structure of the configuration set of Fig. 1 in terms of rewriting.

(b); the configuration (c) is rejected because it can be rewritten to (a) with (5). The graph in Fig. 5 illustrates how the equivalence and weakening rules conspire to exclude all other configurations.

6 Evaluation

In this section, we evaluate the effectiveness and efficiency of our weakest readings algorithm on a treebank. We compute RTGs for all sentences in the treebank and measure how many weakest readings remain after the intersection, and how much time this computation takes.

Resources. For our experiment, we use the Rondane treebank (version of January 2006), a "Redwoods style" (Oepen et al., 2002) treebank containing underspecified representations (USRs) in the MRS formalism (Copestake et al., 2005) for sentences from the tourism domain.

Our implementation of the relative normal forms algorithm is based on Utool (Koller and Thater, 2005), which (among other things) can translate a large class of MRS descriptions into hypernormally connected dominance graphs and further into RTGs as in Section 3. The implementation exploits certain properties of RTGs computed from dominance graphs to maximize efficiency. We will make this implementation publically available as part of the next Utool release.

We use Utool to automatically translate the 999 MRS descriptions for which this is possible into RTGs. To simplify the specification of the rewrite systems, we restrict ourselves to the subcorpus in which all scope-taking operators (labels with arity > 0) occur at least ten times. This subset contains 624 dominance graphs. We refer to this subset as "RON10."

Signature and annotations. For each dominance graph D that we obtain by converting an MRS description, we take G_D as a grammar over the signature $\Sigma = \{f_u \mid u \in W_D, f = L_D(u)\}$. That is, we distinguish possible different occurrences of the same symbol in D by marking each occur-

rence with the name of the node. This makes G_D a deterministic grammar.

We then specify an annotator over Σ that assigns polarities for the weakening rewrite system. We distinguish three polarities: $+$ for positive occurrences, $-$ for negative occurrences (as in predicate logic), and $\perp$ for contexts in which a weakening rule neither weakens or strengthens the entire formula. The starting annotation is $+$.

Finally, we need to decide upon each scope-taking operator's effects on these annotations. To this end, we build upon Barwise and Cooper's (1981) classification of the monotonicity properties of determiners. A determiner is *upward (downward) monotonic* if making the denotation of the determiner's argument bigger (smaller) makes the sentence logically weaker. For instance, *every* is downward monotonic in its first argument and upward monotonic in its second argument, i.e. *every girl kissed a boy* entails *every blond girl kissed someone*. Thus $\mathsf{ann}(\mathsf{every}_u, a, 1) = -a$ and $\mathsf{ann}(\mathsf{every}_u, a, 2) = a$ (where u is a node name as above). There are also determiners with non-monotonic argument positions, which assign the annotation $\perp$ to this argument. Negation reverses positive and negative polarity, and all other non-quantifiers simply pass on their annotation to the arguments.

Weakest readings. We use the following weakening rewrite system for our experiment, where $i \in \{1,2\}$:

1. [+] $(\mathsf{E}/i, \mathsf{D}/1)$, $(\mathsf{D}/2, \mathsf{D}/1)$
2. [+] $(\mathsf{E}/i, \mathsf{P}/1)$, $(\mathsf{D}/2, \mathsf{P}/1)$
3. [+] $(\mathsf{E}/i, \mathsf{A}/2)$, $(\mathsf{D}/1, \mathsf{A}/2)$
4. [+] $(\mathsf{A}/2, \mathsf{N}/1)$
5. [+] $(\mathsf{N}/1, \mathsf{E}/i)$, $(\mathsf{N}/1, \mathsf{D}/2)$
6. [+] $(\mathsf{E}/i, \mathsf{M}/1)$, $(\mathsf{D}/1, \mathsf{M}/1)$

Here the symbols E, D, etc. stand for classes of labels in Σ, and a rule schema $[a]$ $(\mathsf{C}/i, \mathsf{C}'/k)$ is to be read as shorthand for a set of rewrite rules which rearrange a tree where the i-th child of a symbol from C is a symbol from C' into a tree where the symbol from C becomes the k-th child of the symbol from C'. For example, because we have $\mathsf{all}_u \in \mathsf{A}$ and $\mathsf{not}_v \in \mathsf{N}$, Schema 4 licenses the following annotated rewrite rule:

$$[+]\ \mathsf{all}_u(P, \mathsf{not}_v(Q)) \rightarrow \mathsf{not}_v(\mathsf{all}_u(P, Q)).$$

We write E and D for existential and definite determiners. P stands for proper names and pronouns, A stands for universal determiners like *all* and *each*, N for the negation *not,* and M for modal operators like *can* or *would*. M also includes intensional verbs like *have to* and *want*. Notice that while the reverse rules are applicable in negative polarities, no rules are applicable in polarity $\perp$.

Rule schema 1 states, for instance, that the specific (wide-scope) reading of the indefinite in *the president of a company* is logically stronger than the reading in which *a company* is within the restriction of the definite determiner. The schema is intuitively plausible, and it can also be proved to be logically sound if we make the standard assumption that the definite determiner *the* means "exactly one" (Montague, 1974). A similar argument applies to rule schema 2.

Rule schema 3 encodes the classical entailment (1). Schema 4 is similar to the rule (2). Notice that it is not, strictly speaking, logically sound; however, because strong determiners like *all* or *every* carry a presupposition that their restrictions have a non-empty denotation (Lasersohn, 1993), the schema becomes sound for all instances that can be expressed in natural language. Similar arguments apply to rule schemas 5 and 6, which are potentially unsound for subtle reasons involving the logical interpretation of intensional expressions. However, these cases of unsoundness did not occur in our test corpus.

Redundancy elimination. In addition, we assume the following equation system for redundancy elimination for $i, j \in \{1,2\}$ and $k \in \mathbb{N}$ (again written in an analogous shorthand as above):

7. $\mathsf{E}/i = \mathsf{E}/j$
8. $\mathsf{D}/1 = \mathsf{E}/i,\ \mathsf{E}/i = \mathsf{D}/1$
9. $\mathsf{D}/1 = \mathsf{D}/1$
10. $\Sigma/k = \mathsf{P}/2$

These rule schemata state that permuting existential determiners with each other is an equivalence transformation, and so is permuting definite determiners with existential and definite determiners if one determiner is the second argument (in the scope) of a definite. Schema 10 states that proper names and pronouns, which the ERG analyzes as scope-bearing operators, can permute with any other label.

We orient these equalities into rewrite rules by ordering symbols in P before symbols that are not

in P, and otherwise ordering a symbol f_u before a symbol g_v if $u < v$ by comparison of the (arbitrary) node names.

Results. We used these rewrite systems to compute, for each USR in RON10, the number of all configurations, the number of configurations that remain after redundancy elimination, and the number of weakest readings (i.e., the relative normal forms of the combined equivalence and weakening rewrite systems). The results are summarized in Fig. 6. By computing weakest readings (WR), we reduce the ambiguity of over 80% of all sentences to one or two readings; this is a clear improvement even over the results of the redundancy elimination (RE). Computing weakest readings reduces the mean number of readings from several million to 4.5, and improves over the RE results by a factor of 30. Notice that the RE algorithm from Section 5 is itself an improvement over Koller et al.'s (2008) system ("KRT08" in the table), which could not process the rule schema 10.

Finally, computing the weakest readings takes only a tiny amount of extra runtime compared to the RE elimination or even the computation of the RTGs (reported as the runtime for "All").[1] This remains true on the entire Rondane corpus (although the reduction factor is lower because we have no rules for the rare scope-bearers): RE+WR computation takes 32 seconds, compared to 30 seconds for RE. In other words, our algorithm brings the semantic ambiguity in the Rondane Treebank down to practically useful levels at a mean runtime investment of a few milliseconds per sentence.

It is interesting to note how the different rule schemas contribute to this reduction. While the instances of Schemata 1 and 2 are applicable in 340 sentences, the other schemas 3–6 together are only applicable in 44 sentences. Nevertheless, where these rules do apply, they have a noticeable effect: Without them, the mean number of configurations in RON10 after RE+WR increases to 12.5.

[1] Runtimes were measured on an Intel Core 2 Duo CPU at 2.8 GHz, under MacOS X 10.5.6 and Apple Java 1.5.0_16, after allowing the JVM to just-in-time compile the bytecode.

7 Conclusion

In this paper, we have shown how to compute the weakest readings of a dominance graph, characterized by an annotated rewrite system. Evaluating our algorithm on a subcorpus of the Rondane Treebank, we reduced the mean number of configurations of a sentence from several million to 4.5, in negligible runtime. Our algorithm can be applied to other problems in which an underspecified representation is to be disambiguated, as long as the remaining readings can be characterized as the relative normal forms of a linear annotated rewrite system. We illustrated this for the case of redundancy elimination.

The algorithm presented here makes it possible, for the first time, to derive a single meaningful semantic representation from the syntactic analysis of a deep grammar on a large scale. In the future, it will be interesting to explore how these semantic representations can be used in applications. For instance, it seems straightforward to adapt MacCartney and Manning's (2008) "natural logic"-based Textual Entailment system, because our annotator already computes the polarities needed for their monotonicity inferences. We could then perform such inferences on (cleaner) semantic representations, rather than strings (as they do).

On the other hand, it may be possible to reduce the set of readings even further. We retain more readings than necessary in many treebank sentences because the combined weakening and equivalence rewrite system is not confluent, and therefore may not recognize a logical relation between two configurations. The rewrite system could be made more powerful by running the Knuth-Bendix completion algorithm (Knuth and Bendix, 1970). Exploring the practical tradeoff between the further reduction in the number of remaining configurations and the increase in complexity of the rewrite system and the RTG would be worthwhile.

Acknowledgments. We are indebted to Joachim Niehren, who pointed out a crucial simplification in the algorithm to us. We also thank our reviewers for their constructive comments.

Identifying Generic Noun Phrases

Nils Reiter and **Anette Frank**
Department of Computational Linguistics
Heidelberg University, Germany
{reiter,frank}@cl.uni-heidelberg.de

Abstract

This paper presents a supervised approach for identifying generic noun phrases in context. Generic statements express rule-like knowledge about kinds or events. Therefore, their identification is important for the automatic construction of knowledge bases. In particular, the distinction between generic and non-generic statements is crucial for the correct encoding of generic and instance-level information. Generic expressions have been studied extensively in formal semantics. Building on this work, we explore a corpus-based learning approach for identifying generic NPs, using selections of linguistically motivated features. Our results perform well above the baseline and existing prior work.

1 Introduction

Generic expressions come in two basic forms: generic noun phrases and generic sentences. Both express rule-like knowledge, but in different ways.

A **generic noun phrase** is a noun phrase that does not refer to a specific (set of) individual(s), but rather to a kind or class of individuals. Thus, the NP *The lion* in (1.a)[1] is understood as a reference to the class "lion" instead of a specific individual. Generic NPs are not restricted to occur with kind-related predicates as in (1.a). As seen in (1.b), they may equally well be combined with predicates that denote specific actions. In contrast to (1.a), the property defined by the verb phrase in (1.b) may hold of individual lions.

(1) a. The lion was the most widespread mammal.

b. Lions eat up to 30 kg in one sitting.

[1] All examples are taken from Wikipedia unless stated otherwise.

Generic sentences are characterising sentences that quantify over situations or events, expressing rule-like knowledge about habitual actions or situations (2.a). This is in contrast with sentences that refer to specific events and individuals, as in (2.b).

(2) a. After 1971 [Paul Erdős] also took amphetamines.

b. Paul Erdős was born [...] on March 26, 1913.

The genericity of an expression may arise from the generic (kind-referring, class-denoting) interpretation of the NP or the characterising interpretation of the sentence predicate. Both sources may concur in a single sentence, as illustrated in Table 1, where we have cross-classified the examples above according to the genericity of the NP and the sentence.

This classification is extremely difficult, because (i) the criteria for generic interpretation are far from being clear-cut and (ii) both sources of genericity may freely interact.

	S[gen+]	S[gen-]
NP[gen+]	(1.b)	(1.a)
NP[gen-]	(2.a)	(2.b)

Table 1: Generic NPs and generic sentences

The above classification of generic expressions is well established in traditional formal semantics (cf. Krifka et al. (1995))[2]. As we argue in this paper, these distinctions are relevant for semantic processing in computational linguistics, especially for information extraction and ontology learning and population tasks. With appropriate semantic analysis of generic statements, we can not only formally capture and exploit generic knowledge,

[2] The literature draws some finer distinctions including aspects like specificity, which we will ignore in this work.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 40–49,
Uppsala, Sweden, 11-16 July 2010.

but also distinguish between information pertaining to individuals vs. classes. We will argue that the automatic identification of generic expressions should be cast as a machine learning problem instead of a rule-based approach, as there is (i) no transparent marking of genericity in English (as in most other European languages) and (ii) the phenomenon is highly context dependent.

In this paper, we build on insights from formal semantics to establish a corpus-based machine learning approach for the automatic classification of generic expressions. In principle our approach is applicable to the detection of both generic NPs and generic sentences, and in fact it would be highly desirable and possibly advantageous to cover both types of genericity simultaneously. Our current work is confined to generic NPs, as there are no corpora available at present that contain annotations for genericity at the sentence level.

The paper is organised as follows. Section 2 introduces generic expressions and motivates their relevance for knowledge acquisition and semantic processing tasks in computational linguistics. Section 3 reviews prior and related work. In section 4 we motivate the choice of feature sets for the automatic identification of generic NPs in context. Sections 5 and 6 present our experiments and results obtained for this task on the ACE-2 data set. Section 7 concludes.

2 Generic Expressions & their Relevance for Computational Linguistics

2.1 Interpretation of generic expressions

Generic NPs There are two contrasting views on how to formally interpret generic NPs. According to the first one, a generic NP involves a special form of **quantification**. Quine (1960), for example, proposes a universally quantified reading for generic NPs. This view is confronted with the most important problem of all quantification-based approaches, namely that the exact determination of the quantifier restriction (QR) is highly dependent on the context, as illustrated in (3)[3].

(3) a. Lions are mammals. QR: *all lions*

b. Mammals give birth to live young. QR: *less than half of all mammals*

c. Rats are bothersome to people. QR: *few rats*[4]

In view of this difficulty, several approaches restrict the quantification to only "relevant" (Declerck, 1991) or "normal" (Dahl, 1975) individuals.

According to the second view, generic noun phrases denote **kinds**. Following Carlson (1977), a kind can be considered as an individual that has properties on its own. On this view, the generic NP cannot be analysed as a quantifier over individuals pertaining to the kind. For some predicates, this is clearly marked. (1.a), for instance, attributes a property to the kind lion that cannot be attributed to individual lions.

Generic sentences are usually analysed using a special dyadic operator, as first proposed by Heim (1982). The dyadic operator relates two semantic constituents, the *restrictor* and the *matrix*:

$$Q[x_1, ..., x_i](\underbrace{[x1, ..., x_i]}_{\textit{Restrictor}}; \underbrace{\exists y_1, ..., y_i[x_1, .., x_i, y_1, ..., y_i]}_{\textit{Matrix}})$$

By choosing GEN as a generic dyadic operator, it is possible to represent the two readings (a) and (b) of the characterising sentence (4) by variation in the specification of restrictor and matrix (Krifka et al., 1995).

(4) Typhoons arise in this part of the pacific.

(a) Typhoons in general have a common origin in this part of the pacific.

(b) There arise typhoons in this part of the pacific.

(a') GEN$[x; y]$(Typhoon(x);this-part-of-the-pacific$(y) \wedge$arise-in(x, y))

(b') GEN$[x; y]$(this-part-of-the-pacific(x);Typhoon$(y) \wedge$arise-in(y, x))

In order to cope with characterising sentences as in (2.a), we must allow the generic operator to quantify over situations or events, in this case, "normal" situations which were such that Erdős took amphetamines.

2.2 Relevance for computational linguistics

Knowledge acquisition The automatic acquisition of formal knowledge for computational applications is a major endeavour in current research

[3] Some of these examples are taken from Carlson (1977).

[4] Most rats are not even noticed by people.

and could lead to big improvements of semantics-based processing. Bos (2009), e.g., describes systems using automated deduction for language understanding tasks using formal knowledge.

There are manually built formal ontologies such as SUMO (Niles and Pease, 2001) or Cyc (Lenat, 1995) and linguistic ontologies like WordNet (Fellbaum, 1998) that capture linguistic and world knowledge to a certain extent. However, these resources either lack coverage or depth. Automatically constructed ontologies or taxonomies, on the other hand, are still of poor quality (Cimiano, 2006; Ponzetto and Strube, 2007).

Attempts to automatically induce knowledge bases from text or encyclopaedic sources are currently not concerned with the distinction between generic and non-generic expressions, concentrating mainly on factual knowledge. However, rule-like knowledge can be found in textual sources in the form of generic expressions[5].

In view of the properties of generic expressions discussed above, this lack of attention bears two types of risks. The first concerns the distinction between classes and instances, regarding the attribution of properties. The second concerns modelling exceptions in both representation and inferencing.

The distinction between **classes and instances** is a serious challenge even for the simplest methods in automatic ontology construction, e.g., Hearst (1992) patterns. The so-called IS-A patterns do not only identify subclasses, but also instances. *Shakespeare*, e.g., would be recognised as a hyponym of *author* in the same way as *temple* is recognised as a hyponym of *civic building*.

Such a missing distinction between classes and instances is problematic. First, there are predicates that can only attribute properties to a kind (1.a). Second, even for properties that in principle can be attributed to individuals of the class, this is highly dependent on the selection of the quantifier's restriction in context (3). In both cases, it holds that properties attributed to a class are not necessarily inherited by any or all instances pertaining to the class.

Zirn et al. (2008) are the first to present fully automatic, heuristic methods to distinguish between classes and instances in the Wikipedia taxonomy derived by Ponzetto and Strube (2007). They report an accuracy of 81.6% and 84.5% for different classification schemes. However, apart from a plural feature, all heuristics are tailored to specific properties of the Wikipedia resource.

Modelling exceptions is a cumbersome but necessary problem to be handled in ontology building, be it manually or by automatic means, and whether or not the genericity of knowledge is formalised explicitly. In artificial intelligence research, this area has been tackled for many years. Default reasoning (Reiter, 1980) is confronted with severe efficiency problems and therefore has not extended beyond experimental systems. However, the emerging paradigm of Answer Set Programming (ASP, Lifschitz (2008)) seems to be able to model exceptions efficiently. In ASP a given problem is cast as a logic program, and an answer set solver calculates all possible answer sets, where an answer set corresponds to a solution of the problem. Efficient answer set solvers have been proposed (Gelfond, 2007). Although ASP may provide us with very efficient reasoning systems, it is still necessary to distinguish and mark default rules explicitly (Lifschitz, 2002). Hence, the recognition of generic expressions is an important precondition for the adequate representation and processing of generic knowledge.

3 Prior Work

Suh (2006) applied a rule-based approach to automatically identify generic noun phrases. Suh used patterns based on part of speech tags that identify bare plural noun phrases, reporting a precision of 28.9% for generic entities, measured against an annotated corpus, the ACE 2005 (Ferro et al., 2005). Neither recall nor f-measure are reported. To our knowledge, this is the single prior work on the task of identifying generic NPs.

Next to the ACE corpus (described in more detail below), Herbelot and Copestake (2008) offer a study on annotating genericity in a corpus. Two annotators annotated 48 noun phrases from the British National Corpus for their genericity (and specificity) properties, obtaining a kappa value of 0.744. Herbelot and Copestake (2008) leave su-

[5] In the field of cognitive science, research on the acquisition of generic knowledge in humans has shown that adult speakers tend to use generic expressions very often when talking to children (Pappas and Gelman, 1998). We are not aware of any detailed assessment of the proportion of generic noun phrases in educational text genres or encyclopaedic resources like Wikipedia. Concerning generic sentences, Mathew and Katz (2009) report that 19.9% of the sentences in their annotated portion of the Penn Treebank are habitual (generic) and 80.1% episodic (non-generic).

pervised learning for the identification of generic expressions as future work.

Recent work by Mathew and Katz (2009) presents automatic classification of generic and non-generic sentences, yet restricted to habitual interpretations of generic sentences. They use a manually annotated part of the Penn TreeBank as training and evaluation set[6]. Using a selection of syntactic and semantic features operating mainly on the sentence level, they achieved precision between 81.2% and 84.3% and recall between 60.6% and 62.7% for the identification of habitual generic sentences.

4 Characterising Generic Expressions for Automatic Classification

4.1 Properties of generic expressions

Generic NPs come in various syntactic forms. These include definite and indefinite singular count nouns, bare plural count and singular and plural mass nouns as in (5.a-f). (5.f) shows a construction that makes the kind reading unambiguous. As Carlson (1977) observed, the generic reading of "well-established" kinds seems to be more prominent (g vs. h).

(5) a. The lion was the most widespread mammal.

b. A lioness is weaker [...] than a male.

c. Lions died out in northern Eurasia.

d. Metals are good conductors.

e. Metal is also used for heat sinks.

f. The zoo has one kind of tiger.

g. The Coke bottle has a narrow neck.

h. The green bottle has a narrow neck.

Apart from being all NPs, there is no obvious syntactic property that is shared by all examples. Similarly, generic sentences come in a range of syntactic forms (6).

(6) a. John walks to work.

b. John walked to work (when he lived in California).

c. John will walk to work (when he moves to California).

[6]The corpus has not been released.

Although generic NPs and generic sentences can be combined freely (cf. Section 1; Table 1), both phenomena highly interact and quite often appear in the same sentence (Krifka et al., 1995). Also, genericity is highly dependent on contextual factors. Present tense, e.g., may be indicative for genericity, but with appropriate temporal modification, generic sentences may occur in past or future tense (6). Presence of a copular construction as in (5.a,b,d) may indicate a generic NP reading, but again we find generic NPs with event verbs, as in (5.e) or (1.b). Lexical semantic factors, such as the semantic type of the clause predicate (5.c,e), or "well-established" kinds (5.g) may favour a generic reading, but such lexical factors are difficult to capture in a rule-based setting.

In our view, these observations call for a corpus-based machine learning approach that is able to capture a variety of factors indicating genericity in combination and in context.

4.2 Feature set and feature classes

In Table 2 we give basic information about the individual features we investigate for identifying generic NPs. In the following, we will structure this feature space along two dimensions, distinguishing NP- and sentence-level factors as well as syntactic and semantic (including lexical semantic) factors. Table 3 displays the grouping into corresponding feature classes.

NP-level features are extracted from the local NP without consideration of the sentence context.

Sentence-level features are extracted from the clause (in which the NP appears), as well as sentential and non-sentential adjuncts of the clause. We also included the (dependency) relations between the target NP and its governing clause.

Syntactic features are extracted from a parse tree or shallow surface-level features. The feature set includes NP-local and global features.

Semantic features include semantic features abstracted from syntax, such as tense and aspect or type of modification, but also lexical semantic features such as word sense classes, sense granularity or verbal predicates.

Our aim is to determine indicators for genericity from combinations of these feature classes.

Feature	Description
Number	sg, pl
Person	1, 2, 3
Countability	ambig, no noun, count, uncount
Noun Type	common, proper, pronoun
Determiner Type	def, indef, demon
Granularity	The number of edges in the WordNet hypernymy graph between the synset of the entity and a top node
Part of Speech	POS-tag (Penn TreeBank tagset; Marcus et al. (1993)) of the head of the phrase
Bare Plural	false, true
Sense[0-3]	WordNet sense. Sense[0] represents the sense of the head of the entity, Sense[1] its direct hypernym sense and so forth.
Sense[Top]	The top sense in the hypernym hierarchy (often referred to as "super sense")
Dependency Relation [0-4]	Dependency Relations. Relation[0] represents the relation between entity and its governor, Relation[1] the relation between the governor and its governor and so forth.
Embedded Predicate.Pred	Lemma of the head of the directly governing predicate of the entity
C.Tense	past, pres, fut
C.Progressive	false, true
C.Perfective	false, true
C.Mood	indicative, imperative, subjunctive
C.Passive	false, true
C.Temporal Modifier?	false, true
C.Number of Modifiers	numeric
C.Part of Speech	POS-tag (Penn TreeBank tagset; Marcus et al. (1993)) of the head of the phrase
C.Pred	Lemma of the head of the clause
C.Adjunct.Time	true, false
C.Adjunct.VType	main, copular
C.Adjunct.Adverbial Type	vpadv, sadv
C.Adjunct.Degree	positive, comparative, superlative
C.Adjunct.Pred	Lemma of the head of the adjunct of the clause
XLE.Quality	How complete is the parse by the XLE parser? fragmented, complete, no parse

Table 2: The features used in our system. C stands for the clause in which the noun phrase appears, "Embedding Predicate" its direct predicate. In most cases, we just give the value range, if necessary, we give descriptions. All features may have a NULL value.

	Syntactic	Semantic
NP-level	Number, Person, Part of Speech, Determiner Type, Bare Plural	Countability, Granularity, Sense[0-3, Top]
S-level	Clause.{Part of Speech, Passive, Number of Modifiers}, Dependency Relation[0-4], Clause.Adjunct.{Verbal Type, Adverbial Type}, XLE.Quality	Clause.{Tense, Progressive, Perfective, Mood, Pred, Has temporal Modifier}, Clause.Adjunct.{Time, Pred}, Embedded Predicate.Pred

Table 3: Feature classes

Name	Descriptions and Features
Set 1	Five best single features: Bare Plural, Person, Sense [0], Clause.Pred, Embedding Predicate.Pred
Set 2	Five best feature tuples: a. Number, Part of Speech b. Countability, Part of Speech c. Sense [0], Part of Speech d. Number, Countability e. Noun Type, Part of Speech
Set 3	Five best feature triples: a. Number, Clause.Tense, Part of Speech b. Number, Clause.Tense, Noun Type c. Number, Clause.Part of Speech, Part of Speech d. Number, Part of Speech, Noun Type e. Number, Clause.Part of Speech, Noun Type

Table 4: Derived feature sets

5 Experiments

5.1 Dataset

As data set we are using the ACE-2 (Mitchell et al., 2003) corpus, a collection of newspaper texts annotated with entities marked for their genericity. In this version of the corpus, the classification of entities is a binary one.

Annotation guidelines The ACE-2 annotation guidelines describe generic NPs as referring to an arbitrary member of the set in question, rather than to a particular individual. Thus, a property attributed to a generic NP is in principle applicable to arbitrary members of the set (although not to all of them). The guidelines list several tests that are either local syntactic tests involving determiners or tests that cannot be operationalised as they involve world knowledge and context information.

The guidelines give a number of criteria to identify generic NPs referring to specific properties. These are (i) types of entities (*lions* in 3.a), (ii) suggested attributes of entities (*mammals* in 3.a), (iii) hypothetical entities (7) and (iv) generalisations across sets of entities (5.d).

(7) If a person steps over the line, they must be punished.

The general description of generic NPs as denoting arbitrary members of sets obviously does not capture kind-referring readings. However, the properties characterised (i) can be understood to admit kinds. Also, some illustrations in the guidelines explicitly characterise kind-referring NPs as generic. Thus, while at first sight the guidelines do not fully correspond to the characterisation of generics we find in the formal semantics literature, we argue that both characterisations have similar extensions, i.e., include largely overlapping sets of noun phrases. In fact, all of the examples for generic noun phrases presented in this paper would also be classified as generic according to the ACE-2 guidelines.

We also find annotated examples of generic NPs that are not discussed in the formal semantics literature (8.a), but that are well captured by the ACE-2 guidelines. However, there are also cases that are questionable (8.b).

(8) a. "It's probably not the perfect world, but you kind of have to deal with what you have to work with," he said.

b. Even more remarkable is the Internet, where information of all kinds is available about the government and the economy.

This shows that the annotation of generics is difficult, but also highlights the potential benefit of a corpus-driven approach that allows us to gather a wider range of realisations. This in turn can contribute to novel insights and discussion.

Data analysis A first investigation of the corpus shows that generic NPs are much less common than non-generic ones, at least in the newspaper genre at hand. Of the 40,106 annotated entities, only 5,303 (13.2%) are marked as generic. In order to control for bias effects in our classifier, we will experiment with two different training sets, a balanced and an unbalanced one.

5.2 Preprocessing

The texts have been (pre-)processed to add several layers of linguistic annotation (Table 5). We use MorphAdorner for sentence splitting and TreeTagger with the standard parameter files for part of speech tagging and lemmatisation. As we do not have a word sense disambiguation system available that outperforms the most frequent sense baseline, we simply used the most frequent sense (MFS). The countability information is taken from Celex. Parsing was done using the English LFG grammar (cf. Butt et al. (2002)) in the XLE parsing platform and the Stanford Parser.

Task	Tool
Sentence splitting	MorphAdorner [7]
POS, lemmatisation	TreeTagger (Schmid, 1994)
WSD	MFS (according to WordNet 3.0)
Countability	Celex (Baayen et al., 1996)
Parsing	XLE (Crouch et al., 2010)
	Stanford (Klein and Manning, 2003)

Table 5: Preprocessing pipeline

As the LFG-grammar produced full parses only for the sentences of 56% of the entities (partial parses: 37% of the entities), we chose to integrate the Stanford parser as a fallback. If we are unable to extract feature values from the f-structure produced by the XLE parser, we extract them from the Stanford Parser, if possible. Experimentation showed using the two parsers in tandem yields best results, compared to individual use.

Table 6: Results of the classification, using different feature and training sets

5.3 Experimental setup

Given the unclear dependencies of features, we chose to use a Bayesian network. A Bayesian network represents the dependencies of random variables in a directed acyclic graph, where each node represents a random variable and each edge a dependency between variables. In fact, a number of feature selection tests uncovered feature dependencies (see below). We used the Weka (Witten and Frank, 2002) implementation BayesNet in all our experiments.

To control for bias effects, we created balanced data sets by oversampling the number of generic entities and simultaneously undersampling non-generic entities. This results in a dataset of 20,053 entities with approx. 10,000 entities for each class. All experiments are performed on balanced and unbalanced data sets using 10-fold cross-validation, where balancing has been performed for each training fold separately (if any).

Feature classes We performed evaluation runs for different combinations of feature sets: NP- vs. S-level features (with further distinction between syntactic and semantic NP-/S-level features), as well as overall syntactic vs. semantic features. This was done in order to determine the effect of different types of linguistic factors for the detection of genericity (cf. Table 3).

Feature selection We experimented with two methods for feature selection. Table 4 shows the resulting feature sets.

In **ablation testing**, a single feature in turn is temporarily omitted from the feature set. The feature whose omission causes the biggest drop in f-measure is set aside as a strong feature. This process is repeated until we are left with an empty feature set. From the ranked list of features f_1 to f_n we evaluate increasingly extended feature sets $f_1..f_i$ for i = 2..n. We select the feature set that yields the best balanced performance, at 45.7% precision and 53.6% f-measure. The features are given as Set 5 in Table 4.

As ablation testing does not uncover feature dependencies, we also experimented with **single, tuple** and **triple feature combinations** to determine features that perform well in combination. We ran evaluations using features in isolation and each possible pair and triple of features. We select the resulting five best features, tuples and triples of features. The respective feature sets are given as Set 1 to Set 3 in Table 4. The features that appear most often in Set 1 to Set 3 are grouped in Set 4.

Baseline Our results are evaluated against three baselines. Since the class distribution is unequal, a majority baseline consists in classifying each entity as non-generic. As a second baseline we chose the performance of the feature *Person*, as this feature gave the best performance in precision among those that are similarly easy to extract. Finally, we compare our results to (Suh, 2006).

6 Results and Discussion

The results of classification are summarised in Table 6. The columns Generic and Non-generic give the results for the respective class. Overall shows the weighted average of the classes.

Comparison to baselines Given the bias for non-generic NPs in the unbalanced data, the majority baseline achieves high performance overall (F: 80.6). Of course, it does not detect any generic NPs. The *Person*-based baseline also suffers from very low recall (R: 10.2%), but achieves the highest precision (P: 60.5 %). (Suh, 2006) reported only precision of the generic class, so we can only compare against this value (28.9 %). Most of the features and feature sets yield precision values above the results of Suh.

Feature classes, unbalanced data For the identification of generic NPs, syntactic features achieve the highest precision and recall (P: 40.1%, R: 66.6 %). Using syntactic features on the NP- or sentence-level only, however, leads to a drop in precision as well as recall. The recall achieved by syntactic features can be improved at the cost of precision by adding semantic features (R: 66.6 → 72.1, P: 40.1 → 37). Semantic features in separation perform lower than the syntactic ones, in terms of recall and precision.

Even though our results achieve a lower precision than the *Person* baseline, in terms of f-measure, we achieve a result of over 50%, which is almost three times the baseline.

Feature classes, balanced data Balancing the training data leads to a moderate drop in performance. All feature classes perform lower than on the unbalanced data set, yielding an increase in recall and a drop in precision. The overall performance differences between the balanced and unbalanced data for the best achieved values for the generic class are -4.7 (P), +13.2 (R) and -1.7 (F). This indicates that (i) the features prove to perform rather effectively, and (ii) the distributional bias in the data can be exploited in practical experiments, as long as the data distribution remains constant.

We observe that generally, the recall for the generic class improves for the balanced data. This is most noticeable for the S-level features with an increase of 55 (syntactic) and 29.7 (semantic). This could indicate that S-level features are useful for detecting genericity, but are too sparse in the non-oversampled data to become prominent. This holds especially for the lexical semantic features.

As a general conclusion, syntactic features prove most important in both setups. We also observe that the margin between syntactic and semantic features reduces in the balanced dataset, and that both NP- and S-level features contribute to classification performance, with NP-features generally outperforming the S-level features. This confirms our hypothesis that all feature classes contribute important information.

Feature selection While the above figures were obtained for the entire feature space, we now discuss the effects of feature selection both on performance and the distribution over feature classes. The results for each feature set are given in Table 6. In general, we find a behaviour similar to

	Syntactic	Semantic
NP	Number, Person, Part of Speech, Determiner Type, Bare Plural	Sense[0]
S	Clause.Part of Speech, Dependency Relation[2]	Clause.{Tense, Pred}

Table 7: Best performing features by feature class

the homogeneous classes, in that balanced training data increases recall at the cost of precision.

With respect to overall f-measure, the best single features are strong on the unbalanced data. They even yield a relatively high precision for the generic NPs (49.5%), the highest value among the selected feature sets. This, however, comes at the price of one of the lowest recalls. The best performing feature in terms of f-measure on both balanced and unbalanced data is Set 5 with Set 4 as a close follow-up. Set 5 achieves an f-score of 53.6 (unbalanced) and 51.0 (balanced). The highest recall is achieved using Set 4 (69.6% on the unbalanced and 83.1% on the balanced dataset). The results for Set 5 represent an improvement of 3.5 respectively 2.6 (unbalanced and balanced) over the best achieved results on homogeneous feature classes. In fact, Table 7 shows that these features, selected by ablation testing, distribute over all homogeneous classes.

We trained a decision tree to gain insights into the dependencies among these features. Figure 1 shows an excerpt of the obtained tree. The classifier learned to classify singular proper names as non-generic, while the genericity of singular nouns depends on their predicate. At this point, the classifier can correctly classify some of the NPs in (5) as kind-referring (given the training data contains predicates like "widespread", "die out", ...).

7 Conclusions and Future Work

This paper addresses a linguistic phenomenon that has been thoroughly studied in the formal semantics literature but only recently is starting to be addressed as a task in computational linguistics. We presented a data-driven machine learning approach for identifying generic NPs in context that in turn can be used to improve tasks such as knowledge acquisition and organisation. The classification of generic NPs has proven difficult even for humans. Therefore, a machine learning approach seemed promising, both for the identification of relevant features as for capturing contextual factors. We explored a range of features using homogeneous and mixed classes gained by alternative methods of feature selection. In terms of f-measure on the generic class, all feature sets performed above the baseline(s). In the overall classification, the selected sets perform above the majority and close to or above the *Person* baseline.

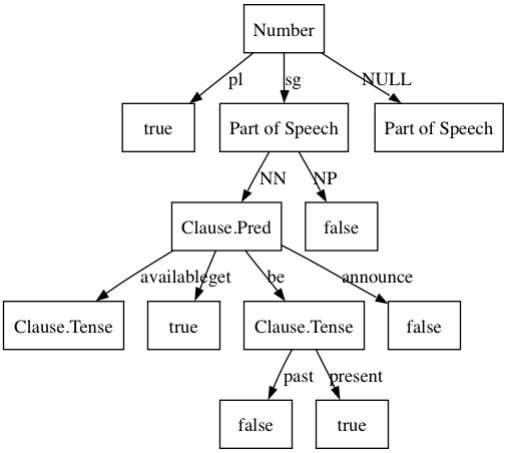

Figure 1: A decision tree trained on feature Set 5

The final feature set that we established characterises generic NPs as a phenomenon that exhibits both syntactic and semantic as well as sentence- and NP-level properties. Although our results are satisfying, in future work we will extend the range of features for further improvements. In particular, we will address lexical semantic features, as they tend to be effected by sparsity. As a next step, we will apply our approach to the classification of generic sentences. Treating both cases simultaneously could reveal insights into dependencies between them.

The classification of generic expressions is only a first step towards a full treatment of the challenges involved in their semantic processing. As discussed, this requires a contextually appropriate selection of the quantifier restriction[8], as well as determining inheritance of properties from classes to individuals and the formalisation of defaults.

Structural Semantic Relatedness: A Knowledge-Based Method to Named Entity Disambiguation

{xphan,jzhao}@nlpr.ia.ac.cn

Abstract

Name ambiguity problem has raised urgent demands for efficient, high-quality named entity disambiguation methods. In recent years, the increasing availability of large-scale, rich semantic knowledge sources (such as *Wikipedia* and *WordNet*) creates new opportunities to enhance the named entity disambiguation by developing algorithms which can exploit these knowledge sources at best. The problem is that these knowledge sources are heterogeneous and most of the semantic knowledge within them is embedded in complex structures, such as graphs and networks. This paper proposes a knowledge-based method, called *Structural Semantic Relatedness* (*SSR*), which can enhance the named entity disambiguation by capturing and leveraging the structural semantic knowledge in multiple knowledge sources. Empirical results show that, in comparison with the classical BOW based methods and social network based methods, our method can significantly improve the disambiguation performance by respectively 8.7% and 14.7%.

1 Introduction

Name ambiguity problem is common on the Web. For example, the name "Michael Jordan" represents more than ten persons in the Google search results. Some of them are shown below:

Michael (Jeffrey) Jordan, Basketball Player
Michael (I.) Jordan, Professor of Berkeley
Michael (B.) Jordan, American Actor

The name ambiguity has raised serious problems in many relevant areas, such as web person search, data integration, link analysis and knowledge base population. For example, in response to a person query, search engine returns a long, flat list of results containing web pages about several namesakes. The users are then forced either to refine their query by adding terms, or to browse through the search results to find the person they are seeking. Besides, an ever-increasing number of question answering and information extraction systems are coming to rely on data from multi-sources, where name ambiguity will lead to wrong answers and poor results. For example, in order to extract the birth date of the Berkeley professor *Michael Jordan*, a system may return the birth date of his popular namesakes, e.g., the basketball player *Michael Jordan*.

So there is an urgent demand for efficient, high-quality named entity disambiguation methods. Currently, the common methods for named entity disambiguation include name observation clustering (Bagga and Baldwin, 1998) and entity linking with knowledge base (McNamee and Dang, 2009). In this paper, we focus on the method of name observation clustering. Given a set of observations $O = \{o_1, o_2, \ldots, o_n\}$ of the target name to be disambiguated, a named entity disambiguation system should group them into a set of clusters $C = \{c_1, c_2, \ldots, c_m\}$, with each resulting cluster corresponding to one specific entity. For example, consider the following four observations of *Michael Jordan*:

1) ***Michael Jordan*** *is a researcher in Computer Science.*
2) ***Michael Jordan*** *plays basketball in Chicago Bulls.*
3) ***Michael Jordan*** *wins NBA MVP.*
4) *Learning in Graphical Models:* ***Michael Jordan****.*

A named entity disambiguation system should group the 1st and 4th *Michael Jordan* observations into one cluster for they both refer to the Berke-

* Corresponding author

Uppsala, Sweden, 11-16 July 2010.

ley professor *Michael Jordan*, meanwhile group the other two *Michael Jordan* into another cluster as they refer to another person, the Basketball Player *Michael Jordan*.

To a human, named entity disambiguation is usually not a difficult task as he can make decisions depending on not only contextual clues, but also the prior background knowledge. For example, as shown in Figure 1, with the background knowledge that both *Learning* and *Graphical models* are the topics related to *Machine learning*, while *Machine learning* is the sub domain of *Computer science*, a human can easily determine that the two *Michael Jordan* in the 1st and 4th observations represent the same person. In the same way, a human can also easily identify that the two *Michael Jordan* in the 2nd and 3rd observations represent the same person.

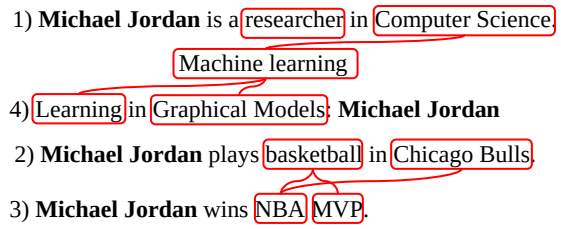

Figure 1. The exploitation of knowledge in human named entity disambiguation

The development of systems which could replicate the human disambiguation ability, however, is not a trivial task because it is difficult to capture and leverage the semantic knowledge as humankind. Conventionally, the named entity disambiguation methods measure the similarity between name observations using the *bag of words* (BOW) model (Bagga and Baldwin (1998); Mann and Yarowsky (2006); Fleischman and Hovy (2004); Pedersen et al. (2005)), where a name observation is represented as a feature vector consisting of the contextual terms. This model measures similarity based on only the co-occurrence statistics of terms, without considering all the semantic relations like social relatedness between named entities, associative relatedness between concepts, and lexical relatedness (e.g., acronyms, synonyms) between key terms.

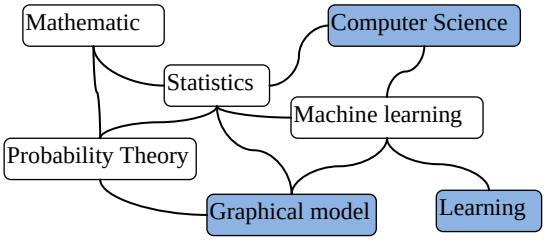

Figure 2. Part of the link structure of Wikipedia

Fortunately, in recent years, due to the evolution of Web (e.g., the *Web 2.0* and the *Semantic Web*) and many research efforts for the construction of knowledge bases, there is an increasing availability of large-scale knowledge sources, such as *Wikipedia* and *WordNet*. These large-scale knowledge sources create new opportunities for knowledge-based named entity disambiguation methods as they contain rich semantic knowledge. For example, as shown in Figure 2, the link structure of Wikipedia contains rich semantic relations between concepts. And we believe that the disambiguation performance can be greatly improved by designing algorithms which can exploit these knowledge sources at best.

The problem of these knowledge sources is that they are heterogeneous (e.g., they contain different types of semantic relations and different types of concepts) and most of the semantic knowledge within them is embedded in complex structures, such as graphs and networks. For example, as shown in Figure 2, the semantic relation between *Graphical Model* and *Computer Science* is embedded in the link structure of the Wikipedia. In recent years, some research has investigated to exploit some specific semantic knowledge, such as the social connection between named entities in the Web (Kalashnikov et al. (2008), Wan et al. (2005) and Lu et al. (2007)), the ontology connection in DBLP (Hassell et al., 2006) and the semantic relations in Wikipedia (Cucerzan (2007), Han and Zhao (2009)). These knowledge-based methods, however, usually are specialized to the knowledge sources they used, so they often have the knowledge coverage problem. Furthermore, these methods can only exploit the semantic knowledge to a limited extent because they cannot take the structural semantic knowledge into consideration.

To overcome the deficiencies of previous methods, this paper proposes a knowledge-based method, called *Structural Semantic Relatedness* (*SSR*), which can enhance the named entity disambiguation by capturing and leveraging the structural semantic knowledge from multiple knowledge sources. The key point of our method is a reliable semantic relatedness measure between concepts (including WordNet concepts, NEs and Wikipedia concepts), called *Structural Semantic Relatedness*, which can capture both the explicit semantic relations between concepts and the implicit semantic knowledge embedded in graphs and networks. In particular, we first extract the semantic relations between two concepts from a variety of knowledge sources and

represent them using a graph-based model, *semantic-graph*. Then based on the principle that "two concepts are semantic related if they are both semantic related to the neighbor concepts of each other", we construct our *Structural Semantic Relatedness* measure. In the end, we leverage the structural semantic relatedness measure for named entity disambiguation and evaluate the performance on the standard WePS data sets. The experimental results show that our *SSR* method can significantly outperform the traditional methods.

This paper is organized as follows. Section 2 describes how to construct the structural semantic relatedness measure. Next in Section 3 we describe how to leverage the captured knowledge for named entity disambiguation. Experimental results are demonstrated in Sections 4. Section 5 briefly reviews the related work. Section 6 concludes this paper and discusses the future work.

2 The Structural Semantic Relatedness Measure

In this section, we demonstrate the structural semantic relatedness measure, which can capture the structural semantic knowledge in multiple knowledge sources. Totally, there are two problems we need to address:

1) How to extract and represent the semantic relations between concepts, since there are many types of semantic relations and they may exist as different patterns (the semantic knowledge may exist as explicit semantic relations or be embedded in complex structures).

2) How to capture all the extracted semantic relations between concepts in our semantic relatedness measure.

To address the above two problems, in following we first introduce how to extract the semantic relations from multiple knowledge sources; then we represent the extracted semantic relations using the semantic-graph model; finally we build our structural semantic relatedness measure.

2.1 Knowledge Sources

We extract three types of semantic relations (semantic relatedness between Wikipedia concepts, lexical relatedness between WordNet concepts and social relatedness between NEs) correspondingly from three knowledge sources: Wikipedia, WordNet and NE Co-occurrence Corpus.

1. **Wikipedia**[1], a large-scale online encyclopedia, its English version includes more than 3,000,000 concepts and new articles are added quickly and up-to-date. Wikipedia contains rich semantic knowledge in the form of hyperlinks between Wikipedia articles, such as *Polysemy* (disambiguation pages), *Synonym* (redirect pages) and *Associative relation* (hyperlinks between Wikipedia articles). In this paper, we extract the semantic relatedness *sr* between Wikipedia concepts using the method described in Milne and Witten(2008):

$$sr(a,b) = 1 - \frac{\log(\max(|A|,|B|)) - \log(|A \cap B|)}{\log(|W|) - \log(\min(|A|,|B|))}$$

where *a* and *b* are the two concepts of interest, *A* and *B* are the sets of all the concepts that are respectively linked to *a* and *b*, and *W* is the entire Wikipedia. For demonstration, we show the semantic relatedness between four selected concepts in Table 1.

	Statistics	**Basketball**
Machine learning	0.58	0.00
MVP	0.00	0.45

Table 1. The semantic relatedness table of four selected Wikipedia concepts

2. **WordNet 3.0**[2] (Fellbaum et al., 1998), a lexical knowledge source includes over 110,000 WordNet concepts (word senses about English words). Various lexical relations are recorded between WordNet concepts, such as *hyponyms*, *holonym* and *synonym*. The lexical relatedness *lr* between two WordNet concepts are measured using the Lin (1998)'s WordNet semantic similarity measure. Table 2 shows some examples of the lexical relatedness.

	school	**science**
university	0.67	0.10
research	0.54	0.39

Table 2. The lexical relatedness table of four selected WordNet concepts

3. **NE Co-occurrence Corpus**, a corpus of documents for capturing the social relatedness between named entities. According to the fuzzy set theory (Baeza-Yates et al., 1999), the degree of named entities co-occurrence in a corpus is a measure of the relatedness between them. For example, in Google search results, the "Chicago Bulls" co-occurs with "NBA" in more than

[1] http://www.wikipedia.org/
[2] http:// wordnet.princeton.edu/

7,900,000 web pages, while only co-occurs with "EMNLP" in less than *1,000* web pages. So the co-occurrence statistics can be used to measure the social relatedness between named entities. In this paper, given a NE Co-occurrence Corpus *D*, the social relatedness *scr* between two named entities ne_1 and ne_2 is measured using the Google Similarity Distance (Cilibrasi and Vitanyi, 2007):

$$scr(ne_1, ne_2) = 1 - \frac{\log(\max(|D_1|, |D_2|)) - \log(|D_1 \cap D_2|)}{\log(|D|) - \log(\min(|D_1|, |D_2|))}$$

where D_1 and D_2 are the document sets correspondingly containing ne_1 and ne_2. An example of social relatedness is shown in Table 3, which is computed using the Web corpus through Google.

	ACL	NBA
EMNLP	0.61	0.00
Chicago Bulls	0.19	0.55

Table 3. The social relatedness table of four selected named entities

2.2 The Semantic-Graph Model

In this section we present a graph-based representation, called *semantic-graph*, to model the extracted semantic relations as a graph within which the semantic relations are interconnected and transitive. Concretely, the semantic-graph is defined as follows:

*A **semantic-graph** is a weighted graph **G = (V, E)**, where each node represents a distinct concept; and each edge between a pair of nodes represents the semantic relation between the two concepts corresponding to these nodes, with the edge weight indicating the strength of the semantic relation.*

For demonstration, Figure 3 shows a semantic-graph which models the semantic knowledge extracted from Wikipedia for the *Michael Jordan* observations in Section 1.

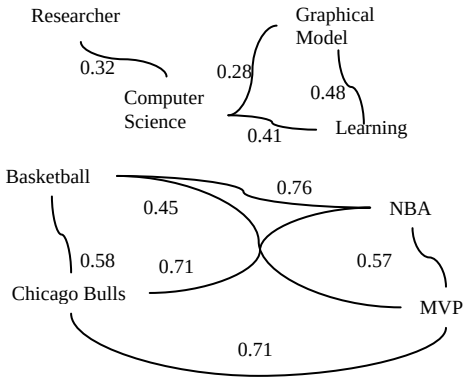

Figure 3. An example of semantic-graph

Given a set of name observations, the construction of semantic-graph takes two steps: concept extraction and concept connection. In the following we respectively describe each step.

1) Concept Extraction. In this step we extract all the concepts in the contexts of name observations and represent them as the nodes in the semantic-graph. We first gather all the N-grams (up to 8 words) and identify whether they correspond to semantically meaningful concepts: if a N-gram is contained in the WordNet, we identify it as a WordNet concept, and use its primary word sense as its semantic meaning; to find whether a N-gram is a named entity, we match it to the named entity list extracted using the open-Calais API3, which contains more than 30 types of named entities, such as Person, Organization and Award; to find whether a N-gram is a Wikipedia concept, we match it to the Wikipedia anchor dictionary, then find its corresponding Wikipedia concept using the method described in (Medelyan et al, 2008). After concept identification, we filter out all the N-grams which do not correspond to the semantic meaningful concepts, such as the N-grams "*learning in*" and "*wins NBA MVP*". The retained N-grams are identified as concepts, corresponding with their semantic meanings (a concept may have multiple semantic meaning explanation, e.g., the "*MVP*" has three semantic meaning, as "*most valuable player, MVP*" in WordNet, as the "*Most Valuable Player*" in Wikipedia and as a named entity of Award type).

2) Concept Connection. In this step we represent the semantic relations as the edges between nodes. That is, for each pair of extracted concepts, we identify whether there are semantic relations between them: 1) If there is only one semantic relation between them, we connect these two concepts with an edge, where the edge weight is the strength of the semantic relation; 2) If there is more than one semantic relations between them, we choose the most reliable semantic relation, i.e., we choose the semantic relation in the knowledge sources according to the order of WordNet, Wikipedia and NE Co-concurrence corpus (Suchanek et al., 2007). For example, if both Wikipedia and WordNet provide the semantic relation between *MVP* and *NBA*, we choose the semantic relation provided by WordNet.

[3] http://www.opencalais.com/

2.3 The Structural Semantic Relatedness Measure

In this section, we describe how to capture the semantic relations between the concepts in semantic-graph using a semantic relatedness measure. Totally, the semantic knowledge between concepts is modeled in two forms:

1) The edges of semantic-graph. The edges model the direct semantic relations between concepts. We call this form of semantic knowledge as *explicit semantic knowledge*.

2) The structure of semantic-graph. Except for the edges, the structure of the semantic-graph also models the semantic knowledge of concepts. For example, the neighbors of a concept represent all the concepts which are explicitly semantic-related to this concept; and the paths between two concepts represent all the explicit and implicit semantic relations between them. We call this form of semantic knowledge as *structural semantic knowledge*, or *implicit semantic knowledge*.

Therefore, in order to deduce a reliable semantic relatedness measure, we must take both the edges and the structure of semantic-graph into consideration. Under the semantic-graph model, the measurement of semantic relatedness between concepts equals to quantifying the similarity between nodes in a weighted graph. To simplify the description, we assign each node in semantic-graph an integer index from 1 to $|\boldsymbol{V}|$ and use this index to represent the node, then we can write the adjacency matrix of the semantic-graph $\boldsymbol{G}$ as $\boldsymbol{A}$, where $\boldsymbol{A[i,j]}$ or $\boldsymbol{A_{ij}}$ is the edge weight between node *i* and node *j*.

The problem of quantifying the relatedness between nodes in a graph is not a new problem, e.g., the *structural equivalence* and *structural similarity* (the SimRank in Jeh and Widom (2002) and the similarity measure in Leicht et al. (2006)). However, these similarity measures are not suitable for our task, because all of them assume that the edges are uniform so that they cannot take edge weight into consideration.

In order to take both the graph structure and the edge weight into account, we design the structural semantic relatedness measure by extending the measure introduced in Leicht et al. (2006). The fundamental principle behind our measure is "a node *u* is semantically related to another node *v* if its immediate neighbors are semantically related to *v*". This definition is natural, for example, as shown in Figure 3, the concept *Basketball* and its neighbors *NBA* and *Chicago Bulls* are all semantically related to *MVP*. This definition is recursive, and the starting point we choose is the semantic relatedness in the edge. Thus our structural semantic relatedness has two components: the neighbor term of the previous recursive phase which captures the graph structure and the semantic relatedness which captures the edge information. Thus, the recursive form of the structural semantic relatedness S_{ij} between the node *i* and the node *j* can be written as:

$$S_{ij} = \lambda \sum_{l \in N_i} \frac{A_{il}}{d_i} S_{lj} + \mu A_{ij}$$

where λ and μ control the relative importance of the two components and

$N_i=\{j \mid A_{ij} > 0\}$ is the set of the immediate neighbors of node *i*;

$d_i = \sum_{j \in N_i} A_{ij}$ is the degree of node *i*.

In order to solve this formula, we introduce the following two notations:

$\boldsymbol{T}$: The relatedness transition matrix, where $T[i,j]=A_{ij}/d_i$, indicating the transition rate of relatedness from node *j* to its neighbor *i*.

$\boldsymbol{S}$: The structural semantic relatedness matrix, where $S[i,j]=S_{ij}$.

Now we can turn our first form of structural semantic relatedness into the matrix form:

$$S = \lambda TS + \mu A$$

By solving this equation, we can get:

$$S = \mu(I - \lambda T)^{-1} A$$

where $\boldsymbol{I}$ is the identity matrix. Since μ is a parameter which only contributes an overall scale factor to the relatedness value, we can ignore it and get the final form of the structural semantic relatedness as:

$$S = (I - \lambda T)^{-1} A$$

Because the *S* is asymmetric, the finally relatedness between node *i* and node *j* is the average of S_{ij} and S_{ji}.

The meaning of λ : The last question of our structural semantic relatedness measure is how to set the free parameter λ . To understand the meaning of λ**,** let us expand the similarity as a power series thus:

$$S = (I + \lambda T + \lambda^2 T^2 + ... + \lambda^k T^k + ...)A$$

Noting that the $[T^k]_{ij}$ element is the relatedness transition rate from node *i* to node *j* with path length *k*, we can view the λ as a penalty factor for the transition path length: by setting the λ with a value within (0, 1), a longer graph path will contribute less to the final relatedness value. The optimal value of λ is 0.6 through a learning

process shown in Section 4. For demonstration, Table 4 shows some structural semantic relatedness values of the Semantic-graph in Figure 3 (*CS* represents *computer science* and *GM* represents *Graphical model*). From Table 4, we can see that the structural semantic relatedness can successfully capture the semantic knowledge embedded in the structure of semantic-graph, such as the implicit semantic relation between *Researcher* and *Learning*.

	Researcher	CS	GM	Learning
Researcher	---	0.50	0.27	0.31
CS	0.50	---	0.62	0.73
GM	0.27	0.62	---	0.80
Learning	0.31	0.73	0.80	---

Table 4. The structural semantic relatedness of the semantic-graph shown in Figure 3

3 Named Entity Disambiguation by Leveraging Semantic Knowledge

In this section we describe how to leverage the semantic knowledge captured in the structural semantic relatedness measure for named entity disambiguation. Because the key problem of named entity disambiguation is to measure the similarity between name observations, we integrate the structural semantic relatedness in the similarity measure, so that it can better reflect the actual similarity between name observations.

Concretely, our named entity disambiguation system works as follows: 1) Measuring the similarity between name observations; 2) Grouping name observations using the clustering algorithm. In the following we describe each step in detail.

3.1 Measuring the Similarity between Name Observations

Intuitively, if two observations of the target name represent the same entity, it is highly possible that the concepts in their contexts are closely related, i.e., the named entities in their contexts are socially related and the Wikipedia concepts in their contexts are semantically related. In contrast, if two name observations represent different entities, the concepts within their contexts will not be closely related. Therefore we can measure the similarity between two name observations by summarizing all the semantic relatedness between the concepts in their contexts.

To measure the similarity between name observations, we represent each name observation as a weighted vector of concepts (including named entities, Wikipedia concepts and WordNet concepts), where the concepts are extracted using the same method described in Section 2.2, so they are just the same concepts within the semantic-graph. Using the same concept index as the semantic-graph, a name observation o_i is then represented as $o_i = \{w_{i1}, w_{i2}, ..., w_{in}\}$, where w_{ik} is the k^{th} concept's weight in observation o_i, computed using the standard TFIDF weight model, where the DF is computed using the Google Web1T 5-gram corpus[4]. Given the concept vector representation of two name observations o_i and o_j, their similarity is computed as:

$$SIM(o_i, o_j) = \sum_l \sum_k w_{il} w_{jk} S_{lk} \Big/ \sum_l \sum_k w_{il} w_{jk}$$

which is the weighted average of all the structural semantic relatedness between the concepts in the contexts of the two name observations.

3.2 Grouping Name Observations through Hierarchical Agglomerative Clustering

Given the computed similarities, name observations are disambiguated by grouping them according to their represented entities. In this paper, we group name observations using the hierarchical agglomerative clustering(HAC) algorithm, which is widely used in prior disambiguation research and evaluation task (WePS1 and WePS2). The HAC produce clusters in a bottom-up way as follows: Initially, each name observation is an individual cluster; then we iteratively merge the two clusters with the largest similarity value to form a new cluster until this similarity value is smaller than a preset merging threshold or all the observations reside in one common cluster. The merging threshold can be determined through cross-validation. We employ the single-link method to compute the similarity between two clusters, which has been applied widely in prior research (Bagga and Baldwin (1998); Mann and Yarowsky (2003)).

4 Experiments

To assess the performance of our method and compare it with traditional methods, we conduct a series of experiments. In the experiments, we evaluate the proposed *SSR* method on the task of personal name disambiguation, which is the most common type of named entity disambiguation. In the following, we first explain the general experimental settings in Section 4.1, 4.2 and 4.3; then evaluate and discuss the performance of our method in Section 4.4.

[4] www.ldc.upenn.edu/Catalog/docs/LDC2006T13/

4.1 Disambiguation Data Sets

We adopted the standard data sets used in the First Web People Search Clustering Task (**WePS1**) (Artiles et al., 2007) and the Second Web People Search Clustering Task (**WePS2**) (Artiles et al., 2009). The three data sets we used are **WePS1_training** data set, **WePS1_test** data set, and **WePS2_test** data set. Each of the three data sets consists of a set of ambiguous personal names (totally 109 personal names); and for each name, we need to disambiguate its observations in the web pages of the top *N* (100 for **WePS1** and 150 for **WePS2**) Yahoo! search results.

The experiment made the standard "one person per document" assumption, which is widely used in the participated systems in WePS1 and WePS2, i.e., all the observations of the same name in a document are assumed to represent the same entity. Based on this assumption, the features within the entire web page are used to disambiguate personal names.

4.2 Knowledge Sources

There were three knowledge sources we used for our experiments: the WordNet 3.0; the Sep. 9, 2007 English version of Wikipedia; and the Web pages of each ambiguous name in WePS datasets as the NE Co-occurrence Corpus.

4.3 Evaluation Criteria

We adopted the measures used in WePS1 to evaluate the performance of name disambiguation. These measures are:

Purity (**Pur**): *measures the homogeneity of name observations in the same cluster*;

Inverse purity (**Inv_Pur**): *measures the completeness of a cluster*;

F-Measure (**F**): *the harmonic mean of purity and inverse purity*.

The detailed definitions of these measures can be found in Amigo, et al. (2008). We use F-measure as the primary measure just liking WePS1 and WePS2.

4.4 Experimental Results

We compared our method with four baselines: (1) ***BOW:*** The first one is the traditional *Bag of Words* model (*BOW*) based methods: hierarchical agglomerative clustering (HAC) over term vector similarity, where the features including single words and NEs, and all the features are weighted using TFIDF. This baseline is also the state-of-art method in WePS1 and WePS2. (2) ***SocialNetwork:*** The second one is the social network based methods, which is the same as the method described in Malin et al. (2005): HAC over the similarity obtained through random walk over the social network built from the web pages of the top *N* search results. (3)***SSR-NoKnowledge:*** The third one is used as a baseline for evaluating the efficiency of semantic knowledge: HAC over the similarity computed on semantic-graph with no knowledge integrated, i.e., the similarity is computed as:

$$SIM(o_i, o_j) = \sum_l w_{il} w_{jl} \Big/ \sum_l \sum_k w_{il} w_{jk}$$

(4) ***SSR-NoStructure***: The fourth one is used as a baseline for evaluating the efficiency of the semantic knowledge embedded in complex structures: HAC over the similarity computed by only integrating the explicit semantic relations, i.e., the similarity is computed as:

$$SIM(o_i, o_j) = \sum_l \sum_k w_{il} w_{jk} A_k \Big/ \sum_l \sum_k w_{il} w_{jk}$$

4.4.1 Overall Performance

We conducted several experiments on all the three WePS data sets: the four baselines, the proposed ***SSR*** method and the proposed ***SSR*** method with only one special type knowledge added, respectively ***SSR-NE***, ***SSR-WordNet*** and ***SSR-Wikipedia***. All the optimal merging thresholds used in HAC were selected by applying leave-one-out cross validation. The overall performance is shown in Table 5.

Method	WePS1_training		
	Pur	**Inv_Pur**	**F**
BOW	0.71	0.88	**0.78**
SocialNetwork	0.66	0.98	**0.76**
SSR-NoKnowledge	0.79	0.89	**0.81**
SSR-NoStructure	0.87	0.83	**0.83**
SSR-NE	0.80	0.86	**0.82**
SSR-WordNet	0.80	0.91	**0.83**
SSR-Wikipedia	0.82	0.90	**0.84**
SSR	0.82	0.92	**0.85**
	WePS1_test		
	Pur	**Inv_Pur**	**F**
BOW	0.74	0.87	**0.74**
SocialNetwork	0.83	0.63	**0.65**
SSR-NoKnowledge	0.80	0.74	**0.75**
SSR-NoStructure	0.80	0.78	**0.78**
SSR-NE	0.73	0.80	**0.74**
SSR-WordNet	0.81	0.77	**0.77**
SSR-Wikipedia	0.88	0.77	**0.81**
SSR	0.85	0.83	**0.84**
	WePS2_test		
	Pur	**Inv_Pur**	**F**
BOW	0.80	0.80	**0.77**
SocialNetwork	0.62	0.93	**0.70**
SSR-NoKnowledge	0.84	0.80	**0.80**
SSR-NoStructure	0.84	0.83	**0.81**
SSR-NE	0.78	0.88	**0.80**
SSR-WordNet	0.85	0.82	**0.83**
SSR-Wikipedia	0.84	0.81	**0.82**
SSR	0.89	0.84	**0.86**

Table 5. Performance results of baselines and SSR methods

From the performance results in Table 5, we can see that:

1) The semantic knowledge can greatly improve the disambiguation performance: compared with the BOW and the SocialNetwork baselines, SSR respectively gets 8.7% and 14.7% improvement on average on the three data sets.

2) By leveraging the semantic knowledge from multiple knowledge sources, we can obtain a better named entity disambiguation performance: compared with the *SSR-NE*'s 0% improvement, the *SSR-WordNet*'s 2.3% improvement and the *SSR-Wikipedia*'s 3.7% improvement, the *SSR* gets 6.3% improvement over the *SSR-NoKnowledge* baseline, which is larger than all the *SSR* methods with only one type of semantic knowledge integrated.

3) The exploitation of the structural semantic knowledge can further improve the disambiguation performance: compared with *SSR-NoStructure*, our *SSR* method achieves 4.3% improvement.

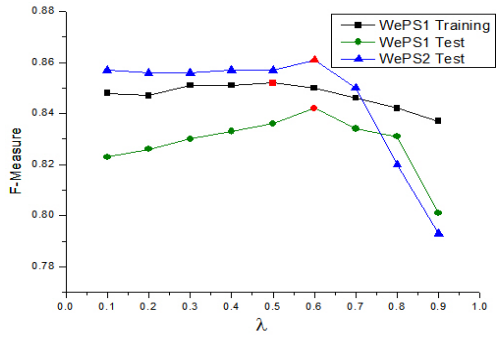

Figure 4. The F-Measure vs. λ on three data sets

4.4.2 *Optimizing Parameters*

There is only one parameter λ needed to be configured, which is the penalty factor for the relatedness transition path length in the structural semantic relatedness measure. Usually a smaller λ will make the structural semantic knowledge contribute less in the resulting relatedness value. Figure 4 plots the performance of our method corresponding to the special λ settings. As shown in Figure 4, the SSR method is not very sensitive to the λ and can achieve its best average performance when the value of λ is *0.6*.

4.4.3 *Detailed Analysis*

To better understand the reasons why our *SSR* method works well and how the exploitation of structural semantic knowledge can improve performance, we analyze the results in detail.

The Exploitation of Semantic Knowledge. The primary advantage of our method is the exploitation of semantic knowledge. Our method exploits the semantic knowledge in two directions:

1) *The Integration of Multiple Semantic Knowledge Sources.* Using the semantic-graph model, our method can integrate the semantic knowledge extracted from multiple knowledge sources, while most traditional knowledge-based methods are usually specialized to one type of knowledge. By integrating multiple semantic knowledge sources, our method can improve the semantic knowledge coverage.

2) *The exploitation of Semantic Knowledge embedded in complex structures.* Using the structural semantic relatedness measure, our method can exploit the implicit semantic knowledge embedded in complex structures; while traditional knowledge-based methods usually lack this ability.

The Rich Meaningful Features. One another advantage of our method is the rich meaningful features, which is brought by the multiple semantic knowledge sources. With more meaningful features, our method can better describe the name observations with less information loss. Furthermore, unlike the traditional N-gram features, the features enriched by semantic knowledge sources are all semantically meaningful units themselves, so little noisy features will be added. The effect of rich meaningful features can also be shown in Table 5: by adding these features, the *SSR-NoKnowledge* respectively achieves 2.3% and 9.7% improvement over the *BOW* and the *SocialNetwork* baseline.

5 Related Work

In this section, we briefly review the related work. Totally, the traditional named entity disambiguation methods can be classified into two categories: the shallow methods and the knowledge-based methods.

Most of previous named entity disambiguation researches adopt the shallow methods, which are mostly the natural extension of the *bag of words* (*BOW*) model. Bagga and Baldwin (1998) represented a name as a vector of its contextual words, then two names were predicted to be the same entity if their cosine similarity is above a threshold. Mann and Yarowsky (2003) and Niu et al. (2004) extended the vector representation with extracted biographic facts. Pedersen et al. (2005) employed significant bigrams to represent

a name observation. Chen and Martin (2007) explored a range of syntactic and semantic features.

In recent years some research has investigated employing knowledge sources to enhance the named entity disambiguation. Bunescu and Pasca (2006) disambiguated the names using the category information in Wikipedia. Cucerzan (2007) disambiguated the names by combining the *BOW* model with the Wikipedia category information. Han and Zhao (2009) leveraged the Wikipedia semantic knowledge for computing the similarity between name observations. Bekkerman and McCallum (2005) disambiguated names based on the link structure of the Web pages between a set of socially related persons. Kalashnikov et al. (2008) and Lu et al. (2007) used the co-occurrence statistics between named entities in the Web. The social network was also exploited for named entity disambiguation, where similarity is computed through random walking, such as the work introduced in Malin (2005), Malin and Airoldi (2005), Yang et al.(2006) and Minkov et al. (2006). Hassell et al. (2006) used the relationships from DBLP to disambiguate names in research domain.

6 Conclusions and Future Works

In this paper we demonstrate how to enhance the named entity disambiguation by capturing and exploiting the semantic knowledge existed in multiple knowledge sources. In particular, we propose a semantic relatedness measure, *Structural Semantic Relatedness*, which can capture both the explicit semantic relations and the implicit structural semantic knowledge. The experimental results on the WePS data sets demonstrate the efficiency of the proposed method. For future work, we want to develop a framework which can uniformly model the semantic knowledge and the contextual clues for named entity disambiguation.

Correcting errors in speech recognition with articulatory dynamics

Frank Rudzicz
University of Toronto, Department of Computer Science
Toronto, Ontario, Canada
frank@cs.toronto.edu

Abstract

We introduce a novel mechanism for incorporating articulatory dynamics into speech recognition with the theory of task dynamics. This system reranks sentence-level hypotheses by the likelihoods of their hypothetical articulatory realizations which are derived from relationships learned with aligned acoustic/articulatory data. Experiments compare this with two baseline systems, namely an acoustic hidden Markov model and a dynamic Bayes network augmented with discretized representations of the vocal tract. Our system based on task dynamics reduces word-error rates significantly by 10.2% relative to the best baseline models.

1 Introduction

Although modern automatic speech recognition (ASR) takes several cues from the biological perception of speech, it rarely models its biological production. The result is that speech is treated as a surface acoustic phenomenon with lexical or phonetic hidden dynamics but without any physical constraints in between. This omission leads to some untenable assumptions. For example, speech is often treated out of convenience as a sequence of discrete, non-overlapping packets, such as phonemes, despite the fact that some major difficulties in ASR, such as co-articulation, are by definition the result of concurrent physiological phenomena (Hardcastle and Hewlett, 1999).

Many acoustic ambiguities can be resolved with knowledge of the vocal tract's configuration (O'Shaughnessy, 2000). For example, the three nasal sonorants, */m/*, */n/*, and */ng/*, are acoustically similar (i.e., they have large concentrations of energy at the same frequencies) but uniquely and reliably involve bilabial closure, tongue-tip elevation, and tongue-dorsum elevation, respectively. Having access to the articulatory goals of the speaker would, in theory, make the identification of linguistic intent almost trivial. Although we don't typically have access to the vocal tract during speech recognition, its configuration *can* be estimated reasonably well from acoustics alone within adequate models or measurements of the vocal tract (Richmond et al., 2003; Toda et al., 2008). Evidence that such inversion takes place naturally in humans during speech perception suggests that the discriminability of speech sounds depends powerfully on their production (Liberman and Mattingly, 1985; D'Ausilio et al., 2009).

This paper describes the use of explicit models of physical speech production within recognition systems. Initially, we augment traditional models of ASR with probabilistic relationships between acoustics and articulation learned from appropriate data. This leads to the incorporation of a high-level, goal-oriented, and control-based theory of speech production within a novel ASR system.

2 Background and related work

The use of theoretical (phonological) features of the vocal tract has provided some improvement over traditional acoustic ASR systems in phoneme recognition with neural networks (Kirchhoff, 1999; Roweis, 1999), but there has been very little work in ASR informed by direct measurements of the vocal tract. Recently, Markov et al. (2006) have augmented hidden Markov models with Bayes networks trained to describe articulatory constraints from a small amount of Japanese vocal tract data, resulting in a small phoneme-error reduction. This work has since been expanded upon to inform ASR systems sensitive to physiological speech disorders (Rudzicz, 2009). Common among previous efforts is an interpretation of speech as a sequence of short, instantaneous observations devoid of long-term dynamics.

2.1 Articulatory phonology

Articulatory phonology bridges the divide between the physical manifestation of speech and its underlying lexical intentions. Within this discipline, the theory of *task dynamics* is a combined model of physical articulator motion and the planning of abstract vocal tract configurations (Saltzman, 1986). This theory introduces the notion that all observed patterns of speech are the result of overlapping *gestures*, which are abstracted goal-oriented reconfigurations of the vocal tract, such as bilabial closure or velar opening (Saltzman and Munhall, 1989). Each gesture occurs within one of the following *tract variables* (TVs): velar opening (**VEL**), lip aperture (**LA**) and protrusion (**LP**), tongue tip constriction location (**TTCL**) and degree (**TTCD**) [1], tongue body constriction location (**TBCL**) and degree (**TBCD**), lower tooth height (**LTH**), and glottal vibration (**GLO**). For example, the syllable *pub* consists of an onset (*/p/*), a nucleus (*/ah/*), and a coda (*/b/*). Four gestural goals are associated with the onset, namely the shutting of GLO and of VEL, and the closure and release of LA. Similarly, the nucleus of the syllable consists of three goals, namely the relocation of TBCD and TBCL, and the opening of GLO. The presence and extent of these gestural goals are represented by filled rectangles in figure 1. Inter-gestural timings between these goals are specified relative to one another according to human data as described by Nam and Saltzman (2003).

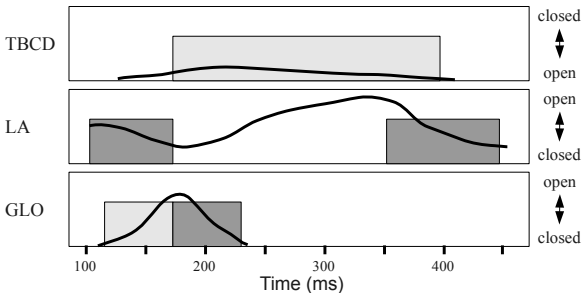

Figure 1: Canonical example *pub* from Saltzman and Munhall (1989).

The presence of these discrete goals influences the vocal tract dynamically and continuously as modelled by the following non-homogeneous second-order linear differential equation:

$$Mz'' + Bz' + K(z - z^*) = 0. \quad (1)$$

[1] Constriction *locations* generally refer to the front-back dimension of the vocal tract and constriction *degrees* generally refer to the top-down dimension.

Here, z is a continuous vector representing the instantaneous positions of the nine tract variables, z^* is the target (equilibrium) positions of those variables, and vectors z' and z'' represent the first and second derivatives of z with respect to time (i.e., velocity and acceleration), respectively. The matrices M, B, and K are syllable-specific coefficients describing the inertia, damping, and stiffness, respectively, of the virtual gestures. Generally, this theory assumes that the tract variables are mutually independent, and that the system is critically damped (i.e., the tract variables do not oscillate around their equilibrium positions) (Nam and Saltzman, 2003). The continuous state, z, of equation (1) is exemplified by black curves in figure 1.

2.2 Articulatory data

Tract variables provide the dimensions of an abstract gestural space independent of the physical characteristics of the speaker. In order to complete our articulatory model, however, we require physical data from which to infer these high-level articulatory goals.

Electromagnetic articulography (EMA) is a method to measure the motion of the vocal tract during speech. In EMA, the speaker is placed within a low-amplitude electromagnetic field produced within a cube of a known geometry. Tiny sensors within this field induce small electric currents whose energy allows the inference of articulator positions and velocities to within 1 mm of error (Yunusova et al., 2009). We derive data for the following study from two EMA sources:

- The University of Edinburgh's MOCHA database, which provides phonetically-balanced sentences repeated from TIMIT (Zue et al., 1989) uttered by a male and a female speaker (Wrench, 1999), and
- The University of Toronto's TORGO database, from which we select sentences repeated from TIMIT from two females and three males (Rudzicz et al., 2008). (Cerebrally palsied speech, which is the focus of this database, is not included here).

For the following study we use the eight 2D positions common to both databases, namely the upper lip (UL), lower lip (LL), upper incisor (UI), lower incisor (LI), tongue tip (TT), tongue blade (TB), and tongue dorsum (TD). Since these positions are recorded in 3D in TORGO, we project

these onto the midsagittal plane. (Additionally, the MOCHA database provides velum (V) data on this plane, and TORGO provides the left and right lip corners (LL and RL) but these are excluded from study except where noted).

All articulatory data is aligned with its associated acoustic data, which is transformed to Mel-frequency cepstral coefficients (MFCCs). Since the 2D EMA system in MOCHA and the 3D EMA system in TORGO differ in their recording rates, the length of each MFCC frame in each database must differ in order to properly align acoustics with articulation in time. Therefore, each MFCC frame covers 16 ms in the TORGO database, and 32 ms in MOCHA. Phoneme boundaries are determined automatically in the MOCHA database by forced alignment, and by a speech-language pathologist in the TORGO database.

We approximate the tract variable space from the physical space of the articulators, in general, through principal component analysis (PCA) on the latter, and subsequent sigmoid normalization on $[0, 1]$. For example, the LTH tract variable is inferred by calculating the first principal component of the two-dimensional lower incisor (LI) motion in the midsagittal plane, and by normalizing the resulting univariate data through a scaled sigmoid. The VEL variable is inferred similarly from velum (V) EMA data. Tongue tip constriction location and degree (TTCL and TTCD, respectively) are inferred from the 1^{st} and 2^{nd} principal components of tongue tip (TT) EMA data, with TBCL and TBCD inferred similarly from tongue body (TB) data. Finally, the glottis (GLO) is inferred by voicing detection on acoustic energy below 150 Hz (O'Shaughnessy, 2000), lip aperture (LA) is the normalized Euclidean distance between the lips, and lip protrusion (LP) is the normalized 2^{nd} principal component of the midpoint between the lips. All PCA is performed without segmentation of the data. The result is a low-dimensional set of continuous curves describing goal-relevant articulatory variables. Figure 2, for example, shows the degree of the lip aperture (LA) over time for all instances of the */b/* phoneme in the MOCHA database. The relevant articulatory goal of lip closure is evident.

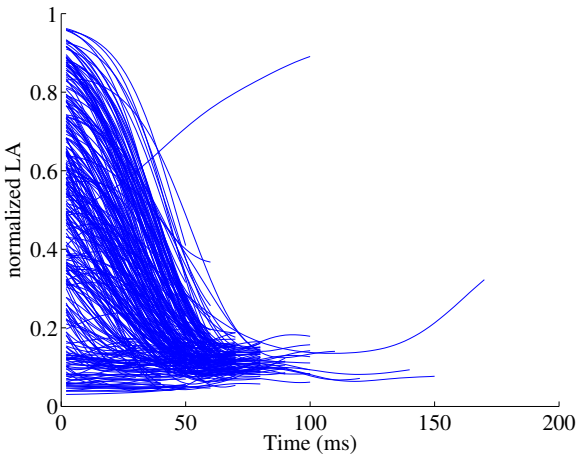

Figure 2: Lip aperture (LA) over time during all MOCHA instances of */b/*.

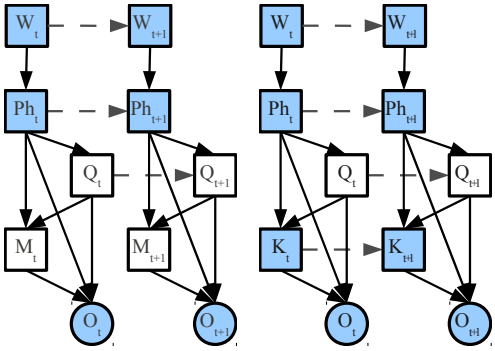
3 Baseline systems

We now turn to the task of speech recognition. Traditional Bayesian learning is restricted to universal or immutable relationships, and is agnostic towards dynamic systems or time-varying relationships. Dynamic Bayes networks (DBNs) are directed acyclic graphs that generalize the powerful stochastic mechanisms of Bayesian representation to temporal sequences. We are free to explicitly provide topological (i.e., dependency) relationships between relevant variables in our models, which can include measurements of tract data.

We examine two baseline systems. The first is the standard acoustic hidden Markov model (HMM) augmented with a bigram language model, as shown in figure 3(a). Here, $W_t \rightarrow W_{t+1}$ represents word transition probabilities, learned by maximum likelihood estimation, and $Ph_t \rightarrow Ph_{t+1}$ represents phoneme transition probabilities whose order is explicitly specified by the relationship $W_t \rightarrow Ph_t$. Likewise, each phoneme Ph conditions the sub-phoneme state, Q_t, whose transition probabilities $Q_t \rightarrow Q_{t+1}$ describe the dynamics within phonemes. The variable M_t refers to hidden Gaussian indices so that the likelihoods of acoustic observations, O_t, are represented by a mixture of 4, 8, 16, or 32 Gaussians for each state and each phoneme. See Murphy (2002) for a further description of this representation.

The second baseline model is the articulatory dynamic Bayes network (DBN-A). This augments the standard acoustic HMM by replacing hidden indices, M_t, with discrete observations of the vocal tract, K_t, as shown in figure 3(b). The pattern of acoustics within each phoneme is dependent on a relatively restricted set of possible articulatory configurations (Roweis, 1999). To find these discrete positions, we obtain k vectors that best de-

scribe the articulatory data according to k-means clustering with the sum-of-squares error function. During training, the DBN variable K_t is set explicitly to the *index* of the mean vector nearest to the current frame of EMA data at time t. In this way, the relationship $K_t \rightarrow O_t$ allows us to learn how discretized articulatory configurations affect acoustics. The training of DBNs involves a specialized version of expectation-maximization, as described in the literature (Murphy, 2002; Ghahramani, 1998). During inference, variables W_t, Ph_t, and K_t become hidden and we marginalize over their possible values when computing their likelihoods. Bigrams are computed by maximum likelihood on lexical annotations in the training data.



(a) HMM (b) DBN-A

Figure 3: Baseline systems: (a) acoustic hidden Markov model and (b) articulatory dynamic Bayes network. Node W_t represents the current word, Ph_t is the current phoneme, Q_t is that phoneme's dynamic state, O_t is the acoustic observation, M_t is the Gaussian mixture component, and K_t is the discretized articulatory configuration. Filled nodes represent observed variables during training, although only O_t is observed during recognition. Square nodes are discrete variables while circular nodes are continuous variables.

4 Switching Kalman filter

Our first experimental system attempts speech recognition given only articulatory data. The true state of the tract variables at time $t-1$ constitutes a 9-dimensional vector, $\mathbf{x}_{t-1}$, of continuous values. Under the task dynamics model of section 2.1, the motions of these tract variables obey critically damped second-order oscillatory relationships. We start with the simplifying assumption of linear dynamics here with allowances for random Gaussian *process noise*, $\mathbf{v}_t$, since articulatory behaviour is non-deterministic. Moreover, we know that EMA recordings are subject to some error (usually less than 1 mm (Yunusova et al., 2009)), so the actual observation at time t, $\mathbf{y}_t$, will not in general be the true position of the articulators. Assuming that the relationship between $\mathbf{y}_t$ and $\mathbf{x}_t$ is also linear, and that the *measurement noise*, $\mathbf{w}_t$, is also Gaussian, then the dynamical articulatory system can be described by

$$\begin{aligned} \mathbf{x}_t &= D_t \mathbf{x}_{t-1} + \mathbf{v}_t \\ \mathbf{y}_t &= C_t \mathbf{x}_t + \mathbf{w}_t. \end{aligned} \tag{2}$$

Eqs. 2 form the basis of the Kalman filter which allows us to use EMA measurements directly, rather than quantized abstractions thereof as in the DBN-A model. Obviously, since articulatory dynamics vary significantly for different goals, we replicate eq. (2) for each phoneme and connect these continuous Kalman filters together with discrete conditioning variables for phoneme and word, resulting in the switching Kalman filter (SKF) model. Here, parameters D_t and $\mathbf{v}_t$ are implicit in the relationship $\mathbf{x}_t \rightarrow \mathbf{x}_{t+1}$, and parameters C_t and $\mathbf{w}_t$ are implicit in $\mathbf{x}_t \rightarrow \mathbf{y}_t$. In this model, observation $\mathbf{y}_t$ is the instantaneous measurements derived from EMA, and $\mathbf{x}_t$ is their true hidden states. These parameters are trained using expectation-maximization, as described in the literature (Murphy, 1998; Deng et al., 2005).

5 Recognition with task dynamics

Our goal is to integrate task dynamics within an ASR system for continuous sentences called TD-ASR. Our approach is to re-rank an N-best list of sentence hypotheses according to a weighted likelihood of their articulatory realizations. For example, if a word sequence $W_i : w_{i,1}\ w_{i,2}\ \ldots\ w_{i,m}$ has likelihoods $L_X(W_i)$ and $L_\Lambda(W_i)$ according to purely acoustic and articulatory interpretations of an utterance, respectively, then its overall score would be

$$L(W_i) = \alpha L_X(W_i) + (1-\alpha) L_\Lambda(W_i) \tag{3}$$

given a weighting parameter α set manually, as in section 6.2. Acoustic likelihoods $L_X(W_i)$ are obtained from Viterbi paths through relevant HMMs in the standard fashion.

5.1 The `TADA` component

In order to obtain articulatory likelihoods, $L_\Lambda(W_i)$, for each word sequence, we first generate articulatory realizations of those sequences according

to task dynamics. To this end, we use components from the open-source TADA system (Nam and Goldstein, 2006), which is a complete implementation of task dynamics. From this toolbox, we use the following components:

- A syllabic dictionary supplemented with the International Speech Lexicon Dictionary (Hasegawa-Johnson and Fleck, 2007). This breaks word sequences W_i into syllable sequences S_i consisting of onsets, nuclei, and coda and covers all of MOCHA and TORGO.
- A syllable-to-gesture lookup table. Given a syllabic sequence, S_i, this table provides the gestural goals necessary to produce those syllables. For example, given the syllable *pub* in figure 1, this table provides the targets for the GLO, VEL, TBCL, and TBCD tract variables, and the parameters for the second-order differential equation, eq. 1, that achieves those goals. These parameters have been empirically tuned by the authors of TADA according to a generic, speaker-independent representation of the vocal tract (Saltzman and Munhall, 1989).
- A component that produces the continuous tract variable paths that produce an utterance. This component takes into account various physiological aspects of human speech production, including intergestural and interarticulator co-ordination and timing (Nam and Saltzman, 2003; Goldstein and Fowler, 2003), and the neutral ("schwa") forces of the vocal tract (Saltzman and Munhall, 1989). This component takes a sequence of gestural goals predicted by the segment-to-gesture lookup table, and produces appropriate paths for each tract variable.

The result of the TADA component is a set of N 9-dimensional articulatory paths, $\mathbf{TV}_i$, necessary to produce the associated word sequences, W_i for $i = 1..N$. Since task dynamics is a prescriptive model and fully deterministic, $\mathbf{TV}_i$ sequences are the *canonical* or default articulatory realizations of the associated sentences. These canonical realizations are independent of our training data, so we transform them in order to more closely resemble the observed articulatory behaviour in our EMA data. Towards this end, we train a switching Kalman filter identical to that in section 4, except the hidden state variable $\mathbf{x}_t$ is replaced by the observed instantaneous *canonical* TVs predicted by TADA. In this way we are explicitly learning a relationship between TADA's task dynamics and human data. Since the lengths of these sequences are generally unequal, we align the articulatory behaviour predicted by TADA with training data from MOCHA and TORGO using standard dynamic time warping (Sakoe and Chiba, 1978). During run-time, the articulatory sequence $\mathbf{y}_t$ most likely to have been produced by the human data given the canonical sequence $\mathbf{TV}_i$ is inferred by the Viterbi algorithm through the SKF model with all other variables hidden. The result is a set of articulatory sequences, $\mathbf{TV}_i^*$, for $i = 1..N$, that represent the predictions of task dynamics that better resemble our data.

5.2 Acoustic-articulatory inversion

In order to estimate the articulatory likelihood of an utterance, we need to evaluate each transformed articulatory sequence, $\mathbf{TV}_i^*$, within probability distributions ranging over all tract variables. These distributions can be inferred using acoustic-articulatory inversion. There are a number of approaches to this task, including vector quantization, and expectation-maximization with Gaussian mixtures (Hogden and Valdez, 2001; Toda et al., 2008). These approaches accurately inferred the *xy* position of articulators to within 0.41 mm and 2.73 mm. Here, we modify the approach taken by Richmond et al. (2003), who estimate probability functions over the 2D midsagittal positions of 7 articulators, given acoustics, with a mixture-density network (MDN). An MDN is essentially a typical discriminative multi-layer neural network whose output consists of the parameters to Gaussian mixtures. Here, each Gaussian mixture describes a probability function over TV positions given the acoustic frame at time t. For example, figure 4 shows an intensity map of the likely values for tongue-tip constriction degree (TTCD) for each frame of acoustics, superimposed with the 'true' trajectory of that TV. Our networks are trained with acoustic and EMA-derived data as described in section 2.2.

5.3 Recognition by reranking

During recognition of a test utterance, a standard acoustic HMM produces word sequence hypotheses, W_i, and associated likelihoods, $L(W_i)$, for $i = 1..N$. The expected canonical motion of the tract variables, $\mathbf{TV}_i$ is then produced by task dynamics

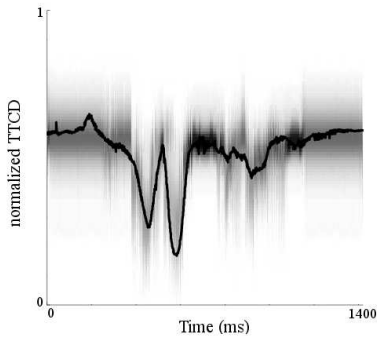


Figure 4: Example probability density of tongue tip constriction degree over time, inferred from acoustics. The true trajectory is superimposed as a black curve.

for each of these word sequences and transformed by an SKF to better match speaker data, giving $\mathbf{TV}_i^*$. The likelihoods of these paths are then evaluated within probability distributions produced by an MDN. The mechanism for producing the articulatory likelihood is shown in figure 5. The overall likelihood, $L(W_i) = \alpha L_X(W_i) + (1-\alpha)L_\Lambda(W_i)$, is then used to produce a final hypothesis list for the given acoustic input.

6 Experiments

Experimental data is obtained from two sources, as described in section 2.2. We procure 1200 sentences from Toronto's TORGO database, and 896 from Edinburgh's MOCHA. In total, there are 460 total unique sentence forms, 1092 total unique word forms, and 11065 total words uttered. Except where noted, all experiments randomly split the data into 90% training and 10% testing sets for 5-cross validation. MOCHA and TORGO data are never combined in a single training set due to differing EMA recording rates. In all cases, models are database-dependent (i.e., all TORGO data is conflated, as is all of MOCHA).

For each of our baseline systems, we calculate the phoneme-error-rate (PER) and word-error-rate (WER) after training. The phoneme-error-rate is calculated according to the proportion of frames of speech incorrectly assigned to the proper phoneme. The word-error-rate is calculated as the sum of insertion, deletion, and substitution errors in the highest-ranked hypothesis divided by the total number of words in the correct orthography. The traditional HMM is compared by varying the number of Gaussians used in the modelling of acoustic observations. Similarly, the DBN-A model is compared by varying the number of discrete quantizations of articulatory configurations, as described in section 3. Results are obtained by direct decoding. The average results across both databases, between which there are no significant differences, are shown in table 1. In all cases the DBN-A model outperforms the HMM, which highlights the benefit of explicitly conditioning acoustic observations on articulatory causes.

System	Parameters	PER (%)	WER (%)
HMM	$\|M\| = 4$	29.3	14.5
	$\|M\| = 8$	27.0	13.9
	$\|M\| = 16$	26.1	10.2
	$\|M\| = 32$	25.6	9.7
DBN-A	$\|K\| = 4$	26.1	13.0
	$\|K\| = 8$	25.2	11.3
	$\|K\| = 16$	24.9	9.8
	$\|K\| = 32$	24.8	9.4

Table 1: Phoneme- and Word-Error-Rate (PER and WER) for different parameterizations of the baseline systems.

	No. of Gaussians			
	1	2	3	4
LTH	−0.28	−0.18	−0.15	−0.11
LA	−0.36	−0.32	−0.30	−0.29
LP	−0.46	−0.44	−0.43	−0.43
GLO	−1.48	−1.30	−1.29	−1.25
TTCD	−1.79	−1.60	−1.51	−1.47
TTCL	−1.81	−1.62	−1.53	−1.49
TBCD	−0.88	−0.79	−0.75	−0.72
TDCL	−0.22	−0.20	−0.18	−0.17

Table 2: Average log likelihood of true tract variable positions in test data, under distributions produced by mixture density networks with varying numbers of Gaussians.

6.1 Efficacy of TD-ASR components

In order to evaluate the whole system, we start by evaluating its parts. First, we test how accurately the mixture-density network (MDN) estimates the position of the articulators given only information from the acoustics available during recognition. Table 2 shows the average log likelihood over each tract variable across both databases. These results are consistent with the state-of-the-art (Toda et al., 2008). In the following experiments, we use MDNs that produce 4 Gaussians.

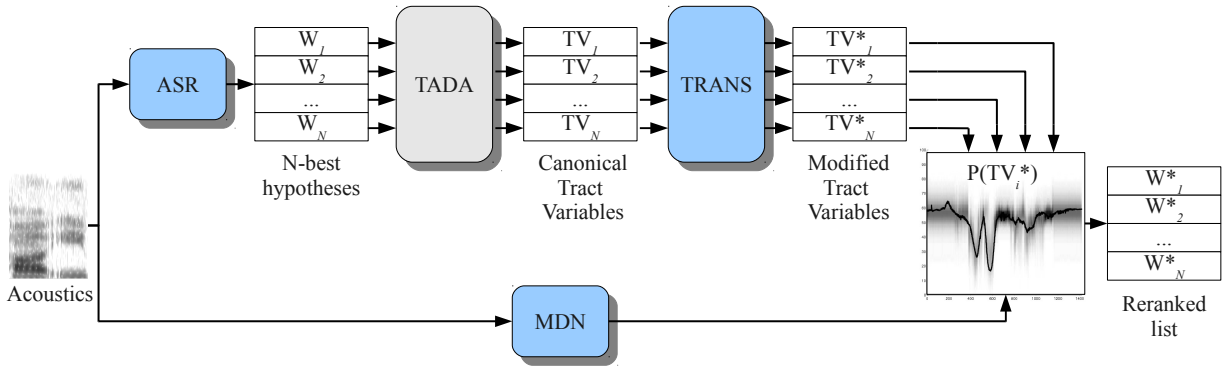

Figure 5: The TD-ASR mechanism for deriving articulatory likelihoods, $L_\Lambda(W_i)$, for each word sequence W_i produced by standard acoustic techniques.

Manner	Canonical	Transformed
approximant	0.19	0.16
fricative	0.37	0.29
nasal*	0.24	0.18
retroflex	0.23	0.19
plosive	0.10	0.08
vowel	0.27	0.25

Table 3: Average difference between predicted tract variables and observed data, on $[0,1]$ scale. (*) Nasals are evaluated only with MOCHA data, since TORGO data lacks velum measurements.

We evaluate how closely transformations to the canonical tract variables predicted by TADA match the data. Namely, we input the known orthography for each test utterance into TADA, obtain the predicted canonical tract variables **TV**, and transform these according to our trained SKF. The resulting predicted and transformed sequences are aligned with our measurements derived from EMA with dynamic time warping. Finally, we measure the average difference between the observed data and the predicted (canonical and transformed) tract variables. Table 3 shows these differences according to the phonological manner of articulation. In all cases the transformed tract variable motion is more accurate, and significantly so at the 95% confidence level for nasal and retroflex phonemes, and at 99% for fricatives. The practical utility of the transformation component is evaluated in its effect on recognition rates, as described below.

6.2 Recognition with TD-ASR

With the performance of the components of TD-ASR better understood, we combine these and study the resulting composite TD-ASR system.

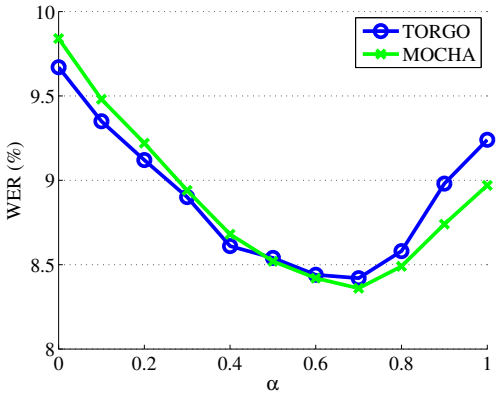

Figure 6: Word-error-rate according to varying α, for both TORGO and MOCHA data.

Figure 6 shows the WER as a function of α with TD-ASR and $N = 4$ hypotheses per utterance. The effect of α is clearly non-monotonic, with articulatory information clearly proving useful. Although systems whose rankings are weighted solely by the articulatory component perform better than the exclusively acoustic systems, the lists available to the former are procured from standard acoustic ASR. Interestingly, the gap between systems trained to the two databases increases as α approaches 1.0. Although this gap is not significant, it may be the result of increased inter-speaker articulatory variation in the TORGO database, which includes more than twice as many speakers as MOCHA.

Figure 7 shows the WER obtained with TD-ASR given varying-length N-best lists and $\alpha = 0.7$. TD-ASR accuracy at $N = 4$ is significantly better than both TD-ASR at $N = 2$ and the baseline approaches of table 1 at the 95% confidence level. However, for $N > 4$ there is a noticeable and systematic worsening of performance.

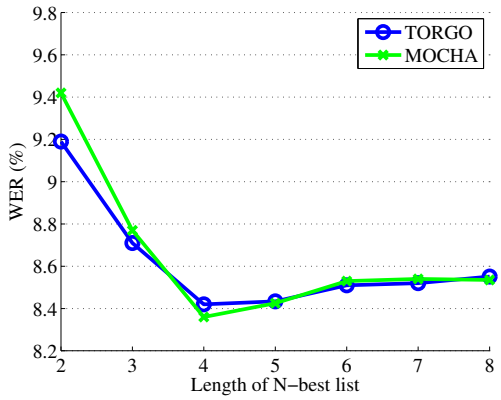

Figure 7: Word-error-rate according to varying lengths of N-best hypotheses used, for both TORGO and MOCHA data.

The optimal parameterization of the TD-ASR model results in an average word-error-rate of 8.43%, which represents a 10.3% relative error reduction over the best parameterization of our baseline models. The SKF model of section 4 differs from the HMM and DBN-A baseline models only in its use of continuous (rather than discrete) hidden dynamics and in its articulatory observations. However, its performance is far more variable, and less conclusive. On the MOCHA database the SKF model had an average of 9.54% WER with a standard deviation of 0.73 over 5 trials, and an average of 9.04% WER with a standard deviation of 0.64 over 5 trials on the TORGO database. Despite the presupposed utility of direct articulatory observations, the SKF system does not perform significantly better than the best DBN-A model.

Finally, the experiments of tables 6 and 7 are repeated with the canonical tract variables passed untransformed to the probability maps generated by the MDNs. Predictably, resulting articulatory likelihoods L_Λ are less representative and increasing their contribution α to the hypothesis reranking does not improve TD-ASR performance significantly, and in some instances worsens it. Although `TADA` is a useful prescriptive model of generic articulation, its use must be tempered with knowledge of inter-speaker variability.

7 Discussion and conclusions

The articulatory medium of speech rarely informs modern speech recognition. We have demonstrated that the use of direct articulatory knowledge can substantially reduce phoneme and word errors in speech recognition, especially if that knowledge is motivated by high-level abstractions of vocal tract behaviour. Task dynamic theory provides a coherent and biologically plausible model of speech production with consequences for phonology (Browman and Goldstein, 1986), neurolinguistics (Guenther and Perkell, 2004), and the evolution of speech and language (Goldstein et al., 2006). We have shown that it is also useful within speech recognition.

We have overcome a conceptual impediment in integrating task dynamics and ASR, which is the former's deterministic nature. This integration is accomplished by stochastically transforming predicted articulatory dynamics and by calculating the likelihoods of these dynamics according to speaker data. However, there are several new avenues for exploration. For example, task dynamics lends itself to more general applications of control theory, including automated self-correction, rhythm, co-ordination, and segmentation (Friedland, 2005). Other high-level questions also remain, such as whether discrete gestures are the correct biological and practical paradigm, whether a purely continuous representation would be more appropriate, and whether this approach generalizes to other languages.

In general, our experiments have revealed very little difference between the use of MOCHA and TORGO EMA data. An *ad hoc* analysis of some of the errors produced by the TD-ASR system found no particular difference between how systems trained to each of these databases recognized nasal phonemes, although only those trained with MOCHA considered velum motion. Other errors common to both sources of data include phoneme insertion errors, normally vowels, which appear to co-occur with some spurious motion of the tongue between segments, especially for longer N-best lists. Despite the relative slow motion of the articulators relative to acoustics, there remains some intermittent noise.

As more articulatory data becomes available and as theories of speech production become more refined, we expect that their combined value to speech recognition will become indispensable.

Abstract

We present a data-driven approach to learn user-adaptive referring expression generation (REG) policies for spoken dialogue systems. Referring expressions can be difficult to understand in technical domains where users may not know the technical 'jargon' names of the domain entities. In such cases, dialogue systems must be able to model the user's (lexical) domain knowledge and use appropriate referring expressions. We present a reinforcement learning (RL) framework in which the system learns REG policies which can adapt to unknown users online. Furthermore, unlike supervised learning methods which require a large corpus of expert adaptive behaviour to train on, we show that effective adaptive policies can be learned from a small dialogue corpus of non-adaptive human-machine interaction, by using a RL framework and a statistical user simulation. We show that in comparison to adaptive hand-coded baseline policies, the learned policy performs significantly better, with an 18.6% average increase in adaptation accuracy. The best learned policy also takes less dialogue time (average 1.07 min less) than the best hand-coded policy. This is because the learned policies can adapt online to changing evidence about the user's domain expertise.

1 Introduction

We present a reinforcement learning (Sutton and Barto, 1998) framework to learn user-adaptive referring expression generation policies from data-driven user simulations. A user-adaptive REG policy allows the system to choose appropriate expressions to refer to domain entities in a dialogue setting. For instance, in a technical support conversation, the system could choose to use more technical terms with an expert user, or to use more descriptive and general expressions with novice users, and a mix of the two with intermediate users of various sorts (see examples in Table 1).

Jargon: Please plug one end of the `broadband cable` into the `broadband filter`.
Descriptive: Please plug one end of the `thin white cable with grey ends` into the `small white box`.

Table 1: Referring expression examples for 2 entities (from the corpus)

In natural human-human conversations, dialogue partners learn about each other and adapt their language to suit their domain expertise (Issacs and Clark, 1987). This kind of adaptation is called `Alignment through Audience Design` (Clark and Murphy, 1982; Bell, 1984). We assume that users are mostly unknown to the system and therefore that a spoken dialogue system (SDS) must be capable of observing the user's dialogue behaviour, modelling his/her domain knowledge, and adapting accordingly, just like human interlocutors. Rule-based and supervised learning approaches to user adaptation in SDS have been proposed earlier (Cawsey, 1993; Akiba and Tanaka, 1994). However, such methods require expensive resources such as domain experts to hand-code the rules, or a corpus of expert-layperson interactions to train on. In contrast, we present a corpus-driven framework using which a user-adaptive REG policy can be learned using RL from a small corpus of non-adaptive human-machine interaction.

We show that these learned policies perform better than simple hand-coded adaptive policies in terms of accuracy of adaptation and dialogue

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 69–78,
Uppsala, Sweden, 11-16 July 2010.

time. We also compared the performance of policies learned using a hand-coded rule-based simulation and a data-driven statistical simulation and show that data-driven simulations produce better policies than rule-based ones.

In section 2, we present some of the related work. Section 3 presents the dialogue data that we used to train the user simulation. Section 4 and section 5 describe the dialogue system framework and the user simulation models. In section 6, we present the training and in section 7, we present the evaluation for different REG policies.

2 Related work

There are several ways in which natural language generation (NLG) systems adapt to users. Some of them adapt to a user's goals, preferences, environment and so on. Our focus in this study is restricted to the user's lexical domain expertise. Several NLG systems adapt to the user's domain expertise at different levels of generation - text planning (Paris, 1987), complexity of instructions (Dale, 1989), referring expressions (Reiter, 1991), and so on. Some dialogue systems, such as COMET, have also incorporated NLG modules that present appropriate levels of instruction to the user (McKeown et al., 1993). However, in all the above systems, the user's knowledge is assumed to be accurately represented in an initial user model using which the system adapts its language. In contrast to all these systems, our adaptive REG policy knows nothing about the user when the conversation starts.

Rule-based and supervised learning approaches have been proposed to learn and adapt during the conversation dynamically. Such systems learned from the user at the start and later adapted to the domain knowledge of the users. However, they either require expensive expert knowledge resources to hand-code the inference rules (Cawsey, 1993) or large corpus of expert-layperson interaction from which adaptive strategies can be learned and modelled, using methods such as Bayesian networks (Akiba and Tanaka, 1994). In contrast, we present an approach that learns in the absence of these expensive resources. It is also not clear how supervised and rule-based approaches choose between when to seek more information and when to adapt. In this study, we show that using reinforcement learning this decision is learned automatically.

Reinforcement Learning (RL) has been successfully used for learning dialogue management policies since (Levin et al., 1997). The learned policies allow the dialogue manager to optimally choose appropriate dialogue acts such as instructions, confirmation requests, and so on, under uncertain noise or other environment conditions. There have been recent efforts to learn information presentation and recommendation strategies using reinforcement learning (Rieser and Lemon, 2009; Hernandez et al., 2003; Rieser and Lemon, 2010), and joint optimisation of Dialogue Management and NLG using hierarchical RL has been proposed by (Lemon, 2010). In contrast, we present a framework to learn to choose appropriate referring expressions based on a user's domain knowledge. Earlier, we reported a proof-of-concept work using a hand-coded rule-based user simulation (Janarthanam and Lemon, 2009c).

3 The Wizard-of-Oz Corpus

We use a corpus of technical support dialogues collected from real human users using a Wizard-of-Oz method (Janarthanam and Lemon, 2009b). The corpus consists of 17 dialogues from users who were instructed to physically set up a home broadband connection using objects like a wireless modem, cables, filters, etc. They listened to the instructions from the system and carried them out using the domain objects laid in front of them. The human 'wizard' played the role of only an interpreter who would understand what the user said and annotate it as a dialogue act. The set-up examined the effect of using three types of referring expressions (jargon, descriptive, and tutorial), on the users.

Out of the 17 dialogues, 6 used a jargon strategy, 6 used a descriptive strategy, and 5 used a tutorial strategy[1]. The task had reference to 13 domain entities, mentioned repeatedly in the dialogue. In total, there are 203 jargon, 202 descriptive and 167 tutorial referring expressions. Interestingly, users who weren't acquainted with the domain objects requested clarification on some of the referring expressions used. The dialogue exchanges between the user and system were logged in the form of dialogue acts and the system's choices of referring expressions. Each user's knowledge of domain entities was recorded both before and after the task and each user's interac-

[1]The tutorial strategy uses both jargon and descriptive expressions together.

tions with the environment were recorded. We use the dialogue data, pre-task knowledge tests, and the environment interaction data to train a user simulation model. Pre and post-task test scores were used to model the learning behaviour of the users during the task (see section 5).

The corpus also recorded the time taken to complete each dialogue task. We used these data to build a regression model to calculate total dialogue time for dialogue simulations. The strategies were never mixed (with some jargon, some descriptive and some tutorial expressions) within a single conversation. Therefore, please note that the strategies used for data collection were *not adaptive* and the human 'wizard' has no role in choosing which referring expression to present to the user. Due to this fact, no user score regarding adaptation was collected. We therefore measure adaptation objectively as explained in section 6.1.

4 The Dialogue System

In this section, we describe the different modules of the dialogue system. The interaction between the different modules is shown in figure 1 (in learning mode). The dialogue system presents the user with instructions to setup a broadband connection at home. In the Wizard of Oz setup, the system and the user interact using speech. However, in our machine learning setup, they interact at the abstract level of dialogue actions and referring expressions. Our objective is to learn to choose the appropriate referring expressions to refer to the domain entities in the instructions.

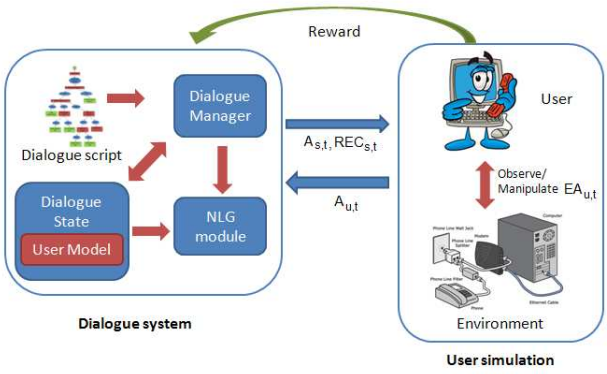

Figure 1: System User Interaction (learning)

4.1 Dialogue Manager

The dialogue manager identifies the next instruction (dialogue act) to give to the user based on the dialogue management policy π_{dm}. Since, in this study, we focus only on learning the REG policy, the dialogue management is coded in the form of a finite state machine. In this dialogue task, the system provides two kinds of instructions - observation and manipulation. For observation instructions, users observe the environment and report back to the system, and for the manipulation instructions (such as plugging in a cable in to a socket), they manipulate the domain entities in the environment. When the user carries out an instruction, the system state is updated and the next instruction is given. Sometimes, users do not understand the referring expressions used by the system and then ask for clarification. In such cases, the system provides clarification on the referring expression ($provide\_clar$), which is information to enable the user to associate the expression with the intended referent. The system action $A_{s,t}$ (t denoting turn, s denoting system) is therefore to either give the user the next instruction or a clarification. When the user responds in any other way, the instruction is simply repeated. The dialogue manager is also responsible for updating and managing the system state $S_{s,t}$ (see section 4.2). The system interacts with the user by passing both the system action $A_{s,t}$ and the referring expressions $REC_{s,t}$ (see section 4.3).

4.2 The dialogue state

The dialogue state $S_{s,t}$ is a set of variables that represent the current state of the conversation. In our study, in addition to maintaining an overall dialogue state, the system maintains a user model $UM_{s,t}$ which records the initial domain knowledge of the user. It is a dynamic model that starts with a state where the system does not have any idea about the user. As the conversation progresses, the dialogue manager records the evidence presented to it by the user in terms of his dialogue behaviour, such as asking for clarification and interpreting jargon. Since the model is updated according to the user's behaviour, it may be inaccurate if the user's behaviour is itself uncertain. So, when the user's behaviour changes (for instance, from novice to expert), this is reflected in the user model during the conversation. Hence, unlike previous studies mentioned in section 2, the user model used in this system is not always an accurate model of the user's knowledge and reflects a level of uncertainty about the user.

Each jargon referring expression x is represented by a three valued variable in the dialogue state: user_knows_x. The three values that each variable takes are yes, no, not_sure. The variables are updated using a simple user model update algorithm. Initially each variable is set to not_sure. If the user responds to an instruction containing the referring expression x with a clarification request, then user_knows_x is set to no. Similarly, if the user responds with appropriate information to the system's instruction, the dialogue manager sets user_knows_x is set to yes.

The dialogue manager updates the variables concerning the referring expressions used in the current system utterance appropriately after the user's response each turn. The user may have the capacity to learn jargon. However, only the user's initial knowledge is recorded. This is based on the assumption that an estimate of the user's knowledge helps to predict the user's knowledge of the rest of the referring expressions. Another issue concerning the state space is its size. Since, there are 13 entities and we only model the jargon expressions, the state space size is 3^{13}.

4.3 REG module

The REG module is a part of the NLG module whose task is to identify the list of domain entities to be referred to and to choose the appropriate referring expression for each of the domain entities for each given dialogue act. In this study, we focus only on the production of appropriate referring expressions to refer to domain entities mentioned in the dialogue act. It chooses between the two types of referring expressions - jargon and descriptive. For example, the domain entity *broadband_filter* can be referred to using the jargon expression "broadband filter" or using the descriptive expression "small white box"[2]. We call this the act of choosing the *REG action*. The tutorial strategy was not investigated here since the corpus analysis showed tutorial utterances to be very time consuming. In addition, they do not contribute to the adaptive behaviour of the system.

The REG module operates in two modes - learning and evaluation. In the learning mode, the REG module is the learning agent. The REG module learns to associate dialogue states with optimal REG actions. This is represented by a REG policy $\pi_{reg} : UM_{s,t} \rightarrow REC_{s,t}$, which maps the states of the dialogue (user model) to optimal REG actions. The referring expression choices $REC_{s,t}$ is a set of pairs identifying the referent R and the type of expression T used in the current system utterance. For instance, the pair $(broadband\_filter, desc)$ represents the descriptive expression "small white box".

$$REC_{s,t} = \{(R_1, T_1), ..., (R_n, T_n)\}$$

In the evaluation mode, a trained REG policy interacts with unknown users. It consults the learned policy π_{reg} to choose the referring expressions based on the current user model.

5 User Simulations

In this section, we present user simulation models that simulate the dialogue behaviour of a real human user. These external simulation models are different from internal user models used by the dialogue system. In particular, our model is the first to be sensitive to a system's choices of referring expressions. The simulation has a statistical distribution of in-built knowledge profiles that determines the dialogue behaviour of the user being simulated. If the user does not know a referring expression, then he is more *likely* to request clarification. If the user is able to interpret the referring expressions and identify the references then he is more likely to follow the system's instruction. This behaviour is simulated by the action selection models described below.

Several user simulation models have been proposed for use in reinforcement learning of dialogue policies (Georgila et al., 2005; Schatzmann et al., 2006; Schatzmann et al., 2007; Ai and Litman, 2007). However, they are suited only for learning dialogue management policies, and not natural language generation policies. Earlier, we presented a two-tier simulation trained on data precisely for REG policy learning (Janarthanam and Lemon, 2009a). However, it is not suited for training on small corpus like the one we have at our disposal. In contrast to the earlier model, we now condition the clarification requests on the referent class rather than the referent itself to handle data sparsity problem.

The user simulation (US) receives the system action $A_{s,t}$ and its referring expression choices $REC_{s,t}$ at each turn. The US responds with a user action $A_{u,t}$ (u denoting user). This can either be a clarification request (cr) or an instruction

[2] We will use italicised forms to represent the domain entities (e.g. *broadband_filter*) and double quotes to represent the referring expressions (e.g. "broadband filter").

response (ir). We used two kinds of action selection models: corpus-driven statistical model and hand-coded rule-based model.

5.1 Corpus-driven action selection model

In the corpus-driven model, the US produces a clarification request cr based on the class of the referent $C(R_i)$, type of the referring expression T_i, and the current domain knowledge of the user for the referring expression $DK_{u,t}(R_i, T_i)$. Domain entities whose jargon expressions raised clarification requests in the corpus were listed and those that had more than the mean number of clarification requests were classified as `difficult` and others as `easy` entities (for example, "power adaptor" is `easy` - all users understood this expression, "broadband filter" is `difficult`). Clarification requests are produced using the following model.

$$P(A_{u,t} = cr(R_i, T_i)|C(R_i), T_i, DK_{u,t}(R_i, T_i))$$
$$\text{where } (R_i, T_i) \in REC_{s,t}$$

One should note that the actual literal expression is not used in the transaction. Only the entity that it is referring to (R_i) and its type (T_i) are used. However, the above model simulates the process of interpreting and resolving the expression and identifying the domain entity of interest in the instruction. The user identification of the entity is signified when there is no clarification request produced (i.e. $A_{u,t} = none$). When no clarification request is produced, the environment action $EA_{u,t}$ is generated using the following model.

$$P(EA_{u,t}|A_{s,t}) \text{ if } A_{u,t} != cr(R_i, T_i)$$

Finally, the user action is an instruction response which is determined by the system action $A_{s,t}$. Instruction responses can be different in different conditions. For an observe and report instruction, the user issues a $provide\_info$ action and for a manipulation instruction, the user responds with an $acknowledgement$ action and so on.

$$P(A_{u,t} = ir|EA_{u,t}, A_{s,t})$$

All the above models were trained on our corpus data using *maximum likelihood estimation* and smoothed using a variant of *Witten-Bell discounting*. According to the data, clarification requests are much more likely when jargon expressions are used to refer to the referents that belong to the `difficult` class and which the user doesn't know about. When the system uses expressions that the user knows, the user generally responds to the instruction given by the system. These user simulation models have been evaluated and found to produce behaviour that is very similar to the original corpus data, using the Kullback-Leibler divergence metric (Cuayahuitl, 2009).

livebox $= 1$	*power_adaptor* $= 1$
wall_phone_socket $= 1$	*broadband_filter* $= 0$

lb_power_light $= 1$	*lb_power_socket* $= 1$
lb_broadband_light $= 0$	*lb_ethernet_light* $= 0$
lb_adsl_socket $= 0$	*lb_ethernet_socket* $= 0$
pc_ethernet_socket $= 1$	

Table 2: Domain knowledge: an Intermediate User

5.2 Rule-based action selection model

We also built a rule-based simulation using the above models but where some of the parameters were set manually instead of estimated from the data. The purpose of this simulation is to investigate how learning with a data-driven statistical simulation compares to learning with a simple hand-coded rule-based simulation. In this simulation, the user *always* asks for a clarification when he does not know a jargon expression (regardless of the class of the referent) and never does this when he knows it. This enforces a stricter, more consistent behaviour for the different knowledge patterns, which we hypothesise should be easier to learn to adapt to, but may lead to less robust REG policies.

5.3 User Domain knowledge

The user domain knowledge is initially set to one of several models at the start of every conversation. The models range from novices to experts which were identified from the corpus using `k-means` clustering. The initial knowledge base ($DK_{u,initial}$) for an intermediate user is shown in table 2. A novice user knows only "power adaptor", and an expert knows all the jargon expressions. We assume that users can interpret the descriptive expressions and resolve their references. Therefore, they are not explicitly represented. We only code the user's knowledge of jargon expressions. This is represented by a boolean variable for each domain entity.

Corpus data shows that users can learn jargon expressions during the conversation. The user's domain knowledge DK_u is modelled to be dynamic and is updated during the conversation. Based on our data, we found that when presented with clarification on a jargon expression, users always learned the jargon.

$$\text{if } A_{s,t} = provide\_clar(R_i, T_i)$$
$$DK_{u,t+1}(R_i, T_i) \leftarrow 1$$

Users also learn when jargon expressions are repeatedly presented to them. Learning by repetition follows the pattern of a learning curve - the greater the number of repetitions $\#(R_i, T_i)$, the higher the likelihood of learning. This is modelled stochastically based on repetition using the parameter $\#(R_i, T_i)$ as follows (where $(R_i, T_i) \in REC_{s,t}$) .

$$P(DK_{u,t+1}(R_i, T_i) \leftarrow 1 | \#(R_i, T_i))$$

The final state of the user's domain knowledge ($DK_{u,final}$) may therefore be different from the initial state ($DK_{u,initial}$) due to the learning effect produced by the system's use of jargon expressions. In most studies done previously, the user's domain knowledge is considered to be static. However in real conversation, we found that the users nearly always learned jargon expressions from the system's utterances and clarifications.

6 Training

The REG module was trained (operated in learning mode) using the above simulations to learn REG policies that select referring expressions based on the user expertise in the domain. As shown in figure 1, the learning agent (REG module) is given a reward at the end of every dialogue. During the training session, the learning agent explores different ways to maximize the reward. In this section, we discuss how to code the learning agent's goals as reward. We then discuss how the reward function is used to train the learning agent.

6.1 Reward function

A reward function generates a numeric reward for the learning agent's actions. It gives high rewards to the agent when the actions are favourable and low rewards when they are not. In short, the reward function is a representation of the goal of the agent. It translates the agent's actions into a scalar value that can be maximized by choosing the right action sequences.

We designed a reward function for the goal of adapting to each user's domain knowledge. We present the Adaptation Accuracy score AA that calculates how accurately the agent chose the expressions for each referent r, with respect to the user's knowledge. Appropriateness of an expression is based on the user's knowledge of the expression. So, when the user knows the jargon expression for r, the appropriate expression to use is jargon, and if s/he doesn't know the jargon, an descriptive expression is appropriate. Although the user's domain knowledge is dynamically changing due to learning, we base appropriateness on the initial state, because our objective is to adapt to the initial state of the user $DK_{u,initial}$. However, in reality, designers might want their system to account for user's changing knowledge as well. We calculate accuracy per referent RA_r as the ratio of number of appropriate expressions to the total number of instances of the referent in the dialogue. We then calculate the overall mean accuracy over all referents as shown below.

$$RA_r = \frac{\#(appropriate\_expressions(r))}{\#(instances(r))}$$
$$Adaptation Accuracy AA = \frac{1}{\#(r)} \Sigma_r RA_r$$

Note that this reward is computed at the end of the dialogue (it is a 'final' reward), and is then back-propagated along the action sequence that led to that final state. Thus the reward can be computed for each system REG action, without the system having access to the user's initial domain knowledge while it is learning a policy.

Since the agent starts the conversation with no knowledge about the user, it may try to use more exploratory moves to learn about the user, although they may be inappropriate. However, by measuring accuracy to the initial user state, the agent is encouraged to restrict its exploratory moves and start predicting the user's domain knowledge as soon as possible. The system should therefore ideally explore less and adapt more to increase accuracy. The above reward function returns 1 when the agent is completely accurate in adapting to the user's domain knowledge and it returns 0 if the agent's REC choices were completely inappropriate. Usually during learning, the reward value lies between these two extremes and the agent tries to maximize it to 1.

6.2 Learning

The REG module was trained in learning mode using the above reward function using the SHARSHA reinforcement learning algorithm (with linear function approximation) (Shapiro and Langley, 2002). This is a hierarchical variant of SARSA, which is an on-policy learning algorithm that updates the current behaviour policy (see (Sutton and Barto, 1998)). The training produced approx. 5000 dialogues. Two types of simulations were used as described above: Data-driven and Hand-coded. Both user simulations were calibrated to produce three types of users: Novice, Int2 (intermediate) and Expert, randomly but with equal probability. Novice users knew just one jargon expression, Int2 knew seven, and Expert users knew all thirteen jargon expressions. There was an underlying pattern in these knowledge profiles. For example, Intermediate users were those who knew the commonplace domain entities but not those specific to broadband connection. For instance, they knew "ethernet cable" and "pc ethernet socket" but not "broadband filter" and "broadband cable".

Initially, the REG policy chooses randomly between the referring expression types for each domain entity in the system utterance, irrespective of the user model state. Once the referring expressions are chosen, the system presents the user simulation with both the dialogue act and referring expression choices. The choice of referring expression affects the user's dialogue behaviour which in turn makes the dialogue manager update the user model. For instance, choosing a jargon expression could evoke a clarification request from the user, which in turn prompts the dialogue manager to update the user model with the new information that the user is ignorant of the particular expression. It should be noted that using a jargon expression is an *information seeking* move which enables the REG module to estimate the user's knowledge level. The same process is repeated for every dialogue instruction. At the end of the dialogue, the system is rewarded based on its choices of referring expressions. If the system chooses jargon expressions for novice users or descriptive expressions for expert users, penalties are incurred and if the system chooses REs appropriately, the reward is high. On the one hand, those actions that fetch more reward are reinforced, and on the other hand, the agent tries out new state-action combinations to explore the possibility of greater rewards. Over time, it stops exploring new state-action combinations and exploits those actions that contribute to higher reward. The REG module learns to choose the appropriate referring expressions based on the user model in order to maximize the overall adaptation accuracy.

Figure 2 shows how the agent learns using the data-driven (**Learned DS**) and hand-coded simulations (**Learned HS**) during training. It can be seen in the figure 2 that towards the end the curve plateaus signifying that learning has converged.

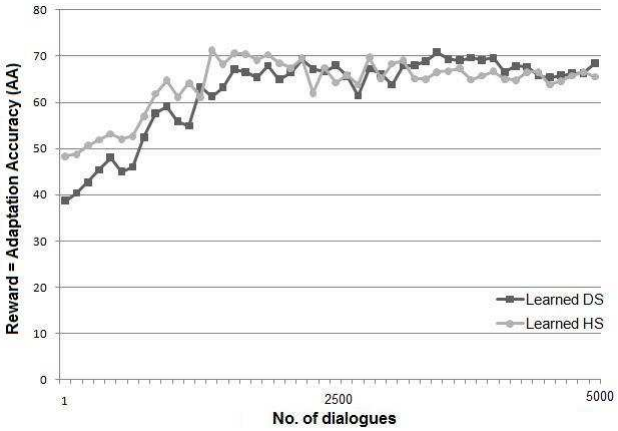

Figure 2: Learning curves - Training

7 Evaluation

In this section, we present the evaluation metrics used, the baseline policies that were hand-coded for comparison, and the results of evaluation.

7.1 Metrics

In addition to the adaptation accuracy mentioned in section 6.1, we also measure other parameters from the conversation in order to show how learned adaptive policies compare with other policies on other dimensions. We calculate the time taken ($Time$) for the user to complete the dialogue task. This is calculated using a regression model from the corpus based on number of words, turns, and mean user response time. We also measure the (normalised) learning gain (LG) produced by using unknown jargon expressions. This is calculated using the pre and post scores from the user domain knowledge (DK_u) as follows.

$$Learning\ Gain\ LG = \frac{Post-Pre}{1-Pre}$$

7.2 Baseline REG policies

In order to compare the performance of the learned policy with hand-coded REG policies, three simple rule-based policies were built. These were built in the absence of expert domain knowledge and a expert-layperson corpus.

- Jargon: Uses jargon for all referents by default. Provides clarifications when requested.
- Descriptive: Uses descriptive expressions for all referents by default.
- Switching: This policy starts with jargon expressions and continues using them until the user requests for clarification. It then switches to descriptive expressions and continues to use them until the user complains. In short, it switches between the two strategies based on the user's responses.

All the policies exploit the user model in subsequent references after the user's knowledge of the expression has been set to either `yes` or `no`. Therefore, although these policies are simple, they do adapt to a certain extent, and are reasonable baselines for comparison in the absence of expert knowledge for building more sophisticated baselines.

7.3 Results

The policies were run under a testing condition (where there is no policy learning or exploration) using a data-driven simulation calibrated to simulate 5 different user types. In addition to the three users - Novice, Expert and Int2, from the training simulations, two other intermediate users (Int1 and Int3) were added to examine how well each policy handles unseen user types. The REG module was operated in evaluation mode to produce around 200 dialogues per policy distributed over the 5 user groups.

Overall performance of the different policies in terms of $Adaptation\ Accuracy\ (AA)$, $Time$ and $Learning\ Gain\ (LG)$ are given in Table 3. Figure 3 shows how each policy performs in terms of accuracy on the 5 types of users.

We found that the Learned DS policy (i.e. learned with the data-driven user simulation) is the most accurate (Mean = 79.70, SD = 10.46) in terms of adaptation to each user's initial state of domain knowledge. Also, it is the only policy that has more or less the same accuracy scores

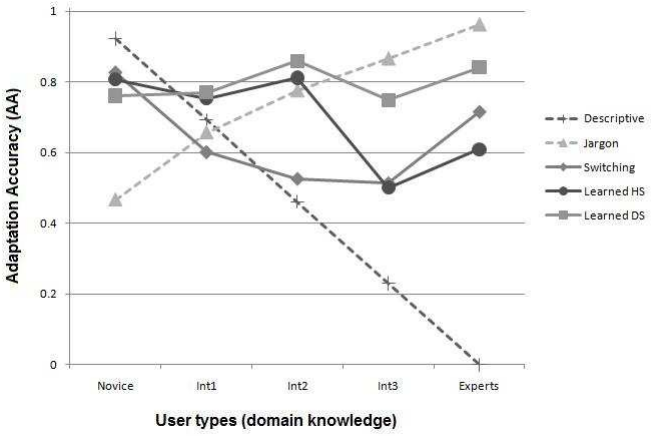

Figure 3: Evaluation - Adaptation Accuracy

Policies	AA	Time T	LG
Descriptive	46.15	7.44	0
Jargon	74.54	9.15*	0.97*
Switching	62.47	7.48	0.30
Learned HS	69.67	7.52	0.33
Learned DS	**79.70***	8.08*	0.63*

* Significantly different from all others ($p < 0.05$).

Table 3: Evaluation on 5 user types

over all different user types (see figure 3). It should also be noted that the it generalised well over user types (Int1 and Int3) which were unseen in training. Learned DS policy outperforms all other policies: Learned HS (Mean = 69.67, SD = 14.18), Switching (Mean = 62.47, SD = 14.18), Jargon (Mean = 74.54, SD = 17.9) and Descriptive (Mean = 46.15, SD = 33.29). The differences between the accuracy (AA) of the Learned DS policy and all other policies were statistically significant with $p < 0.05$ (using a two-tailed paired t-test). Although Learned HS policy is similar to the Learned DS policy, as shown in the learning curves in figure 2, it does not perform as well when confronted with users types that it did not encounter during training. The Switching policy, on the other hand, quickly switches its strategy (sometimes erroneously) based on the user's clarification requests but does not adapt appropriately to evidence presented later during the conversation. Sometimes, this policy switches erroneously because of the uncertain user behaviours. In contrast, learned policies continuously adapt to new evidence. The Jargon policy performs better than

the Learned HS and Switching policies. This because the system can learn more about the user by using more jargon expressions and then use that knowledge for adaptation for known referents. However, it is not possible for this policy to predict the user's knowledge of unseen referents. The Learned DS policy performs better than the Jargon policy, because it is able to accurately predict the user's knowledge of referents unseen in the dialogue so far.

The learned policies are a little more time-consuming than the Switching and Descriptive policies but compared to the Jargon policy, Learned DS takes 1.07 minutes less time. This is because learned policies use a few jargon expressions (giving rise to clarification requests) to learn about the user. On the other hand, the Jargon policy produces more user learning gain because of the use of more jargon expressions. Learned policies compensate on time and learning gain in order to predict and adapt well to the users' knowledge patterns. This is because the training was optimized for accuracy of adaptation and not for learning gain or time taken. The results show that using our RL framework, REG policies can be learned using data-driven simulations, and that such a policy can predict and adapt to a user's knowledge pattern more accurately than policies trained using hand-coded rule-based simulations and hand-coded baseline policies.

7.4 Discussion

The learned policies explore the user's expertise and predict their knowledge patterns, in order to better choose expressions for referents unseen in the dialogue so far. The system learns to identify the patterns of knowledge in the users with a little exploration (information seeking moves). So, when it is provided with a piece of evidence (e.g. the user knows "broadband filter"), it is able to accurately estimate unknown facts (e.g. the user might know "broadband cable"). Sometimes, its choices are wrong due to incorrect estimation of the user's expertise (due to stochastic behaviour of the users). In such cases, the incorrect adaptation move can be considered to be an information seeking move. This helps further adaptation using the new evidence. By continuously using this "seek-predict-adapt" approach, the system adapts dynamically to different users. Therefore, with a little information seeking and better prediction, the learned policies are able to better adapt to users with different domain expertise.

In addition to adaptation, learned policies learn to identify when to seek information from the user to populate the user model (which is initially set to `not_sure`). It should be noted that the system cannot adapt unless it has some information about the user and therefore needs to decisively seek information by using jargon expressions. If it seeks information all the time, it is not adapting to the user. The learned policies therefore learn to trade-off between information seeking moves and adaptive moves in order to maximize the overall adaptation accuracy score.

8 Conclusion

In this study, we have shown that user-adaptive REG policies can be learned from a small corpus of non-adaptive dialogues between a dialogue system and users with different domain knowledge levels. We have shown that such adaptive REG policies learned using a RL framework adapt to unknown users better than simple hand-coded policies built without much input from domain experts or from a corpus of expert-layperson adaptive dialogues. The learned, adaptive REG policies learn to trade off between adaptive moves and information seeking moves automatically to maximize the overall adaptation accuracy. Learned policies start the conversation with information seeking moves, learn a little about the user, and start adapting dynamically as the conversation progresses. We have also shown that a data-driven statistical user simulation produces better policies than a simple hand-coded rule-based simulation, and that the learned policies generalise well to unseen users.

In future work, we will evaluate the learned policies with real users to examine how well they adapt, and examine how real users evaluate them (subjectively) in comparison to baselines. Whether the learned policies perform better or as well as a hand-coded policy painstakingly crafted by a domain expert (or learned using supervised methods from an expert-layperson corpus) is an interesting question that needs further exploration. Also, it would also be interesting to make the learned policy account for the user's learning behaviour and adapt accordingly.

A Risk Minimization Framework for Extractive Speech Summarization

Shih-Hsiang Lin and Berlin Chen

{shlin, berlin}@csie.ntnu.edu.tw

Abstract

In this paper, we formulate extractive summarization as a risk minimization problem and propose a unified probabilistic framework that naturally combines supervised and unsupervised summarization models to inherit their individual merits as well as to overcome their inherent limitations. In addition, the introduction of various loss functions also provides the summarization framework with a flexible but systematic way to render the redundancy and coherence relationships among sentences and between sentences and the whole document, respectively. Experiments on speech summarization show that the methods deduced from our framework are very competitive with existing summarization approaches.

1 Introduction

Automated summarization systems which enable user to quickly digest the important information conveyed by either a single or a cluster of documents are indispensible for managing the rapidly growing amount of textual information and multimedia content (Mani and Maybury, 1999). On the other hand, due to the maturity of text summarization, the research paradigm has been extended to speech summarization over the years (Furui et al., 2004; McKeown et al., 2005). Speech summarization is expected to distill important information and remove redundant and incorrect information caused by recognition errors from spoken documents, enabling user to efficiently review spoken documents and understand the associated topics quickly. It would also be useful for improving the efficiency of a number of potential applications like retrieval and mining of large volumes of spoken documents.

A summary can be either abstractive or extractive. In abstractive summarization, a fluent and concise abstract that reflects the key concepts of a document is generated, whereas in extractive summarization, the summary is usually formed by selecting salient sentences from the original document (Mani and Maybury, 1999). The former requires highly sophisticated natural language processing techniques, including semantic representation and inference, as well as natural language generation, while this would make abstractive approaches difficult to replicate or extend from constrained domains to more general domains. In addition to being extractive or abstractive, a summary may also be generated by considering several other aspects like being generic or query-oriented summarization, single-document or multi-document summarization, and so forth. The readers may refer to (Mani and Maybury, 1999) for a comprehensive overview of automatic text summarization. In this paper, we focus exclusively on generic, single-document extractive summarization which forms the building block for many other summarization tasks.

Aside from traditional ad-hoc extractive summarization methods (Mani and Maybury, 1999), machine-learning approaches with either supervised or unsupervised learning strategies have gained much attention and been applied with empirical success to many summarization tasks (Kupiec et al., 1999; Lin et al., 2009). For supervised learning strategies, the summarization task is usually cast as a two-class (summary and non-summary) sentence-classification problem: A sentence with a set of indicative features is input to the classifier (or summarizer) and a decision is then returned from it on the basis of these features. In general, they usually require a training set, comprised of several documents and their corresponding handcrafted summaries (or labeled data), to train the classifiers. However, manual labeling is expensive in terms of time and personnel. The other potential problem is the so-called "*bag-of-sentences*" assumption implicitly made by most of these summarizers. That is, sentences are classified independently of each other,

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 79–87,
Uppsala, Sweden, 11-16 July 2010.

without leveraging the dependence relationships among the sentences or the global structure of the document (Shen et al., 2007).

Another line of thought attempts to conduct document summarization using unsupervised machine-learning approaches, getting around the need for manually labeled training data. Most previous studies conducted along this line have their roots in the concept of sentence *centrality* (Gong and Liu, 2001; Erkan and Radev, 2004; Radev et al., 2004; Mihalcea and Tarau, 2005). Put simply, sentences more similar to others are deemed more salient to the main theme of the document; such sentences thus will be selected as part of the summary. Even though the performance of unsupervised summarizers is usually worse than that of supervised summarizers, their domain-independent and easy-to-implement properties still make them attractive.

Building on these observations, we expect that researches conducted along the above-mentioned two directions could complement each other, and it might be possible to inherit their individual merits to overcome their inherent limitations. In this paper, we present a probabilistic summarization framework stemming from Bayes decision theory (Berger, 1985) for speech summarization. This framework can not only naturally integrate the above-mentioned two modeling paradigms but also provide a flexible yet systematic way to render the redundancy and coherence relationships among sentences and between sentences and the whole document, respectively. Moreover, we also illustrate how the proposed framework can unify several existing summarization models.

The remainder of this paper is structured as follows. We start by reviewing related work on extractive summarization. In Section 3 we formulate the extractive summarization task as a risk minimization problem, followed by a detailed elucidation of the proposed methods in Section 4. Then, the experimental setup and a series of experiments and associated discussions are presented in Sections 5 and 6, respectively. Finally, Section 7 concludes our presentation and discusses avenues for future work.

2 Background

Speech summarization can be conducted using either supervised or unsupervised methods (Furui et al., 2004, McKeown et al., 2005, Lin et al., 2008). In the following, we briefly review a few celebrated methods that have been applied to extractive speech summarization tasks with good success.

2.1 Supervised summarizers

Extractive speech summarization can be treated as a two-class (positive/negative) classification problem. A spoken sentence S_i is characterized by set of T indicative features $X_i = \{x_{i1}, \cdots, x_{iT}\}$, and they may include lexical features (Koumpis and Renals, 2000), structural features (Maskey and Hirschberg, 2003), acoustic features (Inoue et al., 2004), discourse features (Zhang et al., 2007) and relevance features (Lin et al., 2009). Then, the corresponding feature vector X_i of S_i is taken as the input to the classifier. If the output (classification) score belongs to the positive class, S_i will be selected as part of the summary; otherwise, it will be excluded (Kupiec et al., 1999). Specifically, the problem can be formulated as follows: Construct a sentence ranking model that assigns a classification score (or a posterior probability) of being in the summary class to each sentence of a spoken document to be summarized; important sentences are subsequently ranked and selected according to these scores. To this end, several popular machine-learning methods could be utilized, like Bayesian classifier (BC) (Kupiec et al., 1999), Gaussian mixture model (GMM) (Fattah and Ren, 2009) , hidden Markov model (HMM) (Conroy and O'leary, 2001), support vector machine (SVM) (Kolcz et al., 2001), maximum entropy (ME) (Ferrier, 2001), conditional random field (CRF) (Galley, 2006; Shen et al., 2007), to name a few.

Although such supervised summarizers are effective, most of them (except CRF) usually implicitly assume that sentences are independent of each other (the so-called "*bag-of-sentences*" assumption) and classify each sentence individually without leveraging the relationship among the sentences (Shen et al., 2007). Another major shortcoming of these summarizers is that a set of handcrafted document-reference summary exemplars are required for training the summarizers; however, such summarizers tend to limit their generalization capability and might not be readily applicable for new tasks or domains.

2.2 Unsupervised summarizers

The related work conducted along this direction usually relies on some heuristic rules or statistical evidences between each sentence and the document, avoiding the need of manually labeled training data. For example, the vector space model (VSM) approach represents each sentence of a document and the document itself in vector space (Gong and Liu, 2001), and computes the relevance score between each sentence and the document (e.g., the cosine measure of the simi-

larity between two vectors). Then, the sentences with the highest relevance scores are included in the summary. A natural extension is to represent each document or each sentence vector in a latent semantic space (Gong and Liu, 2001), instead of simply using the literal term information as that done by VSM.

On the other hand, the graph-based methods, such as TextRank (Mihalcea and Tarau, 2005) and LexRank (Erkan and Radev, 2004), conceptualize the document to be summarized as a network of sentences, where each node represents a sentence and the associated weight of each link represents the lexical or topical similarity relationship between a pair of nodes. Document summarization thus relies on the global structural information conveyed by such conceptualized network, rather than merely considering the local features of each node (sentence).

However, due to the lack of document-summary reference pairs, the performance of the unsupervised summarizers is usually worse than that of the supervised summarizers. Moreover, most of the unsupervised summarizers are constructed solely on the basis of the lexical information without considering other sources of information cues like discourse features, acoustic features, and so forth.

3 A risk minimization framework for extractive summarization

Extractive summarization can be viewed as a decision making process in which the summarizer attempts to select a representative subset of sentences or paragraphs from the original documents. Among the several analytical methods that can be employed for the decision process, the Bayes decision theory, which quantifies the tradeoff between various decisions and the potential cost that accompanies each decision, is perhaps the most suited one that can be used to guide the summarizer in choosing a course of action in the face of some uncertainties underlying the decision process (Berger, 1985). Stated formally, a decision problem may consist of four basic elements: 1) an observation O from a random variable $\mathbf{O}$, 2) a set of possible decisions (or actions) $a \in \mathbf{A}$, 3) the state of nature $\theta \in \mathbf{\Theta}$, and 4) a loss function $L(a_i, \theta)$ which specifies the cost associated with a chosen decision a_i given that θ is the true state of nature. The expected risk (or conditional risk) associated with taking decision a_i is given by

$$R(a_i \mid O) = \int_\theta L(a_i, \theta) p(\theta \mid O) d\theta, \quad (1)$$

where $p(\theta|O)$ is the posterior probability of the state of nature being θ given the observation O. Bayes decision theory states that the optimum decision can be made by contemplating each action a_i, and then choosing the action for which the expected risk is minimum:

$$a^* = \arg\min_{a_i} R(a_i \mid O). \quad (2)$$

The notion of minimizing the Bayes risk has gained much attention and been applied with success to many natural language processing (NLP) tasks, such as automatic speech recognition (Goel and Byrne, 2000), statistical machine translation (Kumar and Byrne, 2004) and statistical information retrieval (Zhai and Lafferty, 2006). Following the same spirit, we formulate the extractive summarization task as a Bayes risk minimization problem. Without loss of generality, let us denote $\pi \in \mathbf{\Pi}$ as one of possible selection strategies (or state of nature) which comprises a set of indicators used to address the importance of each sentence S_i in a document D to be summarized. A feasible selection strategy can be fairly arbitrary according to the underlying principle. For example, it could be a set of binary indicators denoting whether a sentence should be selected as part of summary or not. On the contrary, it may also be a ranked list used to address the significance of each individual sentence. Moreover, we refer to the k-th action a_k as choosing the k-th selection strategy π_k, and the observation O as the document D to be summarized. As a result, the expected risk of a certain selection strategy π_k is given by

$$R(\pi_k \mid D) = \int_\pi L(\pi_k, \pi) p(\pi \mid D) d\pi. \quad (3)$$

Consequently, the ultimate goal of extractive summarization could be stated as the search of the best selection strategy from the space of all possible selection strategies that minimizes the expected risk defined as follows:

$$\begin{aligned} \pi^* &= \arg\min_{\pi_k} R(\pi_k \mid D) \\ &= \arg\min_{\pi_k} \int_\pi L(\pi_k, \pi) p(\pi \mid D) d\pi. \end{aligned} \quad (4)$$

Although we have described a general formulation for the extractive summarization problem on the grounds of the Bayes decision theory, we consider hereafter a special case of it where the selection strategy is represented by a binary decision vector, of which each element corresponds to a specific sentence S_i in the document D and designates whether it should be selected as part of the summary or not, as the first such attempt. More concretely, we assume that the summary

sentences of a given document can be iteratively chosen (i.e., one at each iteration) from the document until the aggregated summary reaches a predefined target summarization ratio. It turns out that the binary vector for each possible action will have just one element equal to 1 and all others equal to zero (or the so-called "*one-of-n*" coding). For ease of notation, we denote the binary vector by S_i when the i-th element has a value of 1. Therefore, the risk minimization framework can be reduced to

$$\begin{aligned} S^* &= \arg\min_{S_i \in \widetilde{D}} R(S_i \mid \widetilde{D}) \\ &= \arg\min_{S_i \in \widetilde{D}} \sum_{S_j \in \widetilde{D}} L(S_i, S_j) P(S_j \mid \widetilde{D}), \end{aligned} \tag{5}$$

where $\widetilde{D}$ denotes the remaining sentences that have not been selected into the summary yet (i.e., the "*residual*" document); $P(S_j \mid \widetilde{D})$ is the posterior probability of a sentence S_j given $\widetilde{D}$. According to the Bayes' rule, we can further express $P(S_j \mid \widetilde{D})$ as (Chen et al., 2009)

$$P(S_j \mid \widetilde{D}) = \frac{P(\widetilde{D} \mid S_j) P(S_j)}{P(\widetilde{D})}, \tag{6}$$

where $P(\widetilde{D} \mid S_j)$ is the sentence generative probability, i.e., the likelihood of $\widetilde{D}$ being generated by S_j; $P(S_j)$ is the prior probability of S_j being important; and the evidence $P(\widetilde{D})$ is the marginal probability of $\widetilde{D}$, which can be approximated by

$$P(\widetilde{D}) \approx \sum_{S_m \in \widetilde{D}} P(\widetilde{D} \mid S_m) P(S_m). \tag{7}$$

By substituting (6) and (7) into (5), we obtain the following final selection strategy for extractive summarization:

$$S^* = \arg\min_{S_i \in \widetilde{D}} \sum_{S_j \in \widetilde{D}} L(S_i, S_j) \frac{P(\widetilde{D} \mid S_j) P(S_j)}{\sum_{S_m \in \widetilde{D}} P(\widetilde{D} \mid S_m) P(S_m)}. \tag{8}$$

A remarkable feature of this framework lies in that a sentence to be considered as part of the summary is actually evaluated by three different fundamental factors: (1) $P(S_j)$ is the sentence prior probability that addresses the importance of sentence S_j itself; (2) $P(\widetilde{D} \mid S_j)$ is the sentence generative probability that captures the degree of relevance of S_j to the residual document $\widetilde{D}$; and (3) $L(S_i, S_j)$ is the loss function that characterizes the relationship between sentence S_i and any other sentence S_j. As we will soon see, such a framework can be regarded as a generalization of several existing summarization methods. A detailed account on the construction of these three component models in the framework will be given in the following section.

4 Proposed Methods

There are many ways to construct the above mentioned three component models, i.e., the sentence generative model $P(\widetilde{D} \mid S_j)$, the sentence prior model $P(S_j)$, and the loss function $L(S_i, S_j)$. In what follows, we will shed light on one possible attempt that can accomplish this goal elegantly.

4.1 Sentence generative model

In order to estimate the sentence generative probability, we explore the language modeling (LM) approach, which has been introduced to a wide spectrum of IR tasks and demonstrated with good empirical success, to predict the sentence generative probability. In the LM approach, each sentence in a document can be simply regarded as a probabilistic generative model consisting of a unigram distribution (the so-called "*bag-of-words*" assumption) for generating the document (Chen et al., 2009):

$$P(\widetilde{D} \mid S_j) = \prod_{w \in \widetilde{D}} P(w \mid S_j)^{c(w, \widetilde{D})}, \tag{9}$$

where $c(w, \widetilde{D})$ is the number of times that index term (or word) w occurs in $\widetilde{D}$, reflecting that w will contribute more in the calculation of $P(\widetilde{D} \mid S_j)$ if it occurs more frequently in $\widetilde{D}$. Note that the sentence model $P(w \mid S_j)$ is simply estimated on the basis of the frequency of index term w occurring in the sentence S_j with the maximum likelihood (ML) criterion. In a sense, (9) belongs to a kind of literal term matching strategy (Chen, 2009) and may suffer the problem of unreliable model estimation owing particularly to only a few sampled index terms present in the sentence (Zhai, 2008). To mitigate this potential defect, a unigram probability estimated from a general collection, which models the general distribution of words in the target language, is often used to smooth the sentence model. Interested readers may refer to (Zhai, 2008; Chen et al., 2009) for a thorough discussion on various ways to construct the sentence generative model.

4.2 Sentence prior model

The sentence prior probability $P(S_j)$ can be regarded as the likelihood of a sentence being important without seeing the whole document. It could be assumed uniformly distributed over sentences or estimated from a wide variety of factors, such as the lexical information, the structural information or the inherent prosodic properties of a spoken sentence.

A straightforward way is to assume that the sentence prior probability $P(S_j)$ is in proportion to the posterior probability of a sentence S_j be-

ing included in the summary class when observing a set of indicative features X_j of S_j derived from such factors or other sentence importance measures (Kupiec et al., 1999). These features can be integrated in a systematic way into the proposed framework by taking the advantage of the learning capability of the supervised machine-learning methods. Specifically, the prior probability $P(S_j)$ can be approximated by:

$$P(S_j) \approx \frac{p(X_j \mid \mathbf{S})P(\mathbf{S})}{P(X_j \mid \mathbf{S})P(\mathbf{S}) + P(X_j \mid \overline{\mathbf{S}})P(\overline{\mathbf{S}})}, \quad (10)$$

where $P(X_j \mid \mathbf{S})$ and $P(X_j \mid \overline{\mathbf{S}})$ are the likelihoods that a sentence S_j with features X_j are generated by the summary class $\mathbf{S}$ and the non-summary class $\overline{\mathbf{S}}$, respectively; the prior probability $P(\mathbf{S})$ and $P(\overline{\mathbf{S}})$ are set to be equal in this research. To estimate $P(X_j \mid \mathbf{S})$ and $P(X_j \mid \overline{\mathbf{S}})$, several popular supervised classifiers (or summarizers), like BC or SVM, can be leveraged for this purpose.

4.3 Loss function

The loss function introduced in the proposed summarization framework is to measure the relationship between any pair of sentences. Intuitively, when a given sentence is more dissimilar from most of the other sentences, it may incur higher loss as it is taken as the representative sentence (or summary sentence) to represent the main theme embedded in the other ones. Consequently, the loss function can be built on the notion of the similarity measure. In this research, we adopt the cosine measure (Gong and Liu, 2001) to fulfill this goal. We first represent each sentence S_i in vector form where each dimension specifies the weighted statistic $z_{t,i}$, e.g., the product of the term frequency (TF) and inverse document frequency (IDF) scores, associated with an index term w_t in sentence S_i. Then, the cosine similarity between any given two sentences (S_i, S_j) is

$$Sim(S_i, S_j) = \frac{\sum_{t=1}^{T} z_{t,i} \times z_{t,j}}{\sqrt{\sum_{t=1}^{T} z_{t,i}^2} \times \sqrt{\sum_{t=1}^{T} z_{t,j}^2}}. \quad (10)$$

The loss function is thus defined by

$$L(S_i, S_j) = 1 - Sim(S_i, S_j). \quad (11)$$

Once the sentence generative model $P(\widetilde{D} \mid S_j)$, the sentence prior model $P(S_j)$ and the loss function $L(S_i, S_j)$ have been properly estimated, the summary sentences can be selected iteratively by (8) according to a predefined target summarization ratio. However, as can be seen from (8), a new summary sentence is selected without considering the redundant information that is also contained in the already selected summary sentences. To alleviate this problem, the concept of maximum marginal relevance (MMR) (Carbonell and Goldstein, 1998), which performs sentence selection iteratively by striking the balance between topic relevance and coverage, can be incorporated into the loss function:

$$L(S_i, S_j) = 1 - \left[\begin{array}{l} \beta \cdot Sim(S_i, S_j) \\ -(1-\beta) \cdot \max_{S' \in \mathbf{Summ}} Sim(S_i, S') \end{array} \right], \quad (12)$$

where **Summ** represents the set of sentences that have already been included into the summary and the novelty factor β is used to trade off between relevance and redundancy.

4.4 Relation to other summarization models

In this subsection, we briefly illustrate the relationship between our proposed summarization framework and a few existing summarization approaches. We start by considering a special case where a 0-1 loss function is used in (8), namely, the loss function will take value 0 if the two sentences are identical, and 1 otherwise. Then, (8) can be alternatively represented by

$$\begin{aligned} S^* &= \arg\min_{S_i \in \widetilde{D}} \sum_{S_j \in \widetilde{D}, S_j \neq S_i} \frac{P(\widetilde{D} \mid S_j)P(S_j)}{\sum_{S_m \in \widetilde{D}} P(\widetilde{D} \mid S_m)P(S_m)} \\ &= \arg\max_{S_i \in \widetilde{D}} \frac{P(\widetilde{D} \mid S_i)P(S_i)}{\sum_{S_m \in \widetilde{D}} P(\widetilde{D} \mid S_m)P(S_m)}, \end{aligned} \quad (13)$$

which actually provides a natural integration of the supervised and unsupervised summarizers (Lin et al., 2009), as mentioned previously.

If we further assume the prior probability $P(S_j)$ is uniformly distributed, the important (or summary) sentence selection problem has now been reduced to the problem of measuring the document-likelihood $P(\widetilde{D} \mid S_j)$, or the relevance between the document and the sentence. Alone a similar vein, the important sentences of a document can be selected (or ranked) solely based on the prior probability $P(S_j)$ with the assumption of an equal document-likelihood $P(\widetilde{D} \mid S_j)$.

5 Experimental setup

5.1 Data

The summarization dataset used in this research is a widely used broadcast news corpus collected by the Academia Sinica and the Public Television Service Foundation of Taiwan between November 2001 and April 2003 (Wang et al., 2005). Each story contains the speech of one studio anchor, as well as several field reporters and interviewees. A subset of 205 broadcast news doc-

Kappa	ROGUE-1	ROUGE-2	ROUGE-L
0.400	0.600	0.532	0.527

Table 1: The agreement among the subjects for important sentence ranking for the evaluation set.

Structural features	1.Duration of the current sentence 2.Position of the current sentence 3.Length of the current sentence
Lexical Features	1.Number of named entities 2.Number of stop words 3.Bigram language model scores 4.Normalized bigram scores
Acoustic Features	1.The 1st formant 2.The 2nd formant 3.The pitch value 4.The peak normalized cross-correlation of pitch
Relevance Feature	1.VSM score

Table 2: Basic sentence features used by BC.

uments compiled between November 2001 and August 2002 was reserved for the summarization experiments.

Three subjects were asked to create summaries of the 205 spoken documents for the summarization experiments as references (the gold standard) for evaluation. The summaries were generated by ranking the sentences in the reference transcript of a spoken document by importance without assigning a score to each sentence. The average Chinese character error rate (CER) obtained for the 205 spoken documents was about 35%.

Since broadcast news stories often follow a relatively regular structure as compared to other speech materials like conversations, the positional information would play an important (dominant) role in extractive summarization of broadcast news stories; we, hence, chose 20 documents for which the generation of reference summaries is less correlated with the positional information (or the position of sentences) as the held-out test set to evaluate the general performance of the proposed summarization framework, and 100 documents as the development set.

5.2 Performance evaluation

For the assessment of summarization performance, we adopted the widely used ROUGE measure (Lin, 2004) because of its higher correlation with human judgments. It evaluates the quality of the summarization by counting the number of overlapping units, such as *N*-grams, longest common subsequences or skip-bigram, between the automatic summary and a set of reference summaries. Three variants of the ROGUE measure were used to quantify the utility of the proposed method. They are, respectively, the ROUGE-1 (unigram) measure, the ROUGE-2 (bigram) measure and the ROUGE-L (longest common subsequence) measure (Lin, 2004).

The summarization ratio, defined as the ratio of the number of words in the automatic (or manual) summary to that in the reference transcript of a spoken document, was set to 10% in this research. Since increasing the summary length tends to increase the chance of getting higher scores in the recall rate of the various ROUGE measures and might not always select the right number of informative words in the automatic summary as compared to the reference summary, all the experimental results reported hereafter are obtained by calculating the F-scores of these ROUGE measures, respectively (Lin, 2004). Table 1 shows the levels of agreement (the Kappa statistic and ROUGE measures) between the three subjects for important sentence ranking. They seem to reflect the fact that people may not always agree with each other in selecting the important sentences for representing a given document.

5.3 Features for supervised summarizers

We take BC as the representative supervised summarizer to study in this paper. The input to BC consists of a set of 28 indicative features used to characterize a spoken sentence, including the structural features, the lexical features, the acoustic features and the relevance feature. For each kind of acoustic features, the minimum, maximum, mean, difference value and mean difference value of a spoken sentence are extracted. The difference value is defined as the difference between the minimum and maximum values of the spoken sentence, while the mean difference value is defined as the mean difference between a sentence and its previous sentence. Finally, the relevance feature (VSM score) is use to measure the degree of relevance for a sentence to the whole document (Gong and Liu, 2001). These features are outlined in Table 2, where each of them was further normalized to zero mean and unit variance.

6 Experimental results and discussions

6.1 Baseline experiments

In the first set of experiments, we evaluate the baseline performance of the LM and BC summarizers (cf. Sections 4.1 and 4.2), respectively. The corresponding results are detailed in Table 3,

	Text Document (TD)			Spoken Document (SD)		
	ROGUE-1	ROUGE-2	ROUGE-L	ROGUE-1	ROUGE-2	ROUGE-L
BC	0.445 (0.390 - 0.504)	0.346 (0.201 - 0.415)	0.404 (0.348 - 0.468)	0.369 (0.316 - 0.426)	0.241 (0.183 - 0.302)	0.321 (0.268 - 0.378)
LM	0.387 (0.302 - 0.474)	0.264 (0.168 - 0.366)	0.334 (0.251 - 0.415)	0.319 (0.274 - 0.367)	0.164 (0.115 - 0.224)	0.253 (0.215 - 0.301)

Table 3: The results achieved by the BC and LM summarizers, respectively.

		Text Document (TD)			Spoken Document (SD)		
Prior	Loss	ROGUE-1	ROUGE-2	ROUGE-L	ROGUE-1	ROUGE-2	ROUGE-L
BC	0-1	0.501	0.401	0.459	0.417	0.281	0.356
	SIM	0.524	0.425	0.473	0.475	0.351	0.420
	MMR	0.529	0.426	0.479	0.475	0.351	0.420
Uniform	SIM	0.405	0.281	0.348	0.365	0.209	0.305
	MMR	0.417	0.282	0.359	0.391	0.236	0.338

Table 4: The results achieved by several methods derived from the proposed summarization framework.

where the values in the parentheses are the associated 95% confidence intervals. It is also worth mentioning that TD denotes the summarization results obtained based on manual transcripts of the spoken documents while SD denotes the results using the speech recognition transcripts which may contain speech recognition errors and sentence boundary detection errors. In this research, sentence boundaries were determined by speech pauses. For the TD case, the acoustic features were obtained by aligning the manual transcripts to their spoken documents counterpart by performing word-level forced alignment.

Furthermore, the ROGUE measures, in essence, are evaluated by counting the number of overlapping units between the automatic summary and the reference summary; the corresponding evaluation results, therefore, would be severely affected by speech recognition errors when applying the various ROUGE measures to quantify the performance of speech summarization. In order to get rid of the cofounding effect of this factor, it is assumed that the selected summary sentences can also be presented in speech form (besides text form) such that users can directly listen to the audio segments of the summary sentences to bypass the problem caused by speech recognition errors. Consequently, we can align the ASR transcripts of the summary sentences to their respective audio segments to obtain the correct (manual) transcripts for the summarization performance evaluation (i.e., for the SD case).

Observing Table 3 we notice two particularities. First, there are significant performance gaps between summarization using the manual transcripts and the erroneous speech recognition transcripts. The relative performance degradations are about 15%, 34% and 23%, respectively, for ROUGE-1, ROUGE2 and ROUGE-L measures. One possible explanation is that the erroneous speech recognition transcripts of spoken sentences would probably carry wrong information and thus deviate somewhat from representing the true theme of the spoken document. Second, the supervised summarizer (i.e., BC) outperforms the unsupervised summarizer (i.e., LM). The better performance of BC can be further explained by two reasons. One is that BC is trained with the handcrafted document-summary sentence labels in the development set while LM is instead conducted in a purely unsupervised manner. Another is that BC utilizes a rich set of features to characterize a given spoken sentence while LM is constructed solely on the basis of the lexical (unigram) information.

6.2 Experiments on the proposed methods

We then turn our attention to investigate the utility of several methods deduced from our proposed summarization framework. We first consider the case when a 0-1 loss function is used (cf. (13)), which just show a simple combination of BC and LM. As can be seen from the first row of Table 4, such a combination can give about 4% to 5% absolute improvements as compared to the results of BC illustrated in Table 3. It in some sense confirms the feasibility of combining the supervised and unsupervised summarizers. Moreover, we consider the use of the loss functions defined in (11) (denoted by SIM) and (12) (denoted by MMR), and the corresponding results are shown in the second and the third rows of Table 4, respectively. It can be found that

MMR delivers higher summarization performance than SIM (especially for the SD case), which in turn verifies the merit of incorporating the MMR concept into the proposed framework for extractive summarization. If we further compare the results achieved by MMR with those of BC and LM as shown in Table 3, we can find significant improvements both for the TD and SD cases. By and large, for the TD case, the proposed summarization method offers relative performance improvements of about 19%, 23% and 19%, respectively, in the ROUGE-1, ROUGE-2 and ROUGE-L measures as compared to the BC baseline; while the relative improvements are 29%, 46% and 31%, respectively, in the same measurements for the SD case. On the other hand, the performance gap between the TD and SD cases are reduced to a good extent by using the proposed summarization framework.

In the next set of experiments, we simply assume the sentence prior probability $P(S_j)$ defined in (8) is uniformly distributed, namely, we do not use any supervised information cue but use the lexical information only. The importance of a given sentence is thus considered from two angles: 1) the relationship between a sentence and the whole document, and 2) the relationship between the sentence and the other individual sentences. The corresponding results are illustrated in the lower part of Table 4 (denoted by Uniform). We can see that the additional consideration of the sentence-sentence relationship appears to be beneficial as compared to that only considering the document-sentence relevance information (cf. the second row of Table 3). It also gives competitive results as compared to the performance of BC (cf. the first row of Table 3) for the SD case.

6.3 Comparison with conventional summarization methods

In the final set of experiments, we compare our proposed summarization methods with a few existing summarization methods that have been widely used in various summarization tasks, including LEAD, VSM, LexRank and CRF; the corresponding results are shown in Table 5. It should be noted that the LEAD-based method simply extracts the first few sentences in a document as the summary. To our surprise, CRF does not provide superior results as compared to the other summarization methods. One possible explanation is that the structural evidence of the spoken documents in the test set is not strong enough for CRF to show its advantage of modeling the local structural information among sentences. On the other hand, LexRank gives a very promising performance in spite that it only utilizes lexical information in an unsupervised manner. This somewhat reflects the importance of capturing the global relationship for the sentences in the spoken document to be summarized. As compared to the results shown in the "BC" part of Table 4, we can see that our proposed methods significantly outperform all the conventional summarization methods compared in this paper, especially for the SD case.

		ROGUE-1	ROUGE-2	ROUGE-L
LEAD	TD	0.320	0.197	0.283
	SD	0.312	0.168	0.251
VSM	TD	0.345	0.220	0.287
	SD	0.337	0.189	0.277
LexRank	TD	0.435	0.314	0.377
	SD	0.348	0.204	0.294
CRF	TD	0.431	0.315	0.383
	SD	0.358	0.220	0.291

Table 5: The results achieved by four conventional summarization methods.

7 Conclusions and future work

We have proposed a risk minimization framework for extractive speech summarization, which enjoys several advantages. We have also presented a simple yet effective implementation that selects the summary sentences in an iterative manner. Experimental results demonstrate that the methods deduced from such a framework can yield substantial improvements over several popular summarization methods compared in this paper. We list below some possible future extensions: 1) integrating different selection strategies, e.g., the listwise strategy that defines the loss function on all the sentences associated with a document to be summarized, into this framework, 2) exploring different modeling approaches for this framework, 3) investigating discriminative training criteria for training the component models in this framework, and 4) extending and applying the proposed framework to multi-document summarization tasks.

The Human Language Project: Building a Universal Corpus of the World's Languages

Steven Abney

abney@umich.edu

Steven Bird
University of Melbourne and
University of Pennsylvania
sbird@unimelb.edu.au

Abstract

We present a grand challenge to build a corpus that will include all of the world's languages, in a consistent structure that permits large-scale cross-linguistic processing, enabling the study of universal linguistics. The focal data types, bilingual texts and lexicons, relate each language to one of a set of reference languages. We propose that the ability to train systems to translate into and out of a given language be the yardstick for determining when we have successfully captured a language. We call on the computational linguistics community to begin work on this Universal Corpus, pursuing the many strands of activity described here, as their contribution to the global effort to document the world's linguistic heritage before more languages fall silent.

1 Introduction

The grand aim of linguistics is the construction of a universal theory of human language. To a computational linguist, it seems obvious that the first step is to collect significant amounts of primary data for a large variety of languages. Ideally, we would like a complete digitization of every human language: a Universal Corpus.

If we are ever to construct such a corpus, it must be now. With the current rate of language loss, we have only a small window of opportunity before the data is gone forever. Linguistics may be unique among the sciences in the crisis it faces. The next generation will forgive us for the most egregious shortcomings in theory construction and technology development, but they will not forgive us if we fail to preserve vanishing primary language data in a form that enables future research.

The scope of the task is enormous. At present, we have non-negligible quantities of machine-readable data for only about 20–30 of the world's 6,900 languages (Maxwell and Hughes, 2006). Linguistics as a field is awake to the crisis. There has been a tremendous upsurge of interest in documentary linguistics, the field concerned with the the "creation, annotation, preservation, and dissemination of transparent records of a language" (Woodbury, 2010). However, documentary linguistics alone is not equal to the task. For example, no million-word machine-readable corpus exists for any endangered language, even though such a quantity would be necessary for wide-ranging investigation of the language once no speakers are available. The chances of constructing large-scale resources will be greatly improved if computational linguists contribute their expertise.

This collaboration between linguists and computational linguists will extend beyond the construction of the Universal Corpus to its exploitation for both theoretical and technological ends. We envisage a new paradigm of universal linguistics, in which grammars of individual languages are built from the ground up, combining expert manual effort with the power tools of probabilistic language models and grammatical inference. A universal grammar captures redundancies which exist across languages, constituting a "universal linguistic prior," and enabling us to identify the distinctive properties of specific languages and families. The linguistic prior and regularities due to common descent enable a new economy of scale for technology development: cross-linguistic triangulation can improve performance while reducing per-language data requirements.

Our aim in the present paper is to move beyond generalities to a concrete plan of attack, and to challenge the field to a communal effort to create a Universal Corpus of the world's languages, in consistent machine-readable format, permitting large-scale cross-linguistic processing.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 88–97,
Uppsala, Sweden, 11-16 July 2010.

2 Human Language Project

2.1 Aims and scope

Although language endangerment provides urgency, the corpus is not intended primarily as a Noah's Ark for languages. The aims go beyond the current crisis: we wish to support cross-linguistic research and technology development at the largest scale. There are existing collections that contain multiple languages, but it is rare to have consistent formats and annotation across languages, and few such datasets contain more than a dozen or so languages.

If we think of a multi-lingual corpus as consisting of an array of items, with columns representing languages and rows representing resource types, the usual focus is on "vertical" processing. Our particular concern, by contrast, is "horizontal" processing that cuts indiscriminately across languages. Hence we require an unusual degree of consistency across languages.

The kind of processing we wish to enable is much like the large-scale systematic research that motivated the Human Genome Project.

> One of the greatest impacts of having the sequence may well be in enabling an entirely new approach to biological research. In the past, researchers studied one or a few genes at a time. With whole-genome sequences ... they can approach questions systematically and on a grand scale. They can study ... how tens of thousands of genes and proteins work together in interconnected networks to orchestrate the chemistry of life. (Human Genome Project, 2007)

We wish to make it possible to investigate human language equally systematically and on an equally grand scale: a Human Linguome Project, as it were, though we have chosen the "Human Language Project" as a more inviting title for the undertaking. The product is a Universal Corpus,[1] in two senses of *universal:* in the sense of including (ultimately) all the world's languages, and in the sense of enabling software and processing methods that are language-universal.

However, we do *not* aim for a collection that is universal in the sense of encompassing all language documentation efforts. Our goal is the construction of a specific resource, albeit a very large resource. We contrast the proposed effort with general efforts to develop open resources, standards, and best practices. We do *not* aim to be all-inclusive. The project does require large-scale collaboration, and a task definition that is simple and compelling enough to achieve buy-in from a large number of data providers. But we do not need and do not attempt to create consensus across the entire community. (Although one can hope that what proves successful for a project of this scale will provide a good foundation for future standards.)

Moreover, we do not aim to collect data merely in the vague hope that it will prove useful. Although we strive for maximum generality, we also propose a specific driving "use case," namely, machine translation (MT), (Hutchins and Somers, 1992; Koehn, 2010). The corpus provides a testing ground for the development of MT system-construction methods that are dramatically "leaner" in their resource requirements, and which take advantage of cross-linguistic bootstrapping. The large engineering question is how one can turn the size of the task—constructing MT systems for all the world's languages simultaneously—to one's advantage, and thereby consume dramatically less data per language.

The choice of MT as the use case is also driven by scientific considerations. To explain, we require a bit of preamble.

We aim for a *digitization* of each human language. What exactly does it mean to digitize an entire language? It is natural to think in terms of replicating the body of resources available for well-documented languages, and the pre-eminent resource for any language is a treebank. Producing a treebank involves a staggering amount of manual effort. It is also notoriously difficult to obtain agreement about how parse trees should be defined in one language, much less in many languages simultaneously. The idea of producing treebanks for 6,900 languages is quixotic, to put it mildly. But is a treebank actually necessary?

Let us suppose that the purpose of a parse tree is to mediate interpretation. A treebank, arguably, represents a theoretical hypothesis about how interpretations could be constructed; the primary data is actually the interpretations themselves. This suggests that we annotate sentences with representations of meanings instead of syntactic structures. Now that seems to take us out of the frying pan into the fire. If obtaining consen-

[1] http://universalcorpus.org/

sus on parse trees is difficult, obtaining consensus on meaning representations is impossible. However, if the language under consideration is anything other than English, then a translation into English (or some other reference language) is for most purposes a perfectly adequate meaning representation. That is, we view machine translation as an approximation to language understanding.

Here is another way to put it. One measure of adequacy of a language digitization is the ability of a human—already fluent in a reference language—to acquire fluency in the digitized language using only archived material. Now it would be even better if we could use a language digitization to construct an *artificial speaker* of the language. Importantly, we do not need to solve the AI problem: the speaker need not decide *what* to say, only how to translate from meanings to sentences of the language, and from sentences back to meanings. Taking sentences in a reference language as the meaning representation, we arrive back at machine translation as the measure of success. *In short, we have successfully captured a language if we can translate into and out of the language.*

The key resource that should be built for each language, then, is a collection of primary texts with translations into a reference language. "Primary text" includes both written documents and transcriptions of recordings. Large volumes of primary texts will be useful even without translation for such tasks as language modeling and unsupervised learning of morphology. Thus, we anticipate that the corpus will have the usual "pyramidal" structure, starting from a base layer of unannotated text, some portion of which is translated into a reference language at the document level to make the next layer. Note that, for maximally authentic primary texts, we assume the direction of translation will normally be from primary text to reference language, not the other way around.

Another layer of the corpus consists of sentence and word alignments, required for training and evaluating machine translation systems, and for extracting bilingual lexicons. Curating such annotations is a more specialized task than translation, and so we expect it will only be done for a subset of the translated texts.

In the last and smallest layer, morphology is annotated. This supports the development of morphological analyzers, to preprocess primary texts to identify morpheme boundaries and recognize allomorphs, reducing the amount of data required for training an MT system. This most-refined target annotation corresponds to the *interlinear glossed texts* that are the de facto standard of annotation in the documentary linguistics community.

We postulate that interlinear glossed text is sufficiently fine-grained to serve our purposes. It invites efforts to enrich it by automatic means: for example, there has been work on parsing the English translations and using the word-by-word glosses to transfer the parse tree to the object language, effectively creating a treebank automatically (Xia and Lewis, 2007). At the same time, we believe that interlinear glossed text is sufficiently simple and well-understood to allow rapid construction of resources, and to make cross-linguistic consistency a realistic goal.

Each of these layers—primary text, translations, alignments, and morphological glosses—seems to be an unavoidable piece of the overall solution. The fact that these layers will exist in diminishing quantity is also unavoidable. However, there is an important consequence: the primary texts will be permanently subject to new translation initiatives, which themselves will be subject to new alignment and glossing initiatives, in which each step is an instance of semisupervised learning (Abney, 2007). As time passes, our ability to enhance the quantity and quality of the annotations will only increase, thanks to effective combinations of automatic, professional, and crowd-sourced effort.

2.2 Principles

The basic principles upon which the envisioned corpus is based are the following:

Universality. Covering as many languages as possible is the first priority. Progress will be gauged against concrete goals for numbers of languages, data per language, and coverage of language families (Whalen and Simons, 2009).

Machine readability and consistency. "Covering" languages means enabling machine processing seamlessly across languages. This will support new types of linguistic inquiry and the development and testing of inference methods (for morphology, parsers, machine translation) across large numbers of typologically diverse languages.

Community effort. We cannot expect a single organization to assemble a resource on this scale. It will be necessary to get community buy-in, and

many motivated volunteers. The repository will not be the sole possession of any one institution.

Availability. The content of the corpus will be available under one or more permissive licenses, such as the Creative Commons Attribution License (CC-BY), placing as few limits as possible on community members' ability to obtain and enhance the corpus, and redistribute derivative data.

Utility. The corpus aims to be maximally useful, and minimally parochial. Annotation will be as lightweight as possible; richer annotations will will emerge bottom-up as they prove their utility at the large scale.

Centrality of primary data. Primary texts and recordings are paramount. Secondary resources such as grammars and lexicons are important, but no substitute for primary data. It is desirable that secondary resources be integrated with—if not derived from—primary data in the corpus.

2.3 What to include

What should be included in the corpus? To some extent, data collection will be opportunistic, but it is appropriate to have a well-defined target in mind. We consider the following essential.

Metadata. One means of resource identification is to survey existing documentation for the language, including bibliographic references and locations of web resources. Provenance and proper citation of sources should be included for all data.

For written text. (1) Primary documents in original printed form, e.g. scanned page images or PDF. (2) Transcription. Not only optical character recognition output, but also the output of tools that extract text from PDF, will generally require manual editing.

For spoken text. (1) Audio recordings. Both elicited and spontaneous speech should be included. It is highly desirous to have some connected speech for every language. (2) Slow speech "audio transcriptions." Carefully respeaking a spoken text can be much more efficient than written transcription, and may one day yield to speech recognition methods. (3) Written transcriptions. We do not impose any requirements on the form of transcription, though orthographic transcription is generally much faster to produce than phonetic transcription, and may even be more useful as words are represented by normalized forms.

For both written and spoken text. (1) Translations of primary documents into a reference language (possibly including commentary). (2) Sentence-level segmentation and translation. (3) Word-level segmentation and glossing. (4) Morpheme-level segmentation and glossing.

All documents will be included in primary form, but the percentage of documents with manual annotation, or manually corrected annotation, decreases at increasingly fine-grained levels of annotation. Where manual fine-grained annotation is unavailable, automatic methods for creating it (at a lower quality) are desirable. Defining such methods for a large range of resource-poor languages is an interesting computational challenge.

Secondary resources. Although it is possible to base descriptive analyses exclusively on a text corpus (Himmelmann, 2006, p. 22), the following secondary resources should be secured if they are available: (1) A lexicon with glosses in a reference language. Ideally, everything should be attested in the texts, but as a practical matter, there will be words for which we have only a lexical entry and no instances of use. (2) Paradigms and phonology, for the construction of a morphological analyzer. Ideally, they should be inducible from the texts, but published grammatical information may go beyond what is attested in the text.

2.4 Inadequacy of existing efforts

Our key desideratum is support for automatic processing across a large range of languages. No data collection effort currently exists or is proposed, to our knowledge, that addresses this desideratum. Traditional language archives such as the Audio Archive of Linguistic Fieldwork (UC Berkeley), Documentation of Endangered Languages (Max Planck Institute, Nijmegen), the Endangered Languages Archive (SOAS, University of London), and the Pacific And Regional Archive for Digital Sources in Endangered Cultures (Australia) offer broad coverage of languages, but the majority of their offerings are restricted in availability and do not support machine processing. Conversely, large-scale data collection efforts by the Linguistic Data Consortium and the European Language Resources Association cover less than one percent of the world's languages, with no evident plans for major expansion of coverage. Other efforts concern the definition and aggregation of language resource metadata, including OLAC, IMDI, and

CLARIN (Simons and Bird, 2003; Broeder and Wittenburg, 2006; Váradi et al., 2008), but this is not the same as collecting and disseminating data.

Initiatives to develop standard formats for linguistic annotations are orthogonal to our goals. The success of the project will depend on contributed data from many sources, in many different formats. Converting all data formats to an official standard, such as the RDF-based models being developed by ISO Technical Committee 37 Sub-committee 4 Working Group 2, is simply impractical. These formats have onerous syntactic and semantic requirements that demand substantial further processing together with expert judgment, and threaten to crush the large-scale collaborative data collection effort we envisage, before it even gets off the ground. Instead, we opt for a very lightweight format, sketched in the next section, to minimize the effort of conversion and enable an immediate start. This does not limit the options of community members who desire richer formats, since they are free to invest the effort in enriching the existing data. Such enrichment efforts may gain broad support if they deliver a tangible benefit for cross-language processing.

3 A Simple Storage Model

Here we sketch a simple approach to storage of texts (including transcribed speech), bitexts, interlinear glossed text, and lexicons. We have been deliberately schematic since the goal is just to give grounds for confidence that there exists a general, scalable solution.

For readability, our illustrations will include space-separated sequences of tokens. However, behind the scenes these could be represented as a sequence of pairs of start and end offsets into a primary text or speech signal, or as a sequence of integers that reference an array of strings. Thus, when we write (1a), bear in mind it may be implemented as (1b) or (1c).

(1) a. This is a point of order .
    b. (0,4), (5,7), (8,9), (10,15), (16,18), ...
    c. 9347, 3053, 0038, 3342, 3468, ...

In what follows, we focus on the minimal requirements for storing and disseminating aligned text, not the requirements for efficient in-memory data structures. Moreover, we are agnostic about whether the normalized, tokenized format is stored entire or computed on demand.

We take an aligned text to be composed of a series of aligned sentences, each consisting of a small set of attributes and values, e.g.:

```
ID: europarl/swedish/ep-00-01-17/18
LANGS: swd eng
SENT: det gäller en ordningsfråga
TRANS: this is a point of order
ALIGN: 1-1 2-2 3-3 4-4 4-5 4-6
PROVENANCE: pharaoh-v1.2, ...
REV: 8947 2010-05-02 10:35:06 leobfld12
RIGHTS: Copyright (C) 2010 Uni...; CC-BY
```

The value of `ID` identifies the document and sentence, and any collection to which the document belongs. Individual components of the identifier can be referenced or retrieved. The `LANGS` attribute identifies the source and reference language using ISO 639 codes.[2] The `SENT` attribute contains space-delimited tokens comprising a sentence. Optional attributes `TRANS` and `ALIGN` hold the translation and alignment, if these are available; they are omitted in monolingual text. A provenance attribute records any automatic or manual processes which apply to the record, and a revision attribute contains the version number, timestamp, and username associated with the most recent modification of the record, and a rights attribute contains copyright and license information.

When morphological annotation is available, it is represented by two additional attributes, `LEX` and `AFF`. Here is a monolingual example:

```
ID: example/001
LANGS: eng
SENT: the dogs are barking
LEX: the dog be bark
AFF: - PL PL ING
```

Note that combining all attributes of these two examples—that is, combining word-by-word translation with morphological analysis—yields interlinear glossed text.

A bilingual lexicon is an indispensable resource, whether provided as such, induced from a collection of aligned text, or created by merging contributed and induced lexicons. A bilingual lexicon can be viewed as an inventory of cross-language correspondences between words or groups of words. These correspondences are just aligned text fragments, albeit much smaller than a sentence. Thus, we take a bilingual lexicon to be a kind of text in which each record contains a single lexeme and its translation, represented using the `LEX` and `TRANS` attributes we have already introduced, e.g.:

[2] `http://www.sil.org/iso639-3/`

```
ID: swedishlex/v3.2/0419
LANGS: swd eng
LEX: ordningsfråga
TRANS: point of order
```

In sum, the Universal Corpus is represented as a massive store of records, each representing a single sentence or lexical entry, using a limited set of attributes. The store is indexed for efficient access, and supports access to slices identified by language, content, provenance, rights, and so forth. Many component collections would be "unioned" into this single, large Corpus, with only the record identifiers capturing the distinction between the various data sources.

Special cases of aligned text and wordlists, spanning more than 1,000 languages, are Bible translations and Swadesh wordlists (Resnik et al., 1999; Swadesh, 1955). Here there are obvious use-cases for accessing a particular verse or word across all languages. However, it is not necessary to model n-way language alignments. Instead, such sources are implicitly aligned by virtue of their structure. Extracting all translations of a verse, or all cognates of a Swadesh wordlist item, is an index operation that returns monolingual records, e.g.:

```
ID: swadesh/47          ID: swadesh/47
LANGS: fra              LANGS: eng
LEX: chien              LEX: dog
```

4 Building the Corpus

Data collection on this scale is a daunting prospect, yet it is important to avoid the paralysis of over-planning. We can start immediately by leveraging existing infrastructure, and the voluntary effort of interested members of the language resources community. One possibility is to found a "Language Commons," an open access repository of language resources hosted in the Internet Archive, with a lightweight method for community members to contribute data sets.

A fully processed and indexed version of selected data can be made accessible via a web services interface to a major cloud storage facility, such as Amazon Web Services. A common query interface could be supported via APIs in multiple NLP toolkits such as NLTK and GATE (Bird et al., 2009; Cunningham et al., 2002), and also in generic frameworks such as UIMA and SOAP, leaving developers to work within their preferred environment.

4.1 Motivation for data providers

We hope that potential contributors of data will be motivated to participate primarily by agreement with the goals of the project. Even someone who has specialized in a particular language or language family maintains an interest, we expect, in the universal question—the exploration of Language writ large.

Data providers will find benefit in the availability of volunteers for crowd-sourcing, and tools for (semi-)automated quality control, refinement, and presentation of data. For example, a data holder should be able to contribute recordings and get help in transcribing them, through a combination of volunteer labor and automatic processing.

Documentary linguists and computational linguists have much to gain from collaboration. In return for the data that documentary linguistics can provide, computational linguistics has the potential to revolutionize the tools and practice of language documentation.

We also seek collaboration with communities of language speakers. The corpus provides an economy of scale for the development of literacy materials and tools for interactive language instruction, in support of language preservation and revitalization. For small languages, literacy in the mother tongue is often defended on the grounds that it provides the best route to literacy in the national language (Wagner, 1993, ch. 8). An essential ingredient of any local literacy program is to have a substantial quantity of available texts that represent familiar topics including cultural heritage, folklore, personal narratives, and current events. Transition to literacy in a language of wider communication is aided when transitional materials are available (Waters, 1998, pp. 61ff). Mutual benefits will also flow from the development of tools for low-cost publication and broadcast in the language, with copies of the published or broadcast material licensed to and archived in the corpus.

4.2 Roles

The enterprise requires collaboration of many individuals and groups, in a variety of roles.

Editors. A critical group are people with sufficient engagement to serve as editors for particular language families, who have access to data or are able to negotiate redistribution rights, and oversee the workflow of transcription, translation, and annotation.

CL Research. All manual annotation steps need to be automated. Each step presents a challenging semi-supervised learning and cross-linguistic bootstrapping problem. In addition, the overall measure of success—induction of machine translation systems from limited resources—pushes the state of the art (Kumar et al., 2007). Numerous other CL problems arise: active learning to improve the quality of alignments and bilingual lexicons; automatic language identification for low-density languages; and morphology learning.

Tool builders. We need tools for annotation, format conversion, spidering and language identification, search, archiving, and presentation. Innovative crowd-sourcing solutions are of particular interest, e.g. web-based functionality for transcribing audio and video of oral literature, or setting up a translation service based on aligned texts for a low-density language, and collecting the improved translations suggested by users.

Volunteer annotators. An important reason for keeping the data model as lightweight as possible is to enable contributions from volunteers with little or no linguistic training. Two models are the volunteers who scan documents and correct OCR output in Project Gutenberg, or the undergraduate volunteers who have constructed Greek and Latin treebanks within Project Perseus (Crane, 2010). Bilingual lexicons that have been extracted from aligned text collections might be corrected using crowd-sourcing, leading to improved translation models and improved alignments. We also see the Universal Corpus as an excellent opportunity for undergraduates to participate in research, and for native speakers to participate in the preservation of their language.

Documentary linguists. The collection protocol known as Basic Oral Language Documentation (BOLD) enables documentary linguists to collect 2–3 orders of magnitude more oral discourse than before (Bird, 2010). Linguists can equip local speakers to collect written texts, then to carefully "respeak" and orally translate the texts into a reference language. With suitable tools, incorporating active learning, local speakers could further curate bilingual texts and lexicons. An early need is pilot studies to determine costings for different categories of language.

Data agencies. The LDC and ELRA have a central role to play, given their track record in obtaining, curating, and publishing data with licenses that facilitate language technology development. We need to identify key resources where negotiation with the original data provider, and where payment of all preparation costs plus compensation for lost revenue, leads to new material for the Corpus. This is a new publication model and a new business model, but it can co-exist with the existing models.

Language archives. Language archives have a special role to play as holders of unique materials. They could contribute existing data in its native format, for other participants to process. They could give bilingual texts a distinct status within their collections, to facilitate discovery.

Funding agencies. To be successful, the Human Language Project would require substantial funds, possibly drawing on a constellation of public and private agencies in many countries. However, in the spirit of starting small, and starting now, agencies could require that sponsored projects which collect texts and build lexicons contribute them to the Language Commons. After all, the most effective time to do translation, alignment, and lexicon work is often at the point when primary data is first collected, and this extra work promises direct benefits to the individual project.

4.3 Early tasks

Seed corpus. The central challenge, we believe, is getting critical mass. Data attracts data, and if one can establish a sufficient seed, the effort will snowball. We can make some concrete proposals as to how to collect a seed. Language resources on the web are one source—the Crúbadán project has identified resources for 400 languages, for example (Scannell, 2008); the New Testament of the Bible exists in about 1200 languages and contains of the order of 100k words. We hope that existing efforts that are already well-disposed toward electronic distribution will participate. We particularly mention the Language and Culture Archive of the Summer Institute of Linguistics, and the Rosetta Project. The latter is already distributed through the Internet Archive and contains material for 2500 languages.

Resource discovery. Existing language resources need to be documented, a large un-

dertaking that depends on widely distributed knowledge. Existing published corpora from the LDC, ELRA and dozens of other sources—a total of 85,000 items—are already documented in the combined catalog of the Open Language Archives Community,[3] so there is no need to recreate this information. Other resources can be logged by community members using a public access wiki, with a metadata template to ensure key fields are elicited such as resource owner, license, ISO 639 language code(s), and data type. This information can itself be curated and stored in the form of an OLAC archive, to permit search over the union of the existing and newly documented items. Work along these lines has already been initiated by LDC and ELRA (Cieri et al., 2010).

Resource classification. Editors with knowledge of particular language families will categorize documented resources relative to the needs of the project, using controlled vocabularies. This involves examining a resource, determining the granularity and provenance of the segmentation and alignment, checking its ISO 639 classifications, assigning it to a logarithmic size category, documenting its format and layout, collecting sample files, and assigning a priority score.

Acquisition. Where necessary, permission will be sought to lodge the resource in the repository. Funding may be required to buy the rights to the resource from its owner, as compensation for lost revenue from future data sales. Funding may be required to translate the source into a reference language. The repository's ingestion process is followed, and the resource metadata is updated.

Text collection. Languages for which the available resources are inadequate are identified, and the needs are prioritized, based on linguistic and geographical diversity. Sponsorship is sought for collecting bilingual texts in high priority languages. Workflows are developed for languages based on a variety of factors, such as availability of educated people with native-level proficiency in their mother tongue and good knowledge of a reference language, internet access in the language area, availability of expatriate speakers in a first-world context, and so forth. A classification scheme is required to help predict which workflows will be most successful in a given situation.

[3] http://www.language-archives.org/

Audio protocol. The challenge posed by languages with no written literature should not be underestimated. A promising collection method is Basic Oral Language Documentation, which calls for inexpensive voice recorders and netbooks, project-specific software for transcription and sentence-aligned translation, network bandwidth for upload to the repository, and suitable training and support throughout the process.

Corpus readers. Software developers will inspect the file formats and identify high priority formats based on information about resource priorities and sizes. They will code a corpus reader, an open source reference implementation for converting between corpus formats and the storage model presented in section 3.

4.4 Further challenges

There are many additional difficulties that could be listed, though we expect they can be addressed over time, once a sufficient seed corpus is established. Two particular issues deserve further comment, however.

Licenses. Intellectual property issues surrounding linguistic corpora present a complex and evolving landscape (DiPersio, 2010). For users, it would be ideal for all materials to be available under a single license that permits derivative works, commercial use, and redistribution, such as the Creative Commons Attribution License (CC-BY). There would be no confusion about permissible uses of subsets and aggregates of the collected corpora, and it would be easy to view the Universal Corpus as a single corpus. But to attract as many data contributors as possible, we cannot make such a license a condition of contribution.

Instead, we propose to distinguish between: (1) a digital Archive of contributed corpora that are stored in their original format and made available under a range of licenses, offering preservation and dissemination services to the language resources community at large (i.e. the Language Commons); and (2) the Universal Corpus, which is embodied as programmatic access to an evolving subset of materials from the archive under one of a small set of permissive licenses, licenses whose unions and intersections are understood (e.g. CC-BY and its non-commercial counterpart CC-BY-NC). Apart from being a useful service in its own right, the Archive would provide a staging

ground for the Universal Corpus. Archived corpora having restrictive licenses could be evaluated for their potential as contributions to the Corpus, making it possible to prioritize the work of negotiating more liberal licenses.

There are reasons to distinguish Archive and Corpus even beyond the license issues. The Corpus, but not the Archive, is limited to the formats that support automatic cross-linguistic processing. Conversely, since the primary interface to the Corpus is programmatic, it may include materials that are hosted in many different archives; it only needs to know how to access and deliver them to the user. Incidentally, we consider it an implementation issue whether the Corpus is provided as a web service, a download service with user-side software, user-side software with data delivered on physical media, or a cloud application with user programs executed server-side.

Expenses of conversion and editing. We do not trivialize the work involved in converting documents to the formats of section 3, and in manually correcting the results of noisy automatic processes such as optical character recognition. Indeed, the amount of work involved is one motivation for the lengths to which we have gone to keep the data format simple. For example, we have deliberately avoided specifying any particular tokenization scheme. Variation will arise as a consequence, but we believe that it will be no worse than the variability in input that current machine translation training methods routinely deal with, and will not greatly injure the utility of the Corpus. The utter simplicity of the formats also widens the pool of potential volunteers for doing the manual work that is required. By avoiding linguistically delicate annotation, we can take advantage of motivated but untrained volunteers such as students and members of speaker communities.

5 Conclusion

Nearly twenty years ago, the linguistics community received a wake-up call, when Hale et al. (1992) predicted that 90% of the world's linguistic diversity would be lost or moribund by the year 2100, and warned that linguistics might "go down in history as the only science that presided obliviously over the disappearance of 90 per cent of the very field to which it is dedicated." Today, language documentation is a high priority in mainstream linguistics. However, the field of computational linguistics is yet to participate substantially.

The first half century of research in computational linguistics—from circa 1960 up to the present—has touched on less than 1% of the world's languages. For a field which is justly proud of its empirical methods, it is time to apply those methods to the remaining 99% of languages. We will never have the luxury of richly annotated data for these languages, so we are forced to ask ourselves: can we do more with less?

We believe the answer is "yes," and so we challenge the computational linguistics community to adopt a scalable computational approach to the problem. We need leaner methods for building machine translation systems; new algorithms for cross-linguistic bootstrapping via multiple paths; more effective techniques for leveraging human effort in labeling data; scalable ways to get bilingual text for unwritten languages; and large scale social engineering to make it all happen quickly.

To believe we can build this Universal Corpus is certainly audacious, but not to even try is arguably irresponsible. The initial step parallels earlier efforts to create large machine-readable text collections which began in the 1960s and reverberated through each subsequent decade. Collecting bilingual texts is an orthodox activity, and many alternative conceptions of a Human Language Project would likely include this as an early task.

The undertaking ranks with the largest data-collection efforts in science today. It is not achievable without considerable computational sophistication and the full engagement of the field of computational linguistics. Yet we require no fundamentally new technologies. We can build on our strengths in corpus-based methods, linguistic models, human- and machine-supplied annotations, and learning algorithms. By rising to this, the greatest language challenge of our time, we enable multi-lingual technology development at a new scale, and simultaneously lay the foundations for a new science of empirical universal linguistics.

Acknowledgments

We are grateful to Ed Bice, Doug Oard, Gary Simons, participants of the Language Commons working group meeting in Boston, students in the "Digitizing Languages" seminar (University of Michigan), and anonymous reviewers, for feedback on an earlier version of this paper.

Bilingual Lexicon Generation Using Non-Aligned Signatures

Abstract

Bilingual lexicons are fundamental resources. Modern automated lexicon generation methods usually require parallel corpora, which are not available for most language pairs. Lexicons can be generated using non-parallel corpora or a pivot language, but such lexicons are noisy. We present an algorithm for generating a high quality lexicon from a noisy one, which only requires an independent corpus for each language. Our algorithm introduces *non-aligned signatures (NAS)*, a cross-lingual word context similarity score that avoids the over-constrained and inefficient nature of alignment-based methods. We use NAS to eliminate incorrect translations from the generated lexicon. We evaluate our method by improving the quality of noisy Spanish-Hebrew lexicons generated from two pivot English lexicons. Our algorithm substantially outperforms other lexicon generation methods.

1 Introduction

Bilingual lexicons are useful for both end users and computerized language processing tasks. They provide, for each source language word or phrase, a set of translations in the target language, and thus they are a basic component of dictionaries, which also include syntactic information, sense division, usage examples, semantic fields, usage guidelines, etc.

Traditionally, when bilingual lexicons are not compiled manually, they are extracted from parallel corpora. However, for most language pairs parallel bilingual corpora either do not exist or are at best small and unrepresentative of the general language.

Bilingual lexicons can be generated using non-parallel corpora or pivot language lexicons (see Section 2). However, such lexicons are noisy. In this paper we present a method for generating a high quality lexicon given such a noisy one. Our evaluation focuses on the pivot language case.

Pivot language approaches deal with the scarcity of bilingual data for most language pairs by relying on the availability of bilingual data for each of the languages in question with a third, *pivot*, language. In practice, this third language is often English.

A naive method for pivot-based lexicon generation goes as follows. For each source headword[1], take its translations to the pivot language using the source-to-pivot lexicon, then for each such translation take its translations to the target language using the pivot-to-target lexicon. This method yields highly noisy ('divergent') lexicons, because lexicons are generally intransitive. This intransitivity stems from polysemy in the pivot language that does not exist in the source language. For example, take French-English-Spanish. The English word *spring* is the translation of the French word *printemps*, but only in the season of year sense. Further translating *spring* into Spanish yields both the correct translation *primavera* and an incorrect one, *resorte* (the elastic object).

To cope with the issue of divergence due to lexical intransitivity, we present an algorithm for assessing the correctness of candidate translations. The algorithm is quite simple to understand and to implement and is computationally efficient. In spite of its simplicity, we are not aware of previous work applying it to our problem.

The algorithm utilizes two monolingual corpora, comparable in their domain but otherwise unrelated, in the source and target languages. It does not need a pivot language corpus. The algorithm comprises two stages: signature genera-

[1] In this paper we focus on single word head entries. Multi-word expressions form a major topic in NLP and their handling is deferred to future work.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 98–107,
Uppsala, Sweden, 11-16 July 2010.

tion and signature ranking. The *signature* of word w is the set of words that co-occur with w most strongly. While co-occurrence scores are used to compute signatures, signatures, unlike context vectors, do not contain the score values. For each given source headword we compute its signature and the signatures of all of its candidate translations. We present the *non-aligned signatures (NAS)* similarity score for signature and use it to rank these translations. *NAS* is based on the number of headword signature words that may be translated using the input noisy lexicon into words in the signature of a candidate translation.

We evaluate our algorithm by generating a bilingual lexicon for Hebrew and Spanish using pivot Hebrew-English and English-Spanish lexicons compiled by a professional publishing house. We show that the algorithm outperforms existing algorithms for handling divergence induced by lexical intransitivity.

2 Previous Work

2.1 Parallel Corpora

Parallel corpora are often used to infer word-oriented machine-readable bilingual lexicons. The texts are aligned to each other, at chunk- and/or word-level. Alignment is generally evaluated by consistency (source words should be translated to a small number of target words over the entire corpus) and minimal shifting (in each occurrence, the source should be aligned to a translation nearby). For a review of such methods see (Lopez, 2008). The limited availability of parallel corpora of sufficient size for most language pairs restricts the usefulness of these methods.

2.2 Pivot Language Without Corpora

2.2.1 Inverse Consultation

Tanaka and Umemura (1994) generated a bilingual lexicon using a pivot language. They approached lexical intransitivity divergence using *Inverse Consultation (IC)*. IC examines the intersection of two pivot language sets: the set of pivot translations of a source-language word w, and the set of pivot translations of each target-language word that is a candidate for being a translation to w. IC generally requires that the intersection set contains at least two words, which are synonyms. For example, the intersection of the English translations of French *printemps* and Spanish *resorte* contains only a single word, *spring*. The intersection for a correct translation pair *printemps* and *primavera* may include two synonym words, *spring* and *springtime*. Variations of this method were proposed by (Kaji and Aizono, 1996; Bond et al., 2001; Paik et al., 2004; Ahn and Frampton, 2006).

One weakness of IC is that it relies on pivot language synonyms to identify correct translations. In the above example, if the relatively rare *springtime* had not existed or was missing from the input lexicons, IC would not have been able to discern that *primavera* is a correct translation. This may result in low recall.

2.2.2 Multiple Pivot Languages

Mausam et al. (2009) used many input bilingual lexicons to create bilingual lexicons for new language pairs. They represent the multiple input lexicons in a single undirected graph, with words from all the lexicons as nodes. The input lexicons translation pairs define the edges in the graph. New translation pairs are inferred based on cycles in the graph, that is, the existence of multiple paths between two words in different languages.

In a sense, this is a generalization of the pivot language idea, where multiple pivots are used. In the example above, if both English and German are used as pivots, *printemps* and *primavera* would be accepted as correct because they are linked by both English *spring* and German *Fruehling*, while *printemps* and *resorte* are not linked by any German pivot. This multiple-pivot idea is similar to *Inverse Consultation* in that multiple pivots are required, but using multiple pivot *languages* frees it from the dependency on rich input lexicons that contain a variety of synonyms. This is replaced, however, with the problem of coming up with multiple suitable input lexicons.

2.2.3 Micro-Structure of Dictionary Entries

Dictionaries published by a single publishing house tend to partition the semantic fields of headwords in the same way. Thus the first translation of some English headword in the English-Spanish and in the English-Hebrew dictionaries would correspond to the same sense of the headword, and would therefore constitute translations of each other. The applicability of this method is limited by the availability of machine-readable dictionaries produced by the same publishing house. Not surprisingly, this method has been proposed by lexicographers working in such companies (Sk-

oumalova, 2001).

2.3 Cross-lingual Co-occurrences in Lexicon Construction

Rapp (1999) and Fung (1998) discussed semantic similarity estimation using cross-lingual context vector alignment. Both works rely on a pre-existing large (16-20K entries), correct, one-to-one lexicon between the source and target languages, which is used to align context vectors between languages. The context vector data was extracted from comparable (monolingual but domain-related) corpora. Koehn and Knight (2002) were able to do without the initial large lexicon by limiting themselves to related languages that share a writing system, and using identically-spelled words as context words. Garera et al. (2009) and Pekar et al. (2006) suggested different methods for improving the context vectors data in each language before aligning them. Garera et al. (2009) replaced the traditional window-based co-occurrence counting with dependency-tree based counting, while Pekar et al. (2006) predicted missing co-occurrence values based on similar words in the same language. In the latter work, the one-to-one lexicon assumption was not made: when a context word had multiple equivalents, it was mapped into all of them, with the original probability equally distributed between them.

Pivot Language. Using cross-lingual co-occurrences to improve a lexicon generated using a pivot language was suggested by Tanaka and Iwasaki (1996). Schafer and Yarowsky (2002) created lexicons between English and a target local language (e.g. Gujarati) using a related language (e.g. Hindi) as pivot. An English pivot lexicon was used in conjunction with pivot-target cognates. Cross-lingual co-occurrences were used to remove errors, together with other cues such as edit distance and Inverse Document Frequencies (IDF) scores. It appears that this work assumed a single alignment was possible from English to the target language.

Kaji et al. (2008) used a pivot English lexicon to generate initial Japanese-Chinese and Chinese-Japanese lexicons, then used co-occurrences information, aligned using the initial lexicon, to identify correct translations. Unlike other works, which require alignments of pairs (i.e., two co-occurring words in one language translatable into two co-occurring words in the other), this method relies on alignments of 3-word cliques in each language, every pair of which frequently co-occurring. This is a relatively rare occurrence, which may explain the low recall rates of their results.

3 Algorithm

Our algorithm transforms a noisy lexicon into a high quality one. As explained above, in this paper we focus on noisy lexicons generated using pivot language lexicons. Other methods for obtaining an initial noisy lexicon could be used as well; their evaluation is deferred to future work.

In the setting evaluated in this paper, we first generate an initial noisy lexicon *iLex* possibly containing many translation candidates for each source headword. *iLex* is computed from two pivot-language lexicons, and is the only place in which the algorithm utilizes the pivot language. Afterwards, for each source headword, we compute its signature and the signatures of each of its translation candidates. Signature computation utilizes a monolingual corpus to discover the words that are most strongly related to the word. We now rank the candidates according to the non-aligned signatures (NAS) similarity score, which assesses the similarity between each candidate's signature and that of the headword. For each headword, we select the t translations with the highest NAS scores as correct translations.

3.1 Input Resources

The resources required by our algorithm as evaluated in this paper are: (a) two bilingual lexicons, one from the source to the pivot language and the other from the pivot to the target language. In principle, these two pivot lexicons can be noisy, although in our evaluation we use manually compiled lexicons; (b) two monolingual corpora, one for each of the source and target languages. We have tested the method with corpora of comparable domains, but not covering the same well-defined subjects (the corpora contain news from different countries and over non-identical time periods).

3.2 Initial Lexicon Construction

We create an initial lexicon from the source to the target language using the pivot language: we look up each source language word s in the source-pivot lexicon, and obtain the set P_s of its pivot

translations. We then look up each of the members of P_s in the pivot-target lexicon, and obtain a set T_s of candidate target translations. *iLex* is therefore a mapping from the set of source headwords to the set of candidate target translations. Note that it is possible that not all target lexicon words appear as translation candidates. To create a target to source lexicon, we repeat the process with the directions reversed.

3.3 Signatures

The *signature* of a word w in a language is the set of *N* words most strongly related to w. There are various possible ways to formalize this notion. We use a common and simple one, the words having the highest tendency to co-occur with *w* in a corpus. We count co-occurrences using a sliding fixed-length window of size *k*. We compute, for each pair of words, their Pointwise Mutual Information (PMI), that is:

$$PMI(w_1, w_2) = log\frac{Pr(w_1, w_2)}{Pr(w_1)Pr(w_2)}$$

where $Pr(w_1, w_2)$ is the co-occurrence count, and $Pr(w_i)$ is the total number of appearance of w_i in the corpus (Church and Hanks, 1990). We define the signature $G(w)_{N,k}$ of *w* to be the set of *N* words with the highest PMI with *w*.

Note that a word's signature includes words in the same language. Therefore, two signatures of words in different languages cannot be directly compared; we compare them using a lexicon L as explained below.

Signature is a function of w parameterized by N and k. We discuss the selection of these parameters in section 4.1.5.

3.4 Non-aligned Signatures (NAS) Similarity Scoring

The core strength of our method lies in the way in which we evaluate similarity between words in the source and target languages. For a lexicon *L*, a source word *s* and a target word *t*, $NAS_L(s, t)$ is defined as the number of words in the signature $G(s)_{N,k}$ of *s* that may be translated, using *L*, to words in the signature $G(t)_{N,k}$ of *t*, normalized by dividing it by *N*. Formally,

$$NAS_L(s, t) = \frac{|\{w \in G(s) | L(w) \cap G(t) \neq \emptyset\}|}{N}$$

Where $L(x)$ is the set of candidate translations of x under the lexicon L. Since we use a single lexicon, *iLex*, throughout this work, we usually omit the *L* subscript when referring to NAS.

Language	Sites	Tokens
Hebrew	haartz.co.il, ynet.co.il, nrg.co.il	510M
Spanish	elpais.com, elmundo.com, abc.es	560M

Table 1: Hebrew corpus data.

4 Lexicon Generation Experiments

We tested our algorithm by generating bilingual lexicons for Hebrew and Spanish, using English as a pivot language. We chose a language pair for which basically no parallel corpora exist[2], and that do not share ancestry or writing system in a way that can provide cues for alignment.

We conducted the test twice: once creating a Hebrew-Spanish lexicon, and once creating a Spanish-Hebrew one.

4.1 Experimental Setup

4.1.1 Corpora

The Hebrew and Spanish corpora were extracted from Israeli and Spanish newspaper websites respectively (see table 1 for details). Crawling a small number of sites allowed us to use special-tailored software to extract the textual data from the web pages, thus improving the quality of the extracted texts. Our two corpora are comparable in their domains, news and news commentary.

No kind of preprocessing was used for the Spanish corpus. For Hebrew, closed-class words that are attached to the succeeding word (e.g., 'the', 'and', 'in') were segmented using a simple unsupervised method (Dinur et al., 2009). This method compares the corpus frequencies of the non-prefixed form *x* and the prefixed form *wx*. If *x* is frequent enough, it is assumed to be the correct form, and all the occurrences of *wx* are segmented into two tokens, *w x*. This method was chosen for being simple and effective. However, the segmentation it produces is not perfect. It is context insensitive, segmenting all appearances of a token in the same way, while many *wx* forms are actually ambiguous. Even unambiguous token segmentations may fail when the non-segmented form is very frequent in the domain.

[2]Old testament corpora are for biblical Hebrew, which is very different from modern Hebrew.

Lexicon	# headwords	BF
Eng-Spa	55057	2.4
Spa-Eng	44349	2.9
Eng-Heb	48857	2.5
Heb-Eng	33439	3.7
Spa-Heb	34077	12.6
Heb-Spa	27591	14.8

Table 2: Number of words in lexicons, and branching factors (BF).

Hebrew orthography presents additional difficulties: there are relatively many homographs, and spelling is not quite standardized. These considerations lead us to believe that our choice of language pair is more challenging than, for example, a pair of European languages.

4.1.2 Lexicons

The source of the Hebrew-English lexicon was the Babylon on-line dictionary[3]. For Spanish-English, we used the union of Babylon with the Oxford English-Spanish lexicon. Since the corpus was segmented to words using spaces, lexicon entries containing spaces were discarded.

Lexicon directionality was ignored. All translation pairs extracted for Hebrew-Spanish via English, were also reversed and added to the Spanish-Hebrew lexicon, and vice-versa. Therefore, every *L1-L2* lexicon we mention is identical to the corresponding *L2-L1* lexicon in the set of translation pairs it contains. Our lexicon is thus the 'noisiest' that can be generated using a pivot language and two source-pivot-target lexicons, but it also provides the most complete candidate set possible. Ignoring directionality is also in accordance with the *reversibility principle* of the lexicographic literature (Tomaszczyk, 1998).

Table 2 details the sizes and branching factors (BF) (the average number of translations for headword) of the input lexicons, as well as those of the generated initial noisy lexicon.

4.1.3 Baseline

The performance of our method was compared to three baselines: Inverse Consultation (IC), average cosine distance, and average city block distance. The first is a completely different algorithm, and the last two are a version of our algorithm in which the NAS score is replaced by other scores.

IC (see section 2.2.1) is a corpus-less method. It ranks $t_1, t_2, ...$, the candidate translations of a source word s, by the size of the intersections of the sets of *pivot* translations of t_i and s. Note that IC ranking is a partial order, as the intersection size may be the same for many candidate translations. IC is a baseline for our algorithm as a whole.

Cosine and city block distances are widely used methods for calculating distances of vectors within the same vector space. They are defined here as[4]

$$Cosine(v,u) = 1 - \frac{\sum v_i u_i}{\sqrt{\sum v_i \sum u_i}}$$

$$CityBlock(v,u) = -\sum_i |v_i - u_i|$$

In the case of context vectors, the vector indices, or keys, are words, and their values are co-occurrence based scores. We used the words in our signatures as context vector keys, and PMI scores as values. In this way, the two scores are 'plugged' into our method and serve as baselines for our NAS similarity score.

Since the context vectors are in different languages, we had to translate, or align, the baseline context vectors for the source and target words. Our initial lexicon is a many-to-many relation, so multiple alignments were possible; in fact, the number of possible alignments tends to be very large[5]. We therefore generated *M* random possible alignments, and used the average distance metric across these alignments.

4.1.4 Test Sets and Gold Standard

Following other works (e.g. (Rapp, 1999)), and to simplify the experimental setup, we focused in our experiments on nouns.

A *p-q frequency range* in a corpus is the set of tokens in the places between p and q in the list of corpus tokens, sorted by frequency from high to low. Two types of test sets were used. The first (R1) includes all the singular, correctly segmented (in Hebrew) nouns among the 500 words in the 1001-1500 frequency range. The 1000 highest-frequency tokens were discarded, as a large number of these are utilized as auxiliary syntactic

[3] www.babylon.com.

[4] We modified the standard cosine and city block metrics so that for all measures higher values would be better.

[5] This is another advantage of our NAS score.

	R1		R2	
	Precision	Recall	Precision	Recall
NAS	**82.1%**	**100%**	**56%**	**100%**
Cosine	60.7%	100%	28%	100%
City block	56.3%	100%	32%	100%
IC	55.2%	85.7%	52%	88%

Table 3: Hebrew-Spanish lexicon generation: highest-ranking translation.

	R1		R2	
	Precision	Recall	Precision	Recall
NAS	**87.6%**	**100%**	**80%**	**100%**
Cosine	68%	100%	44%	100%
City block	69.8%	100%	36%	100%
IC	76.4%	100%	48%	92%

Table 4: Spanish-Hebrew Lexicon Generation: highest-ranking translation.

words. This yielded a test set of 112 Hebrew nouns and 169 Spanish nouns. The second (R2), contains 25 words for each of the two languages, obtained by randomly selecting 5 singular correctly segmented nouns from each of the 5 frequency ranges 1-1000 to 4001-5000.

For each of the test words, the correct translations were extracted from a modern professional concise printed Hebrew-Spanish-Hebrew dictionary (Prolog, 2003). This dictionary almost always provides a single Spanish translation for Hebrew headwords. Spanish headwords had 1.98 Hebrew translations on the average. In both cases this is a small number of correct translation comparing to what we might expect with other evaluation methods; therefore this evaluation amounts to a relatively high standard of correctness. Our score comparison experiments (section 5) extend the evaluation beyond this gold standard.

4.1.5 Parameters

The following parameter values were used. The window size for co-occurrence counting, k, was 4. This value was chosen in a small pre-test. Signature size N was 200 (see Section 6.1). The number of alignments M for the baseline scores was 100. The number of translations selected for each headword, t, was set to 1 for ease of testing, but see further notes under results.

4.2 Results

Tables 3 and 4 summarize the results of the Hebrew-Spanish and Spanish-Hebrew lexicon generation respectively, for both the R1 and R2 test sets.

In the three co-occurrence based methods, NAS similarity, cosine distance and and city block distance, the highest ranking translation was selected. Recall is always 100% as a translation from the candidate set is always selected, and all of this set is valid. Precision is computed as the number of test words whose selected translation was one of the translations in the gold standard.

IC translations ranking is a partial order, as usually many translations are scored equally. When *all* translations have the same score, IC is effectively undecided. We calculate recall as the percentage of cases in which there was more than one score rank. A result was counted as precise if *any* of the highest-ranking translations was in the gold-standard, even if other translations were equally ranked, creating a bias in favor of IC.

In both of the Hebrew-Spanish and the Spanish-Hebrew cases, our method significantly outperformed all baselines in generating a precise lexicon on the highest-ranking translations.

All methods performed better in *R1* than in *R2*, which included also lower-frequency words, and this was more noticeable with the corpus-based methods (Hebrew-Spanish) than with IC. This suggests, not surprisingly, that the performance of corpus-based methods is related to the amount of information in the corpus.

That the results for the Spanish-Hebrew lexicon are higher may arise from the difference in the gold standard. As mentioned, Hebrew words only had one "correct" Spanish translation, while Spanish had 1.98 correct translations on the average. If we had used a more comprehensive resource to test against, the precision of the method would be higher than shown here.

In translation pairs generation, the results beyond the top-ranking pair are also of importance. Tables 5 and 6 present the accuracy of the first three translation suggestions, for the three co-occurrence based scores, calculated for the R1 test set. IC results are not included, as they are incomparable to those of the other methods: IC tends to score many candidate translations identically, and in practice, the three highest-scoring sets of translation candidates contained on average 77% of all

	1st	2nd	3rd	total
NAS	**82.1%**	6.3%	1.8%	**90.2%**
Cosine	60.7%	**9.8%**	2.7%	73.2%
City block	56.3%	4.5%	**10.7%**	71.4%

Table 5: Hebrew-Spanish lexicon generation: accuracy of 3 best translations for the R1 condition. The table shows how many of the 2nd and 3rd translations are correct. Note that NAS is always a better solution, even though its numbers for 2nd and 3rd are smaller, because its accumulative percentage, shown in the last column, is higher.

	1st	2nd	3rd	total
NAS	**87.6%**	**77.5%**	**16%**	**163.9%**
Cosine	68%	66.3%	10.1%	144.4%
City block	69.8%	64.5%	**7.7%**	142%

Table 6: Spanish-Hebrew lexicon generation: accuracy of 3 best translations for the R1 condition. The total exceeds 100% because Spanish words had more than one correct translation. See also the caption of Table 5.

the candidates, thus necessarily yielding mostly incorrect translations. Recall was omitted from the tables as it is always 100%.

For all methods, many of the correct translations that do not rank first, rank as second or third. For both languages, NAS ranks highest for total accuracy of the three translations, with considerable advantage.

5 Score Comparison Experiments

Lexicon generation, as defined in our experiment, is a relatively high standard for cross-linguistic semantic distance evaluation. This is especially correct since our gold standard gives only a small set of translations. The set of possible translations in *iLex* tends to include, besides the "correct" translation of the gold standard, other translations that are suitable in certain contexts or are semantically related. For example, for one Hebrew word, *kvuza*, the gold standard translation was *grupo* (group), while our method chose *equipo* (team), which was at least as plausible given the amount of sports news in the corpus.

	Heb-Spa		Spa-Heb	
	SCE1	SCE2	SCE1	SCE2
NAS	**93.8%**	**76.2%**	**94.1%**	**83.7%**
Cosine	74.1%	57.1%	70.7%	63.2%
City block	74.1%	68.3%	78,1%	75.2%

Table 7: Precision of score comparison experiments. The percentage of cases in which each of the scoring methods was able to successfully distinguish the *correct* (SCE1) or *possible correct* (SCE2) translation from the *random* translation.

Thus to better compare the capability of NAS to distinguish correct and incorrect translations with that of other scores, we performed two more experiments. In the first score comparison experiment (SCE1), we used the two R1 test sets, Hebrew and Spanish, from the lexicon generation test (section 4.1.4). For each word in the test set, we used our method to select between one of two translations: a *correct translation*, from the gold standard, and a *random* translation, chosen randomly among all the nouns similar in frequency to the correct translation.

The second score comparison experiment (SCE2) was designed to test the score with a more extensive test set. For each of the two languages, we randomly selected 1000 nouns, and used our method to select between a *possibly correct* translation, chosen randomly among the translations suggested in *iLex*, and a *random* translation, chosen randomly among nouns similar in frequency to the *possibly correct* translation. This test, while using a more extensive test set, is less accurate because it is not guaranteed that any of the input translations is correct.

In both SCE1 and SCE2, cosine and city block distance were used as baselines. Inverse Consultation is irrelevant here because it can only score translation pairs that appear in *iLex*.

Table 7 presents the results of the two score comparison experiments, each of them for each of the translation directions. Recall is by definition 100% and is omitted.

Again, NAS performs better than the baselines in all cases. With all scores, precision values in SCE1 are higher than in the lexicon generation experiment. This is consistent with the expectation that selection between a correct and a random, probably incorrect, translation is easier than selecting among the translations in *iLex*. The precision in SCE2 is lower than that in SCE1. This may be a result of both translations in SCE2 being

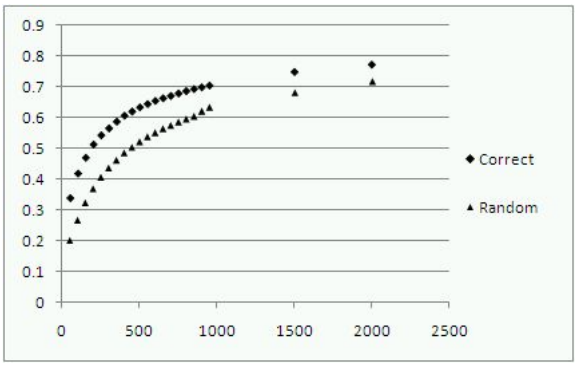

Figure 1: NAS values (not algorithm precision) for various N sizes. NAS is not sensitive to the value of N (see text).

in some cases incorrect. Yet this may also reflect a weakness of all three scores with lower-frequency words, which are represented in the 1000-word samples but not in the ones used in SCE1.

6 NAS Score Properties

6.1 Signature Size

NAS values are in the range $[0, 1]$. The values depend on *N*, the size of the signature used. With an extremely small *N*, NAS values would usually be 0, and would tend to be noisy, due to accidental inclusion of high-frequency or highly ambiguous words in the signature. As *N* approaches the size of the lexicon used for alignment, NAS values approach 1 for all word pairs.

This suggests that choosing a suitable value of *N* is critical for effectively using NAS. Yet an empirical test has shown that NAS may be useful for a wide range of *N* values: we computed NAS values for the *correct* and *random* translations used in the Hebrew-Spanish SCE1 experiment (section 5), using *N* values between 50 and 2000.

Figure 1 shows the average score values (note that these are not precision values) for the correct and random translations across that *N* range. The scores for the correct translations are consistently higher than those of the random translations, even while there is a discernible decline in the difference between them. In fact, the precision of the selection between the correct and random translation is persistent throughout the range. This suggests that while extreme *N* values should be avoided, the selection of *N* is not a major issue.

6.2 Dependency on Alignment Lexicon

NAS_L values depend on L, the lexicon in use. Clearly again, in the extremes, an almost empty lexicon or a lexicon containing every possible pair of words (a Cartesian product), this score would not be useful. In the first case, it would yield 0 for every pair, and in the second, 1. However as our experiments show, it performed well with real-world examples of a noisy lexicon, with branching factors of 12.6 and 14.8 (see table 2).

6.3 Lemmatization

Lemmatization is the process of extracting the lemmas of words in the corpus. Our experiments show that good results can be achieved without lemmatization, at least for nouns in the pair of languages tested (aside from the simple prefix segmentation we used for Hebrew, see section 4.1.1). For other language pairs lemmatization may be needed. In general, correct lemmatization should improve results, since the signatures would consist of more meaningful information. If automatic lemmatization introduces noise, it may reduce the results' quality.

6.4 Alternative Models for Relatedness

Cosine and city block, as well as other related distance metrics, rely on *context vectors*. The context vector of a word *w* collects words and maps them to some score of their "relatedness" to *w*; in this case, we used PMI. NAS, in contrast, relies on the signature, the set of *N* words most related to *w*. That is, it requires a Boolean relatedness indication, rather than a numeric relatedness score. We used PMI to generate this Boolean indication, and naturally, other similar measures could be used as well. More significantly, it may be possible to use it with corpus-less sources of "relatedness", such as WordNet or search result snippets.

7 Conclusion

We presented a method to create a high quality bilingual lexicon given a noisy one. We focused on the case in which the noisy lexicon is created using two pivot language lexicons. Our algorithm uses two unrelated monolingual corpora. At the heart of our method is the non-aligned signatures (NAS) context similarity score, used for removing incorrect translations using cross-lingual co-occurrences.

Words in one language tend to have multiple translations in another. The common method for context similarity scoring utilizes some algebraic distance between context vectors, and requires a single alignment of context vectors in one language into the other. Finding a single correct alignment is unrealistic even when a perfectly correct lexicon is available. For example, alignment forces us to choose one correct translation for each context word, while in practice a few possible terms may be used interchangeably in the other language. In our task, moreover, the lexicon used for alignment was automatically generated from pivot language lexicons and was expected to contain errors.

NAS does not depend on finding a single correct alignment. While it measures how well the sets of words that tend to co-occur with these two words align to each other, its strength may lie in bypassing the question of *which* word in one language should be aligned to a certain context word in the other language. Therefore, unlike other scoring methods, it is not effected by incorrect alignments.

We have shown that NAS outperforms the more traditional distance metrics, which we adapted to the many-to-many scenario by amortizing across multiple alignments. Our results confirm that alignment is problematic in using co-occurrence methods across languages, at least in our settings. NAS constitutes a way to avoid this problem.

While the purpose of this work was to discern correct translations from incorrect one, it is worth noting that our method actually ranks translation correctness. This is a stronger property, which may render it useful in a wider range of scenarios.

In fact, NAS can be viewed as a general measure for word similarity between languages. It would be interesting to further investigate this observation with other sources of lexicons (e.g., obtained from parallel or comparable corpora) and for other tasks, such as cross-lingual word sense disambiguation and information retrieval.

Abstract

As described in this paper, we propose a new automatic evaluation method for machine translation using noun-phrase chunking. Our method correctly determines the matching words between two sentences using corresponding noun phrases. Moreover, our method determines the similarity between two sentences in terms of the noun-phrase order of appearance. Evaluation experiments were conducted to calculate the correlation among human judgments, along with the scores produced using automatic evaluation methods for MT outputs obtained from the 12 machine translation systems in NTCIR-7. Experimental results show that our method obtained the highest correlations among the methods in both sentence-level adequacy and fluency.

1 Introduction

High-quality automatic evaluation has become increasingly important as various machine translation systems have developed. The scores of some automatic evaluation methods can obtain high correlation with human judgment in document-level automatic evaluation(Coughlin, 2007). However, sentence-level automatic evaluation is insufficient. A great gap exists between language processing of automatic evaluation and the processing by humans. Therefore, in recent years, various automatic evaluation methods particularly addressing sentence-level automatic evaluations have been proposed. Methods based on word strings (*e.g.*, BLEU(Papineni et al., 2002), NIST(NIST, 2002), METEOR(Banerjee and Lavie., 2005), ROUGE-L(Lin and Och, 2004), and IMPACT(Echizen-ya and Araki, 2007)) calculate matching scores using only common words between MT outputs and references from bilingual humans. However, these methods cannot determine the correct word correspondences sufficiently because they fail to focus solely on phrase correspondences. Moreover, various methods using syntactic analytical tools(Pozar and Charniak, 2006; Mutton et al., 2007; Mehay and Brew, 2007) are proposed to address the sentence structure. Nevertheless, those methods depend strongly on the quality of the syntactic analytical tools.

As described herein, for use with MT systems, we propose a new automatic evaluation method using noun-phrase chunking to obtain higher sentence-level correlations. Using noun phrases produced by chunking, our method yields the correct word correspondences and determines the similarity between two sentences in terms of the noun phrase order of appearance. Evaluation experiments using MT outputs obtained by 12 machine translation systems in NTCIR-7(Fujii et al., 2008) demonstrate that the scores obtained using our system yield the highest correlation with the human judgments among the automatic evaluation methods in both sentence-level adequacy and fluency. Moreover, the differences between correlation coefficients obtained using our method and other methods are statistically significant at the 5% or lower significance level for adequacy. Results confirmed that our method using noun-phrase chunking is effective for automatic evaluation for machine translation.

2 Automatic Evaluation Method using Noun-Phrase Chunking

The system based on our method has four processes. First, the system determines the corre-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 108–117,
Uppsala, Sweden, 11-16 July 2010.

spondences of noun phrases between MT outputs and references using chunking. Secondly, the system calculates word-level scores based on the correct matched words using the determined correspondences of noun phrases. Next, the system calculates phrase-level scores based on the noun-phrase order of appearance. The system calculates the final scores combining word-level scores and phrase-level scores.

2.1 Correspondence of Noun Phrases by Chunking

The system obtains the noun phrases from each sentence by chunking. It then determines corresponding noun phrases between MT outputs and references calculating the similarity for two noun phrases by the PER score(Su et al., 1992). In that case, PER scores of two kinds are calculated. One is the ratio of the number of match words between an MT output and reference for the number of all words of the MT output. The other is the ratio of the number of match words between the MT output and reference for the number of all words of the reference. The similarity is obtained as an F-measure between two PER scores. The high score represents that the similarity between two noun phrases is high. Figure 1 presents an example of the determination of the corresponding noun phrases.

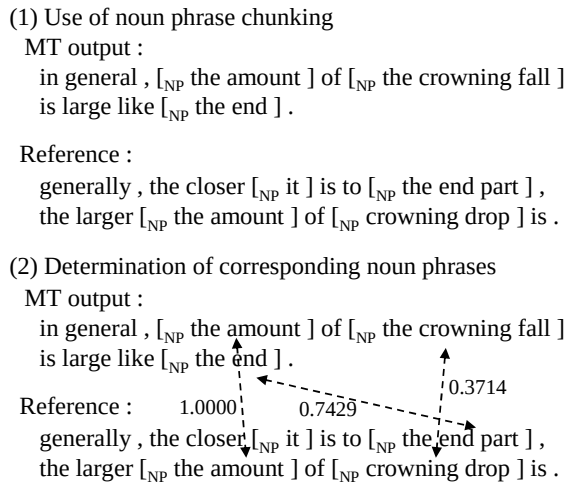

Figure 1: Example of determination of corresponding noun phrases.

In Fig. 1, "the amount", "the crowning fall" and "the end" are obtained as noun phrases in MT output by chunking, and "it", "the end part", "the amount" and "crowning drop" are obtained in the reference by chunking. Next, the system determines the corresponding noun phrases from these noun phrases between the MT output and reference. The score between "the end" and "the end part" is the highest among the scores between "the end" in the MT output and "it", "the end part", "the amount", and "crowning drop" in the reference. Moreover, the score between "the end part" and "the end" is the highest among the scores between "the end part" in reference and "the amount", "the crowning fall", "the end" in the MT output. Consequently, "the end" and "the end part" are selected as noun phrases with the highest mutual scores: "the end" and "the end part" are determined as one corresponding noun phrase. In Fig. 1, "the amount" in the MT output and "the amount" in reference, and "the crowning fall" in the MT output and "crowning drop" in the reference also are determined as the respective corresponding noun phrases. The noun phrase for which the score between it and other noun phrases is 0.0 (*e.g.*, "it" in reference) has no corresponding noun phrase. The use of the noun phrases is effective because the frequency of the noun phrases is higher than those of other phrases. The verb phrases are not used for this study, but they can also be generated by chunking. It is difficult to determine the corresponding verb phrases correctly because the words in each verb phrase are often fewer than the noun phrases.

2.2 Word-level Score

The system calculates the word-level scores between MT output and reference using the corresponding noun phrases. First, the system determines the common words based on Longest Common Subsequence (LCS). The system selects only one LCS route when several LCS routes exist. In such cases, the system calculates the Route Score (RS) using the following Eqs. (1) and (2):

$$RS = \sum_{c \in LCS} \left(\sum_{w \in c} weight(w) \right)^{\beta} \qquad (1)$$

$$weight(w) = \begin{cases} 2 & \text{words in corresponding noun phrase} \\ 1 & \text{words in non-corresponding noun phrase} \end{cases} \quad (2)$$

In Eq. (1), β is a parameter for length weighting of common parts; it is greater than 1.0. Figure 2 portrays an example of determination of the common parts. In the first process of Fig. 2, LCS is 7. In this example, several LCS routes exist. The system selects the LCS route which has ",", "the amount of", "crowning", "is", and "." as the common parts. The common part is the part for which the common words appear continuously. In contrast, IMPACT selects a different LCS route that includes ", the", "amount of", "crowning", "is", and "." as the common parts. In IMPACT, using no analytical knowledge, the LCS route is determined using the information of the number of words in the common parts and the position of the common parts. The RS for LCS route selected using our method is 32 $(= 1^{2.0} + (2 + 2 + 1)^{2.0} + 2^{2.0} + 1^{2.0} + 1^{2.0})$ when β is 2.0. The RS for LCS route selected by IMPACT is 19 $(= (1 + 1)^{2.0} + (2 + 1)^{2.0} + 2^{2.0} + 1^{2.0} + 1^{2.0})$. In the LCS route selected by IMPACT, the weight of "the" in the common part ", the" is 1 because "the" in the reference is not included in the corresponding noun phrase. In the LCS route selected using our method, the weight of "the" in "the amount of" is 2 because "the" in MT output and "the" in the reference are included in the corresponding noun phrase "NP1". Therefore, the system based on our method can select the correct LCS route.

Moreover, the word-level score is calculated using the common parts in the selected LCS route as the following Eqs. (3), (4), and (5).

$$R_{wd} = \left(\frac{\sum_{i=0}^{RN} \left(\alpha^i \sum_{c \in LCS} length(c)^\beta \right)}{m^\beta} \right)^{\frac{1}{\beta}} \quad (3)$$

$$P_{wd} = \left(\frac{\sum_{i=0}^{RN} \left(\alpha^i \sum_{c \in LCS} length(c)^\beta \right)}{n^\beta} \right)^{\frac{1}{\beta}} \quad (4)$$

(1) First process for determination of common parts :
LCS = 7
Our method

Figure 2: Example of common-part determination.

$$score_{wd} = \frac{(1 + \gamma^2) R_{wd} P_{wd}}{R_{wd} + \gamma^2 P_{wd}} \quad (5)$$

Equation (3) represents recall and Eq. (4) represents precision. Therein, m signifies the word number of the reference in Eq. (3), and n stands for the word number of the MT output in Eq. (4). Here, RN denotes the repetition number of the determination process of the LCS route, and i, which has initial value 0, is the counter for RN. In Eqs. (3) and (4), α is a parameter for the repetition process of the determination of LCS route, and is less than 1.0. Therefore, R_{wd} and P_{wd} becomes small as the appearance order of the common parts between MT output and reference is different. Moreover, $length(c)$ represents the number of words in each common part; β is a parameter related to the length weight of common parts, as in Eq. (1). In this case, the weight of each common word in the common part is 1. The system calculates $score_{wd}$ as the word-level score in Eq. (5). In Eq. (5), γ is determined as P_{wd}/R_{wd}. The $score_{wd}$ is between 0.0 and 1.0.

In the first process of Fig. 2, $\alpha^i \sum_{c \in LCS} length(c)^\beta$ is 13.0 ($=0.5^0 \times (1^{2.0} + 3^{2.0} + 1^{2.0} + 1^{2.0} + 1^{2.0})$) when α and β are 0.5 and 2.0, respectively. In this case, the counter i is 0. Moreover, in the second process of Fig. 2, $\alpha^i \sum_{c \in LCS} length(c)^\beta$ is 2.5 ($=0.5^1 \times (1^{2.0} + 2^{2.0})$) using two common parts "the" and "the end", except the common parts determined using the first process. In Fig. 2, RN is 1 because the system finishes calculating $\alpha^i \sum_{c \in LCS} length(c)^\beta$ when counter i became 1: this means that all common parts were processed until the second process. As a result, R_{wd} is 0.1969 ($=\sqrt{(13.0 + 2.5)/20^{2.0}} = \sqrt{0.0388}$), and P_{wd} is 0.2625 ($=\sqrt{(13.0 + 2.5)/15^{2.0}} = \sqrt{0.0689}$). Consequently, $score_{wd}$ is 0.2164 ($=\frac{(1+1.3332^2) \times 0.1969 \times 0.2625}{0.1969 + 1.3332^2 \times 0.2625}$). In this case, γ becomes 1.3332 ($=\frac{0.2625}{0.1969}$). The system can determine the matching words correctly using the corresponding noun phrases between the MT output and the reference.

The system calculates $score_{wd\text{-}multi}$ using $R_{wd\text{-}multi}$ and $P_{wd\text{-}multi}$ which are, respectively, maximum R_{wd} and P_{wd} when multiple references are used as the following Eqs. (6), (7) and (8). In Eq. (8), γ is determined as $P_{wd\text{-}multi}/R_{wd\text{-}multi}$. The $score_{wd\text{-}multi}$ is between 0.0 and 1.0.

$$R_{wd\text{-}multi} = \max_{j=1}^{u} \left(\left(\frac{\left(\sum_{i=0}^{RN} \left(\alpha^i \sum_{c \in LCS} length(c)^\beta \right) \right)_j}{m_j^\beta} \right)^{\frac{1}{\beta}} \right) \quad (6)$$

$$P_{wd\text{-}multi} = \max_{j=1}^{u} \left(\left(\frac{\left(\sum_{i=0}^{RN} \left(\alpha^i \sum_{c \in LCS} length(c)^\beta \right) \right)_j}{n_j^\beta} \right)^{\frac{1}{\beta}} \right) \quad (7)$$

$$score_{wd\text{-}multi} = \frac{(1 + \gamma^2 R_{wd\text{-}multi}) P_{wd\text{-}multi}}{R_{wd\text{-}multi} + \gamma^2 P_{wd\text{-}multi}} \quad (8)$$

2.3 Phrase-level Score

The system calculates the phrase-level score using the noun phrases obtained by chunking. First, the system extracts only noun phrases from sentences. Then it generalizes each noun phrase as each word. Figure 3 presents examples of generalization by noun phrases.

(1) Corresponding noun phrases
MT output :
in general , [$_{NP1}$ the amount] of [$_{NP2}$ the crowning fall] is large like [$_{NP3}$ the end] .
Reference :
generally , the closer [$_{NP}$ it] is to [$_{NP3}$ the end part] , the larger [$_{NP1}$ the amount] of [$_{NP2}$ crowning drop] is .
(2) Generalization by noun phrases
MT output :
NP1 NP2 NP3
Reference :
NP NP3 NP1 NP2

Figure 3: Example of generalization by noun phrases.

Figure 3 presents three corresponding noun phrases between the MT output and the reference. The noun phrase "it", which has no corresponding noun phrase, is expressed as "NP" in the reference. Consequently, the MT output is generalized as "NP1 NP2 NP3"; the reference is generalized as "NP NP3 NP1 NP2". Subsequently, the system obtains the phrase-level score between the generalized MT output and reference as the following Eqs. (9), (10), and (11).

$$R_{np} = \left(\frac{\sum_{i=0}^{RN} \left(\alpha^i \sum_{cnpp \in LCS} length(cnpp)^\beta \right)}{\left(m_{cnp} \times \sqrt{m_{no\text{-}cnp}} \right)^\beta} \right)^{\frac{1}{\beta}} \quad (9)$$

$$P_{np} = \left(\frac{\sum_{i=0}^{RN} \left(\alpha^i \sum_{cnpp \in LCS} length(cnpp)^\beta \right)}{\left(n_{cnp} \times \sqrt{n_{no\text{-}cnp}} \right)^\beta} \right)^{\frac{1}{\beta}} \quad (10)$$

Table 1: Machine translation system types.

	System No. 1	System No. 2	System No. 3	System No. 4	System No. 5	System No. 6
Type	SMT	SMT	RBMT	SMT	SMT	SMT
	System No. 7	System No. 8	System No. 9	System No. 10	System No. 11	System No. 12
Type	SMT	SMT	EBMT	SMT	SMT	RBMT

$$score_{np} = \frac{(1+\gamma^2)R_{np}P_{np}}{R_{np}+\gamma^2 P_{np}} \quad (11)$$

In Eqs. (9) and (10), *cnpp* denotes the common noun phrase parts; m_{cnp} and n_{cnp} respectively signify the quantities of common noun phrases in the reference and MT output. Moreover, $m_{no\text{-}cnp}$ and $n_{no\text{-}cnp}$ are the quantities of noun phrases except the common noun phrases in the reference and MT output. The values of $m_{no\text{-}cnp}$ and $n_{no\text{-}cnp}$ are processed as 1 when no non-corresponding noun phrases exist. The square root used for $m_{no\text{-}cnp}$ and $n_{no\text{-}cnp}$ is to decrease the weight of the non-corresponding noun phrases. In Eq. (11), γ is determined as P_{np}/R_{np}. In Fig. 3, R_{np} and P_{np} are 0.7071 ($=\sqrt{\frac{1\times 2^{2.0}+0.5\times 1^{2.0}}{(3\times 1)^{2.0}}}$) when α is 0.5 and β is 2.0. Therefore, $score_{np}$ is 0.7071.

The system obtains $score_{np\text{-}multi}$ calculating the average of $score_{np}$ when multiple references are used as the following Eq. (12).

$$score_{np\text{-}multi} = \frac{\sum_{j=0}^{u}\left(score_{np}\right)_j}{u} \quad (12)$$

2.4 Final Score

The system calculates the final score by combining the word-level score and the phrase-level score as shown in the following Eq. (13).

$$score = \frac{score_{wd} + \delta \times score_{np}}{1+\delta} \quad (13)$$

Therein, δ represents a parameter for the weight of $score_{np}$: it is between 0.0 and 1.0. The ratio of $score_{wd}$ to $score_{np}$ is 1:1 when δ is 1.0. Moreover, $score_{wd\text{-}multi}$ and $score_{np\text{-}multi}$ are used for Eq. (13) in multiple references. In Figs. 2 and 3, the final score between the MT output and the reference is 0.4185 ($=\frac{0.2164+0.7\times 0.7071}{1+0.7}$) when δ is 0.7. The system can realize high-quality automatic evaluation using both word-level information and phrase-level information.

3 Experiments

3.1 Experimental Procedure

We calculated the correlation between the scores obtained using our method and scores produced by human judgment. The system based on our method obtained the evaluation scores for 1,200 English output sentences related to the patent sentences. These English output sentences are sentences that 12 machine translation systems in NTCIR-7 translated from 100 Japanese sentences. Moreover, the number of references to each English sentence in 100 English sentences is four. These references were obtained from four bilingual humans. Table 1 presents types of the 12 machine translation systems.

Moreover, three human judges evaluated 1,200 English output sentences from the perspective of adequacy and fluency on a scale of 1–5. We used the median value in the evaluation results of three human judges as the final scores of 1–5. We calculated Pearson's correlation efficient and Spearman's rank correlation efficient between the scores obtained using our method and the scores by human judgments in terms of sentence-level adequacy and fluency.

Additionally, we calculated the correlations between the scores using seven other methods and the scores by human judgments to compare our method with other automatic evaluation methods. The other seven methods were IMPACT, ROUGE-L, BLEU[1], NIST, NMG-WN(Ehara, 2007; Echizen-ya et al., 2009), METEOR[2], and WER(Leusch et al., 2003). Using our method, 0.1 was used as the value of the parameter α in Eqs. (3)-(10) and 1.1 was used as the value of the parameter β in Eqs. (1)–(10). Moreover, 0.3 was used as the value of the parameter δ in Eq. (13). These val-

[1]BLEU was improved to perform sentence-level evaluation: the maximum N value between MT output and reference is used(Echizen-ya et al., 2009).

[2]The matching modules of METEOR are the exact and stemmed matching module, and a WordNet-based synonym-matching module.

ues of the parameter are determined using English sentences from Reuters articles(Utiyama and Isahara, 2003). Moreover, we obtained the noun phrases using a shallow parser(Sha and Pereira, 2003) as the chunking tool. We revised some erroneous results that were obtained using the chunking tool.

3.2 Experimental Results

As described in this paper, we performed comparison experiments using our method and seven other methods. Tables 2 and 3 respectively show Pearson's correlation coefficient for sentence-level adequacy and fluency. Tables 4 and 5 respectively show Spearman's rank correlation coefficient for sentence-level adequacy and fluency. In Tables 2–5, bold typeface signifies the maximum correlation coefficients among eight automatic evaluation methods. Underlining in our method signifies that the differences between correlation coefficients obtained using our method and IMPACT are statistically significant at the 5% significance level. Moreover, "Avg." signifies the average of the correlation coefficients obtained by 12 machine translation systems in respective automatic evaluation methods, and "All" are the correlation coefficients using the scores of 1,200 output sentences obtained using the 12 machine translation systems.

3.3 Discussion

In Tables 2–5, the "Avg." score of our method is shown to be higher than those of other methods. Especially in terms of the sentence-level adequacy shown in Tables 2 and 4, "Avg." of our method is about 0.03 higher than that of IMPACT. Moreover, in system No. 8 and "All" of Tables 2 and 4, the differences between correlation coefficients obtained using our method and IMPACT are statistically significant at the 5% significance level.

Moreover, we investigated the correlation of machine translation systems of every type. Table 6 shows "All" of Pearson's correlation coefficient and Spearman's rank correlation coefficient in SMT (*i.e.*, system Nos. 1–2, system Nos. 4–8 and system Nos. 10–11) and RBMT (*i.e.*, system Nos. 3 and 12). The scores of 900 output sentences obtained by 9 machine

translation systems in SMT and the scores of 200 output sentences obtained by 2 machine translation systems in RBMT are used respectively. However, EBMT is not included in Table 6 because EBMT is only system No. 9. In Table 6, our method obtained the highest correlation among the eight methods, except in terms of the adequacy of RBMT in Pearson's correlation coefficient. The differences between correlation coefficients obtained using our method and IMPACT are statistically significant at the 5% significance level for adequacy of SMT.

To confirm the effectiveness of noun-phrase chunking, we performed the experiment using a system combining BLEU with our method. In this case, BLEU scores were used as $score_{wd}$ in Eq. (13). This experimental result is shown as "BLEU with our method" in Tables 2–5. In the results of "BLEU with our method" in Tables 2–5, underlining signifies that the differences between correlation coefficients obtained using BLEU with our method and BLEU alone are statistically significant at the 5% significance level. The coefficients of correlation for BLEU with our method are higher than those of BLEU in any machine translation system, "Avg." and "All" in Tables 2–5. Moreover, for sentence-level adequacy, BLEU with our method is significantly better than BLEU in almost all machine translation systems and "All" in Tables 2 and 4. These results indicate that our method using noun-phrase chunking is effective for some methods and that it is statistically significant in each machine translation system, not only "All", which has large sentences.

Subsequently, we investigated the precision of the determination process of the corresponding noun phrases described in section 2.1: in the results of system No. 1, we calculated the precision as the ratio of the number of the correct corresponding noun phrases for the number of all noun-phrase correspondences obtained using the system based on our method. Results show that the precision was 93.4%, demonstrating that our method can determine the corresponding noun phrases correctly.

Moreover, we investigated the relation be-

tween the correlation obtained by our method and the quality of chunking. In "Our method" shown in Tables 2–5, noun phrases for which some erroneous results obtained using the chunking tool were revised. "Our method II" of Tables 2–5 used noun phrases that were given as results obtained using the chunking tool. Underlining in "Our method II" of Tables 2–5 signifies that the differences between correlation coefficients obtained using our method II and IMPACT are statistically significant at the 5% significance level. Fundamentally, in both "Avg." and "All" of Tables 2–5, the correlation coefficients of our method II without the revised noun phrases are lower than those of our method using the revised noun phrases. However, the difference between our method and our method II in "Avg." and "All" of Tables 2–5 is not large. The performance of the chunking tool has no great influence on the results of our method because $score_{wd}$ in Eqs. (3), (4), and (5) do not depend strongly on the performance of the chunking tool. For example, in sentences shown in Fig. 2, all common parts are the same as the common parts of Fig. 2 when "the crowning fall" in the MT output and "crowning drop" in the reference are not determined as the noun phrases. Other common parts are determined correctly because the weight of the common part "the amount of" is higher than those of other common parts by Eqs. (1) and (2). Consequently, the determination of the common parts except "the amount of" is not difficult.

In other language sentences, we already performed the experiments using Japanese sentences from Reuters articles(Oyamada et al., 2010). Results show that the correlation coefficients of IMPACT with our method, for which IMPACT scores were used as $score_{wd}$ in Eq. (13), were highest among some methods. Therefore, our method might not be language-dependent. Nevertheless, experiments using various language data are necessary to elucidate this point.

4 Conclusion

As described herein, we proposed a new automatic evaluation method for machine transla-

tion. Our method calculates the scores for MT outputs using noun-phrase chunking. Consequently, the system obtains scores using the correctly matched words and phrase-level information based on the corresponding noun phrases. Experimental results demonstrate that our method yields the highest correlation among eight methods in terms of sentence-level adequacy and fluency.

Future studies will improve our method, enabling it to achieve high correlation in sentence-level fluency. Future studies will also include experiments using data of various languages.

Abstract

Information-extraction (IE) systems seek to distill semantic relations from natural-language text, but most systems use supervised learning of relation-specific examples and are thus limited by the availability of training data. *Open* IE systems such as TextRunner, on the other hand, aim to handle the unbounded number of relations found on the Web. But how well can these open systems perform?

This paper presents WOE, an open IE system which improves dramatically on TextRunner's precision and recall. The key to WOE's performance is a novel form of self-supervised learning for open extractors — using heuristic matches between Wikipedia infobox attribute values and corresponding sentences to construct training data. Like TextRunner, WOE's extractor eschews lexicalized features and handles an unbounded set of semantic relations. WOE can operate in two modes: when restricted to POS tag features, it runs as quickly as TextRunner, but when set to use dependency-parse features its precision and recall rise even higher.

1 Introduction

The problem of information-extraction (IE), generating relational data from natural-language text, has received increasing attention in recent years. A large, high-quality repository of extracted tuples can potentially benefit a wide range of NLP tasks such as question answering, ontology learning, and summarization. The vast majority of IE work uses supervised learning of relation-specific examples. For example, the WebKB project (Craven et al., 1998) used labeled examples of the `courses-taught-by` relation to induce rules for identifying additional instances of the relation. While these methods can achieve high precision and recall, they are limited by the availability of training data and are unlikely to scale to the thousands of relations found in text on the Web.

An alternative paradigm, *Open* IE, pioneered by the TextRunner system (Banko et al., 2007) and the "preemptive IE" in (Shinyama and Sekine, 2006), aims to handle an unbounded number of relations and run quickly enough to process Web-scale corpora. Domain independence is achieved by extracting the relation name as well as its two arguments. Most open IE systems use self-supervised learning, in which automatic heuristics generate labeled data for training the extractor. For example, TextRunner uses a small set of hand-written rules to heuristically label training examples from sentences in the Penn Treebank.

This paper presents WOE (Wikipedia-based Open Extractor), the first system that autonomously transfers knowledge from random editors' effort of collaboratively editing Wikipedia to train an open information extractor. Specifically, WOE generates *relation-specific* training examples by matching *Infobox*[1] attribute values to corresponding sentences (as done in Kylin (Wu and Weld, 2007) and Luchs (Hoffmann et al., 2010)), but WOE abstracts these examples to *relation-independent* training data to learn an unlexicalized extractor, akin to that of TextRunner. WOE can operate in two modes: when restricted to shallow features like part-of-speech (POS) tags, it runs as quickly as Textrunner, but when set to use dependency-parse features its precision and recall rise even higher. We present a thorough experimental evaluation, making the following contributions:

- We present WOE, a new approach to open IE that uses Wikipedia for self-supervised learn-

[1] An infobox is a set of tuples summarizing the key attributes of the subject in a Wikipedia article. For example, the infobox in the article on "Sweden" contains attributes like *Capital, Population* and *GDP*.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 118–127,
Uppsala, Sweden, 11-16 July 2010.

ing of unlexicalized extractors. Compared with TextRunner (the state of the art) on three corpora, WOE yields between 72% and 91% improved F-measure — generalizing well beyond Wikipedia.

- Using the same learning algorithm and features as TextRunner, we compare four different ways to generate positive and negative training data with TextRunner's method, concluding that our Wikipedia heuristic is responsible for the bulk of WOE's improved accuracy.
- The biggest win arises from using parser features. Previous work (Jiang and Zhai, 2007) concluded that parser-based features are unnecessary for information extraction, but that work assumed the presence of lexical features. We show that abstract dependency paths are a highly informative feature when performing unlexicalized extraction.

2 Problem Definition

An open information extractor is a function from a document, d, to a set of triples, $\{\langle \texttt{arg}_1, \texttt{rel}, \texttt{arg}_2 \rangle\}$, where the args are noun phrases and rel is a textual fragment indicating an implicit, semantic relation between the two noun phrases. The extractor should produce one triple for every relation stated *explicitly* in the text, but is not required to infer implicit facts. In this paper, we assume that all relational instances are stated within a single sentence. Note the difference between open IE and the traditional approaches (*e.g.*, as in WebKB), where the task is to decide whether some pre-defined relation holds between (two) arguments in the sentence.

We wish to learn an open extractor *without direct supervision*, *i.e.* without annotated training examples or hand-crafted patterns. Our input is Wikipedia, a collaboratively-constructed encyclopedia[2]. As output, WOE produces an unlexicalized and relation-independent open extractor. Our objective is an extractor which generalizes beyond Wikipedia, handling other corpora such as the general Web.

3 Wikipedia-based Open IE

The key idea underlying WOE is the automatic construction of training examples by heuristically matching Wikipedia infobox values and corresponding text; these examples are used to generate an unlexicalized, relation-independent (open) extractor. As shown in Figure 1, WOE has three main components: preprocessor, matcher, and learner.

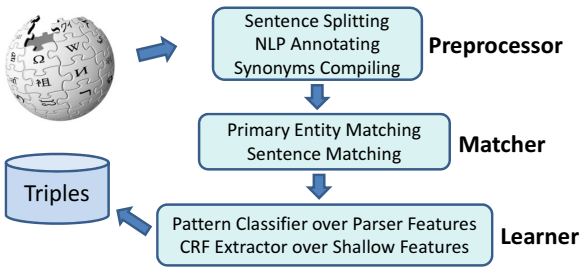

Figure 1: Architecture of WOE.

3.1 Preprocessor

The preprocessor converts the raw Wikipedia text into a sequence of sentences, attaches NLP annotations, and builds synonym sets for key entities. The resulting data is fed to the matcher, described in Section 3.2, which generates the training set.

Sentence Splitting: The preprocessor first renders each Wikipedia article into HTML, then splits the article into sentences using OpenNLP.

NLP Annotation: As we discuss fully in Section 4 (Experiments), we consider several variations of our system; one version, WOE^{parse}, uses parser-based features, while another, WOE^{pos}, uses shallow features like POS tags, which may be more quickly computed. Depending on which version is being trained, the preprocessor uses OpenNLP to supply POS tags and NP-chunk annotations — or uses the Stanford Parser to create a dependency parse. When parsing, we force the hyperlinked anchor texts to be a single token by connecting the words with an underscore; this transformation improves parsing performance in many cases.

Compiling Synonyms: As a final step, the preprocessor builds sets of synonyms to help the matcher find sentences that correspond to infobox relations. This is useful because Wikipedia editors frequently use multiple names for an entity; for example, in the article titled "University of Washington" the token "UW" is widely used to refer the university. Additionally, attribute values are often described differently within the infobox than they are in surrounding text. Without knowledge of these synonyms, it is impossible to construct good matches. Following (Wu and Weld, 2007; Nakayama and Nishio, 2008), the preprocessor uses Wikipedia redirection pages and back-

[2]We also use DBpedia (Auer and Lehmann, 2007) as a collection of conveniently parsed Wikipedia *infoboxes*

ward links to automatically construct synonym sets. Redirection pages are a natural choice, because they explicitly encode synonyms; for example, "USA" is redirected to the article on the "United States." Backward links for a Wikipedia entity such as the "Massachusetts Institute of Technology" are hyperlinks pointing to this entity from other articles; the anchor text of such links (*e.g.*, "MIT") forms another source of synonyms.

3.2 Matcher

The matcher constructs training data for the learner component by heuristically matching attribute-value pairs from Wikipedia articles containing infoboxes with corresponding sentences in the article. Given the article on "Stanford University," for example, the matcher should associate $\langle \texttt{established}, 1891 \rangle$ with the sentence "The university was founded in 1891 by ..." Given a Wikipedia page with an infobox, the matcher iterates through all its attributes looking for a unique sentence that contains references to both the subject of the article and the attribute value; these noun phrases will be annotated $\texttt{arg}_1$ and $\texttt{arg}_2$ in the training set. The matcher considers a sentence to contain the attribute value if the value or its synonym is present. Matching the article subject, however, is more involved.

Matching Primary Entities: In order to match shorthand terms like "MIT" with more complete names, the matcher uses an ordered set of heuristics like those of (Wu and Weld, 2007; Nguyen et al., 2007):

- Full match: strings matching the full name of the entity are selected.
- Synonym set match: strings appearing in the entity's synonym set are selected.
- Partial match: strings matching a prefix or suffix of the entity's name are selected. If the full name contains punctuation, only a prefix is allowed. For example, "Amherst" matches "Amherst, Mass," but "Mass" does not.
- Patterns of "the <*type*>": The matcher first identifies the type of the entity (*e.g.*, "city" for "Ithaca"), then instantiates the pattern to create the string "the city." Since the first sentence of most Wikipedia articles is stylized (*e.g.* "The city of Ithaca sits ..."), a few patterns suffice to extract most entity types.
- The most frequent pronoun: The matcher assumes that the article's most frequent pronoun denotes the primary entity, *e.g.*, "he" for the page on "Albert Einstein." This heuristic is dropped when "it" is most common, because the word is used in too many other ways.

When there are multiple matches to the primary entity in a sentence, the matcher picks the one which is closest to the matched infobox attribute value in the parser dependency graph.

Matching Sentences: The matcher seeks a *unique* sentence to match the attribute value. To produce the best training set, the matcher performs three filterings. First, it skips the attribute completely when multiple sentences mention the value or its synonym. Second, it rejects the sentence if the subject and/or attribute value are not heads of the noun phrases containing them. Third, it discards the sentence if the subject and the attribute value do not appear in the same clause (or in parent/child clauses) in the parse tree.

Since Wikipedia's Wikimarkup language is semantically ambiguous, parsing infoboxes is surprisingly complex. Fortunately, DBpedia (Auer and Lehmann, 2007) provides a cleaned set of infoboxes from 1,027,744 articles. The matcher uses this data for attribute values, generating a training dataset with a total of 301,962 labeled sentences.

3.3 Learning Extractors

We learn two kinds of extractors, one (WOE^{parse}) using features from dependency-parse trees and the other (WOE^{pos}) limited to shallow features like POS tags. WOE^{parse} uses a pattern learner to classify whether the shortest dependency path between two noun phrases indicates a semantic relation. In contrast, WOE^{pos} (like TextRunner) trains a conditional random field (CRF) to output certain text between noun phrases when the text denotes such a relation. Neither extractor uses individual words or lexical information for features.

3.3.1 Extraction with Parser Features

Despite some evidence that parser-based features have limited utility in IE (Jiang and Zhai, 2007), we hoped dependency paths would improve precision on long sentences.

Shortest Dependency Path as Relation: Unless otherwise noted, WOE uses the Stanford Parser to create dependencies in the "collapsedDependency" format. Dependencies involving prepositions, conjuncts as well as information about the referent of relative clauses are collapsed to get direct dependencies between content words. As

noted in (de Marneffe and Manning, 2008), this collapsed format often yields simplified patterns which are useful for relation extraction. Consider the sentence:

Dan was not born in Berkeley.

The Stanford Parser dependencies are:

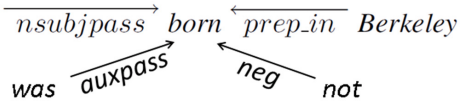
nsubjpass(born-4, Dan-1)
auxpass(born-4, was-2)
neg(born-4, not-3)
prep_in(born-4, Berkeley-6)

where each atomic formula represents a binary dependence from dependent token to the governor token.

These dependencies form a directed graph, $\langle V, E \rangle$, where each token is a vertex in V, and E is the set of dependencies. For any pair of tokens, such as "Dan" and "Berkeley", we use the shortest connecting path to represent the possible relation between them:

Dan $\overrightarrow{nsubjpass}$ *born* $\overleftarrow{prep\_in}$ *Berkeley*

We call such a path a *corePath*. While we will see that corePaths are useful for indicating *when* a relation exists between tokens, they don't necessarily capture the *semantics* of that relation. For example, the path shown above doesn't indicate the existence of negation! In order to capture the *meaning* of the relation, the learner augments the corePath into a tree by adding all adverbial and adjectival modifiers as well as dependencies like "neg" and "auxpass". We call the result an *expandPath* as shown below:



WOE traverses the expandPath with respect to the token orders in the original sentence when *outputting* the final expression of `rel`.

Building a Database of Patterns: For each of the 301,962 sentences selected and annotated by the matcher, the learner generates a corePath between the tokens denoting the subject and the infobox attribute value. Since we are interested in eventually extracting "subject, relation, object" triples, the learner rejects corePaths that don't start with subject-like dependencies, such as *nsubj*, *nsubjpass*, *partmod* and *rcmod*. This leads to a collection of 259,046 corePaths.

To combat data sparsity and improve learning performance, the learner further generalizes the corePaths in this set to create a smaller set of *generalized-corePaths*. The idea is to eliminate distinctions which are irrelevant for recognizing (domain-independent) relations. Lexical words in corePaths are replaced with their POS tags. Further, all Noun POS tags and "PRP" are abstracted to "N", all Verb POS tags to "V", all Adverb POS tags to "RB" and all Adjective POS tags to "J". The preposition dependencies such as "prep_in" are generalized to "prep". Take the corePath "*Dan* $\overrightarrow{nsubjpass}$ *born* $\overleftarrow{prep\_in}$ *Berkeley*" for example, its generalized-corePath is "*N* $\overrightarrow{nsubjpass}$ *V* $\overleftarrow{prep}$ *N*". We call such a generalized-corePath an extraction pattern. In total, WOE builds a database (named DB_p) of 15,333 distinct patterns and each pattern p is associated with a frequency — the number of matching sentences containing p. Specifically, 185 patterns have $f_p \geq 100$ and 1929 patterns have $f_p \geq 5$.

Learning a Pattern Classifier: Given the large number of patterns in DB_p, we assume few valid open extraction patterns are left behind. The learner builds a simple pattern classifier, named WOE^{parse}, which checks whether the generalized-corePath from a test triple is present in DB_p, and computes the normalized logarithmic frequency as the probability[3]:

$$w(p) = \frac{max(log(f_p) - log(f_{min}), 0)}{log(f_{max}) - log(f_{min})}$$

where f_{max} (50,259 in this paper) is the maximal frequency of pattern in DB_p, and f_{min} (set 1 in this work) is the controlling threshold that determines the minimal frequency of a valid pattern.

Take the previous sentence "*Dan was not born in Berkeley*" for example. WOE^{parse} first identifies *Dan* as $\texttt{arg}_1$ and *Berkeley* as $\texttt{arg}_2$ based on NP-chunking. It then computes the corePath "*Dan* $\overrightarrow{nsubjpass}$ *born* $\overleftarrow{prep\_in}$ *Berkeley*" and abstracts to *p*="*N* $\overrightarrow{nsubjpass}$ *V* $\overleftarrow{prep}$ *N*". It then queries DB_p to retrieve the frequency $f_p = 29112$ and assigns a probability of 0.95. Finally, WOE^{parse} traverses the triple's expandPath to output the final expression $\langle Dan, wasNotBornIn, Berkeley \rangle$. As shown in the experiments on three corpora, WOE^{parse} achieves an F-measure which is between 72% to 91% greater than TextRunner's.

3.3.2 Extraction with Shallow Features

WOE^{parse} has a dramatic performance improvement over TextRunner. However, the improvement comes at the cost of speed — TextRunner

[3]How to learn a more sophisticated weighting function is left as a future topic.

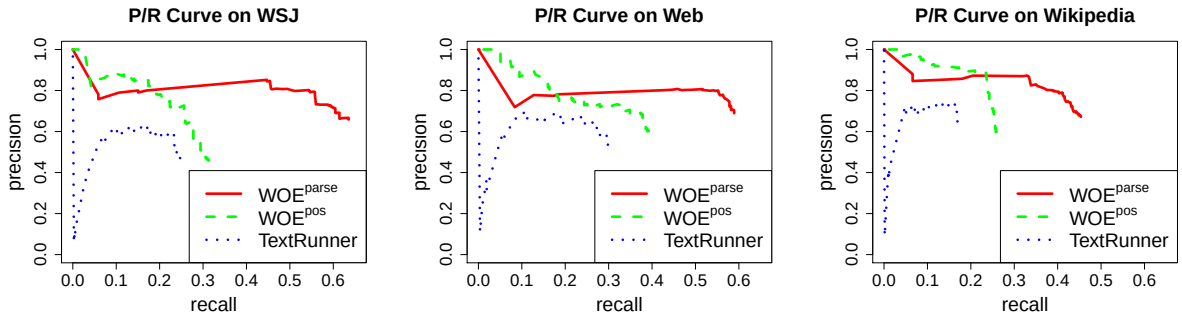


Figure 2: WOE^{pos} performs better than TextRunner, especially on precision. WOE^{parse} dramatically improves performance, especially on recall.

runs about $30X$ faster by only using shallow features. Since high speed can be crucial when processing Web-scale corpora, we additionally learn a CRF extractor WOE^{pos} based on shallow features like POS-tags. In both cases, however, we generate training data from Wikipedia by matching sentences with infoboxes, while TextRunner used a small set of hand-written rules to label training examples from the Penn Treebank.

We use the same matching sentence set behind DB_p to generate positive examples for WOE^{pos}. Specifically, for each matching sentence, we label the subject and infobox attribute value as $\texttt{arg}_1$ and $\texttt{arg}_2$ to serve as the ends of a linear CRF chain. Tokens involved in the expandPath are labeled as `rel`. Negative examples are generated from random noun-phrase pairs in other sentences when their generalized-CorePaths are not in DB_p.

WOE^{pos} uses the same learning algorithm and selection of features as TextRunner: a two-order CRF chain model is trained with the Mallet package (McCallum, 2002). WOE^{pos}'s features include POS-tags, regular expressions (*e.g.*, for detecting capitalization, punctuation, *etc.*.), and conjunctions of features occurring in adjacent positions within six words to the left and to the right of the current word.

As shown in the experiments, WOE^{pos} achieves an improved F-measure over TextRunner between 18% to 34% on three corpora, and this is mainly due to the increase on precision.

4 Experiments

We used three corpora for experiments: WSJ from Penn Treebank, Wikipedia, and the general Web. For each dataset, we randomly selected 300 sentences. Each sentence was examined by two people to label all reasonable triples. These candidate triples are mixed with pseudo-negative ones and submitted to Amazon Mechanical Turk for verification. Each triple was examined by 5 Turkers. We mark a triple's final label as positive when more than 3 Turkers marked them as positive.

4.1 Overall Performance Analysis

In this section, we compare the overall performance of WOE^{parse}, WOE^{pos} and TextRunner (shared by the Turing Center at the University of Washington). In particular, we are going to answer the following questions: 1) How do these systems perform against each other? 2) How does performance vary w.r.t. sentence length? 3) How does extraction speed vary w.r.t. sentence length?

Overall Performance Comparison

The detailed P/R curves are shown in Figure 2. To have a close look, for each corpus, we randomly divided the 300 sentences into 5 groups and compared the best F-measures of three systems in Figure 3. We can see that:

- WOE^{pos} is better than TextRunner, especially on precision. This is due to better training data from Wikipedia via self-supervision. Section 4.2 discusses this in more detail.
- WOE^{parse} achieves the best performance, especially on recall. This is because the parser features help to handle complicated and long-distance relations in difficult sentences. In particular, WOE^{parse} outputs 1.42 triples per sentence on average, while WOE^{pos} outputs 1.05 and TextRunner outputs 0.75.

Note that we measure TextRunner's precision & recall differently than (Banko et al., 2007) did. Specifically, we compute the precision & recall based on *all* extractions, while Banko et al. counted only *concrete* triples where $\texttt{arg}_1$ is a proper noun, $\texttt{arg}_2$ is a proper noun or date, and

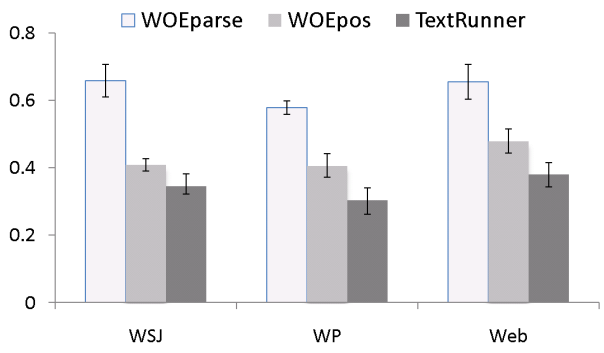

Figure 3: WOE^{pos}achieves an F-measure, which is between 18% and 34% better than TextRunner's. WOE^{parse}achieves an improvement between 72% and 91% over TextRunner. The error bar indicates one standard deviation.

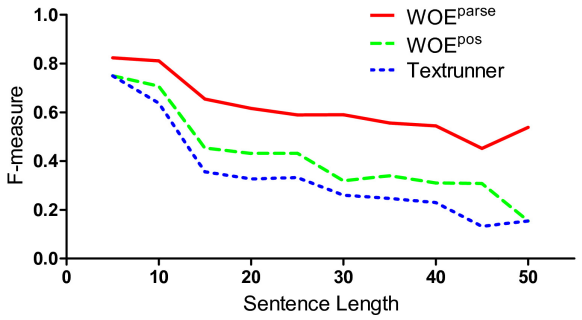

Figure 4: WOE^{parse}'s F-measure decreases more slowly with sentence length than WOE^{pos} and TextRunner, due to its better handling of difficult sentences using parser features.

the frequency of `rel` is over a threshold. Our experiments show that focussing on concrete triples generally improves precision at the expense of recall.[4] Of course, one can apply a concreteness filter to any open extractor in order to trade recall for precision.

The extraction errors by WOE^{parse} can be categorized into four classes. We illustrate them with the WSJ corpus. In total, WOE^{parse} got 85 wrong extractions on WSJ, and they are caused by: 1) Incorrect $\texttt{arg}_1$ and/or $\texttt{arg}_2$ from NP-Chunking (18.6%); 2) A erroneous dependency parse from Stanford Parser (11.9%); 3) Inaccurate meaning (27.1%) — for example, $\langle she, isNominatedBy, PresidentBush\rangle$ is wrongly extracted from the sentence "If she is nominated by President Bush ..."[5]; 4) A pattern inapplicable for the test sentence (42.4%).

Note WOE^{parse} is worse than WOE^{pos} in the low recall region. This is mainly due to parsing errors (especially on long-distance dependencies), which misleads WOE^{parse} to extract false high-confidence triples. WOE^{pos} won't suffer from such parsing errors. Therefore it has better precision on high-confidence extractions.

We noticed that TextRunner has a dip point in the low recall region. There are two typical errors responsible for this. A sample error of the first type is $\langle Sources, sold, theCompany\rangle$ extracted from the sentence "Sources said he sold the company", where "Sources" is wrongly treated as the subject of the object clause. A sample error of the second type is $\langle thisYear, willStarIn, theMovie\rangle$ extracted from the sentence "Coming up this year, Long will star in the new movie.", where "this year" is wrongly treated as part of a compound subject. Taking the WSJ corpus for example, at the dip point with recall=0.002 and precision=0.059, these two types of errors account for 70% of all errors.

Extraction Performance *vs.* **Sentence Length**

We tested how extractors' performance varies with sentence length; the results are shown in Figure 4. TextRunner and WOE^{pos} have good performance on short sentences, but their performance deteriorates quickly as sentences get longer. This is because long sentences tend to have complicated and long-distance relations which are difficult for shallow features to capture. In contrast, WOE^{parse}'s performance decreases more slowly w.r.t. sentence length. This is mainly because parser features are more useful for handling difficult sentences and they help WOE^{parse} to maintain a good recall with only moderate loss of precision.

Extraction Speed *vs.* **Sentence Length**

We also tested the extraction speed of different extractors. We used Java for implementing the extractors, and tested on a Linux platform with a 2.4GHz CPU and 4G memory. On average, it takes WOE^{parse} 0.679 seconds to process a sentence. For TextRunner and WOE^{pos}, it only takes 0.022 seconds — $30X$ times faster. The detailed extraction speed *vs.* sentence length is in Figure 5, showing that TextRunner and WOE^{pos}'s extraction time grows approximately linearly with sentence length, while WOE^{parse}'s extraction time grows

[4]For example, consider the Wikipedia corpus. From our 300 test sentences, TextRunner extracted 257 triples (at 72.0% precision) but only extracted 16 concrete triples (with 87.5% precision).

[5]These kind of errors might be excluded by monitoring whether sentences contain words such as 'if,' 'suspect,' 'doubt,' *etc.*. We leave this as a topic for the future.

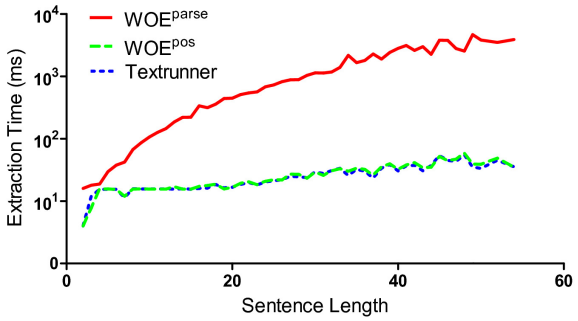

Figure 5: Textrnner and WOE^{pos}'s running time seems to grow linearly with sentence length, while WOE^{parse}'s time grows quadratically.

quadratically ($R^2 = 0.935$) due to its reliance on parsing.

4.2 Self-supervision with Wikipedia Results in Better Training Data

In this section, we consider how the process of matching Wikipedia infobox values to corresponding sentences results in better training data than the hand-written rules used by TextRunner.

To compare with TextRunner, we tested four different ways to generate training examples from Wikipedia for learning a CRF extractor. Specifically, positive and/or negative examples are selected by TextRunner's hand-written rules (*tr* for short), by WOE's heuristic of matching sentences with infoboxes (*w* for short), or randomly (*r* for short). We use CRF$_{+h_1-h_2}$ to denote a particular approach, where "+" means positive samples, "-" means negative samples, and $h_i \in \{tr, w, r\}$. In particular, "$+w$" results in 221,205 positive examples based on the matching sentence set[6]. All extractors are trained using about the same number of positive and negative examples. In contrast, TextRunner was trained with 91,687 positive examples and 96,795 negative examples generated from the WSJ dataset in Penn Treebank.

The CRF extractors are trained using the same learning algorithm and feature selection as TextRunner. The detailed P/R curves are in Figure 6, showing that using WOE heuristics to label positive examples gives the biggest performance boost. CRF$_{+tr-tr}$ (trained using TextRunner's heuristics) is slightly worse than TextRunner. Most likely, this is because TextRunner's heuristics rely on parse trees to label training examples, and the Stanford parse on Wikipedia is less accurate than the gold parse on WSJ.

[6]This number is smaller than the total number of corePaths (259,046) because we require $\texttt{arg}_1$ to appear before $\texttt{arg}_2$ in a sentence — as specified by TextRunner.

4.3 Design Desiderata of WOE^{parse}

There are two interesting design choices in WOE^{parse}: 1) whether to require $\texttt{arg}_1$ to appear before $\texttt{arg}_2$ (denoted as $1 \prec 2$) in the sentence; 2) whether to allow corePaths to contain prepositional phrase (PP) attachments (denoted as *PPa*). We tested how they affect the extraction performance; the results are shown in Figure 7.

We can see that filtering PP attachments ($\overline{PPa}$) gives a large precision boost with a noticeable loss in recall; enforcing a lexical ordering of relation arguments ($1 \prec 2$) yields a smaller improvement in precision with small loss in recall. Take the WSJ corpus for example: setting $1 \prec 2$ and $\overline{PPa}$ achieves a precision of 0.792 (with recall of 0.558). By changing $1 \prec 2$ to $1 \sim 2$, the precision decreases to 0.773 (with recall of 0.595). By changing $\overline{PPa}$ to *PPa* and keeping $1 \prec 2$, the precision decreases to 0.642 (with recall of 0.687) — in particular, if we use gold parse, the precision decreases to 0.672 (with recall of 0.685). We set $1 \prec 2$ and $\overline{PPa}$ as default in WOE^{parse} as a logical consequence of our preference for high precision over high recall.

4.3.1 Different parsing options

We also tested how different parsing might effect WOE^{parse}'s performance. We used three parsing options on the WSJ dataset: Stanford parsing, CJ50 parsing (Charniak and Johnson, 2005), and the gold parses from the Penn Treebank. The Stanford Parser is used to derive dependencies from CJ50 and gold parse trees. Figure 8 shows the detailed P/R curves. We can see that although today's statistical parsers make errors, they have negligible effect on the accuracy of WOE.

5 Related Work

Open or Traditional Information Extraction: Most existing work on IE is relation-specific. Occurrence-statistical models (Agichtein and Gravano, 2000; M. Ciaramita, 2005), graphical models (Peng and McCallum, 2004; Poon and Domingos, 2008), and kernel-based methods (Bunescu and R.Mooney, 2005) have been studied. Snow et al. (Snow et al., 2005) utilize WordNet to learn dependency path patterns for extracting the hypernym relation from text. Some seed-based frameworks are proposed for open-domain extraction (Pasca, 2008; Davidov et al., 2007; Davidov and Rappoport, 2008). These works focus

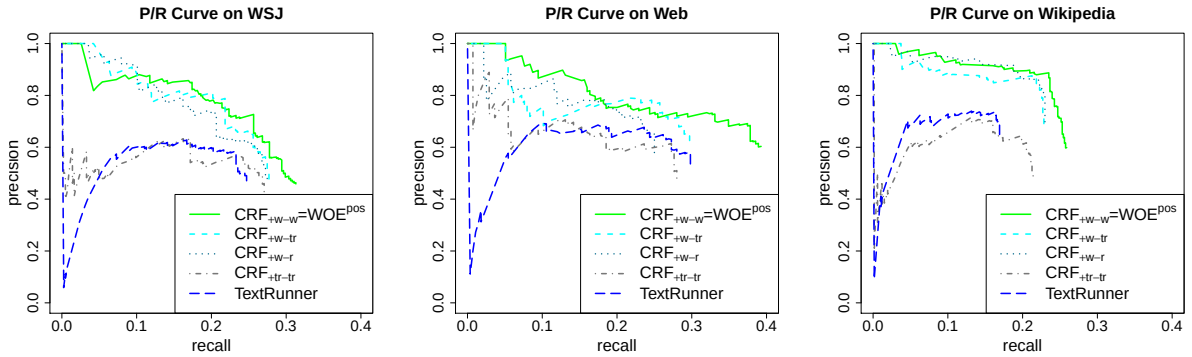

Figure 6: Matching sentences with Wikipedia infoboxes results in better training data than the hand-written rules used by TextRunner.

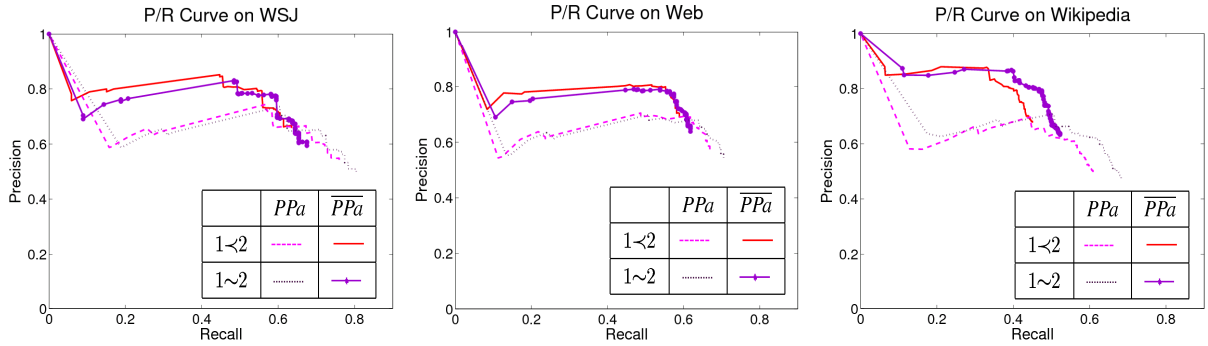

Figure 7: Filtering prepositional phrase attachments ($\overline{PPa}$) shows a strong boost to precision, and we see a smaller boost from enforcing a lexical ordering of relation arguments ($1 \prec 2$).

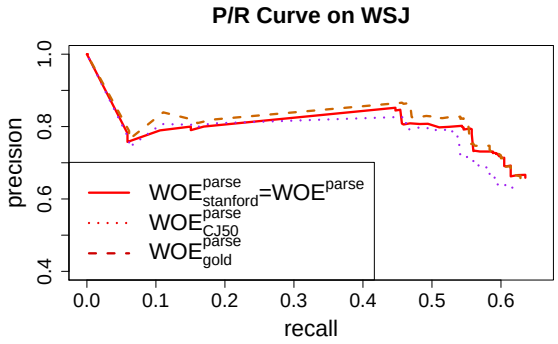

Figure 8: Although today's statistical parsers make errors, they have negligible effect on the accuracy of WOE compared to operation on gold standard, human-annotated data.

on identifying general relations such as class attributes, while open IE aims to extract relation instances from given sentences. Another seed-based system StatSnowball (Zhu et al., 2009) can perform both relation-specific and open IE by iteratively generating weighted extraction patterns. Different from WOE, StatSnowball only employs shallow features and uses L1-normalization to weight patterns. Shinyama and Sekine proposed the "preemptive IE" framework to avoid relation-specificity (Shinyama and Sekine, 2006). They first group documents based on pairwise vector-space clustering, then apply an additional clustering to group entities based on documents clusters. The two clustering steps make it difficult to meet the scalability requirement necessary to process the Web. Mintz et al. (Mintz et al., 2009) uses Freebase to provide distant supervision for relation extraction. They applied a similar heuristic by matching Freebase tuples with unstructured sentences (Wikipedia articles in their experiments) to create features for learning relation extractors. Matching Freebase with arbitrary sentences instead of matching Wikipedia infobox with corresponding Wikipedia articles will potentially increase the size of matched sentences at a cost of accuracy. Also, their learned extractors are relation-specific. Alan Akbik et al. (Akbik and Broß, 2009) annotated 10,000 sentences parsed with LinkGrammar and selected 46 general linkpaths as patterns for relation extraction. In contrast, WOE learns 15,333 general patterns based on an automatically annotated set of

301,962 Wikipedia sentences. The KNext system (Durme and Schubert, 2008) performs open knowledge extraction via significant heuristics. Its output is knowledge represented as logical statements instead of information represented as segmented text fragments.

Information Extraction with Wikipedia: The YAGO system (Suchanek et al., 2007) extends WordNet using facts extracted from Wikipedia categories. It only targets a limited number of predefined relations. Nakayama et al. (Nakayama and Nishio, 2008) parse selected Wikipedia sentences and perform extraction over the phrase structure trees based on several handcrafted patterns. Wu and Weld proposed the KYLIN system (Wu and Weld, 2007; Wu et al., 2008) which has the same spirit of matching Wikipedia sentences with infoboxes to learn CRF extractors. However, it only works for relations defined in Wikipedia infoboxes.

Shallow or Deep Parsing: Shallow features, like POS tags, enable fast extraction over large-scale corpora (Davidov et al., 2007; Banko et al., 2007). Deep features are derived from parse trees with the hope of training better extractors (Zhang et al., 2006; Zhao and Grishman, 2005; Bunescu and Mooney, 2005; Wang, 2008). Jiang and Zhai (Jiang and Zhai, 2007) did a systematic exploration of the feature space for relation extraction on the ACE corpus. Their results showed limited advantage of parser features over shallow features for IE. However, our results imply that abstracted dependency path features are highly informative for open IE. There might be several reasons for the different observations. First, Jiang and Zhai's results are tested for traditional IE where local lexicalized tokens might contain sufficient information to trigger a correct classification. The situation is different when features are completely unlexicalized in open IE. Second, as they noted, many relations defined in the ACE corpus are short-range relations which are easier for shallow features to capture. In practical corpora like the general Web, many sentences contain complicated long-distance relations. As we have shown experimentally, parser features are more powerful in handling such cases.

6 Conclusion

This paper introduces WOE, a new approach to open IE that uses self-supervised learning over unlexicalized features, based on a heuristic match between Wikipedia infoboxes and corresponding text. WOE can run in two modes: a CRF extractor (WOE^{pos}) trained with shallow features like POS tags; a pattern classfier (WOE^{parse}) learned from dependency path patterns. Comparing with TextRunner, WOE^{pos} runs at the same speed, but achieves an F-measure which is between 18% and 34% greater on three corpora; WOE^{parse} achieves an F-measure which is between 72% and 91% higher than that of TextRunner, but runs about $30X$ times slower due to the time required for parsing.

Our experiments uncovered two sources of WOE's strong performance: 1) the Wikipedia heuristic is responsible for the bulk of WOE's improved accuracy, but 2) dependency-parse features are highly informative when performing unlexicalized extraction. We note that this second conclusion disagrees with the findings in (Jiang and Zhai, 2007).

In the future, we plan to run WOE over the billion document CMU ClueWeb09 corpus to compile a giant knowledge base for distribution to the NLP community. There are several ways to further improve WOE's performance. Other data sources, such as Freebase, could be used to create an additional training dataset via self-supervision. For example, Mintz et al. consider all sentences containing both the subject and object of a Freebase record as matching sentences (Mintz et al., 2009); while they use this data to learn relation-specific extractors, one could also learn an open extractor. We are also interested in merging lexicalized and open extraction methods; the use of some domain-specific lexical features might help to improve WOE's practical performance, but the best way to do this is unclear. Finally, we wish to combine WOE^{parse} with WOE^{pos} (*e.g.*, with voting) to produce a system which maximizes precision at low recall.

Abstract

As information extraction (IE) becomes more central to enterprise applications, rule-based IE engines have become increasingly important. In this paper, we describe SystemT, a rule-based IE system whose basic design removes the expressivity and performance limitations of current systems based on cascading grammars. SystemT uses a declarative rule language, AQL, and an optimizer that generates high-performance algebraic execution plans for AQL rules. We compare SystemT's approach against cascading grammars, both theoretically and with a thorough experimental evaluation. Our results show that SystemT can deliver result quality comparable to the state-of-the-art and an order of magnitude higher annotation throughput.

1 Introduction

In recent years, enterprises have seen the emergence of important text analytics applications like compliance and data redaction. This increase, combined with the inclusion of text into traditional applications like Business Intelligence, has dramatically increased the use of information extraction (IE) within the enterprise. While the traditional requirement of extraction quality remains critical, enterprise applications also demand efficiency, transparency, customizability and maintainability. In recent years, these systemic requirements have led to renewed interest in rule-based IE systems (Doan et al., 2008; SAP, 2010; IBM, 2010; SAS, 2010).

Until recently, rule-based IE systems (Cunningham et al., 2000; Boguraev, 2003; Drozdzynski et al., 2004) were predominantly based on the cascading grammar formalism exemplified by the Common Pattern Specification Language (CPSL) specification (Appelt and Onyshkevych, 1998). In CPSL, the input text is viewed as a sequence of annotations, and extraction rules are written as pattern/action rules over the lexical features of these annotations. In a single phase of the grammar, a set of rules are evaluated in a left-to-right fashion over the input annotations. Multiple grammar phases are cascaded together, with the evaluation proceeding in a bottom-up fashion.

As demonstrated by prior work (Grishman and Sundheim, 1996), grammar-based IE systems can be effective in many scenarios. However, these systems suffer from two severe drawbacks. First, the expressivity of CPSL falls short when used for complex IE tasks over increasingly pervasive informal text (emails, blogs, discussion forums etc.). To address this limitation, grammar-based IE systems resort to significant amounts of user-defined code in the rules, combined with pre- and post-processing stages beyond the scope of CPSL (Cunningham et al., 2010). Second, the rigid evaluation order imposed in these systems has significant performance implications.

Three decades ago, the database community faced similar expressivity and efficiency challenges in accessing structured information. The community addressed these problems by introducing a relational algebra formalism and an associated declarative query language SQL. The groundbreaking work on System R (Chamberlin et al., 1981) demonstrated how the expressivity of SQL can be efficiently realized in practice by means of a *query optimizer* that translates an SQL query into an optimized query execution plan.

Borrowing ideas from the database community, we have developed SystemT, a declarative IE system based on an algebraic framework, to address both expressivity and performance issues. In SystemT, extraction rules are expressed in a declarative language called AQL. At compilation time,

Uppsala, Sweden, 11-16 July 2010.

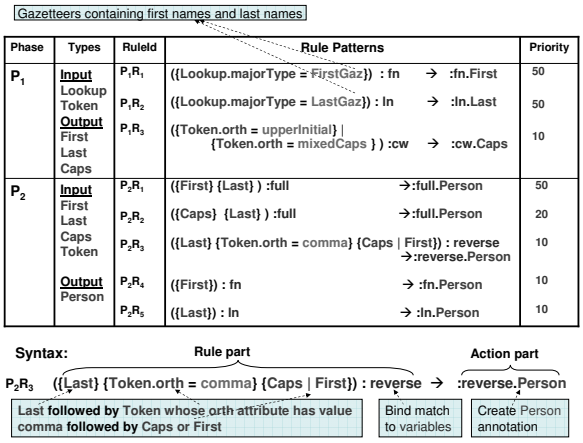

Figure 1: Cascading grammar for identifying Person names

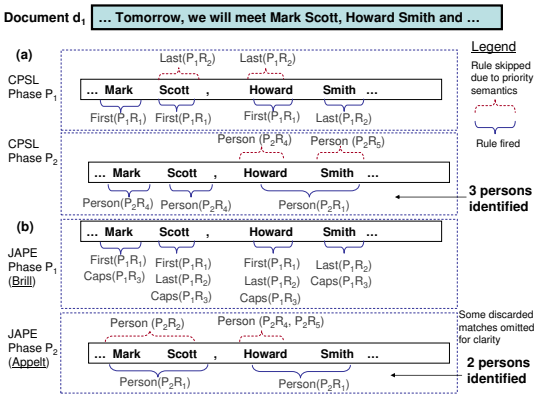

Figure 2: Sample output of CPSL and JAPE

SystemT translates AQL statements into an algebraic expression called an *operator graph* that implements the semantics of the statements. The SystemT optimizer then picks a fast execution plan from many logically equivalent plans. SystemT is currently deployed in a multitude of real-world applications and commercial products[1].

We formally demonstrate the superiority of AQL and SystemT in terms of both expressivity and efficiency (Section 4). Specifically, we show that 1) the expressivity of AQL is a strict superset of CPSL grammars not using external functions and 2) the search space explored by the SystemT optimizer includes operator graphs corresponding to efficient finite state transducer implementations. Finally, we present an extensive experimental evaluation that validates that high-quality annotators can be developed with SystemT, and that their runtime performance is an order of magnitude better when compared to annotators developed with a state-of-the-art grammar-based IE system (Section 5).

2 Grammar-based Systems and CPSL

A cascading grammar consists of a sequence of phases, each of which consists of one or more rules. Each phase applies its rules from left to right over an input sequence of annotations and generates an output sequence of annotations that the next phase consumes. Most cascading grammar systems today adhere to the CPSL standard.

Fig. 1 shows a sample CPSL grammar that identifies person names from text in two phases. The first phase, P_1, operates over the results of the tokenizer and gazetteer (input types *Token* and *Lookup*, respectively) to identify words that may be part of a person name. The second phase, P_2, identifies complete names using the results of phase P_1.

Applying the above grammar to document d_1 (Fig. 2), one would expect that to match "Mark Scott" and "Howard Smith" as *Person*. However, as shown in Fig. 2(a), the grammar actually finds three *Person* annotations, instead of two. CPSL has several limitations that lead to such discrepancies:

L1. Lossy sequencing. In a CPSL grammar, each phase operates on a sequence of annotations from left to right. If the input annotations to a phase may overlap with each other, the CPSL engine must drop some of them to create a non-overlapping sequence. For instance, in phase P_1 (Fig. 2(a)), "Scott" has both a *Lookup* and a *Token* annotation. The system has made an arbitrary choice to retain the *Lookup* annotation and discard the *Token* annotation. Consequently, no *Caps* annotations are output by phase P_1.

L2. Rigid matching priority. CPSL specifies that, for each input annotation, only one rule can actually match. When multiple rules match at the same start position, the following tie-breaker conditions are applied (in order): (a) the rule matching the most annotations in the input stream; (b) the rule with highest priority; and (c) the rule declared earlier in the grammar. This rigid matching priority can lead to mistakes. For instance, as illustrated in Fig. 2(a), phase P_1 only identifies "Scott" as a *First*. Matching priority causes the grammar to skip the corresponding match for "Scott" as a *Last*. Consequently, phase P_2 fails to identify "Mark Scott" as one single *Person*.

L3. Limited expressivity in rule patterns. It is not possible to express rules that compare annotations overlapping with each other. E.g., "Identify

[1] A trial version is available at *http://www.alphaworks.ibm.com/tech/systemt*

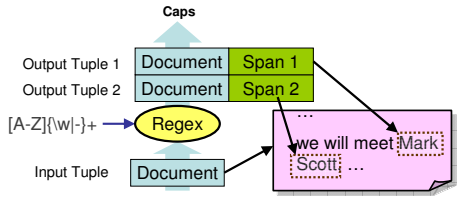

Figure 3: Regular Expression Extraction Operator

words that are both capitalized and present in the *FirstGaz* gazetteer" or "Identify *Person* annotations that occur within an *EmailAddress*".

Extensions to CPSL

In order to address the above limitations, several extensions to CPSL have been proposed in JAPE, AFst and XTDL (Cunningham et al., 2000; Boguraev, 2003; Drozdzynski et al., 2004). The extensions are summarized as below, where each solution S_i corresponds to limitation L_i.

- **S1**. Grammar rules are allowed to operate on graphs of input annotations in JAPE and AFst.
- **S2**. JAPE introduces more matching regimes besides the CPSL's matching priority and thus allows more flexibility when multiple rules match at the same starting position.
- **S3**. The rule part of a pattern has been expanded to allow more expressivity in JAPE, AFst and XTDL.

Fig. 2(b) illustrates how the above extensions help in identifying the correct matches '*Mark Scott*' and '*Howard Smith*' in JAPE. Phase P_1 uses a matching regime (denoted by *Brill*) that allows multiple rules to match at the same starting position, and phase P_2 uses CPSL's matching priority, *Appelt*.

3 SystemT

SystemT is a declarative IE system based on an algebraic framework. In SystemT, developers write rules in a language called AQL. The system then generates a graph of *operators* that implement the semantics of the AQL rules. This decoupling allows for greater rule expressivity, because the rule language is not constrained by the need to compile to a finite state transducer. Likewise, the decoupled approach leads to greater flexibility in choosing an efficient execution strategy, because many possible operator graphs may exist for the same AQL annotator.

In the rest of the section, we describe the parts of SystemT, starting with the algebraic formalism behind SystemT's operators.

3.1 Algebraic Foundation of SystemT

SystemT executes IE rules using graphs of operators. The formal definition of these operators takes the form of an algebra that is similar to the relational algebra, but with extensions for text processing.

The algebra operates over a simple relational data model with three data types: span, tuple, and relation. In this data model, a *span* is a region of text within a document identified by its "begin" and "end" positions; a *tuple* is a fixed-size list of spans. A *relation* is a multiset of tuples, where every tuple in the relation must be of the same size. Each *operator* in our algebra implements a single basic atomic IE operation, producing and consuming sets of tuples.

Fig. 3 illustrates the regular expression extraction operator in the algebra, which performs character-level regular expression matching. Overall, the algebra contains 12 different operators, a full description of which can be found in (Reiss et al., 2008). The following four operators are necessary to understand the examples in this paper:

- The **Extract** operator ($\mathcal{E}$) performs character-level operations such as regular expression and dictionary matching over text, creating a tuple for each match.
- The **Select** operator (σ) takes as input a set of tuples and a predicate to apply to the tuples. It outputs all tuples that satisfy the predicate.
- The **Join** operator ($\bowtie$) takes as input two sets of tuples and a predicate to apply to pairs of tuples from the input sets. It outputs all pairs of input tuples that satisfy the predicate.
- The **consolidate** operator (Ω) takes as input a set of tuples and the index of a particular column in those tuples. It removes selected overlapping spans from the indicated column, according to the specified policy.

3.2 AQL

Extraction rules in SystemT are written in AQL, a declarative relational language similar in syntax to the database language SQL. We chose SQL as a basis for our language due to its expressivity and its familiarity. The expressivity of SQL, which consists of first-order logic predicates

```
create view Caps as
extract regex /[A-Z](\w|-)+/ on D.text as name from Document D;

create view Last as
extract dictionary LastGaz on D.text as name from Document D;

create view CapsLast as
select  CombineSpans(C.name, L.name) as name
from    Caps C, Last L
where   FollowsTok(C.name, L.name, 0, 0);
...
create view PersonAll as
    (select R.name from FirstLast R) union all ...
                    ... union all (select R.name from CapsLast R);

create view Person as select * from PersonAll R
consolidate on R.name using 'ContainedWithin';

output view Person;
```

Figure 4: *Person* annotator as AQL query

over sets of tuples, is well-documented and well-understood (Codd, 1990). As SQL is the primary interface to most relational database systems, the language's syntax and semantics are common knowledge among enterprise application programmers. Similar to SQL terminology, we call a collection of AQL rules an AQL *query*.

Fig. 4 shows portions of an AQL query. As can be seen, the basic building block of AQL is a *view*: A logical description of a set of tuples in terms of either the document text (denoted by a special view called `Document`) or the contents of other views. Every SystemT annotator consists of at least one view. The *output view* statement indicates that the tuples in a view are part of the final results of the annotator.

Fig. 4 also illustrates three of the basic constructs that can be used to define a view.

- The **`extract`** statement specifies basic character-level extraction primitives to be applied directly to a tuple.
- The **`select`** statement is similar to the SQL `select` statement but it contains an additional `consolidate on` clause, along with an extensive collection of text-specific predicates.
- The **`union all`** statement merges the outputs of one or more `select` or `extract` statements.

To keep rules compact, AQL also provides a shorthand *sequence pattern* notation similar to the syntax of CPSL. For example, the `CapsLast` view in Figure 4 could have been written as:

```
create view CapsLast as
extract pattern <C.name> <L.name>
from Caps C, Last L;
```

Internally, SystemT translates each of these *extract pattern* statements into one or more *select* and *extract* statements.

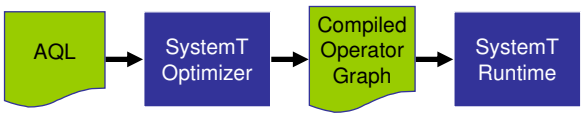

Figure 5: The compilation process in SystemT

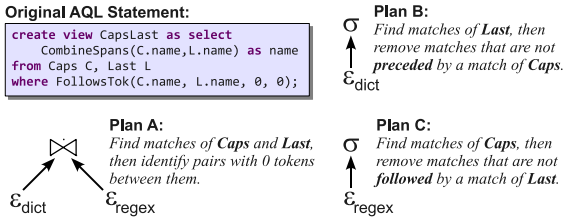

Figure 6: Execution strategies for the *CapsLast* rule in Fig. 4

SystemT has built-in multilingual support including tokenization, part of speech and gazetteer matching for over 20 languages using LanguageWare (IBM, 2010). Rule developers can utilize the multilingual support via AQL without having to configure or manage any additional resources. In addition, AQL allows user-defined functions to be used in a restricted context in order to support operations such as validation (e.g. for extracted credit card numbers), or normalization (e.g., compute abbreviations of multi-token organization candidates that are useful in generating additional candidates). More details on AQL can be found in the AQL manual (SystemT, 2010).

3.3 Optimizer and Operator Graph

Grammar-based IE engines place rigid restrictions on the order in which rules can be executed. Due to the semantics of the CPSL standard, systems that implement the standard must use a finite state transducer that evaluates each level of the cascade with one or more left to right passes over the entire token stream.

In contrast, SystemT places no explicit constraints on the order of rule evaluation, nor does it require that intermediate results of an annotator collapse to a fixed-size sequence. As shown in Fig. 5, the SystemT engine does not execute AQL directly; instead, the SystemT *optimizer* compiles AQL into a graph of operators. By tying a collection of operators together by their inputs and outputs, the system can implement a wide variety of different execution strategies. Different execution strategies are associated with different evaluation costs. The optimizer chooses the execution strategy with the lowest estimated evaluation cost.

Fig. 6 presents three possible execution strategies for the *CapsLast* rule in Fig. 4. If the optimizer estimates that the evaluation cost of *Last* is much lower than that of *Caps*, then it can determine that Plan C has the lowest evaluation cost among the three, because Plan C only evaluates *Caps* in the "left" neighborhood for each instance of *Last*. More details of our algorithms for enumerating plans can be found in (Reiss et al., 2008).

The optimizer in SystemT chooses the best execution plan from a large number of different algebra graphs available to it. Many of these graphs implement strategies that a transducer could not express: such as evaluating rules from right to left, sharing work across different rules, or selectively skipping rule evaluations. Within this large search space, there generally exists an execution strategy that implements the rule semantics far more efficiently than the fastest transducer could. We refer the reader to (Reiss et al., 2008) for a detailed description of the types of plan the optimizer considers, as well as an experimental analysis of the performance benefits of different parts of this search space.

Several parallel efforts have been made recently to improve the efficiency of IE tasks by optimizing low-level feature extraction (Ramakrishnan et al., 2006; Ramakrishnan et al., 2008; Chandel et al., 2006) or by reordering operations at a macroscopic level (Ipeirotis et al., 2006; Shen et al., 2007; Jain et al., 2009). However, to the best of our knowledge, SystemT is the only IE system in which the optimizer generates a full end-to-end plan, beginning with low-level extraction primitives and ending with the final output tuples.

3.4 Deployment Scenarios

SystemT is designed to be usable in various deployment scenarios. It can be used as a standalone system with its own development and runtime environment. Furthermore, SystemT exposes a generic Java API that enables the integration of its runtime environment with other applications. For example, a specific instantiation of this API allows SystemT annotators to be seamlessly embedded in applications using the UIMA analytics framework (UIMA, 2010).

4 Grammar vs. Algebra

Having described both the traditional cascading grammar approach and the declarative approach

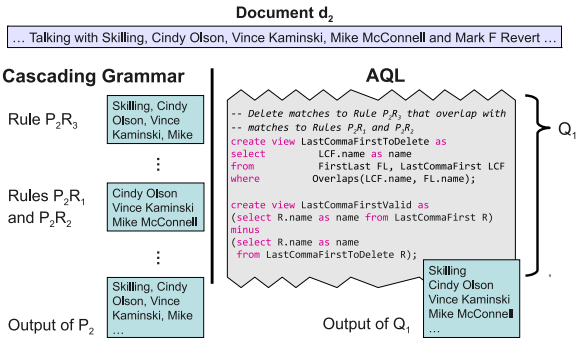

Figure 7: Supporting Complex Rule Interactions

used in SystemT, we now compare the two in terms of expressivity and performance.

4.1 Expressivity

In Section 2, we described three expressivity limitations of CPSL grammars: Lossy sequencing, rigid matching priority, and limited expressivity in rule patterns. As we noted, cascading grammar systems extend the CPSL specification in various ways to provide workarounds for these limitations.

In SystemT, the basic design of the AQL language eliminates these three problems without the need for any special workaround. The key design difference is that AQL views operate over sets of tuples, not sequences of tokens. The input or output tuples of a view can contain spans that overlap in arbitrary ways, so the lossy sequencing problem never occurs. The annotator will retain these overlapping spans across any number of views until a view definition explicitly removes the overlap. Likewise, the tuples that a given view produces are in no way constrained by the outputs of other, unrelated views, so the rigid matching priority problem never occurs. Finally, the *select* statement in AQL allows arbitrary predicates over the cross-product of its input tuple sets, eliminating the limited expressivity in rule patterns problem.

Beyond eliminating the major limitations of CPSL grammars, AQL provides a number of other information extraction operations that even extended CPSL cannot express without custom code.

Complex rule interactions. Consider an example document from the Enron corpus (Minkov et al., 2005), shown in Fig. 7, which contains a list of person names. Because the first person in the list ('*Skilling*') is referred to by only a last name, rule P_2R_3 in Fig. 1 incorrectly identifies '*Skilling, Cindy*' as a person. Consequently, the output of phase P_2 of the cascading grammar contains several mistakes as shown in the figure. This problem

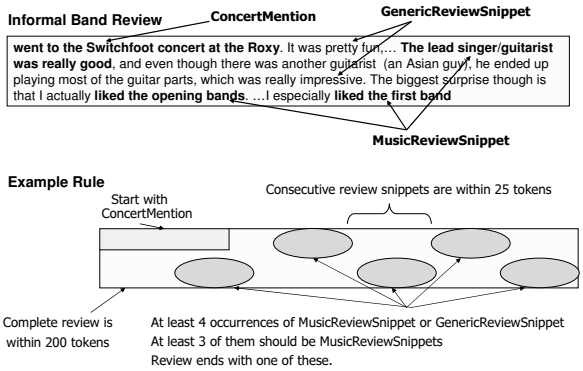

Figure 8: Extracting informal band reviews from web logs

occurs because CPSL only evaluates rules over the input sequence in a strict left-to-right fashion. On the other hand, the AQL query Q_1 shown in the figure applies the following condition: "Always discard matches to Rule P_2R_3 if they overlap with matches to rules P_2R_1 or P_2R_2" (even if the match to Rule P_2R_3 starts earlier). Applying this rule ensures that the person names in the list are identified correctly. Obtaining the same effect in grammar-based systems would require the use of custom code (as recommended by (Cunningham et al., 2010)).

Counting and Aggregation. Complex extraction tasks sometimes require operations such as counting and aggregation that go beyond the expressivity of regular languages, and thus can be expressed in CPSL only using external functions. One such task is that of identifying informal concert reviews embedded within blog entries. Fig. 8 describes, by example, how these reviews consist of reference to a live concert followed by several review snippets, some specific to musical performances and others that are more general review expressions. An example rule to identify informal reviews is also shown in the figure. Notice how implementing this rule requires *c*ounting the number of *MusicReviewSnippet* and *GenericReviewSnippet* annotations within a region of text and *a*ggregating this occurrence count across the two review types. While this rule can be written in AQL, it can only be approximated in CPSL grammars.

Character-Level Regular Expression CPSL cannot specify character-level regular expressions that span multiple tokens. In contrast, the *extract regex* statement in AQL fully supports these expressions.

We have described above several cases where AQL can express concepts that can only be expressed through external functions in a cascading grammar. These examples naturally raise the question of whether similar cases exist where a cascading grammar can express patterns that cannot be expressed in AQL.

It turns out that we can make a strong statement that such examples do not exist. In the absence of an escape to arbitrary procedural code, AQL is strictly more expressive than a CPSL grammar. To state this relationship formally, we first introduce the following definitions.

We refer to a grammar conforming to the CPSL specification as a *CPSL grammar*. When a CPSL grammar contains no external functions, we refer to it as a *Code-free CPSL grammar*. Finally, we refer to a grammar that conforms to one of the CPSL, JAPE, AFst and XTDL specifications as an *expanded CPSL grammar*.

Ambiguous Grammar Specification An *expanded CPSL grammar* may be under-specified in some cases. For example, a single rule containing the disjunction operator (|) may match a given region of text in multiple ways. Consider the evaluation of Rule P_2R_3 over the text fragment "Scott, Howard" from document d_1 (Fig. 1). If "Howard" is identified both as *Caps* and *First*, then there are two evaluations for Rule P_2R_3 over this text fragment. Since the system has to arbitrarily choose one evaluation, the results of the grammar can be non-deterministic (as pointed out in (Cunningham et al., 2010)). We refer to a grammar G as an *ambiguous grammar specification* for a document collection $\mathcal{D}$ if the system makes an arbitrary choice while evaluating G over $\mathcal{D}$.

Definition 1 (*UnambigEquiv*) *A query Q is UnambigEquiv to a cascading grammar $\mathcal{G}$ if and only if for every document collection $\mathcal{D}$, where G is not an ambiguous grammar specification for $\mathcal{D}$, the results of the grammar invocation and the query evaluation are identical.*

We now formally compare the expressivity of AQL and expanded CPSL grammars. The detailed proof is omitted due to space limitations.

Theorem 1 *The class of extraction tasks expressible as AQL queries is a strict superset of that expressible through expanded code-free CPSL grammars. Specifically,*
(a) Every expanded code-free CPSL grammar can be expressed as an UnambigEquiv AQL query.
(b) AQL supports information extraction operations that cannot be expressed in expanded code-free CPSL grammars.

Proof Outline: *(a)* A single CPSL grammar can be expressed in AQL as follows. First, each rule r in the grammar is translated into a set of AQL statements. If r does not contain the disjunct (|) operator, then it is translated into a single AQL *select* statement. Otherwise, a set of AQL statements are generated, one for each disjunct operator in rule r, and the results merged using *union all* statements. Then, a *union all* statement is used to combine the results of individual rules in the grammar phase. Finally, the AQL statements for multiple phases are combined in the same order as the cascading grammar specification.

The main extensions to CPSL supported by expanded CPSL grammars (listed in Sec. 2) are handled as follows. AQL queries operate on graphs on annotations just like expanded CPSL grammars. In addition, AQL supports different matching regimes through consolidation operators, span predicates through selection predicates and coreferences through join operators.
(b) Example operations supported in AQL that cannot be expressed in expanded code-free CPSL grammars include (i) character-level regular expressions spanning multiple tokens, (ii) counting the number of annotations occurring within a given bounded window and (iii) deleting annotations if they overlap with other annotations starting later in the document. □

4.2 Performance

For the annotators we test in our experiments (See Section 5), the SystemT optimizer is able to choose algebraic plans that are faster than a comparable transducer-based implementation. The question arises as to whether there are other annotators for which the traditional transducer approach is superior. That is, for a given annotator, might there exist a finite state transducer that is combinatorially faster than any possible algebra graph? It turns out that this scenario is not possible, as the theorem below shows.

Definition 2 (Token-Based FST) *A* token-based finite state transducer *(FST) is a nondeterministic finite state machine in which state transitions are triggered by predicates on tokens. A token-based FST is* acyclic *if its state graph does not contain any cycles and has exactly one "accept" state.*

Definition 3 (Thompson's Algorithm) Thompson's algorithm *is a common strategy for evaluating a token-based FST (based on (Thompson, 1968)). This algorithm processes the input tokens from left to right, keeping track of the set of states that are currently active.*

Theorem 2 *For any acyclic token-based finite state transducer T, there exists an UnambigEquiv operator graph G, such that evaluating G has the same computational complexity as evaluating T with Thompson's algorithm starting from each token position in the input document.*

Proof Outline: The proof constructs G by structural induction over the transducer T. The base case converts transitions out of the start state into *Extract* operators. The inductive case adds a *Select* operator to G for each of the remaining state transitions, with each selection predicate being the same as the predicate that drives the corresponding state transition. For each state transition predicate that T would evaluate when processing a given document, G performs a constant amount of work on a single tuple. □

5 Experimental Evaluation

In this section we present an extensive comparison study between SystemT and implementations of expanded CPSL grammar in terms of quality, runtime performance and resource requirements.
Tasks We chose two tasks for our evaluation:

- NER : named-entity recognition for Person, Organization, Location, Address, PhoneNumber, EmailAddress, URL and DateTime.
- BandReview : identify informal reviews in blogs (Fig. 8).

We chose NER primarily because named-entity recognition is a well-studied problem and standard datasets are available for evaluation. For this task we use GATE and ANNIE for comparison[3]. We chose BandReview to conduct performance evaluation for a more complex extraction task.
Datasets. For quality evaluation, we use:

- *EnronMeetings* (Minkov et al., 2005): collection of emails with meeting information from the Enron corpus[4] with Person labeled data;
- *ACE* (NIST, 2005): collection of newswire reports and broadcast news/conversations with Person, Organization, Location labeled data[5].

[3]To the best of our knowledge, ANNIE (Cunningham et al., 2002) is the only publicly available NER library implemented in a grammar-based system (JAPE in GATE).
[4]http://www.cs.cmu.edu/ enron/
[5]Only entities of type NAM have been considered.

Table 1: Datasets for performance evaluation.

Dataset	*Description of the Content*	*Number of documents*	*Document size*	
			range	*average*
$Enron_x$	Emails randomly sampled from the Enron corpus of average size xKB $(0.5 < x < 100)$[2]	1000	xKB $+/-$ 10%	xKB
WebCrawl	Small to medium size web pages representing company news, with HTML tags removed	1931	68b - 388.6KB	8.8KB
$Finance_M$	Medium size financial regulatory filings	100	240KB - 0.9MB	401KB
$Finance_L$	Large size financial regulatory filings	30	1MB - 3.4MB	1.54MB

Table 2: Quality of Person on test datasets.

	Precision (%) (Exact/Partial)	*Recall (%) (Exact/Partial)*	*F1 measure (%) (Exact/Partial)*
EnronMeetings			
ANNIE	57.05/76.84	48.59/65.46	52.48/70.69
T-NE	**88.41/92.99**	**82.39/86.65**	**85.29/89.71**
Minkov	81.1/NA	74.9/NA	77.9/NA
ACE			
ANNIE	39.41/78.15	30.39/60.27	34.32/68.06
T-NE	**93.90/95.82**	**90.90/92.76**	**92.38/94.27**

Table 1 lists the datasets used for performance evaluation. The size of $Finance_L$ is purposely small because GATE takes a significant amount of time processing large documents (see Sec. 5.2).

Set Up. The experiments were run on a server with two 2.4 GHz 4-core Intel Xeon CPUs and 64GB of memory. We use GATE 5.1 (build 3431) and two configurations for ANNIE: 1) the *default* configuration, and 2) an *optimized* configuration where the Ontotext Japec Transducer[6] replaces the default NE transducer for optimized performance. We refer to these configurations as ANNIE and ANNIE-Optimized, respectively.

5.1 Quality Evaluation

The goal of our quality evaluation is two-fold: to validate that annotators can be built in SystemT with quality comparable to those built in a grammar-based system; and to ensure a fair performance comparison between SystemT and GATE by verifying that the annotators used in the study are comparable.

Table 2 shows results of our comparison study for Person annotators. We report the classical (*exact*) precision, recall, and $F1$ measures that credit only exact matches, and corresponding *partial* measures that credit partial matches in a fashion similar to (NIST, 2005). As can be seen, T-NE produced results of significantly higher quality than ANNIE on both datasets, for the same Person extraction task. In fact, on *EnronMeetings*, the $F1$ measure of T-NE is 7.4% higher than the best published result (Minkov et al., 2005). Similar results

[6] http://www.ontotext.com/gate/japec.html

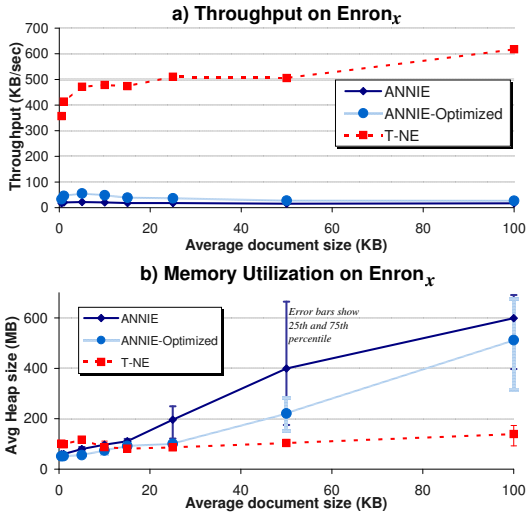

Figure 9: Throughput (a) and memory consumption (b) comparisons on $Enron_x$ datasets.

can be observed for Organization and Location on *ACE* (exact numbers omitted in interest of space).

Clearly, considering the large gap between ANNIE's $F1$ and partial $F1$ measures on both datasets, ANNIE's quality can be improved via dataset-specific tuning as demonstrated in (Maynard et al., 2003). However, dataset-specific tuning for ANNIE is beyond the scope of this paper. Based on the experimental results above and our previous formal comparison in Sec. 4, we believe it is reasonable to conclude that annotators can be built in SystemT of quality at least comparable to those built in a grammar-based system.

5.2 Performance Evaluation

We now focus our attention on the throughput and memory behavior of SystemT, and draw a comparison with GATE. For this purpose, we have configured both ANNIE and T-NE to identify only the same eight types of entities listed for NER task.

Throughput. Fig. 9(a) plots the throughput of the two systems on multiple $Enron_x$ datasets with average document sizes of between 0.5KB and 100KB. For this experiment, both systems ran with a maximum Java heap size of 1GB.

Table 3: Throughput and mean heap size.

Dataset	ANNIE		ANNIE-Optimized		T-NE	
	Throughput (KB/s)	*Memory (MB)*	*Throughput (KB/s)*	*Memory (MB)*	*Throughput (KB/s)*	*Memory (MB)*
WebCrawl	23.9	212.6	42.8	201.8	**498.9**	**77.2**
$Finance_M$	18.82	715.1	26.3	601.8	**703.5**	**143.7**
$Finance_L$	19.2	2586.2	21.1	2683.5	**954.5**	**189.6**

As shown in Fig. 9(a), even though the throughput of ANNIE-Optimized (using the optimized transducer) increases two-fold compared to ANNIE under default configuration, T-NE is between 8 and 24 times faster compared to ANNIE-Optimized. For both systems, throughput varied with document size. For T-NE, the relatively low throughput on very small document sizes (less than 1KB) is due to fixed overhead in setting up operators to process a document. As document size increases, the overhead becomes less noticeable.

We have observed similar trends on the rest of the test collections. Table 3 shows that T-NE is at least an order of magnitude faster than ANNIE-Optimized across all datasets. In particular, on $Finance_L$ T-NE's throughput remains high, whereas the performance of both ANNIE and ANNIE-Optimized degraded significantly.

To ascertain whether the difference in performance in the two systems is due to low-level components such as dictionary evaluation, we performed detailed profiling of the systems. The profiling revealed that 8.2%, 16.2% and respectively 14.2% of the execution time was spent on average on low-level components in the case of ANNIE, ANNIE-Optimized and T-NE, respectively, thus leading us to conclude that the observed differences are due to SystemT's efficient use of resources at a macroscopic level.

Memory utilization. In theory, grammar based systems can stream tuples through each stage for minimal memory consumption, whereas SystemT operator graphs may need to materialize intermediate results for the full document at certain points to evaluate the constraints in the original AQL. The goal of this study is to evaluate whether this potential problem does occur in practice.

In this experiment we ran both systems with a maximum heap size of 2GB, and used the Java garbage collector's built-in telemetry to measure the total quantity of live objects in the heap over time while annotating the different test corpora. Fig. 9(b) plots the minimum, maximum, and mean heap sizes with the $Enron_x$ datasets. On small documents of size up to 15KB, memory consumption is dominated by the fixed size of the data structures used (e.g., dictionaries, FST/operator graph), and is comparable for both systems. As documents get larger, memory consumption increases for both systems. However, the increase is much smaller for T-NE compared to that for both ANNIE and ANNIE-Optimized. A similar trend can be observed on the other datasets as shown in Table 3. In particular, for $Finance_L$, both ANNIE and ANNIE-Optimized required 8GB of Java heap size to achieve reasonable throughput[7], in contrast to T-NE which utilized at most 300MB out of the 2GB of maximum Java heap size allocation.

SystemT requires much less memory than GATE in general due to its runtime, which monitors data dependencies between operators and clears out low-level results when they are no longer needed. Although a streaming CPSL implementation is theoretically possible, in practice mechanisms that allow an escape to custom code make it difficult to decide when an intermediate result will no longer be used, hence GATE keeps most intermediate data in memory until it is done analyzing the current document.

The BandReview Task. We conclude by briefly discussing our experience with the BandReview task from Fig. 8. We built two versions of this annotator, one in AQL, and the other using expanded CPSL grammar. The grammar implementation processed a 4.5GB collection of 1.05 million blogs in 5.6 hours and output 280 reviews. In contrast, the SystemT version (85 AQL statements) extracted 323 reviews in only 10 minutes!

6 Conclusion

In this paper, we described SystemT, a declarative IE system based on an algebraic framework. We presented both formal and empirical arguments for the benefits of our approach to IE. Our extensive experimental results show that high-quality annotators can be built using SystemT, with an order of magnitude throughput improvement compared to state-of-the-art grammar-based systems. Going forward, SystemT opens up several new areas of research, including implementing better optimization strategies and augmenting the algebra with additional operators to support advanced features such as coreference resolution.

Abstract

We present a method for extracting social networks from literature, namely, nineteenth-century British novels and serials. We derive the networks from dialogue interactions, and thus our method depends on the ability to determine when two characters are in conversation. Our approach involves character name chunking, quoted speech attribution and conversation detection given the set of quotes. We extract features from the social networks and examine their correlation with one another, as well as with metadata such as the novel's setting. Our results provide evidence that the majority of novels in this time period do not fit two characterizations provided by literacy scholars. Instead, our results suggest an alternative explanation for differences in social networks.

1 Introduction

Literary studies about the nineteenth-century British novel are often concerned with the nature of the community that surrounds the protagonist. Some theorists have suggested a relationship between the size of a community and the amount of dialogue that occurs, positing that "face to face time" diminishes as the number of characters in the novel grows. Others suggest that as the social setting becomes more urbanized, the quality of dialogue also changes, with more interactions occurring in rural communities than urban communities. Such claims have typically been made, however, on the basis of a few novels that are studied in depth. In this paper, we aim to determine whether an automated study of a much larger sample of nineteenth century novels supports these claims.

The research presented here is concerned with the extraction of social networks from literature. We present a method to automatically construct a network based on dialogue interactions between characters in a novel. Our approach includes components for finding instances of quoted speech, attributing each quote to a character, and identifying when certain characters are in conversation. We then construct a network where characters are vertices and edges signify an amount of bilateral conversation between those characters, with edge weights corresponding to the frequency and length of their exchanges. In contrast to previous approaches to social network construction, ours relies on a novel combination of pattern-based detection, statistical methods, and adaptation of standard natural language tools for the literary genre. We carried out this work on a corpus of 60 nineteenth-century novels and serials, including 31 authors such as Dickens, Austen and Conan Doyle.

In order to evaluate the literary claims in question, we compute various characteristics of the dialogue-based social network and stratify these results by categories such as the novel's setting. For example, the density of the network provides evidence about the cohesion of a large or small community, and cliques may indicate a social fragmentation. Our results surprisingly provide evidence that the majority of novels in this time period do not fit the suggestions provided by literary scholars, and we suggest an alternative explanation for our observations of differences across novels.

In the following sections, we survey related work on social networks as well as computational studies of literature. We then present the literary hypotheses in more detail. We describe the methods we use to extract dialogue and construct conversational networks, along with our approach to analyzing their characteristics. After we present the statistical results, we analyze their significance from a literary perspective.

2 Related Work

Computer-assisted literary analysis has typically occurred at the word level. This level of granularity lends itself to studies of authorial style based on patterns of word use (Burrows, 2004), and researchers have successfully "outed" the writers of anonymous texts by comparing their style to that of a corpus of known authors (Mostellar and Wallace, 1984). Determining instances of "text reuse," a type of paraphrasing, is also a form of analysis at the lexical level, and it has recently been used to validate theories about the lineage of ancient texts (Lee, 2007).

Analysis of literature using more semantically-oriented techniques has been rare, most likely because of the difficulty in automatically determining meaningful interpretations. Some exceptions include recent work on learning common event sequences in news stories (Chambers and Jurafsky, 2008), an approach based on statistical methods, and the development of an event calculus for characterizing stories written by children (Halpin et al., 2004), a knowledge-based strategy. On the other hand, literary theorists, linguists and others have long developed symbolic but non-computational models for novels. For example, Moretti (2005) has graphically mapped out texts according to geography, social connections and other variables.

While researchers have not attempted the automatic construction of social networks representing connections between characters in a corpus of novels, the ACE program has involved entity and relation extraction in unstructured text (Doddington et al., 2004). Other recent work in social network construction has explored the use of structured data such as email headers (McCallum et al., 2007) and U.S. Senate bill cosponsorship (Cho and Fowler, 2010). In an analysis of discussion forums, Gruzd and Haythornthwaite (2008) explored the use of message text as well as posting data to infer who is talking to whom. In this paper, we also explore how to build a network based on conversational interaction, but we analyze the reported dialogue found in novels to determine the links. The kinds of language that is used to signal such information is quite different in the two media. In discussion forums, people tend to use addresses such as "Hi Tom," while in novels, a system must determine both the speaker of a quotation and then the intended recipient of the dialogue act. This is a significantly different problem.

3 Hypotheses

It is commonly held that the novel is a literary form which tries to produce an accurate representation of the social world. Within literary studies, the recurring problem is how that representation is achieved. Theories about the relation between novelistic form (the workings of plot, characters, and dialogue, to take the most basic categories) and changes to real-world social milieux abound. Many of these theories center on nineteenth-century European fiction; innovations in novelistic form during this period, as well as the rapid social changes brought about by revolution, industrialization, and transport development, have traditionally been linked. These theories, however, have used only a select few representative novels as proof. By using statistical methods of analysis, it is possible to move beyond this small corpus of proof texts. We believe these methods are essential to testing the validity of some core theories about social interaction and their representation in literary genres like the novel.

Major versions of the theories about the social worlds of nineteenth-century fiction tend to center on characters, in two specific ways: how many characters novels tend to have, and how those characters interact with one another. These two "formal" facts about novels are usually explained with reference to a novel's setting. From the influential work of the Russian critic Mikhail Bakhtin to the present, a consensus emerged that as novels are increasingly set in urban areas, the number of characters and the quality of their interaction change to suit the setting. Bakhtin's term for this causal relationship was *chronotope*: the "intrinsic interconnectedness of temporal and spatial relationships that are artistically expressed in literature," in which "space becomes charged and responsive to movements of time, plot, and history" (Bakhtin, 1981, 84). In Bakhtin's analysis, different spaces have different social and emotional potentialities, which in turn affect the most basic aspects of a novel's aesthetic technique.

After Bakhtin's invention of the chronotope, much literary criticism and theory devoted itself to filling in, or describing, the qualities of specific chronotopes, particularly those of the village or rural environment and the city or urban environment. Following a suggestion of Bakhtin's that the population of village or rural fictions is modeled on the world of the family, made up of

Table 1: Properties of the nineteenth-century British novels and serials included in our study.

an intimately related set of characters, many critics analyzed the formal expression of this world as constituted by a small set of characters who express themselves conversationally. Raymond Williams used the term "knowable communities" to describe this world, in which face-to-face relations of a restricted set of characters are the primary mode of social interaction (Williams, 1975, 166).

By contrast, the urban world, in this traditional account, is both larger and more complex. To describe the social-psychological impact of the city, Franco Moretti argues, protagonists of urban novels "change overnight from 'sons' into 'young men': their affective ties are no longer vertical ones (between successive generations), but horizontal, within the same generation. They are drawn towards those unknown yet congenial faces seen in gardens, or at the theater; future friends, or rivals, or both" (Moretti, 1999, 65). The result is two-fold: more characters, indeed a mass of characters, and more interactions, although less actual conversation; as literary critic Terry Eagleton argues, the city is where "most of our encounters consist of seeing rather than speaking, glimpsing each other as objects rather than conversing as fellow subjects" (Eagleton, 2005, 145). Moretti argues in similar terms. For him, the difference in number of characters is "not just a matter of quantity... it's a qualitative, morphological one" (Moretti, 1999, 68). As the number of characters increases, Moretti argues (following Bakhtin in his logic), social interactions of different kinds and durations multiply, displacing the family-centered and conversational logic of village or rural fictions. "The narrative system becomes complicated, unstable: the city turns into a gigantic roulette table, where helpers and antagonists mix in unpredictable combinations" (Moretti, 1999, 68). This argument about how novelistic setting produces different forms of social interaction is precisely what our method seeks to evaluate.

Our corpus of 60 novels was selected for its representativeness, particularly in the following categories: authorial (novels from the major canoni-

cal authors of the period), historical (novels from each decade), generic (from the major sub-genres of nineteenth-century fiction), sociological (set in rural, urban, and mixed locales), and technical (narrated in first-person and third-person form). The novels, as well as important metadata we assigned to them (the perspective and setting), are shown in Table 1. We define *urban* to mean set in a metropolitan zone, characterized by multiple forms of labor (not just agricultural). Here, social relations are largely financial or commercial in character. We conversely define *rural* to describe texts that are set in a country or village zone, where agriculture is the primary activity, and where land-owning, non-productive, rent-collecting gentry are socially predominant. Social relations here are still modeled on feudalism (relations of peasant-lord loyalty and family tie) rather than the commercial cash nexus. We also explored other properties of the texts, such as literary genre, but focus on the results found with setting and perspective. We obtained electronic encodings of the texts from Project Gutenberg. All told, these texts total more than 10 million words.

We assembled this representative corpus in order to test two hypotheses, which are derived from the aforementioned theories:

1. That there is an inverse correlation between the amount of dialogue in a novel and the number of characters in that novel. One basic, shared assumption of these theorists is that as the network of characters expands– as, in Moretti's words, a quantitative change becomes qualitative– the importance, and in fact amount, of dialogue decreases. With a method for extracting conversation from a large corpus of texts, it is possible to test this hypothesis against a wide range of data.

2. That a significant difference in the nineteenth-century novel's representation of social interaction is geographical: novels set in urban environments depict a complex but loose social network, in which numerous characters share little conversational interaction, while novels set in rural environments inhabit more tightly bound social networks, with fewer characters sharing much more conversational interaction. This hypothesis is based on the contrast between Williams's rural "knowable communities" and the sprawling, populous, less conversational urban fictions or Moretti's and Eagleton's analyses. If true, it would suggest that the inverse relationship of hypothesis #1 (more characters means less conversation) can be correlated to, and perhaps even caused by, the geography of a novel's setting. The claims about novelistic geography and social interaction have usually been based on comparisons of a selected few novelists (Jane Austen and Charles Dickens preeminently). Do they remain valid when tested against a larger corpus?

4 Extracting Conversational Networks from Literature

In order to test these hypotheses, we developed a novel approach to extracting social networks from literary texts themselves, building on existing analysis tools. We defined "social network" as "conversational network" for purposes of evaluating these literary theories. In a conversational network, vertices represent characters (assumed to be named entities) and edges indicate at least one instance of dialogue interaction between two characters over the course of the novel. The weight of each edge is proportional to the amount of interaction. We define a conversation as a continuous span of narrative time featuring a set of characters in which the following conditions are met:

1. The characters are in the same place at the same time;

2. The characters take turns speaking; and

3. The characters are mutually aware of each other and each character's speech is mutually intended for the other to hear.

In the following subsections, we discuss the methods we devised for the three problems in text processing invoked by this approach: identifying the characters present in a literary text, assigning a "speaker" (if any) to each instance of quoted speech from among those characters, and constructing a social network by detecting conversations from the set of dialogue acts.

4.1 Character Identification

The first challenge was to identify the candidate speakers by "chunking" names (such as *Mr. Holmes*) from the text. We processed each novel

with the Stanford NER tagger (Finkel et al., 2005) and extracted noun phrases that were categorized as persons or organizations. We then clustered the noun phrases into coreferents for the same entity (person or organization). The clustering process is as follows:

1. For each named entity, we generate variations on the name that we would expect to see in a coreferent. Each variation omits certain parts of multi-word names, respecting titles and first/last name distinctions, similar to work by Davis et al. (2003). For example, *Mr. Sherlock Holmes* may refer to the same character as *Mr. Holmes*, *Sherlock Holmes*, *Sherlock* and *Holmes*.

2. For each named entity, we compile a list of other named entities that may be coreferents, either because they are identical or because one is an expected variation on the other.

3. We then match each named entity to the most recent of its possible coreferents. In aggregate, this creates a cluster of mentions for each character.

We also pre-processed the texts to normalize formatting, detect headings and chapter breaks, remove metadata, and identify likely instances of quoted speech (that is, mark up spans of text that fall between quotation marks, assumed to be a superset of the quoted speech present in the text).

4.2 Quoted Speech Attribution

In order to programmatically assign a speaker to each instance of quoted speech, we applied a high-precision subset of a general approach we describe elsewhere (Elson and McKeown, 2010). The first step of this approach was to compile a separate training and testing corpus of literary texts from British, American and Russian authors of the nineteenth and twentieth centuries. The training corpus consisted of about 111,000 words including 3,176 instances of quoted speech. To obtain gold-standard annotations, we conducted an online survey via Amazon's Mechanical Turk program. For each quote, we asked three annotators to independently choose a speaker from the list of contextual candidates– or, choose "spoken by an unlisted character" if the answer was not available, or "not spoken by any character" for non-dialogue cases such as sneer quotes.

We divided this corpus into training and testing sets, and used the training set to develop a categorizer that assigned one of five syntactic categories to each quote. For example, if a quote is followed by a verb that indicates verbal expression (such as "said"), and then a character mention, a category called *Character trigram* is assigned to the quote. The fifth category is a catch-all for quotes that do not fall into the other four. In many cases, the answer can be reliably determined based solely on its syntactic category. For instance, in the *Character trigram* category, the mentioned character is the quote's speaker in 99% of both the training and testing sets.

In all, we were able to determine the speaker of 57% of the testing set with 96% accuracy just on the basis of syntactic categorization. This is the technique we used to construct our conversational networks. In another study, we applied machine learning tools to the data (one model for each syntactic category) and achieved an overall accuracy of 83% over the entire test set (Elson and McKeown, 2010). The other 43% of quotes are left here as "unknown" speakers; however, in the present study, we are interested in *conversations* rather than individual quotes. Each conversation is likely to consist of multiple quotes by each speaker, increasing the chances of detecting the interaction. Moreover, this design decision emphasizes the precision of the social networks over their recall. This tilts "in favor" of hypothesis #1 (that there are fewer social interactions in larger communities); however, we shall see that despite the emphasis of precision over recall, we identify a sufficient mass of interactions in the texts to constitute evidence against this hypothesis.

4.3 Constructing social networks

We then applied the results from our character identification and quoted speech attribution methods toward the construction of conversational networks from literature. We derived one network from each text in our corpus.

We first assigned vertices to character entities that are mentioned repeatedly throughout the novel. Coreferents for the same name (such as *Mr. Darcy* and *Darcy*) were grouped into the same vertex. We found that a network that included incidental or single-mention named entities became too noisy to function effectively, so we filtered out the entities that are mentioned fewer than three

times in the novel or are responsible for less than 1% of the named entity mentions in the novel.

We assigned undirected edges between vertices that represent *adjacency* in quoted speech fragments. Specifically, we set the weight of each undirected edge between two character vertices to the total length, in words, of all quotes that either character speaks from among all pairs of adjacent quotes in which they both speak– implying face to face conversation. We empirically determined that the most accurate definition of "adjacency" is one where the two characters' quotes fall within 300 words of one another with no attributed quotes in between. When such an adjacency is found, the length of the quote is added to the edge weight, under the hypothesis that the significance of the relationship between two individuals is proportional to the length of the dialogue that they exchange. Finally, we normalized each edge's weight by the length of the novel.

An example network, automatically constructed in this manner from Jane Austen's *Mansfield Park*, is shown in Figure 1. The width of each vertex is drawn to be proportional to the character's share of all the named entity mentions in the book (so that protagonists, who are mentioned frequently, appear in larger ovals). The width of each edge is drawn to be proportional to its weight (total conversation length).

We also experimented with two alternate methods for identifying edges, for purposes of a baseline:

1. The "correlation" method divides the text into 10-paragraph segments and counts the number of mentions of each character in each segment (excluding mentions inside quoted speech). It then computes the Pearson product-moment correlation coefficient for the distributions of mentions for each pair of characters. These coefficients are used for the edge weights. Characters that tend to appear together in the same areas of the novel are taken to be more socially connected, and have a higher edge weight.

2. The "spoken mention" method counts occurrences when one character refers to another in his or her quoted speech. These counts, normalized by the length of the text, are used as edge weights. The intuition is that characters who refer to one another are likely to be in conversation.

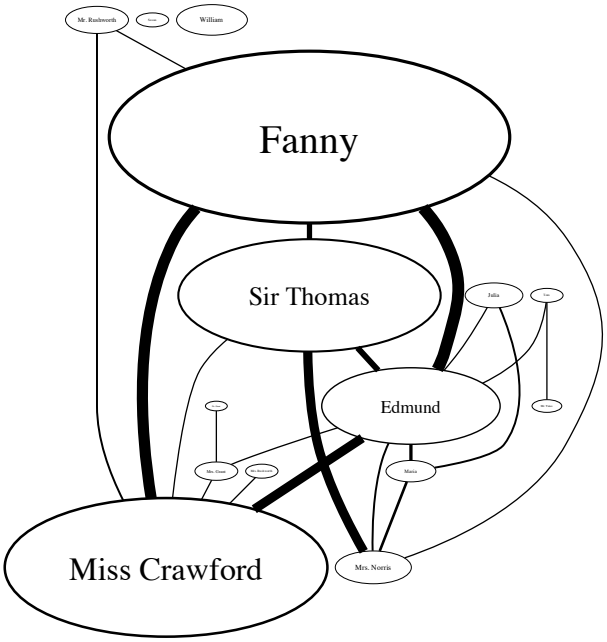

Figure 1: Automatically extracted conversation network for Jane Austen's *Mansfield Park*.

4.4 Evaluation

To check the accuracy of our method for extracting conversational networks, we conducted an evaluation involving four of the novels (*The Sign of the Four*, *Emma*, *David Copperfield* and *The Portrait of a Lady*). We did not use these texts when developing our method for identifying conversations. For each book, we randomly selected 4-5 chapters from among those with significant amounts of quoted speech, so that all excerpts from each novel amounted to at least 10,000 words. We then asked three annotators to identity all the conversations that occur in all 44,000 words. We requested that the annotators include both direct and indirect (unquoted) speech, and define "conversation" as in the beginning of Section 4, but exclude "retold" conversations (those that occur within other dialogue).

We processed the annotation results by breaking down each multi-way conversation into all of its unique two-character interactions (for example, a conversation between four people indicates six bilateral interactions). To calculate inter-annotator agreement, we first compiled a list of all possible interactions between all characters in each text. In this model, each annotator contributed a set of "yes" or "no" decisions, one for every character pair. We then applied the kappa measurement for agreement in a binary classification problem (Co-

Method	Precision	Recall	F
Speech adjacency	.95	.51	.67
Correlation	.21	.65	.31
Spoken-mention	.45	.49	.47

Table 2: Precision, recall, and F-measure of three methods for detecting bilateral conversations in literary texts.

hen, 1960). In 95% of character pairs, annotators were unanimous, which is a high agreement of $k = .82$.

The precision and recall of our method for detecting conversations is shown in Table 2. Precision was .95; this indicates that we can be confident in the specificity of the conversational networks that we automatically construct. Recall was .51, indicating a sensitivity of slightly more than half. There were several reasons that we did not detect the missing links, including indirect speech, quotes attributed to anaphoras or coreferents, and "diffuse" conversations in which the characters do not speak in turn with one another.

To calculate precision and recall for the two baseline social networks, we set a threshold t to derive a binary prediction from the continuous edge weights. The precision and recall values shown for the baselines in Table 2 represent the highest performance we achieved by varying t between 0 and 1 (maximizing F-measure over t). Both baselines performed significantly worse in precision and F-measure than our quoted speech adjacency method for detecting conversations.

5 Data Analysis

5.1 Feature extraction

We extracted features from the conversational networks that emphasize the complexity of the social interactions found in each novel:

1. The number of characters and the number of speaking characters

2. The variance of the distribution of quoted speech (specifically, the proportion of quotes spoken by the n most frequent speakers, for $1 \leq n \leq 5$)

3. The number of quotes, and proportion of words in the novel that are quoted speech

4. The number of 3-cliques and 4-cliques in the social network

5. The *average degree* of the graph, defined as

$$\frac{\sum_{v \in V} |E_v|}{|V|} = \frac{2|E|}{|V|} \quad (1)$$

where $|E_v|$ is the number of edges incident on a vertex v, and $|V|$ is the number of vertices. In other words, this determines the average number of characters connected to each character in the conversational network ("with how many people on average does a character converse?").

6. A variation on *graph density* that normalizes the average degree feature by the number of characters:

$$\frac{\sum_{v \in V} |E_v|}{|V|(|V|-1)} = \frac{2|E|}{|V|(|V|-1)} \quad (2)$$

By dividing again by $|V| - 1$, we use this as a metric for the overall connectedness of the graph: "with what *percent* of the entire network (besides herself) does each character converse, on average?" The weight of the edge, as long as it is greater than 0, does not affect either the network's average degree or graph density.

5.2 Results

We derived results from the data in two ways. First, we examined the strengths of the correlations between the features that we extracted (for example, between number of character vertices and the average degree of each vertex). We used Pearson's product-moment correlation coefficient in these calculations. Second, we compared the extracted features to the metadata we previously assigned to each text (e.g., urban vs. rural).

Hypothesis #1, which we described in Section 3, claims that there is an inverse correlation between the amount of dialogue in a nineteenth-century novel and the number of characters in that novel. We did not find this to be the case. Rather, we found a weak but positive correlation (r=.16) between the number of quotes in a novel and the number of characters (normalizing the quote count for text length). There was a stronger positive correlation (r=.50) between the number of unique speakers (those characters who speak at least once) and the normalized number of quotes, suggesting that larger networks have more conversations than smaller ones. But because the first

correlation is weak, we investigated whether further analysis could identify other evidence that confirms or contradicts the hypothesis.

Another way to interpret hypothesis #1 is that social networks with more characters tend to break apart and be less connected. However, we found the opposite to be true. The correlation between the number of characters in each graph and the average degree (number of conversation partners) for each character was a positive, moderately strong r=.42. This is not a given; a network can easily, for example, break into minimally connected or mutually exclusive subnetworks when more characters are involved. Instead, we found that networks tend to stay close-knit regardless of their size: even the density of the graph (the percentage of the community that each character talks to) grows with the total population size at r=.30. Moreover, as the population of *speakers* grows, the density is likely to increase at r=.49. A higher number of characters (speaking or non-speaking) is also correlated with a higher *rate* of 3-cliques per character (r=.38), as well as with a more balanced distribution of dialogue (the share of dialogue spoken by the top three speakers decreases at r=−.61). This evidence suggests that in nineteenth-century British literature, it is the small communities, rather than the large ones, that tend to be disconnected.

Hypothesis #2, meanwhile, posited that a novel's setting (urban or rural) would have an effect on the structure of its social network. After defining "social network" as a conversational network, we did not find this to be the case. Surprisingly, the numbers of characters and speakers found in the urban novel were *not* significantly greater than those found in the rural novel. Moreover, each of the features we extracted, such as the rate of cliques, average degree, density, and rate of characters' mentions of other characters, did not change in a statistically significant manner between the two genres. For example, Figure 2 shows the mean over all texts of each network's average degree, with confidence intervals, separated by setting into urban and rural. The increase in degree seen in urban texts is not significant.

Rather, the only type of metadata variable that *did* impact the average degree with any significance was the text's perspective. Figure 2 also separates texts into first- and third-person tellings and shows the means and confidence intervals for the

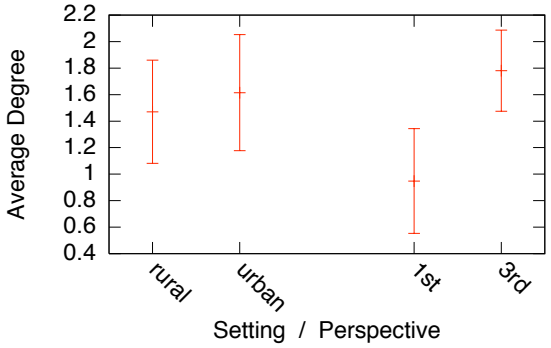

Figure 2: The average degree for each character as a function of the novel's setting and its perspective.

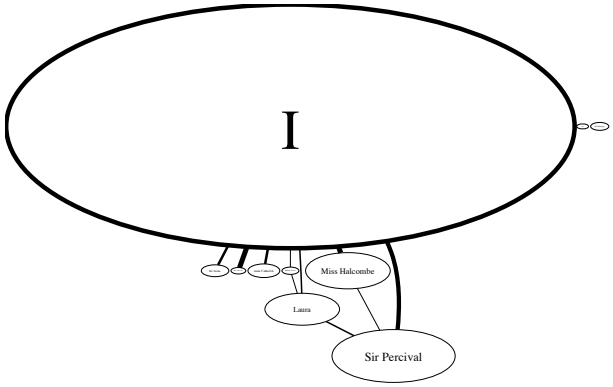

Figure 3: Conversational networks for first-person novels like Collins's *The Woman in White* are less connected due to the structure imposed by the perspective.

average degree measure. Stories told in the third person had much more connected networks than stories told in the first person: not only did the average degree increase with statistical significance (by the homoscedastic t-test to $p < .005$), so too did the graph density ($p < .05$) and the rate of 3-cliques per character ($p < .05$).

We believe the reason for this can be intuited with a visual inspection of a first-person graph. Figure 3 shows the conversational network extracted for Collins's *The Woman in White*, which is told in the first person. Not surprisingly, the most oft-repeated named entity in the text is *I*, referring to the narrator. More surprising is the *lack* of conversation connections between the auxiliary characters. The story's structure revolves around the narrator and each character is understood in terms of his or her relationship to the narrator. Private conversations between auxiliary characters would not include the narrator, and thus do not appear in a

first-hand account. An "omniscient" third person narrator, by contrast, can eavesdrop on any pair of characters conversing. This highlights the importance of detecting reported and indirect speech in future work, as a first-person narrator may hear about other connections without witnessing them.

6 Literary Interpretation of Results

Our data, therefore, markedly do not confirm hypothesis #1. They also suggest, in relation to hypothesis #2 (also not confirmed by the data), a strong reason why.

One of the basic assumptions behind hypothesis #2– that urban novels contain more characters, mirroring the masses of nineteenth-century cities– is not borne out by our data. Our results do, however, strongly correlate a point of view (third-person narration) with more frequently connected characters, implying tighter and more talkative social networks.

We would propose that this suggests that the form of a given novel– the standpoint of the narrative voice, whether the voice is "omniscient" or not– is far more determinative of the kind of social network described in the novel than where it is set or even the number of characters involved. Whereas standard accounts of nineteenth-century fiction, following Bakhtin's notion of the "chronotope," emphasize the content of the novel as determinative (where it is set, whether the novel fits within a genre of "village" or "urban" fiction), we have found that content to be surprisingly irrelevant to the shape of social networks within. Bakhtin's influential theory, and its detailed reworkings by Williams, Moretti, and others, suggests that as the novel becomes more urban, more centered in (and interested in) populous urban settings, the novel's form changes to accommodate the looser, more populated, less conversational networks of city life. Our data suggests the opposite: that the "urban novel" is not as strongly distinctive a form as has been asserted, and that in fact it can look much like the village fictions of the century, as long as the same method of narration is used.

This conclusion leads to some further considerations. We are suggesting that the important element of social networks in nineteenth-century fiction is not where the networks are set, but from what standpoint they are imagined or narrated. Narrative voice, that is, trumps setting.

7 Conclusion

In this paper, we presented a method for characterizing a text of literary fiction by extracting the network of social conversations that occur between its characters. This allowed us to take a systematic and wide look at a large corpus of texts, an approach which complements the narrower and deeper analysis performed by literary scholars and can provide evidence for or against some of their claims. In particular, we described a high-precision method for detecting face-to-face conversations between two named characters in a novel, and showed that as the number of characters in a novel grows, so too do the cohesion, interconnectedness and balance of their social network. In addition, we showed that the form of the novel (first- or third-person) is a stronger predictor of these features than the setting (urban or rural). Our results thus far suggest further review of our methods, our corpus and our results for more insights into the social networks found in this and other genres of fiction.

Pseudo-word for Phrase-based Machine Translation

Xiangyu Duan **Min Zhang** **Haizhou Li**
Institute for Infocomm Research, A-STAR, Singapore
{Xduan, mzhang, hli}@i2r.a-star.edu.sg

Abstract

The pipeline of most Phrase-Based Statistical Machine Translation (PB-SMT) systems starts from automatically word aligned parallel corpus. But word appears to be too fine-grained in some cases such as non-compositional phrasal equivalences, where no clear word alignments exist. Using words as inputs to PB-SMT pipeline has inborn deficiency. This paper proposes pseudo-word as a new start point for PB-SMT pipeline. Pseudo-word is a kind of basic multi-word expression that characterizes minimal sequence of consecutive words in sense of translation. By casting pseudo-word searching problem into a parsing framework, we search for pseudo-words in a monolingual way and a bilingual synchronous way. Experiments show that pseudo-word significantly outperforms word for PB-SMT model in both travel translation domain and news translation domain.

1 Introduction

The pipeline of most Phrase-Based Statistical Machine Translation (PB-SMT) systems starts from automatically word aligned parallel corpus generated from word-based models (Brown et al., 1993), proceeds with step of induction of phrase table (Koehn et al., 2003) or synchronous grammar (Chiang, 2007) and with model weights tuning step. Words are taken as inputs to PB-SMT at the very beginning of the pipeline. But there is a deficiency in such manner that word is too fine-grained in some cases such as non-compositional phrasal equivalences, where clear word alignments do not exist. For example in Chinese-to-English translation, "想" and "would like to" constitute a *1*-to-*n* phrasal equivalence, "多少钱" and "how much is it" constitute a *m*-to-*n* phrasal equivalence. No clear word alignments are there in such phrasal equivalences. Moreover, should basic translational unit be word or coarse-grained multi-word is an open problem for optimizing SMT models.

Some researchers have explored coarse-grained translational unit for machine translation. Marcu and Wong (2002) attempted to directly learn phrasal alignments instead of word alignments. But computational complexity is prohibitively high for the exponentially large number of decompositions of a sentence pair into phrase pairs. Cherry and Lin (2007) and Zhang et al. (2008) used synchronous ITG (Wu, 1997) and constraints to find non-compositional phrasal equivalences, but they suffered from intractable estimation problem. Blunsom et al. (2008; 2009) induced phrasal synchronous grammar, which aimed at finding hierarchical phrasal equivalences.

Another direction of questioning word as basic translational unit is to directly question word segmentation on languages where word boundaries are not orthographically marked. In Chinese-to-English translation task where Chinese word boundaries are not marked, Xu et al. (2004) used word aligner to build a Chinese dictionary to re-segment Chinese sentence. Xu et al. (2008) used a Bayesian semi-supervised method that combines Chinese word segmentation model and Chinese-to-English translation model to derive a Chinese segmentation suitable for machine translation. There are also researches focusing on the impact of various segmentation tools on machine translation (Ma et al. 2007; Chang et al. 2008; Zhang et al. 2008). Since there are many *1*-to-*n* phrasal equivalences in Chinese-to-English translation (Ma and Way. 2009), only focusing on Chinese word as basic translational unit is not adequate to model *1*-to-*n* translations. Ma and Way (2009) tackle this problem by using word aligner to bootstrap bilingual segmentation suitable for machine translation. Lambert and Banchs (2005) detect bilingual multi-word ex-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 148–156,
Uppsala, Sweden, 11-16 July 2010.

pressions by monotonically segmenting a given Spanish-English sentence pair into bilingual units, where word aligner is also used.

IBM model 3, 4, 5 (Brown et al., 1993) and Deng and Byrne (2005) are another kind of related works that allow *1*-to-*n* alignments, but they rarely questioned if such alignments exist in word units level, that is, they rarely questioned word as basic translational unit. Moreover, *m*-to-*n* alignments were not modeled.

This paper focuses on determining the basic translational units on both language sides without using word aligner before feeding them into PB-SMT pipeline. We call such basic translational unit as pseudo-word to differentiate with word. Pseudo-word is a kind of multi-word expression (includes both unary word and multi-word). Pseudo-word searching problem is the same to decomposition of a given sentence into pseudo-words. We assume that such decomposition is in the Gibbs distribution. We use a measurement, which characterizes pseudo-word as minimal sequence of consecutive words in sense of translation, as potential function in Gibbs distribution. Note that the number of decomposition of one sentence into pseudo-words grows exponentially with sentence length. By fitting decomposition problem into parsing framework, we can find optimal pseudo-word sequence in polynomial time. Then we feed pseudo-words into PB-SMT pipeline, and find that pseudo-words as basic translational units improve translation performance over words as basic translational units. Further experiments of removing the power of higher order language model and longer max phrase length, which are inherent in pseudo-words, show that pseudo-words still improve translational performance significantly over unary words.

This paper is structured as follows: In section 2, we define the task of searching for pseudo-words and its solution. We present experimental results and analyses of using pseudo-words in PB-SMT model in section 3. The conclusion is presented at section 4.

2 Searching for Pseudo-words

Pseudo-word searching problem is equal to decomposition of a given sentence into pseudo-words. We assume that the distribution of such decomposition is in the form of Gibbs distribution as below:

$$P(Y \mid X) = \frac{1}{Z_X} \exp(\sum_k Sig_{y_k}) \quad (1)$$

where X denotes the sentence, Y denotes a decomposition of X. *Sig* function acts as potential function on each multi-word y_k, and Z_X acts as partition function. Note that the number of y_k is not fixed given X because X can be decomposed into various number of multi-words.

Given X, Z_X is fixed, so searching for optimal decomposition is as below:

$$\hat{Y} = \underset{Y}{ARGMAX}\, P(Y \mid X) = \underset{Y_1^K}{ARGMAX} \sum_k Sig_{y_k} \quad (2)$$

where Y_1^K denotes K multi-word units from decomposition of X. A multi-word sequence with maximal sum of *Sig* function values is the search target — pseudo-word sequence. From (2) we can see that *Sig* function is vital for pseudo-word searching. In this paper *Sig* function calculates sequence significance which is proposed to characterize pseudo-word as minimal sequence of consecutive words in sense of translation. The detail of sequence significance is described in the following section.

2.1 Sequence Significance

Two kinds of definitions of sequence significance are proposed. One is monolingual sequence significance. X and Y are monolingual sentence and monolingual multi-words respectively in this monolingual scenario. The other is bilingual sequence significance. X and Y are sentence pair and multi-word pairs respectively in this bilingual scenario.

2.1.1 Monolingual Sequence Significance

Given a sentence $w_1, \ldots, w_n$, where w_i denotes unary word, monolingual sequence significance is defined as:

$$Sig_{i,j} = \frac{Freq_{i,j}}{Freq_{i-1,j+1}} \quad (3)$$

where $Freq_{i,j}$ ($i \leq j$) represents frequency of word sequence $w_i, \ldots, w_j$ in the corpus, $Sig_{i,j}$ represents monolingual sequence significance of a word sequence $w_i, \ldots, w_j$. We also denote word sequence $w_i, \ldots, w_j$ as $span[i, j]$, whole sentence as $span[1, n]$. Each span is also a multi-word expression.

Monolingual sequence significance of $span[i, j]$ is proportional to $span[i, j]$'s frequency, while is inversely proportion to frequency of expanded span ($span[i-1, j+1]$). Such definition characterizes minimal sequence of consecutive words which we are looking for. Our target is to find pseudo-word sequence which has maximal sum of spans' significances:

$$pw_1^K = \underset{span_1^K}{ARGMAX} \sum_{k=1}^{K} Sig_{span_k} \quad (4)$$

where *pw* denotes pseudo-word, *K* is equal to or less than sentence's length. $span_k$ is the *k*th span of *K* spans $span_1^K$. Equation (4) is the rewrite of equation (2) in monolingual scenario. Searching for pseudo-words pw_1^K is the same to finding optimal segmentation of a sentence into *K* segments $span_1^K$ (*K* is a variable too). Details of searching algorithm are described in section 2.2.1.

We firstly search for monolingual pseudo-words on source and target side individually. Then we apply word alignment techniques to build pseudo-word alignments. We argue that word alignment techniques will work fine if non-existent word alignments in such as non-compositional phrasal equivalences have been filtered by pseudo-words.

2.1.2 Bilingual Sequence Significance

Bilingual sequence significance is proposed to characterize pseudo-word pairs. Co-occurrence of sequences on both language sides is used to define bilingual sequence significance. Given a bilingual sequence pair: *span-pair*[i_s, j_s, i_t, j_t] (source side *span*[i_s, j_s] and target side *span*[i_t, j_t]), bilingual sequence significance is defined as below:

$$Sig_{i_s, j_s, i_t, j_t} = \frac{Freq_{i_s, j_s, i_t, j_t}}{Freq_{i_s-1, j_s+1, i_t-1, j_t+1}} \quad (5)$$

where *Freq* denotes the frequency of a span-pair. Bilingual sequence significance is an extension of monolingual sequence significance. Its value is proportional to frequency of *span-pair*[i_s, j_s, i_t, j_t], while is inversely proportional to frequency of expanded *span-pair*[i_s-1, j_s+1, i_t-1, j_t+1]. Pseudo-word pairs of one sentence pair are such pairs that maximize the sum of *span-pairs*' bilingual sequence significances:

$$pwp_1^K = \underset{span-pair_1^K}{ARGMAX} \sum_{k=1}^{K} Sig_{span-pair_k} \quad (6)$$

pwp represents pseudo-word pair. Equation (6) is the rewrite of equation (2) in bilingual scenario. Searching for pseudo-word pairs pwp_1^K is equal to bilingual segmentation of a sentence pair into optimal $span\text{-}pair_1^K$. Details of searching algorithm are presented in section 2.2.2.

2.2 Algorithms of Searching for Pseudo-words

Pseudo-word searching problem is equal to decomposition of a sentence into pseudo-words. But the number of possible decompositions of the sentence grows exponentially with the sentence length in both monolingual scenario and bilingual scenario. By casting such decomposition problem into parsing framework, we can find pseudo-word sequence in polynomial time. According to the two scenarios, searching for pseudo-words can be performed in a monolingual way and a synchronous way. Details of the two kinds of searching algorithms are described in the following two sections.

2.2.1 Algorithm of Searching for Monolingual Pseudo-words (SMP)

Searching for monolingual pseudo-words is based on the computation of monolingual sequence significance. Figure 1 presents the search algorithm. It is performed in a way similar to CKY (Cocke-Kasami-Younger) parser.

```
Initialization: W_{i,i} = Sig_{i,i};
                W_{i,j} = 0,  (i≠j);
1: for d = 2 ... n do
2:    for all i, j s.t. j-i=d-1 do
3:       for k = i ... j – 1 do
4:          v = W_{i,k} + W_{k+1,j}
5:          if v > W_{i,j} then
6:             W_{i,j} = v;
7:       u = Sig_{i,j}
8:       if u > W_{i,j} then
9:          W_{i,j} = u;
```

Figure 1. Algorithm of searching for monolingual pseudo-words (SMP).

In this algorithm, $W_{i,j}$ records maximal sum of monolingual sequence significances of sub spans of *span*[*i, j*]. During initialization, $W_{i,i}$ is initialized as $Sig_{i,i}$ (note that this sequence is word w_i only). For all spans that have more than one word ($i \neq j$), $W_{i,j}$ is initialized as zero.

In the main algorithm, *d* represents span's length, ranging from *2* to *n*, *i* represents start position of a span, *j* represents end position of a span, *k* represents decomposition position of *span*[*i,j*]. For *span*[*i, j*], $W_{i,j}$ is updated if higher sum of monolingual sequence significances is found.

The algorithm is performed in a bottom-up way. Small span's computation is first. After maximal sum of significances is found in small spans, big span's computation, which uses small spans' maximal sum, is continued. Maximal sum of significances for whole sentence ($W_{1,n}$, *n* is sentence's length) is guaranteed in this way, and optimal decomposition is obtained correspondingly.

The method of fitting the decomposition problem into CKY parsing framework is located at steps 7-9. After steps 3-6, all possible decompositions of *span*[*i, j*] are explored and $W_{i,j}$ of optimal decomposition of *span*[*i, j*] is recorded. Then monolingual sequence significance $Sig_{i,j}$ of *span*[*i, j*] is computed at step 7, and it is compared to $W_{i,j}$ at step 8. Update of $W_{i,j}$ is taken at step 9 if $Sig_{i,j}$ is bigger than $W_{i,j}$, which indicates that *span*[*i*, *j*] is non-decomposable. Thus whether *span*[*i*, *j*] should be non-decomposable or not is decided through steps 7-9.

2.2.2 Algorithm of Synchronous Searching for Pseudo-words (SSP)

Synchronous searching for pseudo-words utilizes bilingual sequence significance. Figure 2 presents the search algorithm. It is similar to ITG (Wu, 1997), except that it has no production rules and non-terminal nodes of a synchronous grammar. What it cares about is the span-pairs that maximize the sum of bilingual sequence significances.

Initialization: **if** $i_s = j_s$ or $i_t = j_t$ **then**
$W_{i_s,j_s,i_t,j_t} = Sig_{i_s,j_s,i_t,j_t}$;
else
$W_{i_s,j_s,i_t,j_t} = 0$;

1: **for** $d_s = 2 \ldots n_s$, $d_t = 2 \ldots n_t$ **do**
2: **for** all i_s, j_s, i_t, j_t s.t. $j_s - i_s = d_s - 1$ and $j_t - i_t = d_t - 1$ **do**
3: **for** $k_s = i_s \ldots j_s - 1$, $k_t = i_t \ldots j_t - 1$ **do**
4: $v = max\{W_{i_s,k_s,i_t,k_t} + W_{k_s+1,j_s,k_t+1,j_t}, W_{i_s,k_s,k_t+1,j_t} + W_{k_s+1,j_s,i_t,k_t}\}$
5: **if** $v > W_{i_s,j_s,i_t,j_t}$ **then**
6: $W_{i_s,j_s,i_t,j_t} = v$;
7: $u = Sig_{i_s,j_s,i_t,j_t}$
8: **if** $u > W_{i_s,j_s,i_t,j_t}$ **then**
9: $W_{i_s,j_s,i_t,j_t} = u$;

Figure 2. Algorithm of Synchronous Searching for Pseudo-words(SSP).

In the algorithm, W_{i_s,j_s,i_t,j_t} records maximal sum of bilingual sequence significances of sub span-pairs of *span-pair*[i_s, j_s, i_t, j_t]. For *1*-to-*m* span-pairs, *W*s are initialized as bilingual sequence significances of such span-pairs. For other span-pairs, *W*s are initialized as zero.

In the main algorithm, d_s/d_t denotes the length of a span on source/target side, ranging from *2* to n_s/n_t (source/target sentence's length). i_s/i_t is the start position of a span-pair on source/target side, j_s/j_t is the end position of a span-pair on source/target side, k_s/k_t is the decomposition position of a *span-pair*[i_s, j_s, i_t, j_t] on source/target side.

Update steps in Figure 2 are similar to that of Figure 1, except that the update is about span-pairs, not monolingual spans. Reversed and non-reversed alignments inside a span-pair are compared at step 4. For *span-pair*[i_s, j_s, i_t, j_t], W_{i_s,j_s,i_t,j_t} is updated at step 6 if higher sum of bilingual sequence significances is found.

Fitting the bilingually searching for pseudo-words into ITG framework is located at steps 7-9. Steps 3-6 have explored all possible decompositions of *span-pair*[i_s, j_s, i_t, j_t] and have recorded maximal W_{i_s,j_s,i_t,j_t} of these decompositions. Then bilingual sequence significance of *span-pair*[i_s, j_s, i_t, j_t] is computed at step 7. It is compared to W_{i_s,j_s,i_t,j_t} at step 8. Update is taken at step 9 if bilingual sequence significance of *span-pair*[i_s, j_s, i_t, j_t] is bigger than W_{i_s,j_s,i_t,j_t}, which indicates that *span-pair*[i_s, j_s, i_t, j_t] is non-decomposable. Whether the *span-pair*[i_s, j_s, i_t, j_t] should be non-decomposable or not is decided through steps 7-9.

In addition to the initialization step, all span-pairs' bilingual sequence significances are computed. Maximal sum of bilingual sequence significances for one sentence pair is guaranteed through this bottom-up way, and the optimal decomposition of the sentence pair is obtained correspondingly.

- **Algorithm of Excluded Synchronous Searching for Pseudo-words (ESSP)**

The algorithm of SSP in Figure 2 explores all span-pairs, but it neglects NULL alignments, where words and "empty" word are aligned. In fact, SSP requires that all parts of a sentence pair should be aligned. This requirement is too strong because NULL alignments are very common in many language pairs. In SSP, words that should be aligned to "empty" word are programmed to be aligned to real words.

Unlike most word alignment methods (Och and Ney, 2003) that add "empty" word to account for NULL alignment entries, we propose a method to naturally exclude such NULL alignments. We call this method as Excluded Synchronous Searching for Pseudo-words (ESSP).

The main difference between ESSP and SSP is in steps 3-6 in Figure 3. We illustrate Figure 3's span-pair configuration in Figure 4.

Initialization: **if** $i_s = j_s$ or $i_t = j_t$ **then**

$W_{i_s,j_s,i_t,j_t} = Sig_{i_s,j_s,i_t,j_t}$;

else

$W_{i_s,j_s,i_t,j_t} = 0$;

1: **for** $d_s = 2 \ldots n_s$, $d_t = 2 \ldots n_t$ **do**
2: **for** all i_s, j_s, i_t, j_t s.t. $j_s - i_s = d_s - 1$ and $j_t - i_t = d_t - 1$ **do**
3: **for** $k_{s1} = i_s + 1 \ldots j_s$, $k_{s2} = k_{s1} - 1 \ldots j_s - 1$
$k_{t1} = i_t + 1 \ldots j_t$, $k_{t2} = k_{t1} - 1 \ldots j_t - 1$ **do**
4: $v = \max\{W_{i_s,k_{s1}-1,i_t,k_{t1}-1} + W_{k_{s2}+1,j_s,k_{t2}+1,j_t}, W_{i_s,k_{s1}-1,k_{t2}+1,j_t} + W_{k_{s2}+1,j_s,i_t,k_{t1}-1}\}$
5: **if** $v > W_{i_s,j_s,i_t,j_t}$ **then**
6: $W_{i_s,j_s,i_t,j_t} = v$;
7: $u = Sig_{i_s,j_s,i_t,j_t}$
8: **if** $u > W_{i_s,j_s,i_t,j_t}$ **then**
9: $W_{i_s,j_s,i_t,j_t} = u$;

Figure 3. Algorithm of Excluded Synchronous Searching for Pseudo-words (ESSP).

The solid boxes in Figure 4 represent excluded parts of *span-pair*[i_s, j_s, i_t, j_t] in ESSP. Note that, in SSP, there is no excluded part, that is, $k_{s1}=k_{s2}$ and $k_{t1}=k_{t2}$.

We can see that in Figure 4, each monolingual span is configured into three parts, for example: *span*[i_s, k_{s1}-*1*], *span*[k_{s1}, k_{s2}] and *span*[k_{s2}+*1*, j_s] on source language side. k_{s1} and k_{s2} are two new variables gliding between i_s and j_s, *span*[k_{s1}, k_{s2}] is source side excluded part of *span-pair*[i_s, j_s, i_t, j_t]. Bilingual sequence significance is computed only on pairs of blank boxes, solid boxes are excluded in this computation to represent NULL alignment cases.

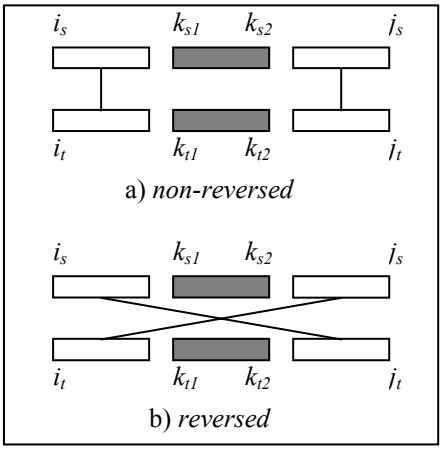

Figure 4. Illustration of excluded configuration.

Note that, in Figure 4, solid box on either language side can be void (i.e., length is zero) if there is no NULL alignment on its side. If all solid boxes are shrunk into void, algorithm of ESSP is the same to SSP.

Generally, span length of NULL alignment is not very long, so we can set a length threshold for NULL alignments, eg. $k_{s2}-k_{s1} \leqslant EL$, where *EL* denotes *Excluded Length* threshold. Computational complexity of the ESSP remains the same to SSP's complexity $O(n_s^3.n_t^3)$, except multiply a constant EL^2.

There is one kind of NULL alignments that ESSP can not consider. Since we limit excluded parts in the middle of a span-pair, the algorithm will end without considering boundary parts of a sentence pair as NULL alignments.

3 Experiments and Results

In our experiments, pseudo-words are fed into PB-SMT pipeline. The pipeline uses GIZA++ model 4 (Brown et al., 1993; Och and Ney, 2003) for pseudo-word alignment, uses Moses (Koehn et al., 2007) as phrase-based decoder, uses the SRI Language Modeling Toolkit to train language model with modified Kneser-Ney smoothing (Kneser and Ney 1995; Chen and Goodman 1998). Note that MERT (Och, 2003) is still on original words of target language. In our experiments, pseudo-word length is limited to no more than six unary words on both sides of the language pair.

We conduct experiments on Chinese-to-English machine translation. Two data sets are adopted, one is small corpus of IWSLT-2008 BTEC task of spoken language translation in travel domain (Paul, 2008), the other is large corpus in news domain, which consists Hong Kong News (LDC2004T08), Sinorama Magazine (LDC2005T10), FBIS (LDC2003E14), Xinhua (LDC2002E18), Chinese News Translation (LDC2005T06), Chinese Treebank (LDC2003E07), Multiple Translation Chinese (LDC2004T07). Table 1 lists statistics of the corpus used in these experiments.

	small		large	
	Ch → En		Ch → En	
Sent.	23k		1,239k	
word	190k	213k	31.7m	35.5m
ASL	8.3	9.2	25.6	28.6

Table 1. Statistics of corpora, "Ch" denotes Chinese, "En" denotes English, "Sent." row is the number of sentence pairs, "word" row is the number of words, "ASL" denotes average sentence length.

For small corpus, we use CSTAR03 as development set, use IWSLT08 official test set for test. A *5*-gram language model is trained on English side of parallel corpus. For large corpus, we use NIST02 as development set, use NIST03 as test set. Xinhua portion of the English Gigaword3 corpus is used together with English side of large corpus to train a *4*-gram language model.

Experimental results are evaluated by case-insensitive BLEU-4 (Papineni et al., 2001). Closest reference sentence length is used for brevity penalty. Additionally, NIST score (Doddington, 2002) and METEOR (Banerjee and Lavie, 2005) are also used to check the consistency of experimental results. Statistical significance in BLEU score differences was tested by paired bootstrap re-sampling (Koehn, 2004).

3.1 Baseline Performance

Our baseline system feeds word into PB-SMT pipeline. We use GIZA++ model 4 for word alignment, use Moses for phrase-based decoding. The setting of language model order for each corpus is not changed. Baseline performances on test sets of small corpus and large corpus are reported in table 2.

	small	Large
BLEU	0.4029	0.3146
NIST	7.0419	8.8462
METEOR	0.5785	0.5335

Table 2. Baseline performances on test sets of small corpus and large corpus.

3.2 Pseudo-word Unpacking

Because pseudo-word is a kind of multi-word expression, it has inborn advantage of higher language model order and longer max phrase length over unary word. To see if such inborn advantage is the main contribution to the performance or not, we unpack pseudo-word into words after GIZA++ aligning. Aligned pseudo-words are unpacked into $m \times n$ word alignments. PB-SMT pipeline is executed thereafter. The advantage of longer max phrase length is removed during phrase extraction, and the advantage of higher order of language model is also removed during decoding since we use language model trained on unary words. Performances of pseudo-word unpacking are reported in section 3.3.1 and 3.4.1. Ma and Way (2009) used the unpacking after phrase extraction, then re-estimated phrase translation probability and lexical reordering model. The advantage of longer max phrase length is still used in their method.

3.3 Pseudo-word Performances on Small Corpus

Table 3 presents performances of SMP, SSP, ESSP on small data set. $pw_{ch}pw_{en}$ denotes that pseudo-words are on both language side of training data, and they are input strings during development and testing, and translations are also pseudo-words, which will be converted to words as final output. $w_{ch}pw_{en}/pw_{ch}w_{en}$ denotes that pseudo-words are adopted only on English/Chinese side of the data set.

We can see from table 3 that, ESSP attains the best performance, while SSP attains the worst performance. This shows that excluding NULL alignments in synchronous searching for pseudo-words is effective. SSP puts overly strong alignment constraints on parallel corpus, which impacts performance dramatically. ESSP is superior to SMP indicating that bilingually motivated searching for pseudo-words is more effective. Both SMP and ESSP outperform baseline consistently in BLEU, NIST and METEOR.

There is a common phenomenon among SMP, SSP and ESSP. $w_{ch}pw_{en}$ always performs better than the other two cases. It seems that Chinese word prefers to have English pseudo-word equivalence which has more than or equal to one word. $pw_{ch}pw_{en}$ in ESSP performs similar to the baseline, which reflects that our direct pseudo-word pairs do not work very well with GIZA++ alignments. Such disagreement is weakened by using pseudo-words on only one language side ($w_{ch}pw_{en}$ or $pw_{ch}w_{en}$), while the advantage of pseudo-words is still leveraged in the alignments.

Best ESSP ($w_{ch}pw_{en}$) is significantly better than baseline ($p<0.01$) in BLEU score, best SMP ($w_{ch}pw_{en}$) is significantly better than baseline ($p<0.05$) in BLEU score. This indicates that pseudo-words, through either monolingual searching or synchronous searching, are more effective than words as to being basic translational units.

Figure 5 illustrates examples of pseudo-words of one Chinese-to-English sentence pair. Gold standard word alignments are shown at the bottom of figure 5. We can see that "front desk" is recognized as one pseudo-word in ESSP. Because SMP performs monolingually, it can not consider "前台" and "front desk" simultaneously. SMP only detects frequent monolingual multi-words as pseudo-words. SSP has a strong constraint that all parts of a sentence pair should be aligned, so source sentence and target sentence have same length after merging words into

	SMP			SSP			ESSP			baseline
	$pw_{ch}pw_{en}$	$w_{ch}pw_{en}$	$pw_{ch}w_{en}$	$pw_{ch}pw_{en}$	$w_{ch}pw_{en}$	$pw_{ch}w_{en}$	$pw_{ch}pw_{en}$	$w_{ch}pw_{en}$	$pw_{ch}w_{en}$	
BLEU	0.3996	0.4155	0.4024	0.3184	0.3661	0.3552	0.3998	**0.4229**	0.4147	0.4029
NIST	7.4711	**7.6452**	7.6186	6.4099	6.9284	6.8012	7.1665	7.4373	7.4235	7.0419
METEOR	0.5900	**0.6008**	0.6000	0.5255	0.5569	0.5454	0.5739	0.5963	0.5891	0.5785

Table 3. Performance of using pseudo-words on small data.

pseudo-words. We can see that too many pseudo-words are detected by SSP.

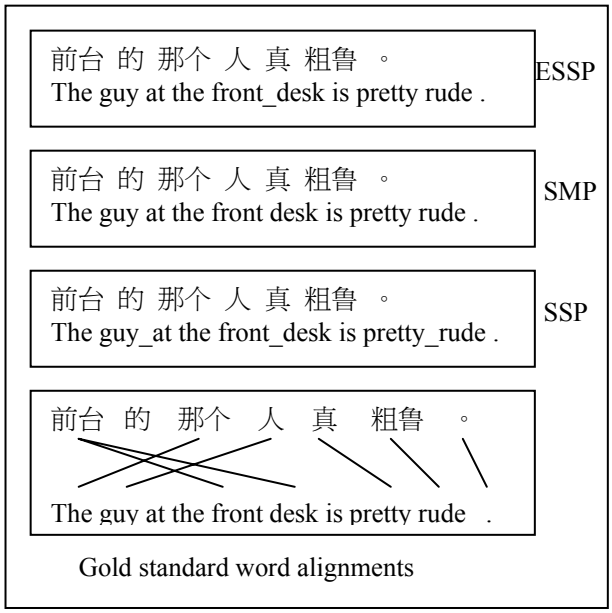

Figure 5. Outputs of the three algorithms ESSP, SMP and SSP on one sentence pair and gold standard word alignments. Words in one pseudo-word are concatenated by "_".

3.3.1 Pseudo-word Unpacking Performances on Small Corpus

We test pseudo-word unpacking in ESSP. Table 4 presents its performances on small corpus.

	$\text{unpacking}_{\text{ESSP}}$			baseline
	$pw_{ch}pw_{en}$	$w_{ch}pw_{en}$	$pw_{ch}w_{en}$	
BLEU	0.4097	**0.4182**	0.4031	0.4029
NIST	**7.5547**	7.2893	7.2670	7.0419
METEOR	**0.5951**	0.5874	0.5846	0.5785

Table 4. Performances of pseudo-word unpacking on small corpus.

We can see that pseudo-word unpacking significantly outperforms baseline. $w_{ch}pw_{en}$ is significantly better than baseline ($p<0.04$) in BLEU score. Unpacked pseudo-word performs comparatively with pseudo-word without unpacking. There is no statistical difference between them. It shows that the improvement derives from pseudo-word itself as basic translational unit, does not rely very much on higher language model order or longer max phrase length setting.

3.4 Pseudo-word Performances on Large Corpus

Table 5 lists the performance of using pseudo-words on large corpus. We apply SMP on this task. ESSP is not applied because of its high computational complexity. Table 5 shows that all three configurations ($pw_{ch}pw_{en}$, $w_{ch}pw_{en}$, $pw_{ch}w_{en}$) of SMP outperform the baseline. If we go back to the definition of sequence significance, we can see that it is a data-driven definition that utilizes corpus frequencies. Corpus scale has an influence on computation of sequence significance in long sentences which appear frequently in news domain. SMP benefits from large corpus, and $w_{ch}pw_{en}$ is significantly better than baseline ($p<0.01$). Similar to performances on small corpus, $w_{ch}pw_{en}$ always performs better than the other two cases, which indicates that Chinese word prefers to have English pseudo-word equivalence which has more than or equal to one word.

	SMP			baseline
	$pw_{ch}pw_{en}$	$w_{ch}pw_{en}$	$pw_{ch}w_{en}$	
BLEU	0.3185	**0.3230**	0.3166	0.3146
NIST	8.9216	**9.0447**	8.9210	8.8462
METEOR	0.5402	**0.5489**	0.5435	0.5335

Table 5. Performance of using pseudo-words on large corpus.

3.4.1 Pseudo-word Unpacking Performances on Large Corpus

Table 6 presents pseudo-word unpacking performances on large corpus. All three configurations improve performance over baseline after pseudo-word unpacking. $pw_{ch}pw_{en}$ attains the best BLEU among the three configurations, and is significantly better than baseline ($p<0.03$). $w_{ch}pw_{en}$ is also significantly better than baseline ($p<0.04$). By comparing table 6 with table 5, we can see that unpacked pseudo-word performs comparatively with pseudo-word without unpacking. There is no statistical difference be-

tween them. It shows that the improvement derives from pseudo-word itself as basic translational unit, does not rely very much on higher language model order or longer max phrase length setting. In fact, slight improvement in $pw_{ch}pw_{en}$ and $pw_{ch}w_{en}$ is seen after pseudo-word unpacking, which indicates that higher language model order and longer max phrase length impact the performance in these two configurations.

	Unpacking$_{SMP}$			Baseline
	$pw_{ch}pw_{en}$	$w_{ch}pw_{en}$	$pw_{ch}w_{en}$	
BLEU	**0.3219**	0.3192	0.3187	0.3146
NIST	8.9458	8.9325	**8.9801**	8.8462
METEOR	**0.5429**	0.5424	0.5411	0.5335

Table 6. Performance of pseudo-word unpacking on large corpus.

3.5 Comparison to English Chunking

English chunking is experimented to compare with pseudo-word. We use FlexCRFs (Xuan-Hieu Phan et al., 2005) to get English chunks. Since there is no standard Chinese chunking data and code, only English chunking is executed. The experimental results show that English chunking performs far below baseline, usually 8 absolute BLEU points below. It shows that simple chunks are not suitable for being basic translational units.

4 Conclusion

We have presented pseudo-word as a novel machine translational unit for phrase-based machine translation. It is proposed to replace too fine-grained word as basic translational unit. Pseudo-word is a kind of basic multi-word expression that characterizes minimal sequence of consecutive words in sense of translation. By casting pseudo-word searching problem into a parsing framework, we search for pseudo-words in polynomial time. Experimental results of Chinese-to-English translation task show that, in phrase-based machine translation model, pseudo-word performs significantly better than word in both spoken language translation domain and news domain. Removing the power of higher order language model and longer max phrase length, which are inherent in pseudo-words, shows that pseudo-words still improve translational performance significantly over unary words.

Hierarchical Search for Word Alignment

Jason Riesa and **Daniel Marcu**
Information Sciences Institute
Viterbi School of Engineering
University of Southern California
{riesa, marcu}@isi.edu

Abstract

We present a simple yet powerful hierarchical search algorithm for automatic word alignment. Our algorithm induces a forest of alignments from which we can efficiently extract a ranked *k*-best list. We score a given alignment within the forest with a flexible, linear discriminative model incorporating hundreds of features, and trained on a relatively small amount of annotated data. We report results on Arabic-English word alignment and translation tasks. Our model outperforms a GIZA++ Model-4 baseline by 6.3 points in F-measure, yielding a 1.1 BLEU score increase over a state-of-the-art syntax-based machine translation system.

1 Introduction

Automatic word alignment is generally accepted as a first step in training any statistical machine translation system. It is a vital prerequisite for generating translation tables, phrase tables, or syntactic transformation rules. Generative alignment models like IBM Model-4 (Brown et al., 1993) have been in wide use for over 15 years, and while not perfect (see Figure 1), they are completely unsupervised, requiring no annotated training data to learn alignments that have powered many current state-of-the-art translation system.

Today, there exist human-annotated alignments and an abundance of other information for many language pairs potentially useful for inducing accurate alignments. How can we take advantage of all of this data at our fingertips? Using feature functions that encode extra information is one good way. Unfortunately, as Moore (2005) points out, it is usually difficult to extend a given generative model with feature functions without changing the entire generative story. This difficulty has motivated much recent work in discriminative modeling for word alignment (Moore, 2005; Ittycheriah and Roukos, 2005; Liu et al., 2005; Taskar et al., 2005; Blunsom and Cohn, 2006; Lacoste-Julien et al., 2006; Moore et al., 2006).

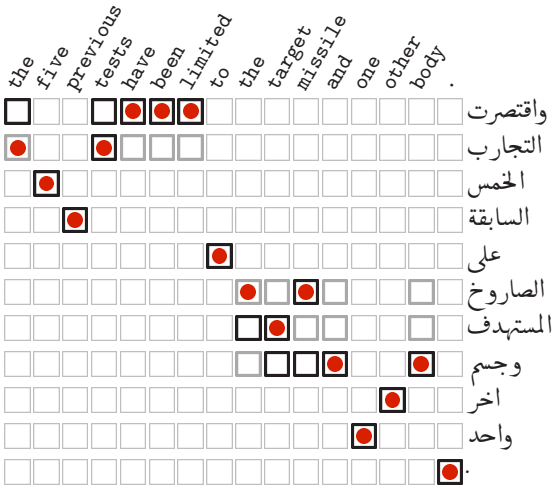

Figure 1: Model-4 alignment vs. a gold standard. Circles represent links in a human-annotated alignment, and black boxes represent links in the Model-4 alignment. Bold gray boxes show links gained after fully connecting the alignment.

We present in this paper a discriminative alignment model trained on relatively little data, with a simple, yet powerful hierarchical search procedure. We borrow ideas from both *k*-best parsing (Klein and Manning, 2001; Huang and Chiang, 2005; Huang, 2008) and forest-based, and hierarchical phrase-based translation (Huang and Chiang, 2007; Chiang, 2007), and apply them to word alignment.

Using a foreign string and an English parse tree as input, we formulate a bottom-up search on the parse tree, with the structure of the tree as a backbone for building a hypergraph of possible alignments. Our algorithm yields a forest of

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 157–166,
Uppsala, Sweden, 11-16 July 2010.

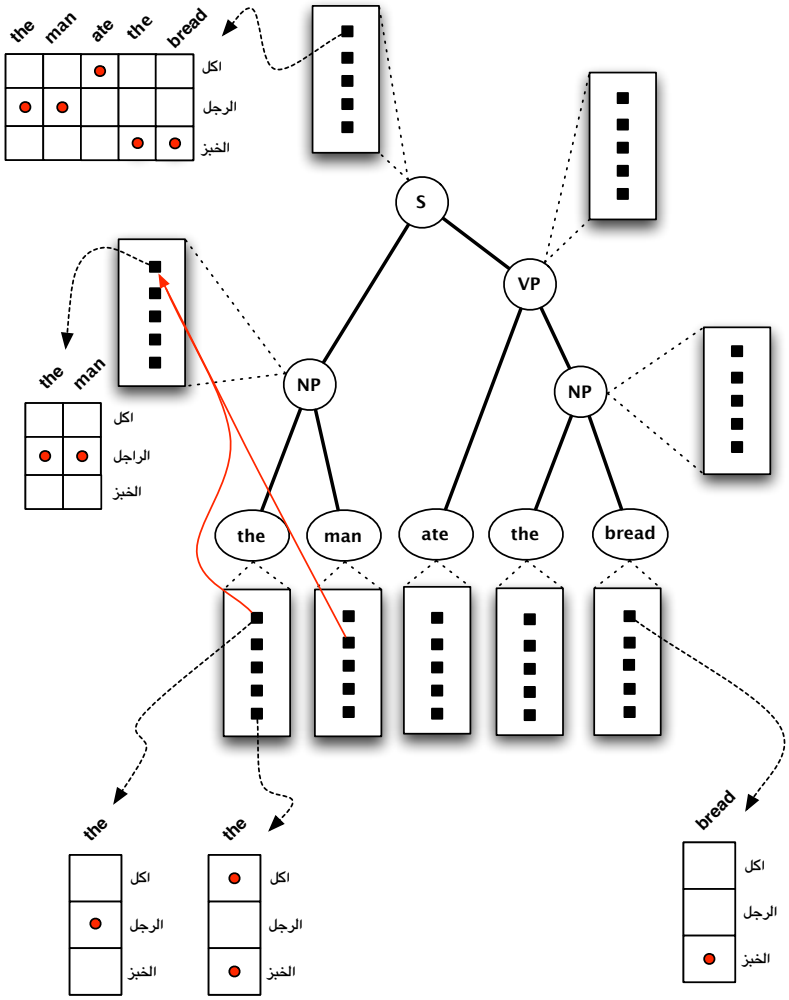

Figure 2: Example of approximate search through a hypergraph with beam size = 5. Each black square implies a partial alignment. Each partial alignment at each node is ranked according to its model score. In this figure, we see that the partial alignment implied by the 1-best hypothesis at the leftmost NP node is constructed by composing the best hypothesis at the terminal node labeled "the" and the 2nd-best hypothesis at the terminal node labeled "man". (We ignore terminal nodes in this toy example.) Hypotheses at the root node imply full alignment structures.

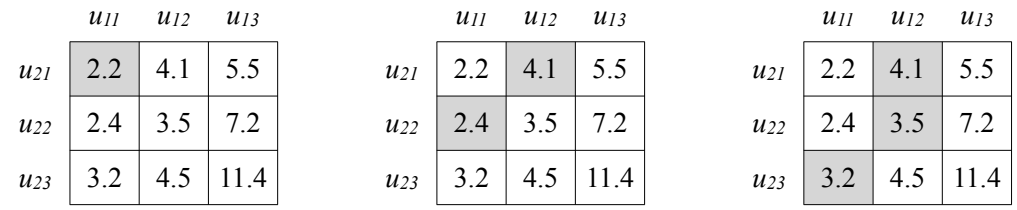
word alignments, from which we can efficiently extract the k-best. We handle an arbitrary number of features, compute them efficiently, and score alignments using a linear model. We train the parameters of the model using averaged perceptron (Collins, 2002) modified for structured outputs, but can easily fit into a max-margin or related framework. Finally, we use relatively little training data to achieve accurate word alignments. Our model can generate arbitrary alignments and learn from arbitrary gold alignments.

2 Word Alignment as a Hypergraph

Algorithm input The input to our alignment algorithm is a sentence-pair (e_1^n, f_1^m) and a parse tree over one of the input sentences. In this work, we parse our English data, and for each sentence $E = e_1^n$, let T be its syntactic parse. To generate parse trees, we use the Berkeley parser (Petrov et al., 2006), and use Collins head rules (Collins, 2003) to head-out binarize each tree.

Overview We present a brief overview here and delve deeper in Section 2.1. Word alignments are built bottom-up on the parse tree. Each node v in the tree holds *partial alignments* sorted by score.



(a) Score the left corner alignment first. Assume it is the 1-best. Numbers in the rest of the boxes are hidden at this point.

(b) Expand the frontier of alignments. We are now looking for the 2nd best.

(c) Expand the frontier further. After this step we have our top k alignments.

Figure 3: Cube pruning with alignment hypotheses to select the top-k alignments at node v with children $\langle u_1, u_2 \rangle$. In this example, $k = 3$. Each box represents the combination of two partial alignments to create a larger one. The score in each box is the sum of the scores of the child alignments plus a combination cost.

Each partial alignment comprises the columns of the alignment matrix for the e-words spanned by v, and each is scored by a linear combination of feature functions. See Figure 2 for a small example.

Initial partial alignments are enumerated and scored at preterminal nodes, each spanning a single column of the word alignment matrix. To speed up search, we can prune at each node, keeping a beam of size k. In the diagram depicted in Figure 2, the beam is size $k = 5$.

From here, we traverse the tree nodes bottom-up, combining partial alignments from child nodes until we have constructed a single full alignment at the root node of the tree. If we are interested in the k-best, we continue to populate the root node until we have k alignments.[1]

We use one set of feature functions for preterminal nodes, and another set for nonterminal nodes. This is analogous to local and nonlocal feature functions for parse-reranking used by Huang (2008). Using nonlocal features at a nonterminal node emits a combination cost for composing a set of child partial alignments.

Because combination costs come into play, we use cube pruning (Chiang, 2007) to approximate the k-best combinations at some nonterminal node v. Inference is exact when only local features are used.

Assumptions There are certain assumptions related to our search algorithm that we must make: (1) that using the structure of 1-best English syntactic parse trees is a reasonable way to frame and drive our search, and (2) that F-measure approximately decomposes over hyperedges.

We perform an oracle experiment to validate these assumptions. We find the oracle for a given (T,e,f) triple by proceeding through our search algorithm, forcing ourselves to always select correct links with respect to the gold alignment when possible, breaking ties arbitrarily. The the F_1 score of our oracle alignment is 98.8%, given this "perfect" model.

2.1 Hierarchical search

Initial alignments We can construct a word alignment hierarchically, bottom-up, by making use of the structure inherent in syntactic parse trees. We can think of building a word alignment as filling in an $M \times N$ matrix (Figure 1), and we begin by visiting each preterminal node in the tree. Each of these nodes spans a single e word. (Line 2 in Algorithm 1).

From here we can assign links from each e word to zero or more f words (Lines 6–14). At this level of the tree the span size is 1, and the partial alignment we have made spans a single column of the matrix. We can make many such partial alignments depending on the links selected. Lines 5 through 9 of Algorithm 1 enumerate either the null alignment, single-link alignments, or two-link alignments. Each partial alignment is scored and stored in a sorted heap (Lines 9 and 13).

In practice enumerating all two-link alignments can be prohibitive for long sentence pairs; we set a practical limit and score only pairwise combina-

[1] We use approximate dynamic programming to store alignments, keeping only scored lists of pointers to initial single-column spans. Each item in the list is a derivation that implies a partial alignment.

Algorithm 1: Hypergraph Alignment

Input:
Source sentence e_1^n
Target sentence f_1^m
Parse tree T over e_1^n
Set of feature functions $\mathbf{h}$
Weight vector $\mathbf{w}$
Beam size k

Output:
A k-best list of alignments over e_1^n and f_1^m

1 **function** ALIGN(e_1^n, f_1^m, T)
2 **for** $v \in T$ *in bottom-up order* **do**
3 $\alpha_v \leftarrow \emptyset$
4 **if** IS-PRETERMINALNODE(v) **then**
5 $i \leftarrow$ index-of(v)
6 **for** $j = 0$ **to** m **do**
7 $links \leftarrow (i, j)$
8 $score \leftarrow \mathbf{w} \cdot \mathbf{h}(links, v, e_1^n, f_1^m)$
9 PUSH(α_v, $\langle score, links \rangle$, k)
10 **for** $k = j + 1$ **to** m **do**
11 $links \leftarrow (i, j), (i, k)$
12 $score \leftarrow \mathbf{w} \cdot \mathbf{h}(links, v, e_1^n, f_1^m)$
13 PUSH(α_v, $\langle score, links \rangle$, k)
14 **end**
15 **end**
16 **else**
17 $\alpha_v \leftarrow$ GROWSPAN(children(v), k)
18 **end**
19 **end**
20 **end**
21 **function** GROWSPAN($\langle u_1, u_2 \rangle, k$)
22 **return** CUBEPRUNING($\langle \alpha_{u_1}, \alpha_{u_2} \rangle, k$,**w**,**h**)
23 **end**

tions of the top $n = \max\left\{\frac{|f|}{2}, 10\right\}$ scoring single-link alignments.

We limit the number of total partial alignments α_v kept at each node to k. If at any time we wish to push onto the heap a new partial alignment when the heap is full, we pop the current worst off the heap and replace it with our new partial alignment if its score is better than the current worst.

Building the hypergraph We now visit internal nodes (Line 16) in the tree in bottom-up order. At each nonterminal node v we wish to combine the partial alignments of its children $u_1, \ldots, u_c$. We use cube pruning (Chiang, 2007; Huang and Chiang, 2007) to select the k-best combinations of the partial alignments of $u_1, \ldots, u_c$ (Line 19). Note

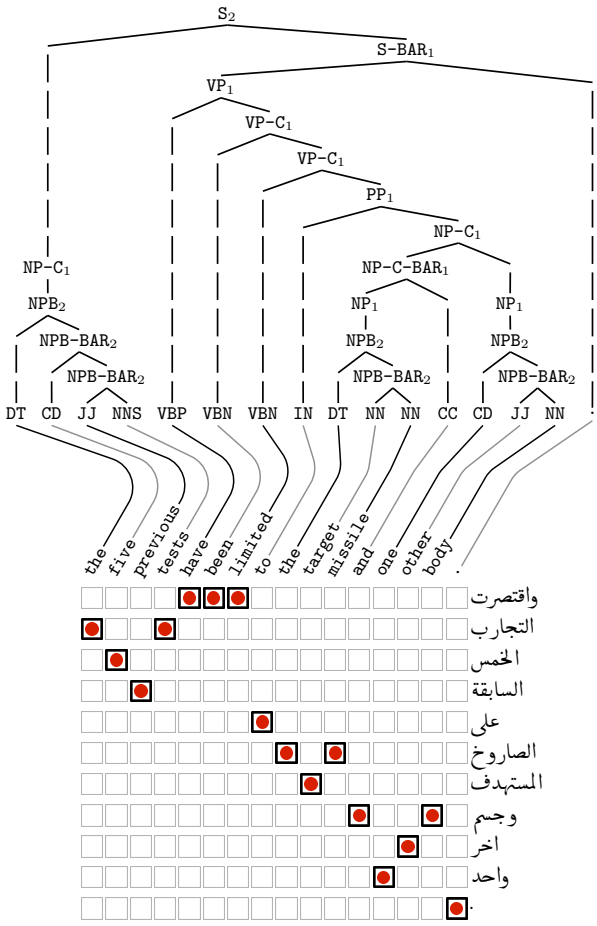


Figure 4: Correct version of Figure 1 after hypergraph alignment. Subscripts on the nonterminal labels denote the branch containing the head word for that span.

that Algorithm 1 assumes a binary tree[2], but is not necessary. In the general case, cube pruning will operate on a d-dimensional hypercube, where d is the branching factor of node v.

We cannot enumerate and score every possibility; without the cube pruning approximation, we will have k^c possible combinations at each node, exploding the search space exponentially. Figure 3 depicts how we select the top-k alignments at a node v from its children $\langle u_1, u_2 \rangle$.

3 Discriminative training

We incorporate all our new features into a linear model and learn weights for each using the online averaged perceptron algorithm (Collins, 2002) with a few modifications for structured outputs inspired by Chiang et al. (2008). We define:

[2]We find empirically that using binarized trees reduces search errors in cube pruning.

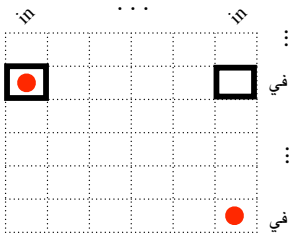

Figure 5: A common problem with GIZA++ Model 4 alignments is a weak distortion model. The second English "in" is aligned to the wrong Arabic token. Circles show the gold alignment.

$$\gamma(y) = \ell(y_i, y) + \mathbf{w} \cdot (\mathbf{h}(y_i) - \mathbf{h}(y)) \quad (1)$$

where $\ell(y_i,y)$ is a loss function describing how bad it is to guess y when the correct answer is y_i. In our case, we define $\ell(y_i,y)$ as $1-F_1(y_i,y)$. We select the oracle alignment according to:

$$y^+ = \arg\min_{y \in \text{CAND}(x)} \gamma(y) \quad (2)$$

where $\text{CAND}(x)$ is a set of hypothesis alignments generated from input x. Instead of the traditional oracle, which is calculated solely with respect to the loss $\ell(y_i,y)$, we choose the oracle that jointly minimizes the loss and the difference in model score to the true alignment. Note that Equation 2 is equivalent to maximizing the sum of the F-measure and model score of y:

$$y^+ = \arg\max_{y \in \text{CAND}(x)} (F_1(y_i, y) + \mathbf{w} \cdot \mathbf{h}(y)) \quad (3)$$

Let $\hat{y}$ be the 1-best alignment according to our model:

$$\hat{y} = \arg\max_{y \in \text{CAND}(x)} \mathbf{w} \cdot \mathbf{h}(y) \quad (4)$$

Then, at each iteration our weight update is:

$$\mathbf{w} \leftarrow \mathbf{w} + \eta(\mathbf{h}(y^+) - \mathbf{h}(\hat{y})) \quad (5)$$

where η is a learning rate parameter.[3] We find that this more conservative update gives rise to a much more stable search. After each iteration, we expect y^+ to get closer and closer to the true y_i.

4 Features

Our simple, flexible linear model makes it easy to throw in many features, mapping a given complex alignment structure into a single high-dimensional feature vector. Our hierarchical search framework allows us to compute these features when needed, and affords us extra useful syntactic information.

We use two classes of features: *local* and *non-local*. Huang (2008) defines a feature h to be local if and only if it can be factored among the local productions in a tree, and non-local otherwise. Analogously for alignments, our class of local features are those that can be factored among the local partial alignments competing to comprise a larger span of the matrix, and non-local otherwise. These features score a set of links and the words connected by them.

Feature development Our features are inspired by analysis of patterns contained among our gold alignment data and automatically generated parse trees. We use both local lexical and nonlocal structural features as described below.

4.1 Local features

These features fire on single-column spans.

- From the output of GIZA++ Model 4, we compute **lexical probabilities** $p(e \mid f)$ and $p(f \mid e)$, as well as a **fertility table** $\phi(e)$. From the fertility table, we fire features $\phi_0(e)$, $\phi_1(e)$, and $\phi_{2+}(e)$ when a word e is aligned to zero, one, or two or more words, respectively. Lexical probability features $p(e \mid f)$ and $p(f \mid e)$ fire when a word e is aligned to a word f.

- Based on these features, we include a binary **lexical-zero** feature that fires if both $p(e \mid f)$ and $p(f \mid e)$ are equal to zero for a given word pair (e, f). Negative weights essentially penalize alignments with links never seen before in the Model 4 alignment, and positive weights encourage such links. We employ a separate instance of this feature for each English part-of-speech tag: $p(f \mid e, t)$.

  We learn a different feature weight for each. Critically, this feature tells us how much to trust alignments involving nouns, verbs, adjectives, function words, punctuation, etc. from the Model 4 alignments from which our $p(e \mid f)$ and $p(f \mid e)$ tables are built. Table 1 shows a sample of learned weights. Intuitively, alignments involving English parts-of-speech more likely to be content words (e.g. NNPS, NNS, NN) are more trustworthy

[3] We set η to 0.05 in our experiments.

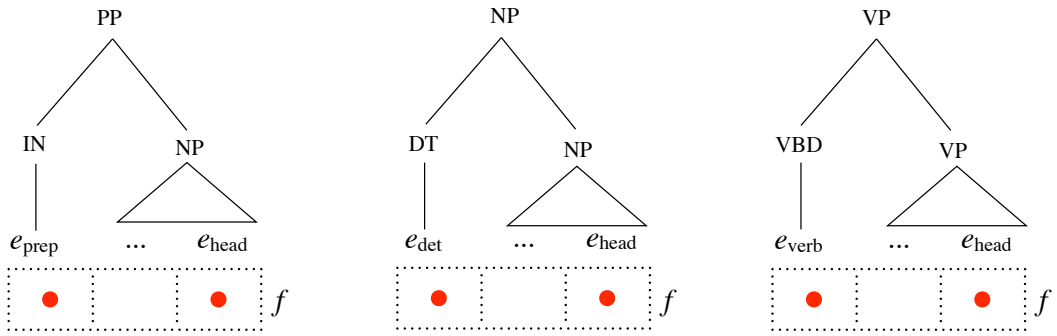

Figure 6: Features PP-NP-head, NP-DT-head, and VP-VP-head fire on these tree-alignment patterns. For example, PP-NP-head fires exactly when the head of the PP is aligned to exactly the same f words as the head of it's sister NP.

	Penalty
NNPS	−1.11
NNS	−1.03
NN	−0.80
NNP	−0.62
VB	−0.54
VBG	−0.52
JJ	−0.50
JJS	−0.46
VBN	−0.45
⋮	⋮
POS	−0.0093
EX	−0.0056
RP	−0.0037
WP$	−0.0011
TO	0.037
	Reward

Table 1: A sampling of learned weights for the **lexical zero** feature. Negative weights penalize links never seen before in a baseline alignment used to initialize lexical $p(e \mid f)$ and $p(f \mid e)$ tables. Positive weights outright reward such links.

than those likely to be function words (e.g. TO, RP, EX), where the use of such words is often radically different across languages.

- We also include a measure of **distortion**. This feature returns the distance to the diagonal of the matrix for any link in a partial alignment. If there is more than one link, we return the distance of the link farthest from the diagonal.

- As a lexical backoff, we include a **tag probability** feature, $p(t \mid f)$ that fires for some link (e, f) if the part-of-speech tag of e is t. The conditional probabilities in this table are computed from our parse trees and the baseline Model 4 alignments.

- In cases where the lexical probabilities are too strong for the distortion feature to overcome (see Figure 5), we develop the **multiple-distortion** feature. Although local features do not know the partial alignments at other spans, they do have access to the entire English sentence at every step because our input is constant. If some e exists more than once in e_1^n we fire this feature on all links containing word e, returning again the distance to the diagonal for that link. We learn a strong negative weight for this feature.

- We find that binary **identity** and **punctuation-mismatch** features are important. The binary identity feature fires if $e = f$, and proves useful for untranslated numbers, symbols, names, and punctuation in the data. Punctuation-mismatch fires on any link that causes nonpunctuation to be aligned to punctuation.

Additionally, we include fine-grained versions of the lexical probability, fertility, and distortion features. These fire for for each link (e, f) and part-of-speech tag. That is, we learn a separate weight for each feature for each part-of-speech tag in our data. Given the tag of e, this affords the model the ability to pay more or less attention to the features described above depending on the tag given to e.

Arabic-English specific features We describe here language specific features we implement to exploit shallow Arabic morphology.

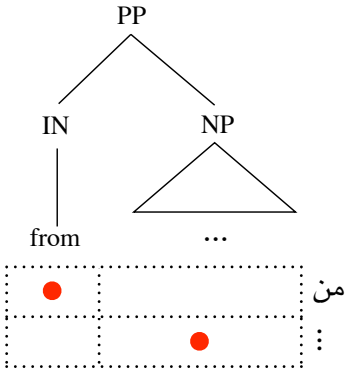

Figure 7: This figure depicts the tree/alignment structure for which the feature **PP-from-prep** fires. The English preposition "from" is aligned to Arabic word من. Any aligned words in the span of the sister NP are aligned to words following من. English preposition structure commonly matches that of Arabic in our gold data. This family of features captures these observations.

- We observe the Arabic prefix و, transliterated `w-` and generally meaning *and*, to prepend to most any word in the lexicon, so we define features $p_{\neg w}(e \mid f)$ and $p_{\neg w}(f \mid e)$. If f begins with `w-`, we strip off the prefix and return the values of $p(e \mid f)$ and $p(f \mid e)$. Otherwise, these features return 0.
- We also include analogous feature functions for several functional and pronominal prefixes and suffixes.[4]

4.2 Nonlocal features

These features comprise the combination cost component of a partial alignment score and may fire when concatenating two partial alignments to create a larger span. Because these features can look into any two arbitrary subtrees, they are considered nonlocal features as defined by Huang (2008).

- Features **PP-NP-head**, **NP-DT-head**, and **VP-VP-head** (Figure 6) all exploit headwords on the parse tree. We observe English prepositions and determiners to often align to the headword of their sister. Likewise, we observe the head of a VP to align to the head of an immediate sister VP.

In Figure 4, when the search arrives at the left-most NPB node, the NP-DT-head feature will fire given this structure and links over the span `[the ... tests]`. When search arrives at the second NPB node, it will fire given the structure and links over the span `[the ... missle]`, but will not fire at the right-most NPB node.

- Local lexical preference features compete with the headword features described above. However, we also introduce nonlocal lexicalized features for the most common types of English and foreign prepositions to also compete with these general headword features.

  PP features **PP-of-prep**, **PP-from-prep**, **PP-to-prep**, **PP-on-prep**, and **PP-in-prep** fire at any PP whose left child is a preposition and right child is an NP. The head of the PP is one of the enumerated English prepositions and is aligned to any of the three most common foreign words to which it has also been observed aligned in the gold alignments. The last constraint on this pattern is that all words under the span of the sister NP, if aligned, must align to words following the foreign preposition. Figure 7 illustrates this pattern.

- Finally, we have a **tree-distance** feature to avoid making too many many-to-one (from many English words to a single foreign word) links. This is a simplified version of and similar in spirit to the tree distance metric used in (DeNero and Klein, 2007). For any pair of links (e_i, f) and (e_j, f) in which the e words differ but the f word is the same token in each, return the tree height of first common ancestor of e_i and e_j.

  This feature captures the intuition that it is much worse to align two English words at different ends of the tree to the same foreign word, than it is to align two English words under the same NP to the same foreign word.

  To see why a string distance feature that counts only the flat horizontal distance from e_i to e_j is not the best strategy, consider the following. We wish to align a determiner to the same f word as its sister head noun under the same NP. Now suppose there are several intermediate adjectives separating the determiner and noun. A string distance met-

[4] Affixes used by our model are currently: بـ, لـ, الـ, بالـ, ـي, ـكم, ـكما, ـهم, ـهما. Others either we did not experiment with, or seemed to provide no significant benefit, and are not included.

ric, with no knowledge of the relationship between determiner and noun will levy a much heavier penalty than its tree distance analog.

5 Related Work

Recent work has shown the potential for syntactic information encoded in various ways to support inference of superior word alignments. Very recent work in word alignment has also started to report downstream effects on BLEU score.

Cherry and Lin (2006) introduce soft syntactic ITG (Wu, 1997) constraints into a discriminative model, and use an ITG parser to constrain the search for a Viterbi alignment. Haghighi et al. (2009) confirm and extend these results, showing BLEU improvement for a hierarchical phrase-based MT system on a small Chinese corpus. As opposed to ITG, we use a linguistically motivated phrase-structure tree to drive our search and inform our model. And, unlike ITG-style approaches, our model can generate arbitrary alignments and learn from arbitrary gold alignments.

DeNero and Klein (2007) refine the distortion model of an HMM aligner to reflect tree distance instead of string distance. Fossum et al. (2008) start with the output from GIZA++ Model-4 union, and focus on increasing precision by deleting links based on a linear discriminative model exposed to syntactic and lexical information.

Fraser and Marcu (2007) take a semi-supervised approach to word alignment, using a small amount of gold data to further tune parameters of a headword-aware generative model. They show a significant improvement over a Model-4 union baseline on a very large corpus.

6 Experiments

We evaluate our model and and resulting alignments on Arabic-English data against those induced by IBM Model-4 using GIZA++ (Och and Ney, 2003) with both the union and grow-diag-final heuristics. We use 1,000 sentence pairs and gold alignments from LDC2006E86 to train model parameters: 800 sentences for training, 100 for testing, and 100 as a second held-out development set to decide when to stop perceptron training. We also align the test data using GIZA++[5] along with 50 million words of English.

[5]We use a standard training procedure: 5 iterations of Model-1, 5 iterations of HMM, 3 iterations of Model-3, and 3 iterations of Model-4.

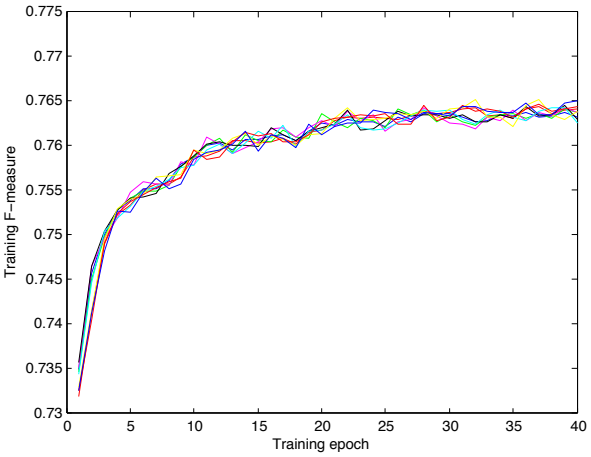

Figure 8: Learning curves for 10 random restarts over time for parallel averaged perceptron training. These plots show the current F-measure on the training set as time passes. Perceptron training here is quite stable, converging to the same general neighborhood each time.

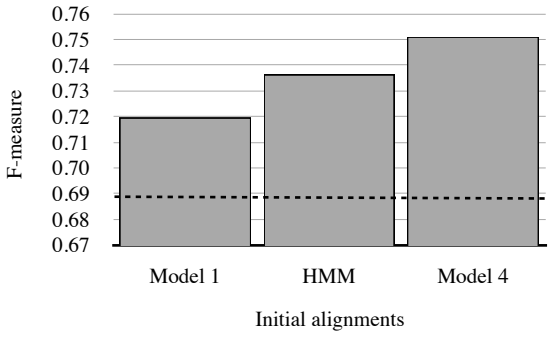

Figure 9: Model robustness to the initial alignments from which the $p(e \mid f)$ and $p(f \mid e)$ features are derived. The dotted line indicates the baseline accuracy of GIZA++ Model 4 alone.

6.1 Alignment Quality

We empirically choose our beam size k from the results of a series of experiments, setting k=1, 2, 4, 8, 16, 32, and 64. We find setting $k = 16$ to yield the highest accuracy on our held-out test data. Using wider beams results in higher F-measure on training data, but those gains do not translate into higher accuracy on held-out data.

The first three columns of Table 2 show the balanced F-measure, Precision, and Recall of our alignments versus the two GIZA++ Model-4 baselines. We report an F-measure 8.6 points over Model-4 union, and 6.3 points over Model-4 grow-diag-final.

	F	P	R	Arabic/English BLEU	# Unknown Words
M4 (union)	.665	.636	.696	45.1	2,538
M4 (grow-diag-final)	.688	.702	.674	46.4	2,262
Hypergraph alignment	**.751**	**.780**	**.724**	**47.5**	**1,610**

Table 2: F-measure, Precision, Recall, the resulting BLEU score, and number of unknown words on a held-out test corpus for three types of alignments. BLEU scores are case-insensitive IBM BLEU. We show a 1.1 BLEU increase over the strongest baseline, Model-4 grow-diag-final. This is statistically significant at the $p < 0.01$ level.

Figure 8 shows the stability of the search procedure over ten random restarts of parallel averaged perceptron training with 40 CPUs. Training examples are randomized at each epoch, leading to slight variations in learning curves over time but all converge into the same general neighborhood.

Figure 9 shows the robustness of the model to initial alignments used to derive lexical features $p(e \mid f)$ and $p(f \mid e)$. In addition to IBM Model 4, we experiment with alignments from Model 1 and the HMM model. In each case, we significantly outperform the baseline GIZA++ Model 4 alignments on a heldout test set.

6.2 MT Experiments

We align a corpus of 50 million words with GIZA++ Model-4, and extract translation rules from a 5.4 million word core subset. We align the same core subset with our trained hypergraph alignment model, and extract a second set of translation rules. For each set of translation rules, we train a machine translation system and decode a held-out test corpus for which we report results below.

We use a syntax-based translation system for these experiments. This system transforms Arabic strings into target English syntax trees Translation rules are extracted from (e-tree, f-string, alignment) triples as in (Galley et al., 2004; Galley et al., 2006).

We use a randomized language model (similar to that of Talbot and Brants (2008)) of 472 million English words. We tune the the parameters of the MT system on a held-out development corpus of 1,172 parallel sentences, and test on a held-out parallel corpus of 746 parallel sentences. Both corpora are drawn from the NIST 2004 and 2006 evaluation data, with no overlap at the document or segment level with our training data.

Columns 4 and 5 in Table 2 show the results of our MT experiments. Our hypergraph alignment algorithm allows us a 1.1 BLEU increase over the best baseline system, Model-4 grow-diag-final. This is statistically significant at the $p < 0.01$ level. We also report a 2.4 BLEU increase over a system trained with alignments from Model-4 union.

7 Conclusion

We have opened up the word alignment task to advances in hypergraph algorithms currently used in parsing and machine translation decoding. We treat word alignment as a parsing problem, and by taking advantage of English syntax and the hypergraph structure of our search algorithm, we report significant increases in both F-measure and BLEU score over standard baselines in use by most state-of-the-art MT systems today.

"Was it good? It was provocative." Learning the meaning of scalar adjectives

Marie-Catherine de Marneffe, Christopher D. Manning and **Christopher Potts**

{mcdm,manning,cgpotts}@stanford.edu

Abstract

Texts and dialogues often express information indirectly. For instance, speakers' answers to yes/no questions do not always straightforwardly convey a 'yes' or 'no' answer. The intended reply is clear in some cases (*Was it good? It was great!*) but uncertain in others (*Was it acceptable? It was unprecedented.*). In this paper, we present methods for interpreting the answers to questions like these which involve scalar modifiers. We show how to ground scalar modifier meaning based on data collected from the Web. We learn scales between modifiers and infer the extent to which a given answer conveys 'yes' or 'no'. To evaluate the methods, we collected examples of question–answer pairs involving scalar modifiers from CNN transcripts and the Dialog Act corpus and use response distributions from Mechanical Turk workers to assess the degree to which each answer conveys 'yes' or 'no'. Our experimental results closely match the Turkers' response data, demonstrating that meanings can be learned from Web data and that such meanings can drive pragmatic inference.

1 Introduction

An important challenge for natural language processing is how to learn not only basic linguistic meanings but also how those meanings are systematically enriched when expressed in context. For instance, answers to polar (yes/no) questions do not always explicitly contain a 'yes' or 'no', but rather give information that the hearer can use to infer such an answer in a context with some degree of certainty. Hockey et al. (1997) find that 27% of answers to polar questions do not contain a direct 'yes' or 'no' word, 44% of which they regard as failing to convey a clear 'yes' or 'no' response. In some cases, interpreting the answer is straightforward (*Was it bad? It was terrible.*), but in others, what to infer from the answer is unclear (*Was it good? It was provocative.*). It is even common for the speaker to explicitly convey his own uncertainty with such answers.

In this paper, we focus on the interpretation of answers to a particular class of polar questions: ones in which the main predication involves a gradable modifier (e.g., *highly unusual*, *not good*, *little*) and the answer either involves another gradable modifier or a numerical expression (e.g., *seven years old*, *twenty acres of land*). Interpreting such question–answer pairs requires dealing with modifier meanings, specifically, learning context-dependent scales of expressions (Horn, 1972; Fauconnier, 1975) that determine how, and to what extent, the answer as a whole resolves the issue raised by the question.

We propose two methods for learning the knowledge necessary for interpreting indirect answers to questions involving gradable adjectives, depending on the type of predications in the question and the answer. The first technique deals with pairs of modifiers: we hypothesized that online, informal review corpora in which people's comments have associated ratings would provide a general-purpose database for mining scales between modifiers. We thus use a large collection of online reviews to learn orderings between adjectives based on contextual entailment (*good* < *excellent*), and employ this scalar relationship to infer a yes/no answer (subject to negation and other qualifiers). The second strategy targets numerical answers. Since it is unclear what kind of corpora would contain the relevant information, we turn to the Web in general: we use distributional information retrieved via Web searches to assess whether the numerical measure counts as a posi-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 167–176,
Uppsala, Sweden, 11-16 July 2010.

tive or negative instance of the adjective in question. Both techniques exploit the same approach: using texts (the Web) to learn meanings that can drive pragmatic inference in dialogue. This paper demonstrates to some extent that meaning can be grounded from text in this way.

2 Related work

Indirect speech acts are studied by Clark (1979), Perrault and Allen (1980), Allen and Perrault (1980) and Asher and Lascarides (2003), who identify a wide range of factors that govern how speakers convey their intended messages and how hearers seek to uncover those messages from uncertain and conflicting signals. In the computational literature, Green and Carberry (1994, 1999) provide an extensive model that interprets and generates indirect answers to polar questions. They propose a logical inference model which makes use of discourse plans and coherence relations to infer *categorical* answers. However, to adequately interpret indirect answers, the uncertainty inherent in some answers needs to be captured (de Marneffe et al., 2009). While a straightforward 'yes' or 'no' response is clear in some indirect answers, such as in (1), the intended answer is less certain in other cases (2):[1]

(1) A: Do you think that's a good idea, that we just begin to ignore these numbers?
B: I think it's an excellent idea.

(2) A: Is he qualified?
B: I think he's young.

In (2), it might be that the answerer does not know about qualifications or does not want to talk about these directly, and therefore shifts the topic slightly. As proposed by Zeevat (1994) in his work on partial answers, the speaker's indirect answer might indicate that he is deliberately leaving the original question only partially addressed, while giving a fully resolving answer to another one. The hearer must then interpret the answer to work out the other question. In (2) in context, we get a sense that the speaker would resolve the issue to 'no', but that he is definitely not committed to that in any strong sense. Uncertainty can thus reside both on the speaker and the hearer sides, and the four following scenarios are attested in conversation:

a. The speaker is certain of 'yes' or 'no' and conveys that directly and successfully to the hearer.
b. The speaker is certain of 'yes' or 'no' but conveys this only partially to the hearer.
c. The speaker is uncertain of 'yes' or 'no' and conveys this uncertainty to the hearer.
d. The speaker is uncertain of 'yes' or 'no', but the hearer infers one of those with confidence.

The uncertainty is especially pressing for predications built around scalar modifiers, which are inherently vague and highly context-dependent (Kamp and Partee, 1995; Kennedy and McNally, 2005; Kennedy, 2007). For example, even if we fix the basic sense for *little* to mean 'young for a human', there is a substantial amount of gray area between the clear instances (babies) and the clear non-instances (adults). This is the source of uncertainty in (3), in which B's children fall into the gray area.

(3) A: Are your kids little?
B: I have a seven year-old and a ten year-old.

3 Corpus description

Since indirect answers are likely to arise in interviews, to gather instances of question–answer pairs involving gradable modifiers (which will serve to evaluate the learning techniques), we use online CNN interview transcripts from five different shows aired between 2000 and 2008 (Anderson Cooper, Larry King Live, Late Edition, Lou Dobbs Tonight, The Situation Room). We also searched the Switchboard Dialog Act corpus (Jurafsky et al., 1997). We used regular expressions and manual filtering to find examples of two-utterance dialogues in which the question and the reply contain some kind of gradable modifier.

3.1 Types of question–answer pairs

In total, we ended up with 224 question–answer pairs involving gradable adjectives. However our collection contains different types of answers, which naturally fall into two categories: (I) in 205 dialogues, both the question and the answer contain a gradable modifier; (II) in 19 dialogues, the reply contains a numerical measure (as in (3) above and (4)).

[1] Here and throughout, the examples come from the corpus described in section 3.

	Modification in answer	Example	Count
I	Other adjective	(1), (2)	125
	Adverb - same adjective	(5)	55
	Negation - same adjective	(6), (7)	21
	Omitted adjective	(8)	4
II	Numerical measure	(3), (4)	19

Table 1: Types of question–answer pairs, and counts in the corpus.

I	Modification in answer	Mean	SD
	Other adjective	1.1	0.6
	Adverb - same adjective	0.8	0.6
	Negation - same adjective	1.0	0.5
	Omitted adjective	1.1	0.2
II	Numerical measure	1.5	0.2

Table 2: Mean entropy values and standard deviation obtained in the Mechanical Turk experiment for each question–answer pair category.

(4) A: Have you been living there very long?
B: I'm in here right now about twelve and a half years.

Category I, which consists of pairs of modifiers, can be further divided. In most dialogues, the answer contains another adjective than the one used in the question, such as in (1). In others, the answer contains the same adjective as in the question, but modified by an adverb (e.g., *very*, *basically*, *quite*) as in (5) or a negation as in (6).

(5) A: That seems to be the biggest sign of progress there. Is that accurate?
B: That's absolutely accurate.

(6) A: Are you bitter?
B: I'm not bitter because I'm a soldier.

The negation can be present in the main clause when the adjectival predication is embedded, as in example (7).

(7) A: [. . .] Is that fair?
B: I don't think that's a fair statement.

In a few cases, when the question contains an adjective modifying a noun, the adjective is omitted in the answer:

(8) A: Is that a huge gap in the system?
B: It is a gap.

Table 1 gives the distribution of the types appearing in the corpus.

3.2 Answer assignment

To assess the degree to which each answer conveys 'yes' or 'no' in context, we use response distributions from Mechanical Turk workers. Given a written dialogue between speakers A and B, Turkers were asked to judge what B's answer conveys: 'definite yes', 'probable yes', 'uncertain', 'probable no', 'definite no'. Within each of the two 'yes' and 'no' pairs, there is a scalar relationship, but the pairs themselves are not in a scalar relationship with each other, and 'uncertain' is arguably a separate judgment. Figure 1 shows the exact formulation used in the experiment. For each dialogue, we got answers from 30 Turkers, and we took the dominant response as the correct one though we make extensive use of the full response distributions in evaluating our approach.[2] We also computed entropy values for the distribution of answers for each item. Overall, the agreement was good: 21 items have total agreement (entropy of 0.0 — 11 in the "adjective" category, 9 in the "adverb-adjective" category and 1 in the "negation" category), and 80 items are such that a single response got chosen 20 or more times (entropy < 0.9). The dialogues in (1) and (9) are examples of total agreement. In contrast, (10) has response entropy of 1.1, and item (11) has the highest entropy of 2.2.

(9) A: Advertisements can be good or bad. Was it a good ad?
B: It was a great ad.

(10) A: Am I clear?
B: I wish you were a little more forthright.

(11) A: 91 percent of the American people still express confidence in the long-term prospect of the U.S. economy; only 8 percent are not confident. Are they overly optimistic, in your professional assessment?

[2] 120 Turkers were involved (the median number of items done was 28 and the mean 56.5). The Fleiss' Kappa score for the five response categories is 0.46, though these categories are partially ordered. For the three-category response system used in section 5, which arguably has no scalar ordering, the Fleiss' Kappa is 0.63. Despite variant individual judgments, aggregate annotations done with Mechanical Turk have been shown to be reliable (Snow et al., 2008; Sheng et al., 2008; Munro et al., 2010). Here, the relatively low Kappa scores also reflect the uncertainty inherent in many of our examples, uncertainty that we seek to characterize and come to grips with computationally.

Indirect Answers to Yes/No Questions
In the following dialogue, speaker A asks a simple Yes/No question, but speaker B answers with something more indirect and complicated.

Which of the following best captures what speaker B meant here:

- B definitely meant to convey "Yes".
- B probably meant to convey "Yes".
- B definitely meant to convey "No".
- B probably meant to convey "No".
- (I really can't tell whether B meant to convey "Yes" or "No".)

Figure 1: Design of the Mechanical Turk experiment.

B: I think it shows how wise the American people are.

Table 2 shows the mean entropy values for the different categories identified in the corpus. Interestingly, the pairs involving an adverbial modification in the answer all received a positive answer ('yes' or 'probable yes') as dominant response. All 19 dialogues involving a numerical measure had either 'probable yes' or 'uncertain' as dominant response. There is thus a significant bias for positive answers: 70% of the category I items and 74% of the category II items have a positive answer as dominant response. Examining a subset of the Dialog Act corpus, we found that 38% of the yes/no questions receive a direct positive answers, whereas 21% have a direct negative answer. This bias probably stems from the fact that people are more likely to use an overt denial expression where they need to disagree, whether or not they are responding indirectly.

4 Methods

In this section, we present the methods we propose for grounding the meanings of scalar modifiers.

4.1 Learning modifier scales and inferring yes/no answers

The first technique targets items such as the ones in category I of our corpus. Our central hypothesis is that, in polar question dialogues, the semantic relationship between the main predication P_Q in the question and the main predication P_A in the answer is the primary factor in determining whether, and to what extent, 'yes' or 'no' was intended. If P_A is at least as strong as P_Q, the intended answer is 'yes'; if P_A is weaker than P_Q, the intended answer is 'no'; and, where no reliable entailment relationship exists between P_A and P_Q, the result is uncertainty.

For example, *good* is weaker (lower on the relevant scale) than *excellent*, and thus speakers infer that the reply in example (1) above is meant to convey 'yes'. In contrast, if we reverse the order of the modifiers — roughly, *Is it a great idea?*; *It's a good idea* — then speakers infer that the answer conveys 'no'. Had B replied with *It's a complicated idea* in (1), then uncertainty would likely have resulted, since *good* and *complicated* are not in a reliable scalar relationship. Negation reverses scales (Horn, 1972; Levinson, 2000), so it flips 'yes' and 'no' in these cases, leaving 'uncertain' unchanged. When both the question and the answer contain a modifier (such as in (9–11)), the yes/no response should correlate with the extent to which the pair of modifiers can be put into a scale based on contextual entailment.

To ground such scales from text, we collected a large corpus of online reviews from IMDB. Each of the reviews in this collection has an associated star rating: one star (most negative) to ten stars (most positive). Table 3 summarizes the distribution of reviews as well as the number of words and vocabulary across the ten rating categories.

As is evident from table 3, there is a significant bias for ten-star reviews. This is a common feature of such corpora of informal, user-provided reviews (Chevalier and Mayzlin, 2006; Hu et al., 2006; Pang and Lee, 2008). However, since we do not want to incorporate the linguistically uninteresting fact that people tend to write a lot of ten-star reviews, we assume uniform priors for the rating categories. Let $\text{count}(w, r)$ be the number of tokens of word w in reviews in rating category r, and let $\text{count}(r)$ be the total word count for all words in rating category r. The probability of w given a rating category r is simply $\Pr(w|r) = \text{count}(w, r)/\,\text{count}(r)$. Then under the assumption of uniform priors, we get $\Pr(r|w) = \Pr(w|r)/\sum_{r' \in R} \Pr(w|r')$.

In reasoning about our dialogues, we rescale the rating categories by subtracting 5.5 from each, to center them at 0. This yields the scale $R =$

Rating	Reviews	Words	Vocabulary	Average words per review
1	124,587	25,389,211	192,348	203.79
2	51,390	11,750,820	133,283	228.66
3	58,051	13,990,519	148,530	241.00
4	59,781	14,958,477	156,564	250.22
5	80,487	20,382,805	188,461	253.24
6	106,145	27,408,662	225,165	258.22
7	157,005	40,176,069	282,530	255.89
8	195,378	48,706,843	313,046	249.30
9	170,531	40,264,174	273,266	236.11
10	358,441	73,929,298	381,508	206.25
Total	1,361,796	316,956,878	1,160,072	206.25

Table 3: Numbers of reviews, words and vocabulary size per rating category in the IMDB review corpus, as well as the average number of words per review.

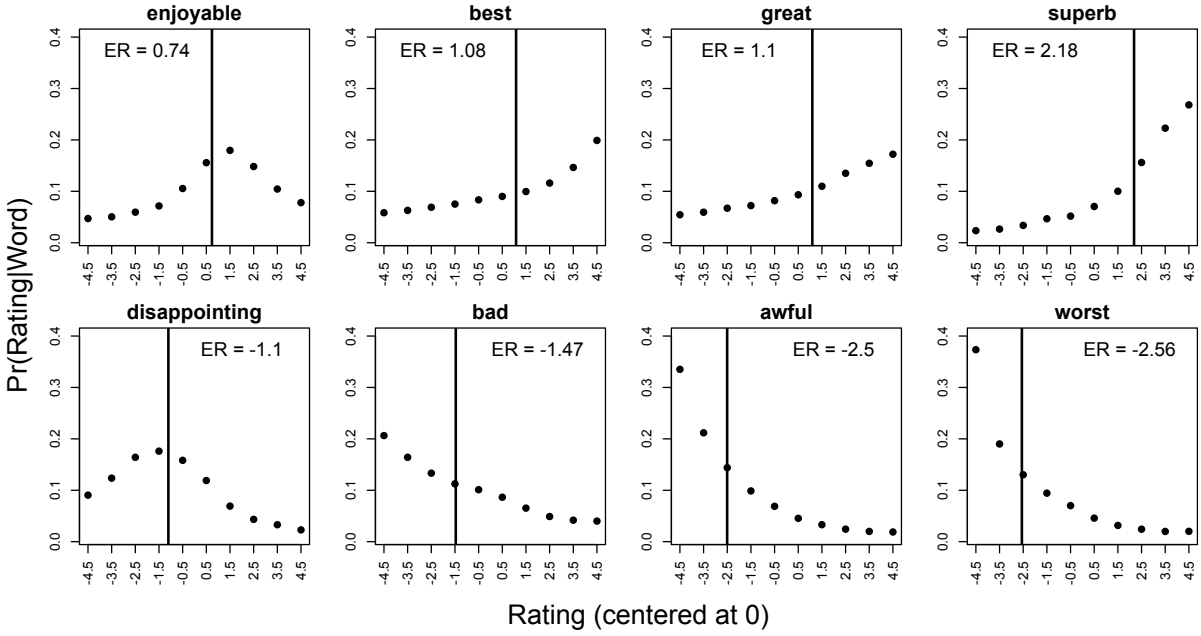

Figure 2: The distribution of some scalar modifiers across the ten rating categories. The vertical lines mark the expected ratings, defined as a weighted sum of the probability values (black dots).

$\langle -4.5, -3.5, -2.5, -1.5, -0.5, 0.5, 1.5, 2.5, 3.5, 4.5 \rangle$. Our rationale for this is that modifiers at the negative end of the scale (*bad*, *awful*, *terrible*) are not linguistically comparable to those at the positive end of the scale (*good*, *excellent*, *superb*). Each group forms its own qualitatively different scale (Kennedy and McNally, 2005). Rescaling allows us to make a basic positive vs. negative distinction. Once we have done that, an increase in absolute value is an increase in strength. In our experiments, we use expected rating values to characterize the polarity and strength of modifiers. The expected rating value for a word w is $\mathrm{ER}(w) = \sum_{r \in R} r \Pr(r|w)$. Figure 2 plots these values for a number of scalar terms, both positive and negative, across the rescaled ratings, with the vertical lines marking their ER values. The weak scalar modifiers all the way on the left are most common near the middle of the scale, with a slight positive bias in the top row and a slight negative bias in the bottom row. As we move from left to right, the bias for one end of the scale grows more extreme, until the words in question are almost never used outside of the most extreme rating category. The resulting scales correspond well with linguistic intuitions and thus provide an initial indication that the rating categories are a reliable guide to strength and polarity for scalar modifiers. We put this information to use in our dialogue corpus via the decision procedure

Let D be a dialogue consisting of (i) a polar question whose main predication is based on scalar predicate P_Q and (ii) an indirect answer whose main predication is based on scalar predicate P_A. Then:

1. if P_A or P_Q is missing from our data, infer 'Uncertain';
2. else if ER(P_Q) and ER(P_A) have different signs, infer 'No';
3. else if abs(ER(P_Q)) $\leqslant$ abs(ER(P_A)), infer 'Yes';
4. else infer 'No'.
5. In the presence of negation, map 'Yes' to 'No', 'No' to 'Yes', and 'Uncertain' to 'Uncertain'.

Figure 3: Decision procedure for using the word frequencies across rating categories in the review corpus to decide what a given answer conveys.

described in figure 3.

4.2 Interpreting numerical answers

The second technique aims at determining whether a numerical answer counts as a positive or negative instance of the adjective in the question (category II in our corpus).

Adjectives that can receive a conventional unit of measure, such as *little* or *long*, inherently possess a degree of vagueness (Kamp and Partee, 1995; Kennedy, 2007): while in the extreme cases, judgments are strong (e.g., *a six foot tall woman* can clearly be called "a tall woman" whereas *a five foot tall woman* cannot), there are borderline cases for which it is difficult to say whether the adjectival predication can truthfully be ascribed to them. A logistic regression model can capture these facts. To build this model, we gather distributional information from the Web.

For instance, in the case of (3), we can retrieve from the Web positive and negative examples of age in relation to the adjective and the modified entity "little kids". The question contains the adjective and the modified entity. The reply contains the unit of measure (here "year-old") and the numerical answer. Specifically we query the Web using Yahoo! BOSS (Academic) for *"little kids" year-old* (positive instances) as well as for *"not little kids" year-old* (negative instances). Yahoo! BOSS is an open search services platform that provides a query API for Yahoo! Web search. We then extract ages from the positive and negative snippets obtained, and we fit a logistic regression to these data. To remove noise, we discard low counts (positive and negative instances for a given unit < 5). Also, for some adjectives, such as *little* or *young*, there is an inherent ambiguity between absolute and relative uses. Ideally, a word sense disambiguation system would be used to filter these cases. For now, we extract the largest contiguous range for which the data counts are over the noise threshold.[3] When not enough data is retrieved for the negative examples, we expand the query by moving the negation outside the search phrase. We also replace the negation and the adjective by the antonyms given in WordNet (using the first sense).

The logistic regression thus has only one factor — the unit of measure (age in the case of *little kids*). For a given answer, the model assigns a probability indicating the extent to which the adjectival property applies to that answer. If the factor is a significant predictor, we can use the probabilities from the model to decide whether the answer qualifies as a positive or negative instance of the adjective in the question, and thus interpret the indirect response as a 'yes' or a 'no'. The probabilistic nature of this technique adheres perfectly to the fact that indirect answers are intimately tied up with uncertainty.

5 Evaluation and results

Our primary goal is to evaluate how well we can learn the relevant scalar and entailment relationships from the Web. In the evaluation, we thus applied our techniques to a manually coded corpus version. For the adjectival scales, we annotated each example for its main predication (modifier, or adverb–modifier bigram), including whether that predication was negated. For the numerical cases, we manually constructed the initial queries: we identified the adjective and the modified entity in the question, and the unit of measure in the answer. However, we believe that identifying the requisite predications and recognizing the presence of negation or embedding could be done automatically using dependency graphs.[4]

[3] Otherwise, our model is ruined by references to "young 80-year olds", using the relative sense of *young*, which are moderately frequent on the Web.

[4] As a test, we transformed our corpus into the Stanford dependency representation (de Marneffe et al., 2006), using the Stanford parser (Klein and Manning, 2003) and were able to automatically retrieve all negated modifier predications, except one (*We had a view of it, not a particularly good one*),

	Modification in answer	Precision	Recall
I	Other adjective	60	60
	Adverb - same adjective	95	95
	Negation - same adjective	100	100
	Omitted adjective	100	100
II	Numerical	89	40
Total		75	71

Table 4: Summary of precision and recall (%) by type.

	Response	Precision	Recall	F1
I	Yes	87	76	81
	No	57	71	63
II	Yes	100	36	53
	Uncertain	67	40	50

Table 5: Precision, recall, and F1 (%) per response category. In the case of the scalar modifiers experiment, there were just two examples whose dominant response from the Turkers was 'Uncertain', so we have left that category out of the results. In the case of the numerical experiment, there were not any 'No' answers.

To evaluate the techniques, we pool the Mechanical Turk 'definite yes' and 'probable yes' categories into a single category 'Yes', and we do the same for 'definite no' and 'probable no'. Together with 'uncertain', this makes for three-response categories. We count an inference as successful if it matches the dominant Turker response category. To use the three-response scheme in the numerical experiment, we simply categorize the probabilities as follows: 0–0.33 = 'No', 0.33–0.66 = 'Uncertain', 0.66–1.00 = 'Yes'.

Table 4 gives a breakdown of our system's performance on the various category subtypes. The overall accuracy level is 71% (159 out of 224 inferences correct). Table 5 summarizes the results per response category, for the examples in which both the question and answer contain a gradable modifier (category I), and for the numerical cases (category II).

6 Analysis and discussion

Performance is extremely good on the "Adverb – same adjective" and "Negation – same adjective" cases because the 'Yes' answer is fairly direct for them (though adverbs like *basically* introduce an interesting level of uncertainty). The results are somewhat mixed for the "Other adjective" category.

Inferring the relation between scalar adjectives has some connection with work in sentiment detection. Even though most of the research in that domain focuses on the orientation of one term using seed sets, techniques which provide the orientation strength could be used to infer a scalar relation between adjectives. For instance, Blair-Goldensohn et al. (2008) use WordNet to develop sentiment lexicons in which each word has a positive or negative value associated with it, representing its strength. The algorithm begins with seed sets of positive, negative, and neutral terms, and then uses the synonym and antonym structure of WordNet to expand those initial sets and refine the relative strength values. Using our own seed sets, we built a lexicon using Blair-Goldensohn et al. (2008)'s method and applied it as in figure 3 (changing the ER values to sentiment scores). Both approaches achieve similar results: for the "Other adjective" category, the WordNet-based approach yields 56% accuracy, which is not significantly different from our performance (60%); for the other types in category I, there is no difference in results between the two methods. Table 6 summarizes the results per response category for the WordNet-based approach (which can thus be compared to the category I results in table 5). However in contrast to the WordNet-based approach, we require no hand-built resources: the synonym and antonym structures, as well as the strength values, are learned from Web data alone. In addition, the WordNet-based approach must be supplemented with a separate method for the numerical cases.

	Response	Precision	Recall	F1
WordNet-based	Yes	82	83	82.5
(items I)	No	60	56	58

Table 6: Precision, recall, and F1 (%) per response category for the WordNet-based approach.

In the "Other adjective" category, 31 items involve oppositional terms: canonical antonyms (e.g., *right*/*wrong*, *good*/*bad*) as well as terms that are "statistically oppositional" (e.g., *ready*/*premature*, *true*/*preposterous*, *confident*/*nervous*). "Statistically oppositional" terms are not oppositional by definition, but as a matter of contingent fact. Our technique accurately deals with most

because of a parse error which led to wrong dependencies.

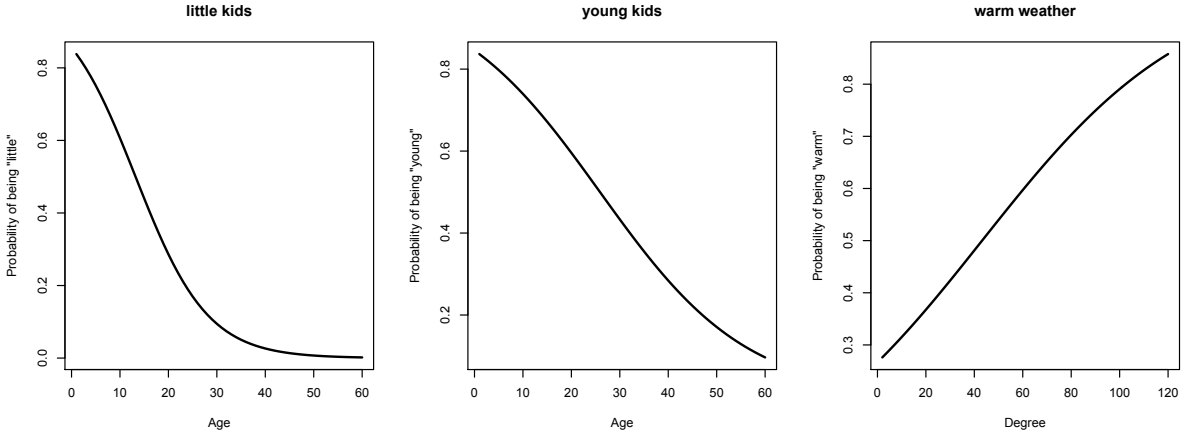

Figure 4: Probabilities of being appropriately described as “little”, “young” or “warm”, fitted on data retrieved when querying the Web for “little kids”, “young kids” and “warm weather”.

of the canonical antonyms, and also finds some contingent oppositions (*qualified/young*, *wise/ neurotic*) that are lacking in antonymy resources or automatically generated antonymy lists (Mohammad et al., 2008). Out of these 31 items, our technique correctly marks 18, whereas Mohammad et al.’s list of antonyms only contains 5 and Blair-Goldensohn et al. (2008)’s technique finds 11. Our technique is solely based on unigrams, and could be improved by adding context: making use of dependency information, as well as moving beyond unigrams.

In the numerical cases, precision is high but recall is low. For roughly half of the items, not enough negative instances can be gathered from the Web and the model lacks predictive power (as for items (4) or (12)).

(12) A: Do you happen to be working for a large firm?

B: It’s about three hundred and fifty people.

Looking at the negative hits for item (12), one sees that few give an indication about the number of people in the firm, but rather qualifications about colleagues or employees (*great people*, *people’s productivity*), or the hits are less relevant: “Most of the *people* I talked to were actually pretty optimistic. They were rosy on the job market and many had jobs, although most were *not large firm* jobs”. The lack of data comes from the fact that the queries are very specific, since the adjective depends on the product (e.g., “expensive exercise bike”, “deep pond”). However when we do get a predictive model, the probabilities corre-

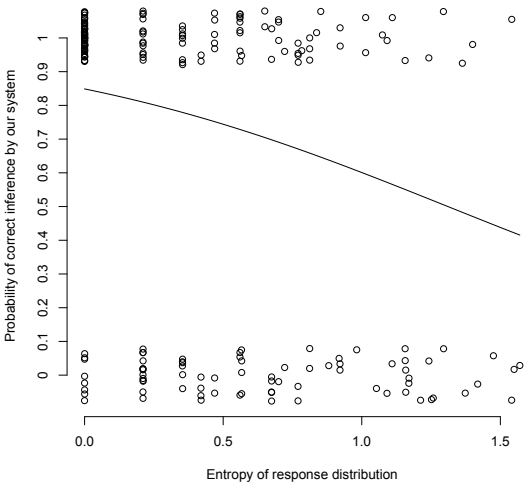

Figure 5: Correlation between agreement among Turkers and whether the system gets the correct answer. For each dialogue, we plot a circle at Turker response entropy and either 1 = correct inference or 0 = incorrect inference, except the points are jittered a little vertically to show where the mass of data lies. As the entropy rises (i.e., as agreement levels fall), the system’s inferences become less accurate. The fitted logistic regression model (black line) has a statistically significant coefficient for response entropy ($p < 0.001$).

late almost perfectly with the Turkers' responses. This happens for 8 items: "expensive to call (50 cents a minute)", "little kids (7 and 10 year-old)", "long growing season (3 months)", "lot of land (80 acres)", "warm weather (80 degrees)", "young kids (5 and 2 year-old)", "young person (31 year-old)" and "large house (2450 square feet)". In the latter case only, the system output (uncertain) doesn't correlate with the Turkers' judgment (where the dominant answer is 'probable yes' with 15 responses, and 11 answers are 'uncertain').

The logistic curves in figure 4 capture nicely the intuitions that people have about the relation between age and "little kids" or "young kids", as well as between Fahrenheit degrees and "warm weather". For "little kids", the probabilities of being little or not are clear-cut for ages below 7 and above 15, but there is a region of vagueness in between. In the case of "young kids", the probabilities drop less quickly with age increasing (an 18 year-old can indeed still be qualified as a "young kid"). In sum, when the data is available, this method delivers models which fit humans' intuitions about the relation between numerical measure and adjective, and can handle pragmatic inference.

If we restrict attention to the 66 examples on which the Turkers completely agreed about which of these three categories was intended (again pooling 'probable' and 'definite'), then the percentage of correct inferences rises to 89% (59 correct inferences). Figure 5 plots the relationship between the response entropy and the accuracy of our decision procedure, along with a fitted logistic regression model using response entropy to predict whether our system's inference was correct. The handful of empirical points in the lower left of the figure show cases of high agreement between Turkers but incorrect inference from the system. The few points in the upper right indicate low agreement between Turkers and correct inference from the system. Three of the high-agreement/incorrect-inference cases involve the adjectives *right–correct*. For low-agreement/correct-inference, the disparity could trace to context dependency: the ordering is clear in the context of product reviews, but unclear in a television interview. The analysis suggests that overall agreement is positively correlated with our system's chances of making a correct inference: our system's accuracy drops as human agreement levels drop.

7 Conclusion

We set out to find techniques for grounding basic meanings from text and enriching those meanings based on information from the immediate linguistic context. We focus on gradable modifiers, seeking to learn scalar relationships between their meanings and to obtain an empirically grounded, probabilistic understanding of the clear and fuzzy cases that they often give rise to (Kamp and Partee, 1995). We show that it is possible to learn the requisite scales between modifiers using review corpora, and to use that knowledge to drive inference in indirect responses. When the relation in question is not too specific, we show that it is also possible to learn the strength of the relation between an adjective and a numerical measure.

Abstract

Current turn-taking approaches for spoken dialogue systems rely on the speaker releasing the turn before the other can take it. This reliance results in restricted interactions that can lead to inefficient dialogues. In this paper we present a model we refer to as *Importance-Driven Turn-Bidding* that treats turn-taking as a negotiative process. Each conversant bids for the turn based on the importance of the intended utterance, and Reinforcement Learning is used to indirectly learn this parameter. We find that Importance-Driven Turn-Bidding performs better than two current turn-taking approaches in an artificial collaborative slot-filling domain. The negotiative nature of this model creates efficient dialogues, and supports the improvement of mixed-initiative interaction.

1 Introduction

As spoken dialogue systems are designed to perform ever more elaborate tasks, the need for mixed-initiative interaction necessarily grows. Mixed-initiative interaction, where agents (both artificial and human) may freely contribute to reach a solution efficiently, has long been a focus of dialogue systems research (Allen et al., 1999; Guinn, 1996). Simple slot-filling tasks might not require the flexible environment that mixed-initiative interaction brings but those of greater complexity, such as collaborative task completion or long-term planning, certainly do (Ferguson et al., 1996). However, translating this interaction into working systems has proved problematic (Walker et al., 1997), in part to issues surrounding turn-taking: the transition from one speaker to another.

Many computational turn-taking approaches seek to minimize silence and utterance overlap during transitions. This leads to the speaker controlling the turn transition. For example, systems using the Keep-Or-Release approach will not attempt to take the turn unless it is sure the user has released it. One problem with this approach is that the system might have important information to give but will be unable to get the turn. The speaker-centric nature of current approaches does not enable mixed-initiative interaction and results in inefficient dialogues. Primarily, these approaches have been motivated by smooth transitions reported in the human turn-taking studies of Sacks et al. (1974) among others.

Sacks et al. also acknowledge the negotiative nature of turn-taking, stating that the "the turn as unit is interactively determined"(p. 727). Other studies have supported this, suggesting that humans negotiate the turn assignment through the use of cues and that these cues are motivated by the importance of what the conversant wishes to contribute (Duncan and Niederehe, 1974; Yang and Heeman, 2010; Schegloff, 2000). Given this, any dialogue system hoping to interact with humans efficiently and naturally should have a negotiative and importance-driven quality to its turn-taking protocol. We believe that, by focusing on the rationale of human turn-taking behavior, a more effective turn-taking system may be achieved. We propose the Importance-Driven Turn-Bidding (IDTB) model where conversants bid for the turn based on the importance of their utterance. We use Reinforcement Learning to map a given situation to the optimal utterance and bidding behavior. By allowing conversants to bid for the turn, the IDTB model enables negotiative turn-taking and supports true mixed-initiative interaction, and with it, greater dialogue efficiency.

We compare the IDTB model to current turn-taking approaches. Using an artificial collaborative dialogue task, we show that the IDTB model enables the system and user to complete

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 177–185,
Uppsala, Sweden, 11-16 July 2010.

the task more efficiently than the other approaches. Though artificial dialogues are not ideal, they allow us to test the validity of the IDTB model before embarking on costly and time-consuming human studies. Since our primary evaluation criteria is model comparison, consistent user simulations provide a constant needed for such measures and increase the external validity of our results.

2 Current Turn-Taking Approaches

Current dialogue systems focus on the release-turn as the most important aspect of turn-taking, in which a listener will only take the turn after the speaker has released it. The simplest of these approaches only allows a single utterance per turn, after which the turn necessarily transitions to the next speaker. This Single-Utterance (SU) model has been extended to allow the speaker to keep the turn for multiple utterances: the Keep-Or-Release (KR) approach. Since the KR approach gives the speaker sole control of the turn, it is overwhelmingly speaker-centric, and so necessarily unnegotiative. This restriction is meant to encourage smooth turn-transitions, and is inspired by the order, smoothness, and predictability reported in human turn-taking studies (Duncan, 1972; Sacks et al., 1974).

Systems using the KR approach differ on how they detect the user's release-turn. Turn releases are commonly identified in two ways: either using a silence-threshold (Sutton et al., 1996), or the predictive nature of turn endings (Sacks et al., 1974) and the cues associated with them (e.g. Gravano and Hirschberg, 2009). Raux and Eskenazi (2009) used decision theory with lexical cues to predict appropriate places to take the turn. Similarly, Jonsdottir, Thorisson, and Nivel (2008) used Reinforcement Learning to reduce silences between turns and minimize overlap between utterances by learning the specific turn-taking patterns of individual speakers. Skantze and Schlangan (2009) used incremental processing of speech and prosodic turn-cues to reduce the reaction time of the system, finding that that users rated this approach as more human-like than a baseline system.

In our view, systems built using the KR turn-taking approach suffer from two deficits. First, the speaker-centricity leads to inefficient dialogues since the speaker may continue to hold the turn even when the listener has vital information to give. In addition, the lack of negotiation forces the turn to necessarily transition to the listener after the speaker releases it. The possibility that the dialogue may be better served if the listener *does not* get the turn is not addressed by current approaches.

Barge-in, which generally refers to allowing users to speak at any time (Ström and Seneff, 2000), has been the primary means to create a more flexible turn-taking environment. Yet, since barge-in recasts speaker-centric systems as user-centric, the system's contributions continue to be limited. System barge-in has also been investigated. Sato et al. (2002) used decision trees to determine whether the system should take the turn or not when the user pauses. An incremental method by DeVault, Sagae, and Traum (2009) found possible points that a system could interrupt without loss of user meaning, but failed to supply a reasonable model as to when to use such information. Despite these advances, barge-in capable systems lack a negotiative turn-taking method, and continue to be deficient for reasons similar to those described above.

3 Importance-Driven Turn-Bidding (IDTB)

We introduce the IDTB model to overcome the deficiencies of current approaches. The IDTB model has two foundational components: (1) The importance of speaking is the primary motivation behind turn-taking behavior, and (2) conversants use turn-cue strength to bid for the turn based on this importance. Importance may be broadly defined as how well the utterance leads to some predetermined conversational success, be it solely task completion or encompassing a myriad of social etiquette components.

Importance-Driven Turn-Bidding is motivated by empirical studies of human turn-conflict resolution. Yang and Heeman (2010) found an increase of turn conflicts during tighter time constraints, which suggests that turn-taking is influenced by the importance of task completion. Schlegoff (2000) proposed that persistent utterance overlap was indicative of conversants having a strong interest in holding the turn. Walker and Whittaker (1990) show that people will interrupt to remedy some understanding discrepancy, which is certainly important to the conversation's success. People communicate the importance of their utterance through turn-cues. Duncan and

Niederehe (1974) found that turn-cue strength was the best predictor of who won the turn, and this finding is consistent with the use of volume to win turns found by Yang and Heeman (2010).

The IDTB model uses turn-cue strength to bid for the turn based on the importance of the utterance. Stronger turn-cues should be used when the intended utterance is important to the overall success of the dialogue, and weaker ones when it is not. In the prototype described in Section 5, both the system and user agents bid for the turn after every utterance and the bids are conceptualized here as utterance onset: conversants should be quick to speak important utterances but slow with less important ones. This is relatively consistent with Yang and Heeman (2010). A mature version of our work will use cues in addition to utterance onset, such as those recently detailed in Gravano and Hirshberg (2009).[1]

A crucial element of our model is the judgment and quantization of utterance importance. We use Reinforcement Learning (RL) to determine importance by conceptualizing it as maximizing the reward over an entire dialogue. Whatever actions lead to a higher return may be thought of as more important than ones that do not.[2] By using RL to learn both the utterance and bid behavior, the system can find an optimal pairing between them, and choose the best combination for a given conversational situation.

4 Information State Update and Reinforcement Learning

We build our dialogue system using the Information State Update approach (Larsson and Traum, 2000) and use Reinforcement Learning for action selection (Sutton and Barto, 1998). The system architecture consists of an Information State (IS) that represents the agent's knowledge and is updated using a variety of rules. The IS also uses rules to propose possible actions. A condensed and compressed subset of the IS — the Reinforcement Learning State — is used to learn which proposed action to take (Heeman, 2007). It has been shown that using RL to learn dialogue polices is generally more effective than "hand crafted" dialogue policies since the learning algorithm may capture environmental dynamics that are unattended to by human designers (Levin et al., 2000).

Reinforcement Learning learns an optimal policy, a mapping between a state s and action a, where performing a in s leads to the lowest expected cost for the dialogue (we use minimum cost instead of maximum reward). An *ϵ-greedy* search is used to estimate Q-scores, the expected cost of some state–action pair, where the system chooses a random action with ϵ probability and the $\mathit{argmin}_a Q(s,a)$ action with 1-ϵ probability. For Q-learning, a popular RL algorithm and the one used here, ϵ is commonly set at 0.2 (Sutton and Barto, 1998). Q-learning updates $Q(s,a)$ based on the best action of the next state, given by the following equation, with the step size parameter $\alpha = 1/\sqrt{N(s,a)}$ where $N(s,a)$ is the number of times the s,a pair has been seen since the beginning of training.

$$Q(s_t,a_t) = Q(s_t,a_t) + \alpha[\mathit{cost}_{t+1} + \mathit{argmin}_a Q(s_{t+1},a) - Q(s_t,a_t)]$$

The state space should be formulated as a Markov Decision Process (MDP) for Q-learning to update Q-scores properly. An MDP relies on a first-order Markov assumption in that the transition and reward probability from some s_t, a_t pair is completely contained by that pair and is unaffected by the history $s_{t-1}a_{t-1}, s_{t-2}a_{t-2}, \ldots$. For this assumption to be met, care is required when deciding which features to include for learning. The RL State features we use are described in the following section.

5 Domain and Turn-Taking Models

In this section, we show how the IDTB approach can be implemented for a collaborative slot filling domain. We also describe the Single-Utterance and Keep-Or-Release domain implementations that we use for comparison.

5.1 Domain Task

We use a food ordering domain with two participants, the system and a user, and three slots: drink, burger, and side. The system's objective is to fill all three slots with the available fillers as quickly as possible. The user's role is to specify its desired filler for each slot, though that specific filler may not be available. The user simulation, while intended to be realistic, is not based on empirical data. Rather, it is designed to provide a rich turn-

[1] Our work (present and future) is distinct from some recent work on user pauses (Sato et al., 2002) since we treat turn-taking as an integral piece of dialogue success.

[2] We gain an inherent flexibility in using RL since the reward can be computed by a wide array of components. This is consistent with the broad definition of importance.

taking domain to evaluate the performance of different turn-taking designs. We consider this a collaborative slot-filling task since both conversants must supply information to determine the intersection of available and desired fillers.

Users have two fillers for each slot.[3] A user's top choice is either available, in which case we say that the user has adequate filler knowledge, or their second choice will be available, in which we say it has inadequate filler knowledge. This assures that at least one of the user's filler is available. Whether a user has adequate or inadequate filler knowledge is probabilistically determined based on user type, which will be described in Section 5.2.

Table 1: Agent speech acts

Agent	Actions
System	query slot, inform [yes/no], inform avail. slot fillers, inform filler not available, bye
User	inform slot filler, query filler availability

We model conversations at the speech act level, shown in Table 1, and so do not model the actual words that the user and system might say. Each agent has an Information State that proposes possible actions. The IS is made up of a number of variables that model the environment and is slightly different for the system and the user. Shared variables include *QUD*, a stack which manages the questions under discussion; *lastUtterance*, the previous utterance, and *slotList*, a list of the slot names. The major system specific IS variables that are not included in the RL State are *availSlotFillers*, the available fillers for each slot; and three *slotFiller* variables that hold the fillers given by the user. The major user specific IS variables are three *desiredSlotFiller* variables that hold an ordered list of fillers, and *unvisitedSlots*, a list of slots that the user believes are unfilled.

The system has a variety of speech actions: *inform [yes/no]*, to answer when the user has asked a filler availability question; *inform filler not available*, to inform the user when they have specified an unavailable filler; three *query slot* actions (one for each slot), a query which asks the user for a filler and is proposed if that specific slot is unfilled; three *inform available slot fillers* actions, which lists the available fillers for that slot and is proposed if that specific slot is unfilled or filled with an unavailable filler; and *bye*, which is always proposed.

The user has two actions. They can inform the system of a desired slot filler, *inform slot filler*, or query the availability of a slot's top filler, *query filler availability*. A user will always respond with the same slot as a system query, but may change slots entirely for all other situations. Additional details on user action selection are given in Section 5.2.

Specific information is used to produce an instantiated speech action, what we refer to as an utterance. For example, the speech action *inform slot filler* results in the utterance of "inform drink d1." A sample dialogue fragment using the Single-Utterance approach is shown in Table 2. Notice that in Line 3 the system informs the user that their first filler, *d1*, is unavailable. The user then asks asks about the availability of its second drink choice, *d2* (Line 4), and upon receiving an affirmative response (Line 5), informs the system of that filler preference (Line 6).

Table 2: Single-Utterance dialogue

Spkr	Speech Action	Utterance
1 S:	*q. slot*	q. drink
2 U:	*i. slot filler*	i. drink d1
3 S:	*i. filler not avail*	i. not have d1
4 U:	*q. filler avail*	q. drink have d2
5 S:	*i. slot*	i. yes
6 U:	*i. slot filler*	i. drink d2
7 S:	*i. avail slot fillers*	i. burger have b1

Implementation in RL: The system uses RL to learn which of the IS proposed actions to take. In this domain we use a cost function based on dialogue length and the number of slots filled with an available filler: $C = \text{Number of Utterances} + 25 \cdot \text{unavailablyFilledSlots}$. In the present implementation the system's *bye* utterance is costless. The system chooses the action that minimizes the expected cost of the entire dialogue from the current state.

The RL state for the speaker has seven variables:[4] *QUD-speaker*, the stack of speakers who have unresolved questions; *Incorrect-Slot-Fillers*,

[3] We use two fillers so as to minimize the length of training. This can be increased without substantial effort.

[4] We experimented with a variety of RL States and this one proved to be both small and effective.

a list of slot fillers (ordered chronologically on when the user informed them) that are unavailable and have not been resolved; *Last-Sys-Speech-Action*, the last speech action the system performed; *Given-Slot-Fillers*, a list of slots that the system has performed the *inform available slot filler* action on; and three booleans variables, *slot-RL*, that specify whether a slot has been filled correctly or not (e.g. Drink-RL).

5.2 User Types

We define three different types of users — *Experts*, *Novices*, and *Intermediates*. User types differ probabilistically on two dimensions: slot knowledge, and slot belief strength. We define experts to have a 90 percent chance of having adequate filler knowledge, intermediates a 50 percent chance, and novices a 10 percent chance. These probabilities are independent between slots. Slot belief strength represents the user's confidence that it has adequate domain knowledge for the slot (i.e. the top choice for that slot is available). It is either a strong, warranted, or weak belief (Chu-Carroll and Carberry, 1995). The intuition is that experts should know when their top choice is available, and novices should know that they do not know the domain well.

Initial slot belief strength is dependent on user type and whether their filler knowledge is adequate (their initial top choice is available). Experts with adequate filler knowledge have a 70, 20, and 10 percent chance of having Strong, Warranted, and Weak beliefs respectfully. Similarly, intermediates with adequate knowledge have a 50, 25, and 25 percent chance of the respective belief strengths. When these user types have inadequate filler knowledge the probabilities are reversed to determine belief strength (e.g. Experts with inadequate domain knowledge for a slot have a 70% chance of having a weak belief). Novice users always have a 10, 10, and 80 percent chance of the respective belief strengths.

The user choses whether to use the *query* or *inform* speech action based on the slot's belief strength. A strong belief will always result in an *inform*, a warranted belief resulting in an *inform* with $p = 0.5$, and weak belief will result in an *inform* with $p = 0.25$. If the user is informed of the correct fillers by the system's *inform*, that slot's belief strength is set to strong. If the user is informed that a filler is not available, than that filler is removed from the desired filler list and the belief remains the same.[5]

5.3 Turn-Taking Models

We now discuss how turn-taking works for the IDTB model and the two competing models that we use to evaluate our approach. The system chooses its turn action based on the RL state and we add a boolean variable *turn-action* to the RL State to indicate when the system is performing a turn action or a speech action. The user uses belief to choose its turn action.

Turn-Bidding: Agents bid for the turn at the end of each utterance to determine who will speak next. Each bid is represented as a value between 0 and 1, and the agent with the lower value (stronger bid) wins the turn. This is consistent with the use of utterance onset. There are 5 types of bids, *highest, high, middle, low,* and *lowest*, which are spread over a portion of the range as shown in Figure 1. The system uses RL to choose a bid and a random number (uniform distribution) is generated from that bid's range. The users' bids are determined by their belief strength, which specifies the mean of a Gaussian distribution, as shown in Figure 1 (e.g Strong belief implies a μ = 0.35). Computing bids in this fashion leads to, on average, users with strong beliefs bidding *highest*, warranted beliefs bidding in the *middle*, and weak beliefs bidding *lowest*. The use of the probability distributions allows us to randomly decide ties between system and user bids.

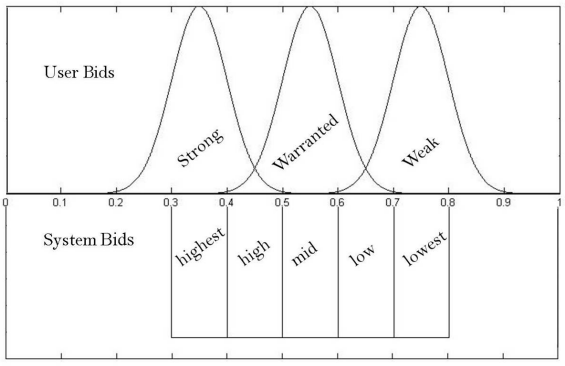

Figure 1: Bid Value Probability Distribution

Single-Utterance: The Single-Utterance (SU) approach, as described in Section 2, has a rigid

[5] In this simple domain the next filler is guaranteed to be available if the first is not. We do not model this with belief strength since it is probably not representative of reality.

turn-taking mechanism. After a speaker makes a single utterance the turn transitions to the listener. Since the turn transitions after every utterance the system must only choose appropriate utterances, not turn-taking behavior. Similarly, user agents do not have any turn-taking behavior and slot beliefs are only used to choose between a *query* and an *inform*.

Keep-Or-Release Model: The Keep-Or-Release (KR) model, as described in Section 2, allows the speaker to either keep the turn to make multiple utterances or release it. Taking the same approach as English and Heeman (2005), the system learns to keep or release the turn after each utterance that it makes. We also use RL to determine which conversant should begin the dialogue. While the use of RL imparts some importance onto the turn-taking behavior, it is not influencing whether the system gets the turn when it did not already have it. This is an crucial distinction between KR and IDTB. IDTB allows the conversants to negotiate the turn using turn-bids motivated by importance, whereas in KR only the speaker determines when the turn can transition.

Users in the KR environment choose whether to keep or release the turn similarly to bid decisions.[6] After a user performs an utterance, it chooses the slot that would be in the next utterance. A number, k, is generated from a Gaussian distribution using belief strength in the same manner as the IDTB users' bids are chosen. If $k \leq 0.55$ then the user keeps the turn, otherwise it releases it.

5.4 Preliminary Turn-Bidding System

We described a preliminary turn-bidding system in earlier work presented at a workshop (Selfridge and Heeman, 2009). A major limitation was an overly simplified user model. We used two user types, expert and novice, who had fixed bids. Experts always bid *high* and had complete domain knowledge, and the novices always bid *low* and had incomplete domain knowledge. The system, using all five bid types, was always able to out bid and under bid the simulated users. Among other things, this situation gives the system complete control of the turn, which is at odds with the negotiative nature of IDTB. The present contribution is a more realistic and mature implementation.

[6]We experimented with a few different KR decision strategies, and chose the one that performed the best.

6 Evaluation and Discussion

We now evaluate the IDTB approach by comparing it against the two competing models: Single-Utterance and Keep-Or-Release. The three turn-taking approaches are trained and tested in four user conditions: novice, intermediate, expert, and combined. In the combined condition, one of the three user types is randomly selected for each dialogue. We train ten policies for each condition and turn-taking approach. Policies are trained using Q-learning, and $\epsilon-greedy$ search for 10000 epochs (1 epoch = 100 dialogues, after which the Q-scores are updated) with $\epsilon = 0.2$. Each policy is then ran over 10000 test dialogues with no exploration ($\epsilon = 0$), and the mean dialogue cost for that policy is determined. The 10 separate policy values are then averaged to create the mean policy cost. The mean policy cost between the turn-taking approaches and user conditions are shown in Table 3. Lower numbers are indicative of shorter dialogues, since the system learns to successfully complete the task in all cases.

Table 3: Mean Policy Cost for Model and User condition[7]

Model	Novice	Int.	Expert	Combined
SU	7.61	7.09	6.43	7.05
KR	**6.00**	6.35	4.46	6.01
IDTB	6.09	**5.77**	**4.35**	**5.52**

Single User Conditions: Single user conditions show how well each turn-taking approach can optimize its behavior for specific user populations and handle slight differences found in those populations. Table 3 shows that the mean policy cost of the SU model is higher than the other two models which indicates longer dialogues on average. Since the SU system must respond to every user utterance and cannot learn a turn-taking strategy to utilize user knowledge, the dialogues are necessarily longer. For example, in the expert condition the best possible dialogue for a SU interaction will have a cost of five (three user utterances for each slot, two system utterances in response). This cost is in contrast to the best expert dialogue cost of three (three user utterances) for KR and IDTB interactions.

The IDTB turn-taking approach outperforms the KR design in all single user conditions ex-

[7]SD between policies ≤ 0.04

cept for novice (6.09 vs. 6.00). In this condition, the KR system takes the turn first, informs the available fillers for each slot, and then releases the turn. The user can then inform its filler easily. The IDTB system attempts a similar dialogue strategy by using *highest* bids but sometimes loses the turn when users also bid *highest*. If the user uses the turn to query or inform an unavailable filler the dialogue grows longer. However, this is quite rare as shown by small difference in performance between the two models. In all other single user conditions, the IDTB approach has shorter dialogues than the KR approach (5.77 and 4.35 vs. 6.35 and 4.46). A detailed explanation of IDTB's performance will be given in Section 6.1.

Combined User Condition: We next measure performance on the combined condition that mixes all three user types. This condition is more realistic than the other three, as it better mimics how a system will be used in actual practice. The IDTB approach (mean policy cost = 5.52) outperforms the KR (mean policy cost = 6.01) and SU (mean policy cost = 7.05) approaches. We also observe that KR outperforms SU. These results suggest that the more a turn-taking design can be flexible and negotiative, the more efficient the dialogues can be.

Exploiting User bidding differences: It follows that IDTB's performance stems from its negotiative turn transitions. These transitions are distinctly different than KR transitions in that there is information inherent in the users bids. A user that has a stronger belief strength is more likely to be have a higher bid and inform an available filler. Policy analysis shows that the IDTB system takes advantage of this information by using moderate bids —neither *highest* nor *lowest* bids— to filter users based on their turn behavior. The distribution of bids used over the ten learned policies is shown in Table 4. The *initial* position refers to the first bid of the dialogue; *final* position, the last bid of the dialogue; and *medial* position, all other bids. Notice that the system uses either the *low* or *mid* bids as its *initial* policy and that 67.2% of dialogue *medial* bids are moderate. These distributions show that the system has learned to use the entire bid range to filter the users, and is not seeking to win or lose the turn outright. This behavior is impossible in the KR approach.

Table 4: Bid percentages over ten policies in the Combined User condition for IDTB

Position	H-est	High	Mid	Low	L-est
Initial	0.0	0.0	70.0	30.0	0.0
Medial	20.5	19.4	24.5	23.3	12.3
Final	49.5	41.0	9.5	0.0	0.0

6.1 IDTB Performance:

In our domain, performance is measured by dialogue length and solution quality. However, since solution quality never affects the dialogue cost for a trained system, dialogue length is the only component influencing the mean policy cost.

The primary cause of longer dialogues are unavailable filler inform and query (UFI–Q) utterances by the user, which are easily identified. These utterances lengthen the dialogue since the system must inform the user of the available fillers (the user would otherwise not know that the filler was unavailable) and then the user must then inform the system of its second choice. The mean number of UFI–Q utterance for each dialogue over the ten learned policies are shown for all user conditions in Table 5. Notice that these numbers are inversely related to performance: the more UFI–Q utterances, the worse the performance. For example, in the combined condition the IDTB users perform 0.38 UFI–Q utterances per dialogue (u/d) compared to the 0.94 UFI–Q u/d for KR users. While a KR user will release the turn if its planned utterance has a weak belief, it may select that weak utterance when first getting the turn (either after a system utterance or at the start of the dialogue). This may lead to a UFI–Q utterance. The IDTB system, however, will outbid the same user, resulting in a shorter dialogue. This situation is shown in Tables 6 and 7. The dialogue is the same until utterance 3, where the IDTB system wins the turn with a *mid* bid over the user's *low* bid. In the KR environment however, the user gets the turn and performs an unavailable filler inform, which the system must react to. This is an instance of the second deficiency of the KR approach, where

Table 5: Mean number of UFI–Q utterances over policies

Model	Novice	Int.	Expert	Combined
KR	**0.0**	1.15	0.53	0.94
IDTB	0.1	**0.33**	**0.39**	**0.38**

Table 6: Sample IDTB dialogue in Combined User condition; Cost=6

Sys	Usr	Spkr	Utt
1 low	mid	U:	inform burger b1
2 h-est	low	S:	inform burger have b3
3 mid	low	S:	inform side have s1
4 mid	h-est	U:	inform burger b3
5 mid	high	U:	inform drink d1
6 l-est	h-est	U:	inform side s1
7 high	mid	S:	bye

Table 7: Sample KR dialogue in Combined User condition; Cost=7

Agent	Utt	Turn-Action
1 U:	inform burger b1	Release
2 S:	inform burger have b3	Release
3 U:	inform side s1	Keep
4 U:	inform drink d1	Keep
5 U:	inform burger b3	Release
6 S:	inform side have s2	Release
7 U:	inform side s2	Release
8 S:	bye	

the speaking system should not have released the turn. The user has the same belief in both scenarios, but the negotiative nature of IDTB enables a shorter dialogues. In short, the IDTB system can win the turn when it should have it, but the KR system cannot.

A lesser cause of longer dialogues is an instance of the first deficiency of the KR systems; the listening user cannot get the turn when it should have it. Usually, this situation presents itself when the user releases the turn, having randomly chosen the weaker of the two unfilled slots. The system then has the turn for more than one utterance, informing the available fillers for two slots. However, the user already had a strong belief and available top filler for one of those slots, and the system has increased the dialogue length unnecessarily. In the combined condition, the KR system produces 0.06 unnecessary informs per dialogue, whereas the IDTB system produces 0.045 per dialogue. The novice and intermediate conditions mirror this (IDTB: 0.009, 0.076 ; KR: 0.019, 0.096 respectfully), but the expert condition does not (IDTB: 0.011, KR: 0.0014). In this case, the IDTB system wins the turn initially using a *low* bid and informs one of the strong slots, whereas the expert user initiates the dialogue for the KR environment and unnecessary informs are rarer. In general, however, the KR approach has more unnecessary informs since the KR system can only infer that one of the user's beliefs was probably weak, otherwise the user would not have released the turn. The IDTB system handles this situation by using a *high* bid, allowing the user to outbid the system as its contribution is more important. In other words, the IDTB user can win the turn when it should have it, but the KR user cannot.

7 Conclusion

This paper presented the Importance-Driven Turn-Bidding model of turn-taking. The IDTB model is motivated by turn-conflict studies showing that the interest in holding the turn influences conversant turn-cues. A computational prototype using Reinforcement Learning to choose appropriate turn-bids performs better than the standard KR and SU approaches in an artificial collaborative dialogue domain. In short, the Importance-Driven Turn-Bidding model provides a negotiative turn-taking framework that supports mixed-initiative interactions.

In the previous section, we showed that the KR approach is deficient for two reasons: the speaking system might not keep the turn when it should have, and might release the turn when it should not have. This is driven by KR's speaker-centric nature; the speaker has no way of judging the potential contribution of the listener. The IDTB approach however, due to its negotiative quality, does not have this problem.

Our performance differences arise from situations when the system is the speaker and the user is the listener. The IDTB model also excels in the opposite situation, when the system is the listener and the user is the speaker, though our domain is not sophisticated enough for this situation to occur. In the future we hope to develop a domain with more realistic speech acts and a more difficult dialogue task that will, among other things, highlight this situation. We also plan on implementing a fully functional IDTB system, using an incremental processing architecture that not only detects, but generates, a wide array of turn-cues.

Entity-based local coherence modelling using topological fields

Abstract

One goal of natural language generation is to produce coherent text that presents information in a logical order. In this paper, we show that topological fields, which model high-level clausal structure, are an important component of local coherence in German. First, we show in a sentence ordering experiment that topological field information improves the entity grid model of Barzilay and Lapata (2008) more than grammatical role and simple clausal order information do, particularly when manual annotations of this information are not available. Then, we incorporate the model enhanced with topological fields into a natural language generation system that generates constituent orders for German text, and show that the added coherence component improves performance slightly, though not statistically significantly.

1 Introduction

One type of coherence modelling that has captured recent research interest is local coherence modelling, which measures the coherence of a document by examining the similarity between neighbouring text spans. The entity-based approach, in particular, considers the occurrences of noun phrase entities in a document (Barzilay and Lapata, 2008). Local coherence modelling has been shown to be useful for tasks like natural language generation and summarization, (Barzilay and Lee, 2004) and genre classification (Barzilay and Lapata, 2008).

Previous work on English, a language with relatively fixed word order, has identified factors that contribute to local coherence, such as the grammatical roles associated with the entities. There is good reason to believe that the importance of these factors vary across languages. For instance, freer-word-order languages exhibit word order patterns which are dependent on discourse factors relating to information structure, in addition to the grammatical roles of nominal arguments of the main verb. We thus expect word order information to be particularly important in these languages in discourse analysis, which includes coherence modelling.

For example, Strube and Hahn (1999) introduce *Functional Centering*, a variant of Centering Theory which utilizes information status distinctions between hearer-old and hearer-new entities. They apply their model to pronominal anaphora resolution, identifying potential antecedents of subsequent anaphora by considering syntactic and word order information, classifying constituents by their familiarity to the reader. They find that their approach correctly resolves more pronominal anaphora than a grammatical role-based approach which ignores word order, and the difference between the two approaches is larger in German corpora than in English ones. Unfortunately, their criteria for ranking potential antecedents require complex syntactic information in order to classify whether proper names are known to the hearer, which makes their algorithm hard to automate. Indeed, all evaluation is done manually.

We instead use topological fields, a model of clausal structure which is indicative of information structure in German, but shallow enough to be automatically parsed at high accuracy. We test the hypothesis that they would provide a good complement or alternative to grammatical roles in local coherence modelling. We show that they are superior to grammatical roles in a sentence ordering experiment, and in fact outperforms simple word-order information as well. We further show that these differences are particularly large when manual syntactic and grammatical role an-

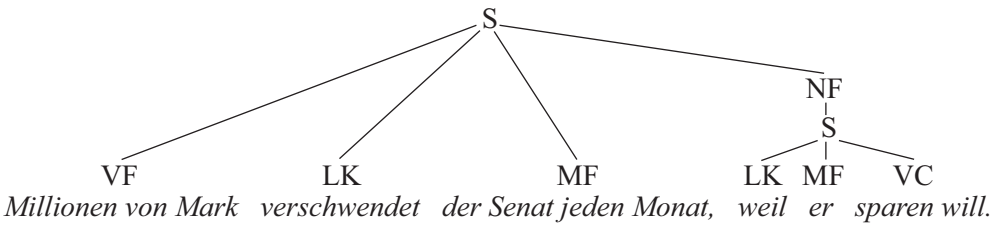

Figure 1: The clausal and topological field structure of a German sentence. Notice that the subordinate clause receives its own topology.

notations are not available.

We then embed these topological field annotations into a natural language generation system to show the utility of local coherence information in an applied setting. We add contextual features using topological field transitions to the model of Filippova and Strube (2007b) and achieve a slight improvement over their model in a constituent ordering task, though not statistically significantly. We conclude by discussing possible reasons for the utility of topological fields in local coherence modelling.

2 Background and Related Work

2.1 German Topological Field Parsing

Topological fields are sequences of one or more contiguous phrases found in an enclosing syntactic region, which is the clause in the case of the German topological field model (Höhle, 1983). These fields may have constraints on the number of words or phrases they contain, and do not necessarily form a semantically coherent constituent. In German, the topology serves to identify all of the components of the verbal head of a clause, as well as clause-level structure such as complementizers and subordinating conjunctions. Topological fields are a useful abstraction of word order, because while Germanic word order is relatively free with respect to grammatical functions, the order of the topological fields is strict and unvarying.

A German clause can be considered to be anchored by two "brackets" which contain modals, verbs and complementizers. The left bracket (*linke Klammer*, **LK**) may contain a complementizer, subordinating conjunction, or a finite verb, depending on the clause type, and the right bracket contains the verbal complex (**VC**). The other topological fields are defined in relation to these two brackets, and contain all other parts of the clause such as verbal arguments, adjuncts, and discourse cues.

The **VF** (*Vorfeld* or "pre-field") is so-named because it occurs before the left bracket. As the first constituent of most matrix clauses in declarative sentences, it has special significance for the coherence of a passage, which we will further discuss below. The **MF** (*Mittelfeld* or "middle field") is the field bounded by the two brackets. Most verb arguments, adverbs, and prepositional phrases are found here, unless they have been fronted and put in the VF, or are prosodically heavy and postposed to the NF field. The **NF** (*Nachfeld* or "post-field") contains prosodically heavy elements such as postposed prepositional phrases or relative clauses, and occasionally postposed noun phrases.

2.2 The Role of the Vorfeld

One of the reasons that we use topological fields for local coherence modelling is the role that the VF plays in signalling the information structure of German clauses, as it often contains the topic of the sentence.

In fact, its role is much more complex than being simply the topic position. Dipper and Zinsmeister (2009) distinguish multiple uses of the VF depending on whether it contains an element related to the surrounding discourse. They find that 45.1% of VFs are clearly related to the previous context by a reference or discourse relation, and a further 21.9% are deictic and refer to the situation described in the passage in a corpus study. They also run a sentence insertion experiment where subjects are asked to place an extracted sentence in its original location in a passage. The authors remark that extracted sentences with VFs that are referentially related to previous context (e.g., they contain a coreferential noun phrase or a discourse relation like "therefore") are reinserted at higher accuracies.

Mentions of the entity *Frauen* are underlined. nom: nominative, acc: accusative, oth: dative, oblique, and other arguments

Filippova and Strube (2007c) also examine the role of the VF in local coherence and natural language generation, focusing on the correlation between VFs and sentential topics. They follow Jacobs (2001) in distinguishing the *topic of addressation*, which is the constituent for which the proposition holds, and *frame-setting topics*, which is the domain in which the proposition holds, such as a temporal expression. They show in a user study that frame-setting topics are preferred to topics of addressation in the VF, except when a constituent needs to be established as the topic of addressation.

2.3 Using Entity Grids to Model Local Coherence

Barzilay and Lapata (2008) introduce the entity grid as a method of representing the coherence of a document. Entity grids indicate the location of the occurrences of an entity in a document, which is important for coherence modelling because mentions of an entity tend to appear in clusters of neighbouring or nearby sentences in coherent documents. This last assumption is adapted from Centering Theory approaches to discourse modelling.

In Barzilay and Lapata (2008), an entity grid is constructed for each document, and is represented as a matrix in which each row represents a sentence, and each column represents an entity. Thus, a cell in the matrix contains information about an entity in a sentence. The cell is marked by the presence or absence of the entity, and can also be augmented with other information about the entity in this sentence, such as the grammatical role of the noun phrase representing that entity in that sentence, or the topological field in which the noun phrase appears.

Consider the document in Table 1. An entity grid representation which incorporates the syntactic role of the noun phrase in which the entity ap-

pears is also shown (not all entities are listed for brevity). We tabulate the transitions of entities between different syntactic positions (or their non-occurrence) in sentences, and convert the frequencies of transitions into a feature vector representation of transition probabilities in the document.

To calculate transition probabilities, we divide the frequency of a particular transition by the total number of transitions of that length.

This model of local coherence was investigated for German by Filippova and Strube (2007a). The main focus of that work, however, was to adapt the model for use in a low-resource situation when perfect coreference information is not available. This is particularly useful in natural language understanding tasks. They employ a semantic clustering model to relate entities. In contrast, our work focuses on improving performance by annotating entities with additional linguistic information, such as topological fields, and is geared towards natural language generation systems where perfect information is available.

Similar models of local coherence include various Centering Theory accounts of local coherence ((Kibble and Power, 2004; Poesio et al., 2004) *inter alia*). The model of Elsner and Charniak (2007) uses syntactic cues to model the discourse-newness of noun phrases. There are also more global content models of topic shifts between sentences like Barzilay and Lee (2004).

3 Sentence Ordering Experiments

3.1 Method

We test a version of the entity grid representation augmented with topological fields in a sentence ordering experiment corresponding to Experiment 1 of Barzilay and Lapata (2008). The task is a binary classification task to identify the original version of a document from another version which contains the sentences in a randomly permuted order, which is taken to be incoherent. We solve this problem in a supervised machine learning setting, where the input is the feature vector representations of the two versions of the document, and the output is a binary value indicating the document with the original sentence ordering. We use `SVMlight`'s ranking module for classification (Joachims, 2002).

The corpus in our experiments consists of the last 480 documents of TüBa-D/Z version 4 (Telljohann et al., 2004), which contains manual coreference, grammatical role and topological field information. This set is larger than the set that was used in Experiment 1 of Barzilay and Lapata (2008), which consists of 400 documents in two English subcorpora on earthquakes and accidents respectively. The average document length in the TüBa-D/Z subcorpus is also greater, at 19.2 sentences compared to about 11 for the two subcorpora. Up to 20 random permutations of sentences were generated from each document, with duplicates removed.

There are 216 documents and 4126 original-permutation pairs in the training set, and 24 documents and 465 pairs in the development set. The remaining 240 documents are in the final test set (4243 pairs). The entity-based model is parameterized as follows.

Transition length – the maximum length of the transitions used in the feature vector representation of a document.

Representation – when marking the presence of an entity in a sentence, what information about the entity is marked (topological field, grammatical role, or none). We will describe the representations that we try in section 3.2.

Salience – whether to set a threshold for the frequency of occurrence of entities. If this is set, all entities below a certain frequency are treated separately from those reaching this frequency threshold when calculating transition probabilities. In the example in Table 1, with a salience threshold of 2, *Frauen* would be treated separately from *Männern* or *Kindern*.

Transition length, salience, and a regularization parameter are tuned on the development set. We only report results using the setting of transition length ≤ 4, and no salience threshold, because they give the best performance on the development set. This is in contrast to the findings of Barzilay and Lapata (2008), who report that transition length ≤ 3 and a salience threshold of 2 perform best on their data.

3.2 Entity Representations

The main goal of this study is to compare word order, grammatical role and topological field information, which is encoded into the entity grid at each occurrence of an entity. Here, we describe the variants of the entity representations that we compare.

Baseline Representations We implement several baseline representations against which we test our topological field-enhanced model. The simplest baseline representation marks the mere appearance of an entity without any additional information, which we refer to as `default`.

Another class of baseline representations mark the order in which entities appear in the clause. The correlation between word order and information structure is well known, and has formed the basis of some theories of syntax such as the Prague School's (Sgall et al., 1986). The two versions of clausal order we tried are `order 1/2/3+`, which marks a noun phrase as the first, the second, or the third or later to appear in a clause, and `order 1/2+`, which marks a noun phrase as the first, or the second or later to appear in a clause. Since noun phrases can be embedded in other noun phrases, overlaps can occur. In this case, the dominating noun phrase takes the smallest order number among its dominated noun phrases.

The third class of baseline representations we employ mark an entity by its grammatical role in the clause. Barzilay and Lapata (2008) found that grammatical role improves performance in this task for an English corpus. Because German distinguishes more grammatical roles morphologically than English, we experiment with various granularities of role labelling. In particular, `subj/obj` distinguishes the subject position, the object position, and another category for all other positions. `cases` distinguishes five types of entities corresponding to the four morphological cases of German in addition to another category for noun phrases which are not complements of the main verb.

Topological Field-Based These representations mark the topological field in which an entity appears. Some versions mark entities which are prepositional objects separately. We try versions which distinguish VF from non-VF, as well as more general versions that make use of a greater set of topological fields. `vf` marks the noun phrase as belonging to a VF (and not in a PP) or not. `vfpp` is the same as above, but allows prepositional objects inside the VF to be marked as VF. `topf/pp` distinguishes entities in the topological fields VF, MF, and NF, contains a separate category for PP, and a category for all other noun phrases. `topf` distinguishes between VF, MF, and NF, on the one hand, and everything else on the other. Prepositional objects are treated the same as other noun phrases here.

Combined We tried a representation which combines grammatical role and topological field into a single representation, `subj/obj`$\times$`vf`, which takes the Cartesian product of `subj/obj` and `vf` above.

Topological fields do not map directly to topic-focus distinctions. For example, besides the topic of the sentence, the Vorfeld may contain discourse cues, expletive pronouns, or the informational or contrastive focus. Furthermore, there are additional constraints on constituent order related to pronominalization. Thus, we devised additional entity representations to account for these aspects of German.

`topic` attempts to identify the sentential topic of a clause. A noun phrase is marked as TOPIC if it is in VF as in `vfpp`, or if it is the first noun phrase in MF and also the first NP in the clause. Other noun phrases in MF are marked as NONTOPIC. Categories for NF and miscellaneous noun phrases also exist. While this representation may appear to be very similar to simply distinguishing the first entity in a clause as for `order 1/2+` in that TOPIC would correspond to the first entity in the clause, they are in fact distinct. Due to issues related to coordination, appositive constructions, and fragments which do not receive a topology of fields, the first entity in a clause is labelled the TOPIC only 80.8% of the time in the corpus. This representation also distinguishes NFs, which clausal order does not.

`topic+pron` refines the above by taking into account a word order restriction in German that pronouns appear before full noun phrases in the MF field. The following set of decisions represents how a noun phrase is marked: If the first NP in the clause is a pronoun in an MF field and is the subject, we mark it as TOPIC. If it is not the subject, we mark it as NONTOPIC. For other NPs, we follow the `topic` representation.

3.3 Automatic annotations

While it is reasonable to assume perfect annotations of topological fields and grammatical roles in many NLG contexts, this assumption may be less appropriate in other applications involving text-to-text generation where the input to the system is text such as paraphrasing or machine translation. Thus, we test the robustness of the entity repre-

Representation	*Manual*	*Automatic*
`topf/pp`	**94.44**	**94.89**
`topic`	94.13	94.53
`topic+pron`	94.08	94.51
`topf`	93.87	93.11
`subj/obj`	93.83[1]	91.7++
`cases`	93.31[2]	90.93++
`order 1/2+`	92.51++	92.1+
`subj/obj`×`vf`	92.32++	90.74++
`default`	91.42++	91.42++
`vfpp`	91.37++	91.68++
`vf`	91.21++	91.16++
`order 1/2/3+`	91.16++	90.71++

Table 2: Accuracy (%) of the permutation detection experiment with various entity representations using manual and automatic annotations of topological fields and grammatical roles. The baseline without any additional annotation is underlined. Two-tailed sign tests were calculated for each result against the best performing model in each column ([1]: $p = 0.101$; [2]: $p = 0.053$; +: statistically significant, $p < 0.05$; ++: very statistically significant, $p < 0.01$).

sentations to automatic extraction in the absence of manual annotations. We employ the following two systems for extracting topological fields and grammatical roles.

To parse topological fields, we use the Berkeley parser of Petrov and Klein (2007), which has been shown to perform well at this task (Cheung and Penn, 2009). The parser is trained on sections of TüBa-D/Z which do not overlap with the section from which the documents for this experiment were drawn, and obtains an overall parsing performance of 93.35% F_1 on topological fields and clausal nodes without gold POS tags on the section of TüBa-D/Z it was tested on.

We tried two methods to obtain grammatical roles. First, we tried extracting grammatical roles from the parse trees which we obtained from the Berkeley parser, as this information is present in the edge labels that can be recovered from the parse. However, we found that we achieved better accuracy by using `RFTagger` (Schmid and Laws, 2008), which tags nouns with their morphological case. Morphological case is distinct from grammatical role, as noun phrases can function as adjuncts in possessive constructions and prepositional phrases. However, we can approximate the grammatical role of an entity using the morphological case. We follow the annotation conventions of TüBa-D/Z in not assigning a grammatical role when the noun phrase is a prepositional object. We also do not assign a grammatical role when the noun phrase is in the genitive case, as genitive objects are very rare in German and are far outnumbered by the possessive genitive construction.

Annotation	*Accuracy* (%)
Grammatical role	83.6
Topological field (+PP)	93.8
Topological field (−PP)	95.7
Clausal order	90.8

Table 3: Accuracy of automatic annotations of noun phrases with coreferents. +PP means that prepositional objects are treated as a separate category from topological fields. −PP means they are treated as other noun phrases.

3.4 Results

Table 2 shows the results of the sentence ordering permutation detection experiment. The top four performing entity representations are all topological field-based, and they outperform grammatical role-based and simple clausal order-based models. These results indicate that the information that topological fields provide about clause structure, appositives, right dislocation, etc. which is not captured by simple clausal order is important for coherence modelling. The representations incorporating linguistics-based heuristics do not outperform purely topological field-based models.

Surprisingly, the VF-based models fare quite poorly, performing worse than not adding any annotations, despite the fact that topological field-based models in general perform well. This result may be a result of the heterogeneous uses of the VF.

The automatic topological field annotations are more accurate than the automatic grammatical role annotations (Table 3), which may partly explain why grammatical role-based models suffer more when using automatic annotations. Note, however, that the models based on automatic topological field annotations outperform even the grammatical role-based models using manual annotation (at marginal significance, $p < 0.1$). The topo-

logical field annotations are accurate enough that automatic annotations produce no decrease in performance.

These results show the upper bound of entity-based local coherence modelling with perfect coreference information. The results we obtain are higher than the results for the English corpora of Barzilay and Lapata (2008) (87.2% on the Earthquakes corpus and 90.4% on the Accidents corpus), but this is probably due to corpus differences as well as the availability of perfect coreference information in our experiments[1].

Due to the high performance we obtained, we calculated Kendall tau coefficients (Lapata, 2006) over the sentence orderings of the cases in which our best performing model is incorrect, to determine whether the remaining errors are instances where the permuted ordering is nearly identical to the original ordering. We obtained a τ of 0.0456 in these cases, compared to a τ of -0.0084 for all the pairs, indicating that this is not the case.

To facilitate comparison to the results of Filippova and Strube (2007a), we rerun this experiment on the same subsections of the corpus as in that work for training and testing. The first 100 articles of TüBa-D/Z are used for testing, while the next 200 are used for training and development.

Unlike the previous experiments, we do not do parameter tuning on this set of data. Instead, we follow Filippova and Strube (2007a) in using transition lengths of up to three. We do not put in a salience threshold. We see that our results are much better than the ones reported in that work, even for the `default` representation. The main reason for this discrepancy is probably the way that entities are created from the corpus. In our experiments, we create an entity for every single noun phrase node that we encounter, then merge the entities that are linked by coreference. Filippova and Strube (2007a) convert the annotations of TüBa-D/Z into a dependency format, then extract entities from the noun phrases found there. They may thus annotate fewer entities, as there may be nested NP nodes in the original corpus. There may also be noise in the dependency conversion process.

[1]Barzilay and Lapata (2008) use the coreference system of Ng and Cardie (2002) to obtain coreference annotations. We are not aware of similarly well-tested, publicly available coreference resolution systems that handle all types of anaphora for German. We considered adapting the BART coreference resolution toolkit (Versley et al., 2008) to German, but a number of language-dependent decisions regarding preprocessing, feature engineering, and the learning paradigm would need to be made in order to achieve reasonable performance comparable to state-of-the-art English coreference resolution systems.

Table 4: Accuracy (%) of permutation detection experiment with various entity representations using manual and automatic annotations of topological fields and grammatical roles on subset of corpus used by Filippova and Strube (2007a).

The relative rankings of different entity representations in this experiment are similar to the rankings of the previous experiment, with topological field-based models outperforming grammatical role and clausal order models.

4 Local Coherence for Natural Language Generation

One of the motivations of the entity grid-based model is to improve surface realization decisions in NLG systems. A typical experimental design would pass the contents of the test section of a corpus as input to the NLG system with the ordering information stripped away. The task is then to regenerate the ordering of the information found in the original corpus. Various coherence models have been tested in corpus-based NLG settings. For example, Karamanis et al. (2009) compare several versions of Centering Theory-based metrics of coherence on corpora by examining how highly the original ordering found in the corpus is ranked compared to other possible orderings of propositions. A metric performs well if it ranks the original ordering better than the alternative orderings.

In our next experiment, we incorporate local co-

herence information into the system of Filippova and Strube (2007b). We embed entity topological field transitions into their probabilistic model, and show that the added coherence component slightly improves the performance of the baseline NLG system in generating constituent orderings in a German corpus, though not to a statistically significant degree.

4.1 Method

We use the WikiBiography corpus[2] for our experiments. The corpus consists of more than 1100 biographies taken from the German Wikipedia, and contains automatic annotations of morphological, syntactic, and semantic information. Each article also contains the coreference chain of the subject of the biography (the biographee). The first 100 articles are used for testing, the next 200 for development, and the rest for training.

The baseline generation system already incorporates topological field information into the constituent ordering process. The system operates in two steps. First, in main clauses, one constituent is selected as the Vorfeld (VF). This is done using a maximum entropy model (call it `MAXENT`). Then, the remaining constituents are ordered using a second maximum entropy model (`MAXENT2`). Significantly, Filippova and Strube (2007b) found that selecting the VF first, and then ordering the remaining constituents results in a 9% absolute improvement over the corresponding model where the selection is performed in one step by the sorting algorithm alone.

The maximum entropy model for both steps rely on the following features:

- features on the voice, valency, and identity of the main verb of the clause
- features on the morphological and syntactic status of the constituent to be ordered
- whether the constituent occurs in the preceding sentence
- features for whether the constituent contains a determiner, an anaphoric pronoun, or a relative clause
- the size of the constituent in number of modifiers, in depth, and in number of words
- the semantic class of the constituent (person, temporal, location, etc.) The biographee, in particular, is marked by its own semantic class.

In the first VF selection step, `MAXENT` simply produces a probability of each constituent being a VF, and the constituent with the highest probability is selected. In the second step, `MAXENT2` takes the featural representation of two constituents, and produces an output probability of the first constituent preceding the second constituent. The final ordering is achieved by first randomizing the order of the constituents in a clause (besides the first one, which is selected to be the VF), then sorting them according to the precedence probabilities. Specifically, a constituent A is put before a constituent B if `MAXENT2`(A,B) > 0.5. Because this precedence relation is not antisymmetric (i.e., `MAXENT2`(A,B) > 0.5 and `MAXENT2`(B,A) > 0.5 may be simultaneously true or simultaneously false), different initializations of the order produce different sorted results. In our experiments, we correct this by defining the precedence relation to be A precedes B iff `MAXENT2`(A,B) $>$ `MAXENT2`(B,A). This change does not greatly impact the performance, and removes the randomized element of the algorithm.

The baseline system does not directly model the context when ordering constituents. All of the features but one in the original maximum entropy models rely on local properties of the clause. We incorporate local coherence information into the model by adding entity transition features which we found to be useful in the sentence ordering experiment in Section 3 above.

Specifically, we add features indicating the topological fields in which entities occur in the previous sentences. We found that looking back up to two sentences produces the best results (by tuning on the development set). Because this corpus does not come with general coreference information except for the coreference chain of the biographee, we use the semantic classes instead. So, all constituents in the same semantic class are treated as one coreference chain. An example of a feature may be **biog-last2**, which takes on a value such as 'v−', meaning that this constituent refers to the biographee, and the biographee occurs in the VF two clauses ago (v), but does not appear in the previous clause (−). For a constituent which is not the biographee, this feature would be marked

Method	*VF Acc* (%)	*Acc* (%)	*Tau*
Baseline	68.7	60.9	**0.72**
+Coherence	**69.2**	**61.5**	**0.72**

Table 5: Results of adding coherence features into a natural language generation system. VF Acc% is the accuracy of selecting the first constituent in main clauses. Acc % is the percentage of perfectly ordered clauses, tau is Kendall's τ on the constituent ordering. The test set contains 2246 clauses, of which 1662 are main clauses.

'na' (not applicable).

4.2 Results

Table 5 shows the results of adding these contextual features into the maximum entropy models. We see that we obtain a small improvement in the accuracy of VF selection, and in the accuracy of correctly ordering the entire clause. These improvements are not statistically significant by McNemar's test. We suggest that the lack of coreference information for all entities in the article may have reduced the benefit of the coherence component. Also, the topline of performance is substantially lower than 100%, as multiple orderings are possible and equally valid. Human judgements on information structuring for both inter- and intra-sentential units are known to have low agreement (Barzilay et al., 2002; Filippova and Strube, 2007c; Lapata, 2003; Chen et al., 2007). Thus, the relative error reduction is higher than the absolute reduction might suggest.

5 Conclusions

We have shown that topological fields are a useful source of information for local coherence modelling. In a sentence-order permutation detection task, models which use topological field information outperform both grammatical role-based models and models based on simple clausal order, with the best performing model achieving a relative error reduction of 40.4% over the original baseline without any additional annotation. Applying our local coherence model in another setting, we have embedded topological field transitions of entities into an NLG system which orders constituents in German clauses. We find that the coherence-enhanced model slightly outperforms the baseline system, but this was not statistically significant.

We suggest that the utility of topological fields in local coherence modelling comes from the interaction between word order and information structure in freer-word-order languages. Crucially, topological fields take into account issues such as coordination, appositives, sentential fragments and differences in clause types, which word order alone does not. They are also shallow enough to be accurately parsed automatically for use in resource-poor applications.

Further refinement of the topological field annotations to take advantage of the fact that they do not correspond neatly to any single information status such as topic or focus could provide additional performance gains. The model also shows promise for other discourse-related tasks such as coreference resolution and discourse parsing.

Acknowledgements

We are grateful to Katja Filippova for providing us with source code for the experiments in Section 4 and for answering related questions, and to Timothy Fowler for useful discussions and comments on a draft of the paper. Abstract

The analysis of reading times can provide insights into the processes that underlie language comprehension, with longer reading times indicating greater cognitive load. There is evidence that the language processor is highly predictive, such that prior context allows upcoming linguistic material to be anticipated. Previous work has investigated the contributions of semantic and syntactic contexts in isolation, essentially treating them as independent factors. In this paper we analyze reading times in terms of a single predictive measure which integrates a model of semantic composition with an incremental parser and a language model.

1 Introduction

Psycholinguists have long realized that language comprehension is highly *incremental*, with readers and listeners continuously extracting the meaning of utterances on a word-by-word basis. As soon as they encounter a word in a sentence, they integrate it as fully as possible into a representation of the sentence thus far (Marslen-Wilson 1973; Konieczny 2000; Tanenhaus et al. 1995; Sturt and Lombardo 2005). Recent research suggests that language comprehension can also be highly *predictive*, i.e., comprehenders are able to anticipate upcoming linguistic material. This is beneficial as it gives them more time to keep up with the input, and predictions can be used to compensate for problems with noise or ambiguity.

Two types of prediction have been observed in the literature. The first type is semantic prediction, as evidenced in semantic priming: a word that is preceded by a semantically related prime or a semantically congruous sentence fragment is processed faster (Stanovich and West 1981; van Berkum et al. 1999; Clifton et al. 2007). Another example is argument prediction: listeners are able to launch eye-movements to the predicted argument of a verb before having encountered it, e.g., they will fixate an edible object as soon as they hear the word *eat* (Altmann and Kamide 1999). The second type of prediction is syntactic prediction. Comprehenders are faster at naming words that are syntactically compatible with prior context, even when they bear no semantic relationship to the context (Wright and Garrett 1984). Another instance of syntactic prediction has been reported by Staub and Clifton (2006): following the word *either*, readers predict *or* and the complement that follows it, and process it faster compared to a control condition without *either*.

Thus, human language processing takes advantage of the constraints imposed by the preceding semantic and syntactic context to derive expectations about the upcoming input. Much recent work has focused on developing computational measures of these constraints and expectations. Again, the literature is split into syntactic and semantic models. Probably the best known measure of syntactic expectation is *surprisal* (Hale 2001) which can be coarsely defined as the negative log probability of word w_t given the preceding words, typically computed using a probabilistic context-free grammar.

Modeling work on semantic constraint focuses on the degree to which a word is related to its preceding context. Pynte et al. (2008) use Latent Semantic Analysis (LSA, Landauer and Dumais 1997) to assess the degree of contextual constraint exerted on a word by its context. In this framework, word meanings are represented as vectors in a high dimensional space and distance in this space is interpreted as an index of processing difficulty. Other work (McDonald and Brew 2004) models contextual constraint in information theoretic terms. The assumption is that words carry prior *semantic expectations* which are updated upon seeing the next word. Expectations are represented by a vector of probabilities which reflects the likely location in semantic space of the upcoming word.

The measures discussed above are typically computed automatically on real-language corpora using data-driven methods and their predictions are verified through analysis of eye-movements that people make while reading. Ample evidence

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 196–206,
Uppsala, Sweden, 11-16 July 2010.

(Rayner 1998) demonstrates that eye-movements are related to the moment-to-moment cognitive activities of readers. They also provide an accurate temporal record of the on-line processing of natural language, and through the analysis of eye-movement measurements (e.g., the amount of time spent looking at a word) can give insight into the processing difficulty involved in reading.

In this paper, we investigate a model of prediction that is incremental and takes into account syntactic as well as semantic constraint. The model essentially integrates the predictions of an incremental parser (Roark 2001) together with those of a semantic space model (Mitchell and Lapata 2009). The latter creates meaning representations *compositionally*, and therefore builds semantic expectations for word sequences (e.g., phrases, sentences, even documents) rather than isolated words. Some existing models of sentence processing integrate semantic information into a probabilistic parser (Narayanan and Jurafsky 2002; Padó et al. 2009); however, the semantic component of these models is limited to semantic role information, rather than attempting to build a full semantic representation for a sentence. Furthermore, the models of Narayanan and Jurafsky (2002) and Padó et al. (2009) do not explicitly model prediction, but rather focus on accounting for garden path effects. The proposed model simultaneously captures semantic and syntactic effects in a single measure which we empirically show is predictive of processing difficulty as manifested in eye-movements.

2 Models of Processing Difficulty

As described in Section 1, reading times provide an insight into the various cognitive activities that contribute to the overall processing difficulty involved in comprehending a written text. To quantify and understand the overall cognitive load associated with processing a word in context, we will break that load down into a sum of terms representing distinct computational costs (semantic and syntactic). For example, surprisal can be thought of as measuring the cost of dealing with unexpected input. When a word conforms to the language processor's expectations, surprisal is low, and the cognitive load associated with processing that input will also be low. In contrast, unexpected words will have a high surprisal and a high cognitive cost.

However, high-level syntactic and semantic factors are only one source of cognitive costs. A sizable proportion of the variance in reading times is accounted for by costs associated with low-level features of the stimuli, e.g.. relating to orthography and eye-movement control (Rayner 1998). In addition, there may also be costs associated with the integration of new input into an incremental representation. Dependency Locality Theory (DLT, Gibson 2000) is essentially a distance-based measure of the amount of processing effort required when the head of a phrase is integrated with its syntactic dependents. We do not consider integration costs here (as they have not been shown to correlate reliably with reading times; see Demberg and Keller 2008 for details) and instead focus on the costs associated with semantic and syntactic constraint and low-level features, which appear to make the most substantial contributions.

In the following subsections we describe the various features which contribute to the processing costs of a word in context. We begin by looking at the low-level costs and move on to consider the costs associated with syntactic and semantic constraint. For readers unfamiliar with the methodology involved in modeling eye-tracking data, we note that regression analysis (or the more general mixed effects models) is typically used to study the relationship between *dependent* and *independent* variables. The independent variables are the various costs of processing effort and the dependent variables are measurements of eye-movements, three of which are routinely used in the literature: *first fixation duration* (the duration of the first fixation on a word regardless of whether it is the first fixation on a word or the first of multiple fixations on the same word), *first pass duration*, also known as *gaze duration*, (the sum of all fixations made on a word prior to looking at another word), and *total reading time* (the sum of all fixations on a word including refixations after moving on to other words).

2.1 Low-level Costs

Low-level features include word frequency (more frequent words are read faster), word length (shorter words are read faster), and the position of the word in the sentence (later words are read faster). Oculomotor variables have also been found to influence reading times. These include previous fixation (indicating whether or not the previous word has been fixated), launch distance (how many characters intervene between the current fixation and the previous fixation), and landing position (which letter in the word the fixation landed on).

Information about the sequential context of a word can also influence reading times. Mc-

Donald and Shillcock (2003) show that forward and backward transitional probabilities are predictive of first fixation and first pass durations: the higher the transitional probability, the shorter the fixation time. Backward transitional probability is essentially the conditional probability of a word given its immediately preceding word, $P(w_k|w_{k-1})$. Analogously, forward probability is the conditional probability of the current word given the next word, $P(w_k|w_{k+1})$.

2.2 Syntactic Constraint

As mentioned earlier, surprisal (Hale 2001; Levy 2008) is one of the best known models of processing difficulty associated with syntactic constraint, and has been previously applied to the modeling of reading times (Demberg and Keller 2008; Ferrara Boston et al. 2008; Roark et al. 2009; Frank 2009). The basic idea is that the processing costs relating to the expectations of the language processor can be expressed in terms of the probabilities assigned by some form of language model to the input. These processing costs are assumed to arise from the change in the expectations of the language processor as new input arrives. If we express these expectations in terms of a distribution over all possible continuations of the input seen so far, then we can measure the magnitude of this change in terms of the Kullback-Leibler divergence of the old distribution to the updated distribution. This measure of processing cost for an input word, w_{k+1}, given the previous context, $w_1 \dots w_k$, can be expressed straightforwardly in terms of its conditional probability as:

$$S = -\log P(w_{k+1}|w_1 \dots w_k) \qquad (1)$$

That is, the processing cost for a word decreases as its probability increases, with zero processing cost incurred for words which must appear in a given context, as these do not result in any change in the expectations of the language processor.

The original formulation of surprisal (Hale 2001) used a probabilistic parser to calculate these probabilities, as the emphasis was on the processing costs incurred when parsing structurally ambiguous garden path sentences.[1] Several variants of calculating surprisal have been developed in the literature since using different parsing strategies (e.g., left-to-right vs. top-down, PCFGs vs dependency parsing) and different degrees of lexicalization (see Roark et al. 2009 for an overview) . For instance, unlexicalized surprisal can be easily derived by substituting the words in Equation (1) with parts of speech (Demberg and Keller 2008). Surprisal could be also defined using a vanilla language model that does not take any structural or grammatical information into account (Frank 2009).

2.3 Semantic Constraint

Distributional models of meaning have been commonly used to quantify the semantic relation between a word and its context in computational studies of lexical processing. These models are based on the idea that words with similar meanings will be found in similar contexts. In putting this idea into practice, the meaning of a word is then represented as a vector in a high dimensional space, with the vector components relating to the strength on occurrence of that word in various types of context. Semantic similarities are then modeled in terms of geometric similarities within the space.

To give a concrete example, Latent Semantic Analysis (LSA, Landauer and Dumais 1997) creates a meaning representation for words by constructing a word-document co-occurrence matrix from a large collection of documents. Each row in the matrix represents a word, each column a document, and each entry the frequency with which the word appeared within that document. Because this matrix tends to be quite large it is often transformed via a singular value decomposition (Berry et al. 1995) into three component matrices: a matrix of word vectors, a matrix of document vectors, and a diagonal matrix containing singular values. Re-multiplying these matrices together using only the initial portions of each (corresponding to the use of a lower dimensional spatial representation) produces a tractable approximation to the original matrix. In this framework, the similarity between two words can be easily quantified, e.g., by measuring the cosine of the angle of the vectors representing them.

As LSA is one the best known semantic space models it comes as no surprise that it has been used to analyze semantic constraint. Pynte et al. (2008) measure the similarity between the next word and its preceding context under the assumption that high similarity indicates high semantic constraint (i.e., the word was expected) and analogously low similarity indicates low semantic constraint (i.e., the word was unexpected). They oper-

[1] While hearing a sentence like *The horse raced past the barn fell* (Bever 1970), English speakers are inclined to interpreted *horse* as the subject of *raced* expecting the sentence to end at the word *barn*. So upon hearing the word *fell* they are forced to revise their analysis of the sentence thus far and adopt a reduced relative reading.

ationalize preceding contexts in two ways, either as the word immediately preceding the next word as the sentence fragment preceding it. Sentence fragments are represented as the average of the words they contain independently of their order. The model takes into account only content words, function words are of little interest here as they can be found in any context.

Pynte et al. (2008) analyze reading times on the French part of the Dundee corpus (Kennedy and Pynte 2005) and find that word-level LSA similarities are predictive of first fixation and first pass durations, whereas sentence-level LSA is only predictive of first pass duration (i.e., for a measure that includes refixation). This latter finding is somewhat counterintuitive, one would expect longer contexts to have an immediate effect as they are presumably more constraining. One reason why sentence-level influences are only visible on first pass duration may be due to LSA itself, which is syntax-blind. Another reason relates to the way sentential context was modeled as vector addition (or averaging). The idea of averaging is not very attractive from a linguistic perspective as it blends the meanings of individual words together. Ideally, the combination of simple elements onto more complex ones must allow the construction of novel meanings which go beyond those of the individual elements (Pinker 1994).

The only other model of semantic constraint we are aware of is Incremental Contextual Distinctiveness (ICD, McDonald 2000; McDonald and Brew 2004). ICD assumes that words carry prior semantic expectations which are updated upon seeing the next word. Context is represented by a vector of probabilities which reflects the likely location in semantic space of the upcoming word. When the latter is observed, the prior expectation is updated using a Bayesian inference mechanism to reflect the newly arrived information. Like LSA, ICD is based on word co-occurrence vectors, however it does not employ singular value decomposition, and constructs a word-word rather than a word-document co-occurrence matrix. Although this model has been shown to successfully simulate single- and multiple-word priming (McDonald and Brew 2004), it failed to predict processing costs in the Embra eye-tracking corpus (McDonald and Shillcock 2003).

In this work we model semantic constraint using the representational framework put forward in Mitchell and Lapata (2008). Their aim is not so much to model processing difficulty, but to construct vector-based meaning representations that go beyond individual words. They introduce a general framework for studying vector *composition*, which they formulate as a function f of two vectors $\mathbf{u}$ and $\mathbf{v}$:

$$\mathbf{h} = f(\mathbf{u}, \mathbf{v}) \tag{2}$$

where $\mathbf{h}$ denotes the composition of $\mathbf{u}$ and $\mathbf{v}$. Different composition models arise, depending on how f is chosen. Assuming that $\mathbf{h}$ is a linear function of the Cartesian product of $\mathbf{u}$ and $\mathbf{v}$ allows to specify *additive* models which are by far the most common method of vector combination in the literature:

$$h_i = u_i + v_i \tag{3}$$

Alternatively, we can assume that $\mathbf{h}$ is a linear function of the tensor product of $\mathbf{u}$ and $\mathbf{v}$, and thus derive models based on *multiplication*:

$$h_i = u_i \cdot v_i \tag{4}$$

Mitchell and Lapata (2008) show that several additive and multiplicative models can be formulated under this framework, including the well-known tensor products (Smolensky 1990) and circular convolution (Plate 1995). Importantly, composition models are not defined with a specific semantic space in mind, they could easily be adapted to LSA, or simple co-occurrence vectors, or more sophisticated semantic representations (e.g., Griffiths et al. 2007), although admittedly some composition functions may be better suited for particular semantic spaces.

Composition models can be straightforwardly used as predictors of processing difficulty, again via measuring the cosine of the angle between a vector $\mathbf{w}$ representing the upcoming word and a vector $\mathbf{h}$ representing the words preceding it:

$$sim(\mathbf{w}, \mathbf{h}) = \frac{\mathbf{w} \cdot \mathbf{h}}{|\mathbf{w}||\mathbf{h}|} \tag{5}$$

where $\mathbf{h}$ is created compositionally, via some (additive or multiplicative) function f.

In this paper we evaluate additive and compositional models in their ability to capture semantic prediction. We also examine the influence of the underlying meaning representations by comparing a simple semantic space similar to McDonald (2000) against Latent Dirichlet Allocation (Blei et al. 2003; Griffiths et al. 2007). Specifically, the simpler space is based on word co-occurrence counts; it constructs the vector representing a given target word, t, by identifying all the tokens of t in a corpus and recording the counts of context words, c_i (within a specific window). The context words, c_i, are limited to a set of the n most

common content words and each vector component is given by the ratio of the probability of a c_i given t to the overall probability of c_i.

$$v_i = \frac{p(c_i|t)}{p(c_i)} \quad (6)$$

Despite its simplicity, the above semantic space (and variants thereof) has been used to successfully simulate lexical priming (e.g., McDonald 2000), human judgments of semantic similarity (Bullinaria and Levy 2007), and synonymy tests (Padó and Lapata 2007) such as those included in the Test of English as Foreign Language (TOEFL).

LDA is a probabilistic topic model offering an alternative to spatial semantic representations. It is similar in spirit to LSA, it also operates on a word-document co-occurrence matrix and derives a reduced dimensionality description of words and documents. Whereas in LSA words are represented as points in a multi-dimensional space, LDA represents words using topics. Specifically, each document in a corpus is modeled as a distribution over K topics, which are themselves characterized as distribution over words. The individual words in a document are generated by repeatedly sampling a topic according to the topic distribution and then sampling a single word from the chosen topic. Under this framework, word meaning is represented as a probability distribution over a set of latent topics, essentially a vector whose dimensions correspond to topics and values to the probability of the word given these topics. Topic models have been recently gaining ground as a more structured representation of word meaning (Griffiths et al. 2007; Steyvers and Griffiths 2007). In contrast to more standard semantic space models where word senses are conflated into a single representation, topics have an intuitive correspondence to coarse-grained sense distinctions.

3 Integrating Semantic Constraint into Surprisal

The treatment of semantic and syntactic constraint in models of processing difficulty has been somewhat inconsistent. While surprisal is a theoretically well-motivated measure, formalizing the idea of linguistic processing being highly predictive in terms of probabilistic language models, the measurement of semantic constraint in terms of vector similarities lacks a clear motivation. Moreover, the two approaches, surprisal and similarity, produce mathematically different types of measures. Formally, it would be preferable to have a single approach to capturing constraint and the obvious solution is to derive some form of semantic surprisal rather than sticking with similarity. This can be achieved by turning a vector model of semantic similarity into a probabilistic language model.

There are in fact a number of approaches to deriving language models from distributional models of semantics (e.g., Bellegarda 2000; Coccaro and Jurafsky 1998; Gildea and Hofmann 1999). We focus here on the model of Mitchell and Lapata (2009) which tackles the issue of the composition of semantic vectors and also integrates the output of an incremental parser. The core of their model is based on the product of a trigram model $p(w_n|w_{n-2}^{n-1})$ and a semantic component $\Delta(w_n,h)$ which determines the factor by which this probability should be scaled up or down given the prior semantic context h:

$$p(w_n) = p(w_n|w_{n-2}^{n-1}) \cdot \Delta(w_n,h) \quad (7)$$

The factor $\Delta(w_n,h)$ is essentially based on a comparison between the vector representing the current word w_n and the vector representing the prior history h. Varying the method for constructing word vectors (e.g., using LDA or a simpler semantic space model) and for combining them into a representation of the prior context h (e.g., using additive or multiplicative functions) produces distinct models of semantic composition.

The calculation of Δ is then based on a weighted dot product of the vector representing the upcoming word w, with the vector representing the prior context h:

$$\Delta(w,h) = \sum_i w_i h_i p(c_i) \quad (8)$$

As shown in Equation (7) this semantic factor then modulates the trigram probabilities, to take account of the effect of the semantic content outside the n-gram window.

Mitchell and Lapata (2009) show that a combined semantic-trigram language model derived from this approach and trained on the Wall Street Journal outperforms a baseline trigram model in terms of perplexity on a held out set. They also linearly interpolate this semantic language model with the output of an incremental parser, which computes the following probability:

$$p(w|h) = \lambda p_1(w|h) + (1-\lambda) p_2(w|h) \quad (9)$$

where $p_1(w|h)$ is computed as in Equation (7) and $p_2(w|h)$ is computed by the parser. Their implementation uses Roark's (2001) top-down incremental parser which estimates the probability of

the next word based upon the previous words of the sentence. These *prefix* probabilities are calculated from a grammar, by considering the likelihood of seeing the next word given the possible grammatical relations representing the prior context.

Equation (9) essentially defines a language model which combines semantic, syntactic and *n*-gram structure, and Mitchell and Lapata (2009) demonstrate that it improves further upon a semantic language model in terms of perplexity. We argue that the probabilities from this model give us a means to model the incrementally and predictivity of the language processor in a manner that integrates both syntactic and semantic constraints. Converting these probabilities to surprisal should result in a single measure of the processing cost associated with semantic and syntactic expectations.

4 Method

Data The models discussed in the previous section were evaluated against an eye-tracking corpus. Specifically, we used the English portion of the Dundee Corpus (Kennedy and Pynte 2005) which contains 20 texts taken from *The Independent* newspaper. The corpus consists of 51,502 tokens and 9,776 types in total. It is annotated with the eye-movement records of 10 English native speakers, who each read the whole corpus. The eye-tracking data was preprocessed following the methodology described in Demberg and Keller (2008). From this data, we computed total reading time for each word in the corpus. Our statistical analyses were based on actual reading times, and so we only included words that were not skipped. We also excluded words for which the previous word had been skipped, and words on which the normal left-to-right movement of gaze had been interrupted, i.e., by blinks, regressions, etc. Finally, because our focus is the influence of semantic context, we selected only content words whose prior sentential context contained at least two further content words. The resulting data set consisted of 53,704 data points, which is about 10% of the theoretically possible total.[2]

Model Implementation All elements of our model were trained on the BLLIP corpus, a collection of texts from the Wall Street Journal (years 1987–89). The training corpus consisted of 38,521,346 words. We used a development corpus of 50,006 words and a test corpus of similar size. All words were converted to lowercase and numbers were replaced with the symbol $\langle$num$\rangle$. A vocabulary of 20,000 words was chosen and the remaining tokens were replaced with $\langle$unk$\rangle$.

Following Mitchell and Lapata (2009), we constructed a simple semantic space based on co-occurrence statistics from the BLLIP training set. We used the 2,000 most frequent word types as contexts and a symmetric five word window. Vector components were defined as in Equation (6). We also trained the LDA model on BLLIP, using the Gibb's sampling procedure discussed in Griffiths et al. (2007). We experimented with different numbers of topics on the development set (from 10 to 1,000) and report results on the test set with 100 topics. In our experiments, the hyperparameter α was initialized to .5, and the β word probabilities were initialized randomly.

We integrated our compositional models with a trigram model which we also trained on BLLIP. The model was built using the SRILM toolkit (Stolcke 2002) with backoff and Kneser-Ney smoothing. As our incremental parser we used Roark's (2001) parser trained on sections 2–21 of the Penn Treebank containing 936,017 words. The parser produces prefix probabilities for each word of a sentence which we converted to conditional probabilities by dividing each current probability by the previous one.

Statistical Analysis The statistical analyses in this paper were carried out using linear mixed effects models (LME, Pinheiro and Bates 2000). The latter can be thought of as generalization of linear regression that allows the inclusion of random factors (such as participants or items) as well as fixed factors (e.g., word frequency). In our analyses, we treat participant as a random factor, which means that our models contain an intercept term for each participant, representing the individual differences in the rates at which they read.[3]

We evaluated the effect of adding a factor to a model by comparing the likelihoods of the models with and without that factor. If a χ^2 test on the

[2]The total of all words read by all subjects is 515,020. The pre-processing recommended by Demberg and Keller's (2008) results in a data sets containing 436,000 data points. Removing non-content words leaves 205,922 data points. It only makes sense to consider words that were actually fixated (the eye-tracking measures used are not defined on skipped words), which leaves 162,129 data points. Following Pynte et al. (2008), we require that the previous word was fixated, with 70,051 data points remaining. We exclude words on which the normal left to right movement of gaze had been interrupted, e.g., by blinks and regressions, which results in the final total to 53,704 data points.

[3]Other random factors that are appropriate for our analyses are word and sentence; however, due to the large number of instances for these factors (given that the Dundee corpus contains 51,502 tokens), we were not able to include them: the model fitting algorithm we used (implemented in the R package `lme4`) does not converge for such large models.

Factor	Coefficient
Intercept	$-.011$
Word Length	.264

likelihood ratio is significant, then this indicates that the new factor significantly improves model fit. We also experimented with adding random slopes for participant to the model (in addition to the random intercept); however, this either led to non-convergence of the model fitting procedure, or failed to result in an increase in model fit according to the likelihood ratio test. Therefore, all models reported in the rest of this paper contain random intercept of participants as the sole random factor.

Rather than model raw reading times, we model times on the log scale. This is desirable for a number of reasons. Firstly, the raw reading times tend to have a skew distribution and taking logs produces something closer to normal, which is preferable for modeling. Secondly, the regression equation makes more sense on the log scale as the contribution of each term to raw reading time is multiplicative rather than additive. That is, $log(t) = \sum_i \beta_i x_i$ implies $t = \prod_i e^{\beta_i x_i}$. In particular, the intercept term for each participant now represents a multiplicative factor by which that participant is slower or faster.

5 Results

We computed separate mixed effects models for three dependent variables, namely first fixation duration, first pass duration, and total reading time. We report results for total times throughout, as the results of the other two dependent variables are broadly similar. Our strategy was to first construct a baseline model of low-level factors influencing reading time, and then to take the residuals from that model as the dependent variable in subsequent analyses. In this way we removed the effects of low-level factors before investigating the factors associated with syntactic and semantic constraint. This avoids problems with collinearity between low-level factors and the factors we are interested in (e.g., trigram probability is highly correlated with word frequency). The baseline model contained the factors word length, word frequency, launch distance, landing position, and the reading time for the last fixated word, and its parameter estimates are given in Table 1. To further reduce collinearity, we also centered all fixed factors, both in the baseline model, and in the models fitted on the residuals that we report in the following. Note that some intercorrelations remain between the factors, which we will discuss at the end of Section 5.

Before investigating whether an integrated model of semantic and syntactic constraint improves the goodness of fit over the baseline, we examined the influence of semantic constraint alone. This was necessary as compositional models have not been previously used to model processing difficulty. Besides, replicating Pynte et al.'s (2008) finding, we were also interested in assessing whether the underlying semantic representation (simple semantic space or LDA) and composition function (additive versus multiplicative) modulate reading times differentially.

We built an LME model that predicted the residual reading times of the baseline model using the similarity scores from our composition models as factors. We then carried out a χ^2 test on the likelihood ratio of a model only containing the random factor and the intercept, and a model also containing the semantic factor (cosine similarity). The addition of the semantic factor significantly improves model fit for both the simple semantic space and LDA. This result is observed for both additive and multiplicative composition functions. Our results are summarized in Table 2 which reports the coefficients of the four LME models fitted against the residuals of the baseline model, together with the p-values of the χ^2 test.

Before evaluating our integrated surprisal measure, we evaluated its components *individually* in order to tease their contributions apart. For example, it may be the case that syntactic surprisal is an overwhelmingly better predictor of reading time than semantic surprisal, however we would not be able to detect this by simply adding a factor based on Equation (9) to the baseline model. The

	Factor	SSS Coef	LDA Coef
	$-\log(p)$	.00760***	.00760***
Add	$-\log(\Delta)$	.03810***	.00622***

Model	Composition	Coefficient
SSS	Additive	.00804***
	Multiplicative	.00819***
LDA	Additive	.00817***
	Multiplicative	.00640***

Table 4: Coefficients of LME models with integrated surprisal measure (based on SSS or LDA) as factor

integrated surprisal measure can be written as:

$$S = -\log(\lambda p_1 + (1-\lambda)p_2) \quad (10)$$

Where p_2 is the incremental parser probability and p_1 is the product of the semantic component, Δ, and the trigram probability, p. This can be broken down into the sum of two terms:

$$S = -\log(p_1) - \log(\lambda + (1-\lambda)\frac{p_2}{p_1}) \quad (11)$$

Since the first term, $-\log(p_1)$ is itself a product it can also be broken down further:

$$S = -\log(p) - \log(\Delta) - \log(\lambda + (1-\lambda)\frac{p_2}{p_1}) \quad (12)$$

Thus, to evaluate the contribution of the three components to the integrated surprisal measure we fitted nested LME models, i.e., we entered these terms one at a time into a mixed effects model and tested the significance of the improvement in model fit for each additional term.

We again start with an LME model that only contains the random factor and the intercept, with the residuals of the baseline models as the dependent variable. Considering the trigram model first, we find that adding this factor to the model gives a significant improvement in fit. Also adding the semantic component ($-\log(\Delta)$) improves fit further, both for additive and multiplicative composition functions using a simple semantic space. Finally, the addition of the parser probabilities ($\log(\lambda + (1-\lambda)\frac{p_2}{p_1})$) again improves model fit significantly. As far as LDA is concerned, the additive model significantly improves model fit, whereas the multiplicative one does not. These results mirror the findings of Mitchell and Lapata (2009), who report that a multiplicative composition function produced the lowest perplexity for the simple semantic space model, whereas an additive function gave the best perplexity for the LDA space. Table 3 lists the coefficients for the nested models for all four variants of our semantic constraint measure.

Finally, we built a separate LME model where we added the integrated surprisal measure (see Equation (9)) to the model only containing the random factor and the intercept (see Table 4). We did this separately for all four versions of the integrated surprisal measure (SSS, LDA; additive, multiplicative). We find that model fit improved significantly all versions of integrated surprisal.

One technical issue that remains to be discussed is collinearity, i.e., intercorrelations between the factors in a model. The presence of collinearity is problematic, as it can render the model fitting procedure unstable; it can also affect the significance of individual factors. As mentioned in Section 4 we used two techniques to reduce collinearity: residualizing and centering. Table 5 gives an overview of the correlation coefficients for all pairs of factors. It becomes clear that collinearity has mostly been removed; there is a remaining relationship between word length and word frequency, which is expected as shorter words tend to be more frequent. This correlation is not a problem for our analysis, as it is confined to the baseline model. Furthermore, word frequency and trigram probability are highly correlated. Again this is expected, given that the frequencies of unigrams and higher-level n-grams tend to be related. This correlation is taken care of by residualizing, which isolates the two factors: word frequency is part of the baseline model, while trigram probability is part of the separate models that we fit on the residuals. All other correlations are small (with coefficients of .27 or less), with one exception: there is a high correlation between the $-\log(\Delta)$ term and the $\log(\lambda + (1-\lambda)\frac{p_2}{p_1})$ term in the multiplicative LDA model. This collinearity issue may explain the absence of a significant improvement in model fit when these two terms are added to the baseline (see Table 3).

	Factor	Len	Freq	$-\mathrm{l}(p)$	$-\mathrm{l}(\Delta)$
	Frequency	$-.310$			
	$-\log(p)$	.230	$-.700$		
SSS Add	$-\log(\Delta)$	.016	$-.120$	.025	
	$\log(\lambda+(1-\lambda)\frac{p_2}{p_1})$	.024	.036	$-.270$	.065

Table 5: Intercorrelations between model factors

6 Discussion

In this paper we investigated the contributions of syntactic and semantic constraint in modeling processing difficulty. Our work departs from previous approaches in that we propose a *single* measure which integrates syntactic and semantic factors. Evaluation on an eye-tracking corpus shows that our measure predicts reading time better than a baseline model that captures low-level factors in reading (word length, landing position, etc.). Crucially, we were able to show that the semantic component of our measure improves reading time predictions over and above a model that includes syntactic measures (based on a trigram model and incremental parser). This means that semantic costs are a significant predictor of reading time *in addition* to the well-known syntactic surprisal.

An open issue is whether a single, integrated measure (as evaluated in Table 4) fits the eye-movement data significantly better than separate measures for trigram, syntactic, and semantic surprisal (as evaluated in Table 3. However, we are not able to investigate this hypothesis: our approach to testing the significance of factors requires nested models; the log-likelihood test (see Section 4) is only able to establish whether adding a factor to a model improves its fit; it cannot compare models with disjunct sets of factors (such as a model containing the integrated surprisal measure and one containing the three separate ones). However, we would argue that a single, integrated measure that captures human predictive processing is preferable over a collection of separate measures. It is conceptually simpler (as it is more parsimonious), and is also easier to use in applications (such as readability prediction). Finally, an integrated measure requires less parameters; our definition of surprisal in 12 is simply the sum of the trigram, syntactic, and semantic components. An LME model containing separate factors, on the other hand, requires a coefficient for each of them, and thus has more parameters.

In evaluating our model, we adopted a broad coverage approach using the reading time data from a naturalistic corpus rather than artificially constructed experimental materials. In doing so, we were able to compare different syntactic and semantic costs on the same footing. Previous analyses of semantic constraint have been conducted on different eye-tracking corpora (Dundee and Embra Corpus) and on different languages (English, French). Moreover, comparisons of the individual contributions of syntactic and semantic factors were generally absent from the literature. Our analysis showed that both of these factors can be captured by our integrated surprisal measure which is uniformly probabilistic and thus preferable to modeling semantic and syntactic costs disjointly using a mixture of probabilistic and non-probabilistic measures.

An interesting question is which aspects of semantics our model is able to capture, i.e., why does the combination of LSA or LDA representations with an incremental parser yield a better fit of the behavioral data. In the psycholinguistic literature, various types of semantic information have been investigated: lexical semantics (word senses, selectional restrictions, thematic roles), sentential semantics (scope, binding), and discourse semantics (coreference and coherence); see Keller (2010) of a detailed discussion. We conjecture that our model is mainly capturing lexical semantics (through the vector space representation of words) and sentential semantics (through the multiplication or addition of words). However, discourse coreference effects (such as the ones reported by Altmann and Steedman (1988) and much subsequent work) are probably not amenable to a treatment in terms of vector space semantics; an explicit representation of discourse entities and coreference relations is required (see Dubey 2010 for a model of human sentence processing that can handle coreference).

A key objective for future work will be to investigate models that integrate semantic constraint with syntactic predictions more tightly. For example, we could envisage a parser that uses semantic representations to guide its search, e.g., by pruning syntactic analyses that have a low semantic probability. At the same time, the semantic model should have access to syntactic information, i.e., the composition of word representations should take their syntactic relationships into account, rather than just linear order.

Abstract

Once released, treebanks tend to remain unchanged despite any shortcomings in their depth of linguistic analysis or coverage of specific phenomena. Instead, separate resources are created to address such problems. In this paper we show how to improve the quality of a treebank, by integrating resources and implementing improved analyses for specific constructions.

We demonstrate this *rebanking* process by creating an updated version of CCGbank that includes the predicate-argument structure of both verbs and nouns, base-NP brackets, verb-particle constructions, and restrictive and non-restrictive nominal modifiers; and evaluate the impact of these changes on a statistical parser.

1 Introduction

Progress in natural language processing relies on direct comparison on shared data, discouraging improvements to the evaluation data. This means that we often spend years competing to reproduce partially incorrect annotations. It also encourages us to approach related problems as discrete tasks, when a new data set that adds deeper information establishes a new incompatible evaluation.

Direct comparison has been central to progress in statistical parsing, but it has also caused problems. Treebanking is a difficult engineering task: coverage, cost, consistency and granularity are all competing concerns that must be balanced against each other when the annotation scheme is developed. The difficulty of the task means that we ought to view treebanking as an ongoing process akin to grammar development, such as the many years of work on the ERG (Flickinger, 2000).

This paper demonstrates how a treebank can be *rebanked* to incorporate novel analyses and information from existing resources. We chose to work on CCGbank (Hockenmaier and Steedman, 2007), a Combinatory Categorial Grammar (Steedman, 2000) treebank acquired from the Penn Treebank (Marcus et al., 1993). This work is equally applicable to the corpora described by Miyao et al. (2004), Shen et al. (2008) or Cahill et al. (2008).

Our first changes integrate four previously suggested improvements to CCGbank. We then describe a novel CCG analysis of NP predicate-argument structure, which we implement using NomBank (Meyers et al., 2004). Our analysis allows the distinction between core and peripheral arguments to be represented for predicate nouns.

With this distinction, an entailment recognition system could recognise that *Google's acquisition of YouTube* entailed *Google acquired YouTube*, because equivalent predicate-argument structures are built for both. Our analysis also recovers non-local dependencies mediated by nominal predicates; for instance, *Google* is the agent of *acquire* in *Google's decision to acquire YouTube*.

The rebanked corpus extends CCGbank with:

1. NP brackets from Vadas and Curran (2008);
2. Restored and normalised punctuation;
3. Propbank-derived verb subcategorisation;
4. Verb particle structure drawn from Propbank;
5. Restrictive and non-restrictive adnominals;
6. Reanalyses to promote better head-finding;
7. Nombank-derived noun subcategorisation.

Together, these changes modify 30% of the labelled dependencies in CCGbank, demonstrating how multiple resources can be brought together in a single, richly annotated corpus. We then train and evaluate a parser for these changes, to investigate their impact on the accuracy of a state-of-the-art statistical CCG parser.

Uppsala, Sweden, 11-16 July 2010.

2 Background and motivation

Formalisms like HPSG (Pollard and Sag, 1994), LFG (Kaplan and Bresnan, 1982), and CCG (Steedman, 2000) are *linguistically motivated* in the sense that they attempt to explain and predict the limited variation found in the grammars of natural languages. They also attempt to specify how grammars construct semantic representations from surface strings, which is why they are sometimes referred to as *deep* grammars. Analyses produced by these formalisms can be more detailed than those produced by skeletal phrase-structure parsers, because they produce fully specified predicate-argument structures.

Unfortunately, statistical parsers do not take advantage of this potential detail. Statistical parsers induce their grammars from corpora, and the corpora for linguistically motivated formalisms currently do not contain high quality predicate-argument annotation, because they were derived from the Penn Treebank (PTB Marcus et al., 1993). Manually written grammars for these formalisms, such as the ERG HPSG grammar (Flickinger, 2000) and the XLE LFG grammar (Butt et al., 2006) produce far more detailed and linguistically correct analyses than any English statistical parser, due to the comparatively coarse-grained annotation schemes of the corpora statistical parsers are trained on. While rule-based parsers use grammars that are carefully engineered (e.g. Oepen et al., 2004), and can be updated to reflect the best linguistic analyses, statistical parsers have so far had to take what they are given.

What we suggest in this paper is that a treebank's grammar need not last its lifetime. For a start, there have been many annotations of the PTB that add much of the extra information needed to produce very high quality analyses for a linguistically motivated grammar. There are also other transformations which can be made with no additional information. That is, sometimes the existing trees allow transformation rules to be written that improve the quality of the grammar.

Linguistic theories are constantly changing, which means that there is a substantial lag between what we (think we) understand of grammar and the annotations in our corpora. The grammar engineering process we describe, which we dub *rebanking*, is intended to reduce this gap, tightening the feedback loop between formal and computational linguistics.

2.1 Combinatory Categorial Grammar

Combinatory Categorial Grammar (CCG; Steedman, 2000) is a lexicalised grammar, which means that all grammatical dependencies are specified in the lexical entries and that the production of derivations is governed by a small set of rules.

Lexical categories are either atomic (S, NP, PP, N), or a functor consisting of a result, directional slash, and argument. For instance, *in* might head a PP-typed constituent with one NP-typed argument, written as PP/NP.

A category can have a functor as its result, so that a word can have a complex valency structure. For instance, a verb phrase is represented by the category $S\backslash NP$: it is a function from a leftward NP (a subject) to a sentence. A transitive verb requires an object to become a verb phrase, producing the category $(S\backslash NP)/NP$.

A CCG grammar consists of a small number of schematic rules, called combinators. CCG extends the basic application rules of pure categorial grammar with (generalised) composition rules and type raising. The most common rules are:

$$\begin{array}{rrcll} X/Y & Y & \Rightarrow & X & (>) \\ Y & X\backslash Y & \Rightarrow & X & (<) \\ X/Y & Y/Z & \Rightarrow & X/Z & (>\mathbf{B}) \\ Y\backslash Z & X\backslash Y & \Rightarrow & X\backslash Z & (<\mathbf{B}) \\ Y/Z & X\backslash Y & \Rightarrow & X/Z & (<\mathbf{B}_{\times}) \end{array}$$

CCGbank (Hockenmaier and Steedman, 2007) extends this compact set of combinatory rules with a set of type-changing rules, designed to strike a better balance between sparsity in the category set and ambiguity in the grammar. We mark type-changing rules **TC** in our derivations.

In wide-coverage descriptions, categories are generally modelled as typed-feature structures (Shieber, 1986), rather than atomic symbols. This allows the grammar to include a notion of headedness, and to unify under-specified features.

We occasionally must refer to these additional details, for which we employ the following notation. Features are annotated in square-brackets, e.g. $S[dcl]$. Head-finding indices are annotated on categories in subscripts, e.g. $(NP_y\backslash NP_y)/NP_z$. The index of the word the category is assigned to is left implicit. We will sometimes also annotate derivations with the heads of categories as they are being built, to help the reader keep track of what lexemes have been bound to which categories.

3 Combining CCGbank corrections

There have been a few papers describing corrections to CCGbank. We bring these corrections together for the first time, before building on them with our further changes.

3.1 Compound noun brackets

Compound noun phrases can nest inside each other, creating bracketing ambiguities:

(1) (crude oil) prices

(2) crude (oil prices)

The structure of such compound noun phrases is left underspecified in the Penn Treebank (PTB), because the annotation procedure involved stitching together partial parses produced by the Fidditch parser (Hindle, 1983), which produced flat brackets for these constructions. The bracketing decision was also a source of annotator disagreement (Bies et al., 1995).

When Hockenmaier and Steedman (2002) went to acquire a CCG treebank from the PTB, this posed a problem. There is no equivalent way to leave these structures under-specified in CCG, because derivations must be binary branching. They therefore employed a simple heuristic: assume all such structures branch to the right. Under this analysis, *crude oil* is not a constituent, producing an incorrect analysis as in (1).

Vadas and Curran (2007) addressed this by manually annotating all of the ambiguous noun phrases in the PTB, and went on to use this information to correct 20,409 dependencies (1.95%) in CCGbank (Vadas and Curran, 2008). Our changes build on this corrected corpus.

3.2 Punctuation corrections

The syntactic analysis of punctuation is notoriously difficult, and punctuation is not always treated consistently in the Penn Treebank (Bies et al., 1995). Hockenmaier (2003) determined that quotation marks were particularly problematic, and therefore removed them from CCGbank altogether. We use the process described by Tse and Curran (2008) to restore the quotation marks and shift commas so that they always attach to the constituent to their left. This allows a grammar rule to be removed, preventing a great deal of spurious ambiguity and improving the speed of the C&C parser (Clark and Curran, 2007) by 37%.

3.3 Verb predicate-argument corrections

Semantic role descriptions generally recognise a distinction between core arguments, whose role comes from a set specific to the predicate, and peripheral arguments, who have a role drawn from a small, generic set. This distinction is represented in the surface syntax in CCG, because the category of a verb must specify its argument structure. In (3) *as a director* is annotated as a complement; in (4) it is an adjunct:

(3) *He* *joined* *as a director*
NP $(S\backslash NP)/PP$ PP

(4) *He* *joined* *as a director*
NP $S\backslash NP$ $(S\backslash NP)\backslash(S\backslash NP)$

CCGbank contains noisy complement and adjunct distinctions, because they were drawn from PTB function labels which imperfectly represent the distinction. In our previous work we used Propbank (Palmer et al., 2005) to convert 1,543 complements to adjuncts and 13,256 adjuncts to complements (Honnibal and Curran, 2007). If a constituent such as *as a director* received an adjunct category, but was labelled as a core argument in Propbank, we changed it to a complement, using its head's part-of-speech tag to infer its constituent type. We performed the equivalent transformation to ensure all peripheral arguments of verbs were analysed as adjuncts.

3.4 Verb-particle constructions

Propbank also offers reliable annotation of verb-particle constructions. This was not available in the PTB, so Hockenmaier and Steedman (2007) annotated all intransitive prepositions as adjuncts:

(5) *He* *woke* *up*
NP $S\backslash NP$ $(S\backslash NP)\backslash(S\backslash NP)$

We follow Constable and Curran (2009) in exploiting the Propbank annotations to add verb-particle distinctions to CCGbank, by introducing a new atomic category PT for particles, and changing their status from adjuncts to complements:

(6) *He* *woke* *up*
NP $(S\backslash NP)/PT$ PT

This analysis could be improved by adding extra head-finding logic to the verbal category, to recognise the multi-word expression as the head.

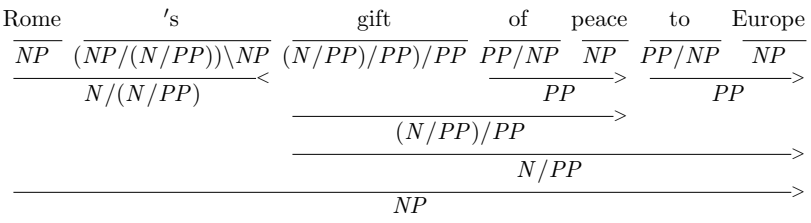

Figure 1: Deverbal noun predicate with agent, patient and beneficiary arguments.

4 Noun predicate-argument structure

Many common nouns in English can receive optional complements and adjuncts, realised by prepositional phrases, genitive determiners, compound nouns, relative clauses, and for some nouns, complementised clauses. For example, deverbal nouns generally have argument structures similar to the verbs they are derived from:

(7) Rome's destruction of Carthage

(8) Rome destroyed Carthage

The semantic roles of *Rome* and *Carthage* are the same in (7) and (8), but the noun cannot case-mark them directly, so *of* and the genitive clitic are pressed into service. The semantic role depends on both the predicate and subcategorisation frame:

(9) Carthage's$_{\mathrm{p}}$ destruction$_{\mathrm{Pred.}}$

(10) Rome's$_{\mathrm{a}}$ destruction$_{\mathrm{Pred.}}$ of Carthage$_{\mathrm{p}}$

(11) Rome's$_{\mathrm{a}}$ gift$_{\mathrm{Pred.}}$

(12) Rome's$_{\mathrm{a}}$ gift$_{\mathrm{Pred.}}$ of peace$_{\mathrm{p}}$ to Europe$_{\mathrm{b}}$

In (9), the genitive introduces the patient, but when the patient is supplied by the PP, it instead introduces the agent. The mapping differs for *gift*, where the genitive introduces the agent.

Peripheral arguments, which supply generically available modifiers of time, place, cause, quality etc, can be realised by pre- and post-modifiers:

(13) The portrait *in the Louvre*

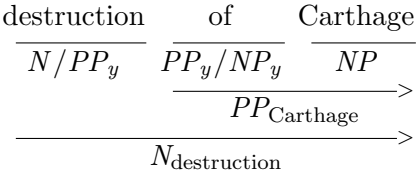
(14) The *fine* portrait

(15) *The Louvre's* portraits

These are distinct from core arguments because their interpretation does not depend on the predicate. The ambiguity can be seen in an NP such as *The nobleman's portrait*, where the genitive could mark possession (peripheral), or it could introduce the patient (core). The distinction between core and peripheral arguments is particularly difficult for compound nouns, as pre-modification is very productive in English.

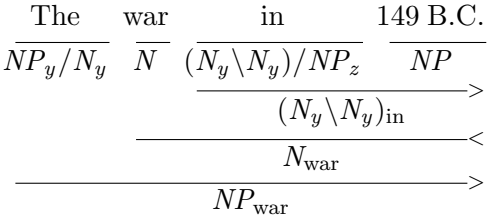
4.1 CCG analysis

We designed our analysis for transparency between the syntax and the predicate-argument structure, by stipulating that all and only the core arguments should be syntactic arguments of the predicate's category. This is fairly straightforward for arguments introduced by prepositions:

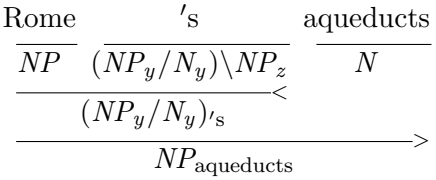


In our analysis, the head of *of Carthage* is *Carthage*, as *of* is assumed to be a semantically transparent case-marker. We apply this analysis to prepositional phrases that provide arguments to verbs as well — a departure from CCGbank.

Prepositional phrases that introduce peripheral arguments are analysed as syntactic adjuncts:



Adjunct prepositional phrases remain headed by the preposition, as it is the preposition's semantics that determines whether they function as temporal, causal, spatial etc. arguments. We follow Hockenmaier and Steedman (2007) in our analysis of genitives which realise peripheral arguments, such as the literal possessive:



Arguments introduced by possessives are a little trickier, because the genitive also functions as a determiner. We achieve this by having the noun subcategorise for the argument, which we type PP, and having the possessive subcategorise for the unsaturated noun to ultimately produce an NP:

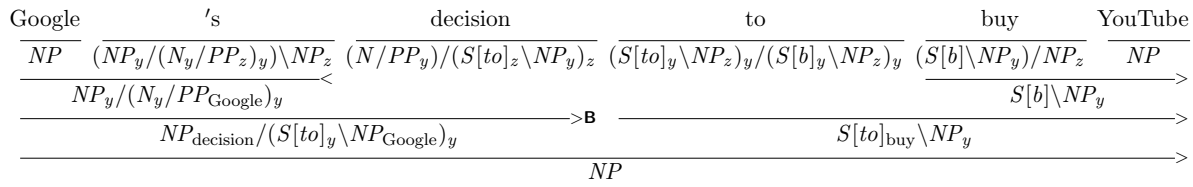


Figure 2: The coindexing on *decision*'s category allows the hard-to-reach agent of *buy* to be recovered. A non-normal form derivation is shown so that instantiated variables can be seen.

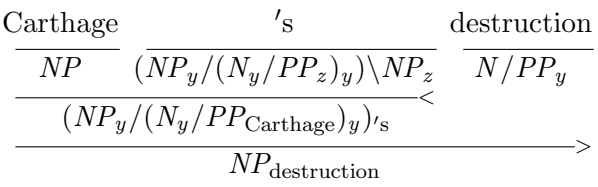


In this analysis, we regard the genitive clitic as a case-marker that performs a movement operation roughly analogous to WH-extraction. Its category is therefore similar to the one used in object extraction, $(N\backslash N)/(S/NP)$. Figure 1 shows an example with multiple core arguments.

This analysis allows recovery of verbal arguments of nominalised raising and control verbs, a construction which both Gildea and Hockenmaier (2003) and Boxwell and White (2008) identify as a problem case when aligning Propbank and CCGbank. Our analysis accommodates this construction effortlessly, as shown in Figure 2. The category assigned to *decision* can coindex the missing NP argument of *buy* with its own PP argument. When that argument is supplied by the genitive, it is also supplied to the verb, *buy*, filling its dependency with its agent, *Google*. This argument would be quite difficult to recover using a shallow syntactic analysis, as the path would be quite long. There are 494 such verb arguments mediated by nominal predicates in Sections 02-21.

These analyses allow us to draw complement/adjunct distinctions for nominal predicates, so that the surface syntax takes us very close to a full predicate-argument analysis. The only information we are not specifying in the syntactic analysis are the role labels assigned to each of the syntactic arguments. We could go further and express these labels in the syntax, producing categories like $(N/PP\{0\}_y)/PP\{1\}_z$ and $(N/PP\{1\}_y)/PP\{0\}_z$, but we expect that this would cause sparse data problems given the limited size of the corpus. This experiment would be an interesting subject of future work.

The only local core arguments that we do not annotate as syntactic complements are compound nouns, such as *decision makers*. We avoided these arguments because of the productivity of noun-noun compounding in English, which makes these argument structures very difficult to recover.

We currently do not have an analysis that allows support verbs to supply noun arguments, so we do not recover any of the long-range dependency structures described by Meyers et al. (2004).

4.2 Implementation and statistics

Our analysis requires semantic role labels for each argument of the nominal predicates in the Penn Treebank — precisely what NomBank (Meyers et al., 2004) provides. We can therefore draw our distinctions using the process described in our previous work, Honnibal and Curran (2007).

NomBank follows the same format as Propbank, so the procedure is exactly the same. First, we align CCGbank and the Penn Treebank, and produce a version of NomBank that refers to CCGbank nodes. We then assume that any prepositional phrase or genitive determiner annotated as a core argument in NomBank should be analysed as a complement, while peripheral arguments and adnominals that receive no semantic role label at all are analysed as adjuncts.

We converted 34,345 adnominal prepositional phrases to complements, leaving 18,919 as adjuncts. The most common preposition converted was *of*, which was labelled as a core argument 99.1% of the 19,283 times it occurred as an adnominal. The most common adjunct preposition was *in*, which realised a peripheral argument in 59.1% of its 7,725 occurrences.

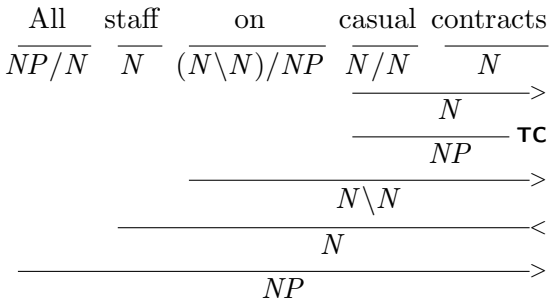
The frequent prepositions were more skewed towards core arguments. 73% of the occurrences of the 5 most frequent prepositions (*of*, *in*, *for*, *on* and *to*) realised peripheral arguments, compared with 53% for other prepositions.

Core arguments were also more common than peripheral arguments for possessives. There are 20,250 possessives in the corpus, of which 75% were converted to complements. The percentage was similar for both personal pronouns (such as *his*) and genitive phrases (such as *the boy's*).

5 Adding restrictivity distinctions

Adnominals can have either a restrictive or a non-restrictive (appositional) interpretation, determining the potential reference of the noun phrase it modifies. This ambiguity manifests itself in whether prepositional phrases, relative clauses and other adnominals are analysed as modifiers of either N or NP, yielding a restrictive or non-restrictive interpretation respectively.

In CCGbank, all adnominals attach to NPs, producing non-restrictive interpretations. We therefore move restrictive adnominals to N nodes:



This corrects the previous interpretation, which stated that there were no permanent staff.

5.1 Implementation and statistics

The Wall Street Journal's style guide mandates that this attachment ambiguity be managed by bracketing non-restrictive relatives with commas (Martin, 2002, p. 82), as in *casual staff, who have no health insurance, support it*. We thus use punctuation to make the attachment decision.

All $NP\backslash NP$ modifiers that are not preceded by punctuation were moved to the lowest N node possible and relabelled $N\backslash N$. We select the lowest (i.e. closest to leaf) N node because some adjectives, such as *present* or *former*, require scope over the qualified noun, making it safer to attach the adnominal first.

Some adnominals in CCGbank are created by the $S\backslash NP \rightarrow NP\backslash NP$ unary type-changing rule, which transforms reduced relative clauses. We introduce a $S\backslash NP \rightarrow N\backslash N$ in its place, and add a binary rule cued by punctuation to handle the relatively rare non-restrictive reduced relative clauses.

The rebanked corpus contains 34,134 $N\backslash N$ restrictive modifiers, and 9,784 non-restrictive modifiers. Most (61%) of the non-restrictive modifiers were relative clauses.

6 Reanalysing partitive constructions

True partitive constructions consist of a quantifier (16), a cardinal (17) or demonstrative (18) applied to an NP via *of*. There are similar constructions headed by common nouns, as in (19):

(16) Some of us

(17) Four of our members

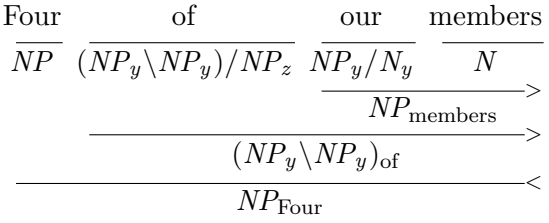
(18) Those of us who smoke

(19) A glass of wine

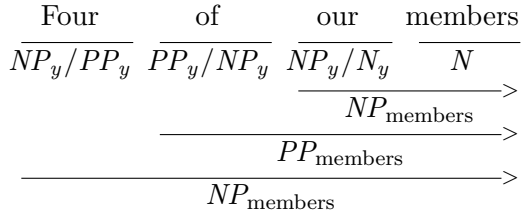
We regard the common noun partitives as headed by the initial noun, such as *glass*, because this noun usually controls the number agreement. We therefore analyse these cases as nouns with prepositional arguments. In (19), *glass* would be assigned the category N/PP.

True partitive constructions are different, however: they are always headed by the head of the NP supplied by *of*. The construction is quite common, because it provides a way to quantify or apply two different determiners.

Partitive constructions are not given special treatment in the PTB, and were analysed as noun phrases with a PP modifier in CCGbank:



This analysis does not yield the correct semantics, and may even hurt parser performance, because the head of the phrase is incorrectly assigned. We correct this with the following analysis, which takes the head from the NP argument of the PP:



The cardinal is given the category NP/PP, in analogy with the standard determiner category which is a function from a noun to a noun phrase (NP/N).

+NP Pred-Arg	1574	511	10.1

Table 2: Effect of the changes on the size of the lexicon.

6.1 Implementation and Statistics

We detect this construction by identifying NPs post-modified by an *of* PP. The NP's head must either have the POS tag CD, or be one of the following words, determined through manual inspection of Sections 02-21:

> *all, another, average, both, each, another, any, anything, both, certain, each, either, enough, few, little, most, much, neither, nothing, other, part, plenty, several, some, something, that, those.*

Having identified the construction, we simply relabel the NP to NP/PP, and the $NP\backslash NP$ adnominal to PP. We identified and reanalysed 3,010 partitive genitives in CCGbank.

7 Similarity to CCGbank

Table 1 shows the percentage of labelled dependencies (L. Deps), unlabelled dependencies (U. Deps) and lexical categories (Cats) that remained the same after each set of changes.

A labelled dependency is a 4-tuple consisting of the head, the argument, the lexical category of the head, and the argument slot that the dependency fills. For instance, the subject fills slot 1 and the object fills slot 2 on the transitive verb category $(S\backslash NP)/NP$. There are more changes to labelled dependencies than lexical categories because one lexical category change alters all of the dependencies headed by a predicate, as they all depend on its lexical category. Unlabelled dependencies consist of only the head and argument.

The biggest changes were those described in Sections 4 and 5. After the addition of nominal predicate-argument structure, over 50% of the labelled dependencies were changed. Many of these changes involved changing an adjunct to a complement, which affects the unlabelled dependencies because the head and argument are inverted.

8 Lexicon statistics

Our changes make the grammar sensitive to new distinctions, which increases the number of lexical categories required. Table 2 shows the number of lexical categories (Cats), the number of lexical categories that occur at least 10 times in Sections 02-21 (Cats ≥ 10), and the average number of categories available for assignment to each token in Section 00 (Cats/Word). We followed Clark and Curran's (2007) process to determine the set of categories a word could receive, which includes a part-of-speech back-off for infrequent words.

The lexicon steadily grew with each set of changes, because each added information to the corpus. The addition of quotes only added two categories (LQU and RQU), and the addition of the quote tokens slightly decreased the average categories per word. The Propbank and verb-particle changes both introduced rare categories for complicated, infrequent argument structures.

The NP predicate-argument structure modifications added the most information. Head nouns were previously guaranteed the category N in CCGbank; possessive clitics always received the category $(NP/N)\backslash NP$; and possessive personal pronouns were always NP/N. Our changes introduce new categories for these frequent tokens, which meant a substantial increase in the number of possible categories per word.

9 Parsing Evaluation

Some of the changes we have made correct problems that have caused the performance of a statistical CCG parser to be over-estimated. Other changes introduce new distinctions, which a parser may or may not find difficult to reproduce. To investigate these issues, we trained and evaluated the C&C CCG parser on our rebanked corpora.

The experiments were set up as follows. We used the highest scoring configuration described by Clark and Curran (2007), the hybrid dependency model, using gold-standard POS tags. We followed Clark and Curran in excluding sentences that could not be parsed from the evaluation. All models obtained similar coverage, between 99.0 and 99.3%. The parser was evaluated using depen-

dencies generated from the gold-standard derivations (Boxwell, p.c., 2010).

Table 3 shows the accuracy of the parser on Sections 00 and 23. The parser scored slightly lower as the NP brackets, Quotes, Propbank and Particles corrections were added. This apparent decline in performance is at least partially an artefact of the evaluation. CCGbank contains some dependencies that are trivial to recover, because Hockenmaier and Steedman (2007) was forced to adopt a strictly right-branching analysis for NP brackets.

There was a larger drop in accuracy on the fully rebanked corpus, which included our analyses of restrictivity, partitive constructions and noun predicate-argument structure. This might also be explained by the evaluation, as the rebanked corpus includes much more fine-grained distinctions. The labelled dependencies evaluation is particularly sensitive to this, as a single category change affects multiple dependencies. This can be seen in the smaller gap in category accuracy.

We investigated whether the differences in performance were due to the different evaluation data by comparing the parsers' performance against the original parser on the dependencies they agreed upon, to allow direct comparison. To do this, we extracted the CCGbank intersection of each corpus's Section 00 dependencies.

Table 4 compares the labelled and unlabelled recall of the rebanked parsers we trained against the CCGbank parser on these intersections. Note that each row refers to a different intersection, so results are not comparable between rows. This comparison shows that the declines in accuracy seen in Table 3 were largely confined to the corrected dependencies. The parser's performance remained fairly stable on the dependencies left unchanged.

The rebanked parser performed 0.8% worse than the CCGbank parser on the intersection dependencies, suggesting that the fine-grained distinctions we introduced did cause some sparse data problems. However, we did not change any of the parser's maximum entropy features or hyperparameters, which are tuned for CCGbank.

10 Conclusion

Research in natural language understanding is driven by the datasets that we have available. The most cited computational linguistics work to date is the Penn Treebank (Marcus et al., 1993)[1]. Propbank (Palmer et al., 2005) has also been very influential since its release, and NomBank has been used for semantic dependency parsing in the CoNLL 2008 and 2009 shared tasks.

This paper has described how these resources can be jointly exploited using a linguistically motivated theory of syntax and semantics. The semantic annotations provided by Propbank and NomBank allowed us to build a corpus that takes much greater advantage of the semantic transparency of a deep grammar, using careful analyses and phenomenon-specific conversion rules.

The major areas of CCGbank's grammar left to be improved are the analysis of comparatives, and the analysis of named entities. English comparatives are diverse and difficult to analyse. Even the XTAG grammar (Doran et al., 1994), which deals with the major constructions of English in enviable detail, does not offer a full analysis of these phenomena. Named entities are also difficult to analyse, as many entity types obey their own specific grammars. This is another example of a phenomenon that could be analysed much better in CCGbank using an existing resource, the BBN named entity corpus.

Our rebanking has substantially improved CCGbank, by increasing the granularity and linguistic fidelity of its analyses. We achieved this by exploiting existing resources and crafting novel analyses. The process we have demonstrated can be used to train a parser that returns dependencies that abstract away as much surface syntactic variation as possible — including, now, even whether the predicate and arguments are expressed in a noun phrase or a full clause.

Abstract

In this paper we present BabelNet – a very large, wide-coverage multilingual semantic network. The resource is automatically constructed by means of a methodology that integrates lexicographic and encyclopedic knowledge from WordNet and Wikipedia. In addition Machine Translation is also applied to enrich the resource with lexical information for all languages. We conduct experiments on new and existing gold-standard datasets to show the high quality and coverage of the resource.

1 Introduction

In many research areas of Natural Language Processing (NLP) lexical knowledge is exploited to perform tasks effectively. These include, among others, text summarization (Nastase, 2008), Named Entity Recognition (Bunescu and Paşca, 2006), Question Answering (Harabagiu et al., 2000) and text categorization (Gabrilovich and Markovitch, 2006). Recent studies in the difficult task of Word Sense Disambiguation (Navigli, 2009b, WSD) have shown the impact of the amount and quality of lexical knowledge (Cuadros and Rigau, 2006): richer knowledge sources can be of great benefit to both knowledge-lean systems (Navigli and Lapata, 2010) and supervised classifiers (Ng and Lee, 1996; Yarowsky and Florian, 2002).

Various projects have been undertaken to make lexical knowledge available in a machine readable format. A pioneering endeavor was WordNet (Fellbaum, 1998), a computational lexicon of English based on psycholinguistic theories. Subsequent projects have also tackled the significant problem of multilinguality. These include EuroWordNet (Vossen, 1998), MultiWordNet (Pianta et al., 2002), the Multilingual Central Repository (Atserias et al., 2004), and many others. However, manual construction methods inherently suffer from a number of drawbacks. First, maintaining and updating lexical knowledge resources is expensive and time-consuming. Second, such resources are typically lexicographic, and thus contain mainly concepts and only a few named entities. Third, resources for non-English languages often have a much poorer coverage since the construction effort must be repeated for every language of interest. As a result, an obvious bias exists towards conducting research in resource-rich languages, such as English.

A solution to these issues is to draw upon a large-scale collaborative resource, namely Wikipedia[1]. Wikipedia represents the perfect complement to WordNet, as it provides multilingual lexical knowledge of a mostly encyclopedic nature. While the contribution of any individual user might be imprecise or inaccurate, the continual intervention of expert contributors in all domains results in a resource of the highest quality (Giles, 2005). But while a great deal of work has been recently devoted to the automatic extraction of structured information from Wikipedia (Wu and Weld, 2007; Ponzetto and Strube, 2007; Suchanek et al., 2008; Medelyan et al., 2009, *inter alia*), the knowledge extracted is organized in a looser way than in a computational lexicon such as WordNet.

In this paper, we make a major step towards the vision of a wide-coverage multilingual knowledge resource. We present a novel methodology that produces a very large multilingual semantic network: BabelNet. This resource is created by linking Wikipedia to WordNet via an automatic mapping and by integrating lexical gaps in resource-

[1] http://download.wikipedia.org. We use the English Wikipedia database dump from November 3, 2009, which includes 3,083,466 articles. Throughout this paper, we use Sans Serif for words, SMALL CAPS for Wikipedia pages and CAPITALS for Wikipedia categories.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 216–225,
Uppsala, Sweden, 11-16 July 2010.

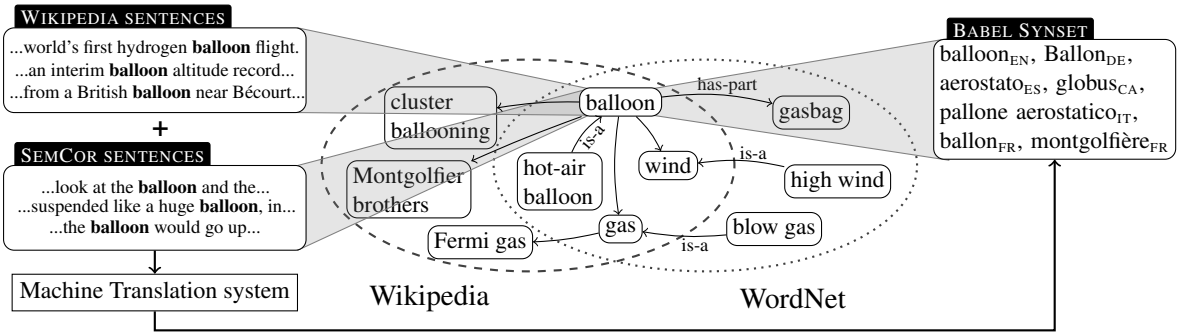

Figure 1: An illustrative overview of BabelNet.

poor languages with the aid of Machine Translation. The result is an "encyclopedic dictionary", that provides concepts and named entities lexicalized in many languages and connected with large amounts of semantic relations.

2 BabelNet

We encode knowledge as a labeled directed graph $G = (V, E)$ where V is the set of *vertices* – i.e. *concepts*[2] such as balloon – and $E \subseteq V \times R \times V$ is the set of *edges* connecting pairs of concepts. Each edge is labeled with a *semantic relation* from R, e.g. {*is-a*, *part-of*, ..., ϵ}, where ϵ denotes an unspecified semantic relation. Importantly, each vertex $v \in V$ contains a set of lexicalizations of the concept for different languages, e.g. { balloon$_{EN}$, Ballon$_{DE}$, aerostato$_{ES}$, ..., montgolfière$_{FR}$ }.

Concepts and relations in BabelNet are harvested from the largest available semantic lexicon of English, WordNet, and a wide-coverage collaboratively edited encyclopedia, the English Wikipedia (Section 3.1). We collect (a) from WordNet, all available word senses (as *concepts*) and all the semantic pointers between synsets (as *relations*); (b) from Wikipedia, all encyclopedic entries (i.e. pages, as *concepts*) and semantically unspecified *relations* from hyperlinked text.

In order to provide a *unified resource*, we merge the intersection of these two knowledge sources (i.e. their concepts in common) by establishing a mapping between Wikipedia pages and WordNet senses (Section 3.2). This avoids duplicate concepts and allows their inventories of concepts to complement each other. Finally, to enable multilinguality, we collect the lexical realizations of the available concepts in different languages by using (a) the human-generated translations provided in Wikipedia (the so-called *inter-language* links), as well as (b) a machine translation system to translate occurrences of the concepts within sense-tagged corpora, namely SemCor (Miller et al., 1993) – a corpus annotated with WordNet senses – and Wikipedia itself (Section 3.3). We call the resulting set of multilingual lexicalizations of a given concept a *babel synset*. An overview of BabelNet is given in Figure 1 (we label vertices with English lexicalizations): unlabeled edges are obtained from links in the Wikipedia pages (e.g. BALLOON (AIRCRAFT) links to WIND), whereas labeled ones from WordNet[3] (e.g. balloon^1_n *has-part* gasbag^1_n). In this paper we restrict ourselves to concepts lexicalized as nouns. Nonetheless, our methodology can be applied to all parts of speech, but in that case Wikipedia cannot be exploited, since it mainly contains nominal entities.

3 Methodology

3.1 Knowledge Resources

WordNet. The most popular lexical knowledge resource in the field of NLP is certainly WordNet, a computational lexicon of the English language. A concept in WordNet is represented as a synonym set (called *synset*), i.e. the set of words that share the same meaning. For instance, the concept wind is expressed by the following synset:

$$\{ \text{wind}^1_n, \text{air current}^1_n, \text{current of air}^1_n \},$$

where each word's subscripts and superscripts indicate their parts of speech (e.g. n stands for noun)

[2] Throughout the paper, unless otherwise stated, we use the general term *concept* to denote either a concept or a named entity.

[3] We use in the following WordNet version 3.0. We denote with w^i_p the i-th sense of a word w with part of speech p. We use word senses to unambiguously denote the corresponding synsets (e.g. plane^1_n for { airplane^1_n, aeroplane^1_n, plane^1_n }). Hereafter, we use *word sense* and *synset* interchangeably.

and sense number, respectively. For each synset, WordNet provides a textual definition, or gloss. For example, the gloss of the above synset is: "air moving from an area of high pressure to an area of low pressure".

Wikipedia. Our second resource, Wikipedia, is a Web-based collaborative encyclopedia. A Wikipedia page (henceforth, Wikipage) presents the knowledge about a specific concept (e.g. BALLOON (AIRCRAFT)) or named entity (e.g. MONTGOLFIER BROTHERS). The page typically contains hypertext linked to other relevant Wikipages. For instance, BALLOON (AIRCRAFT) is linked to WIND, GAS, and so on. The title of a Wikipage (e.g. BALLOON (AIRCRAFT)) is composed of the lemma of the concept defined (e.g. balloon) plus an optional label in parentheses which specifies its meaning if the lemma is ambiguous (e.g. AIRCRAFT VS. TOY). Wikipages also provide inter-language links to their counterparts in other languages (e.g. BALLOON (AIRCRAFT) links to the Spanish page AEROSTATO). Finally, some Wikipages are redirections to other pages, e.g. the Spanish BALÓN AEROSTÁTICO redirects to AEROSTATO.

3.2 Mapping Wikipedia to WordNet

The first phase of our methodology aims to establish links between Wikipages and WordNet senses. We aim to acquire a mapping μ such that, for each Wikipage w, we have:

$$\mu(w) = \begin{cases} s \in Senses_{\text{WN}}(w) & \text{if a link can be established,} \\ \epsilon & \text{otherwise,} \end{cases}$$

where $Senses_{\text{WN}}(w)$ is the set of senses of the *lemma* of w in WordNet. For example, if our mapping methodology linked BALLOON (AIRCRAFT) to the corresponding WordNet sense balloon^1_n, we would have μ(BALLOON (AIRCRAFT)) = balloon^1_n.

In order to establish a mapping between the two resources, we first identify the disambiguation contexts for Wikipages (Section 3.2.1) and WordNet senses (Section 3.2.2). Next, we intersect these contexts to perform the mapping (see Section 3.2.3).

3.2.1 Disambiguation Context of a Wikipage

Given a Wikipage w, we use the following information as disambiguation context:

- **Sense labels**: e.g. given the page BALLOON (AIRCRAFT), the word aircraft is added to the disambiguation context.
- **Links**: the titles' lemmas of the pages linked from the target Wikipage (i.e., outgoing links). For instance, the links in the Wikipage BALLOON (AIRCRAFT) include wind, gas, etc.
- **Categories**: Wikipages are typically classified according to one or more categories. For example, the Wikipage BALLOON (AIRCRAFT) is categorized as BALLOONS, BALLOONING, etc. While many categories are very specific and do not appear in WordNet (e.g., SWEDISH WRITERS or SCIENTISTS WHO COMMITTED SUICIDE), we use their syntactic heads as disambiguation context (i.e. writer and scientist, respectively).

Given a Wikipage w, we define its disambiguation context $Ctx(w)$ as the set of words obtained from all of the three sources above.

3.2.2 Disambiguation Context of a WordNet Sense

Given a WordNet sense s and its synset S, we collect the following information:

- **Synonymy**: all synonyms of s in S. For instance, given the sense airplane^1_n and its corresponding synset { airplane^1_n, aeroplane^1_n, plane^1_n }, the words contained therein are included in the context.
- **Hypernymy/Hyponymy**: all synonyms in the synsets H such that H is either a hypernym (i.e., a generalization) or a hyponym (i.e., a specialization) of S. For example, given balloon^1_n, we include the words from its hypernym { $\text{lighter-than-air craft}^1_n$ } and all its hyponyms (e.g. { $\text{hot-air balloon}^1_n$ }).
- **Sisterhood**: words from the sisters of S. A sister synset S' is such that S and S' have a common direct hypernym. For example, given balloon^1_n, it can be found that { balloon^1_n } and { airship^1_n, dirigible^1_n } are sisters. Thus airship and dirigible are included in the disambiguation context of s.
- **Gloss**: the set of lemmas of the content words occurring within the WordNet gloss of S.

We thus define the disambiguation context $Ctx(s)$ of sense s as the set of words obtained from all of the four sources above.

3.2.3 Mapping Algorithm

In order to link each Wikipedia page to a WordNet sense, we perform the following steps:

- Initially, our mapping μ is empty, i.e. it links each Wikipage w to ϵ.
- For each Wikipage w whose lemma is monosemous both in Wikipedia and WordNet we map w to its only WordNet sense.
- For each remaining Wikipage w for which no mapping was previously found (i.e., $\mu(w) = \epsilon$), we assign the most likely sense to w based on the maximization of the conditional probabilities $p(s|w)$ over the senses $s \in Senses_{\text{WN}}(w)$ (no mapping is established if a tie occurs).

To find the mapping of a Wikipage w, we need to compute the conditional probability $p(s|w)$ of selecting the WordNet sense s given w. The sense s which maximizes this probability is determined as follows:

$$\mu(w) = \underset{s \in Senses_{\text{WN}}(w)}{\operatorname{argmax}} p(s|w) = \underset{s}{\operatorname{argmax}} \frac{p(s,w)}{p(w)} = \underset{s}{\operatorname{argmax}}\, p(s,w)$$

The latter formula is obtained by observing that $p(w)$ does not influence our maximization, as it is a constant independent of s. As a result, determining the most appropriate sense s consists of finding the sense s that maximizes the joint probability $p(s,w)$. We estimate $p(s,w)$ as:

$$p(s,w) = \frac{score(s,w)}{\sum_{\substack{s' \in Senses_{\text{WN}}(w),\\ w' \in Senses_{\text{Wiki}}(w)}} score(s',w')},$$

where $score(s,w) = |Ctx(s) \cap Ctx(w)| + 1$ (we add 1 as a smoothing factor). Thus, in our algorithm we determine the best sense s by computing the intersection of the disambiguation contexts of s and w, and normalizing by the scores summed over all senses of w in Wikipedia and WordNet. More details on the mapping algorithm can be found in Ponzetto and Navigli (2010).

3.3 Translating Babel Synsets

So far we have linked English Wikipages to WordNet senses. Given a Wikipage w, and provided it is mapped to a sense s (i.e., $\mu(w) = s$), we create a babel synset $S \cup W$, where S is the WordNet synset to which sense s belongs, and W includes: (i) w; (ii) all its inter-language links (that is, translations of the Wikipage to other languages); (iii) the redirections to the inter-language links found in the Wikipedia of the target language. For instance, given that μ(BALLOON) = balloon^1_n, the corresponding babel synset is { balloon$_{\text{EN}}$, Ballon$_{\text{DE}}$, aerostato$_{\text{ES}}$, balón aerostático$_{\text{ES}}$, ..., pallone aerostatico$_{\text{IT}}$ }. However, two issues arise: first, a concept might be covered only in one of the two resources (either WordNet or Wikipedia), meaning that no link can be established (e.g., FERMI GAS or gasbag^1_n in Figure 1); second, even if covered in both resources, the Wikipage for the concept might not provide any translation for the language of interest (e.g., the Catalan for BALLOON is missing in Wikipedia).

In order to address the above issues and thus guarantee high coverage for all languages we developed a methodology for translating senses in the babel synset to missing languages. Given a WordNet word sense in our babel synset of interest (e.g. balloon^1_n) we collect its occurrences in SemCor (Miller et al., 1993), a corpus of more than 200,000 words annotated with WordNet senses. We do the same for Wikipages by retrieving sentences in Wikipedia with links to the Wikipage of interest. By repeating this step for each English lexicalization in a babel synset, we obtain a collection of sentences for the babel synset (see left part of Figure 1). Next, we apply state-of-the-art Machine Translation[4] and translate the set of sentences in all the languages of interest. Given a specific term in the initial babel synset, we collect the set of its translations. We then identify the most frequent translation in each language and add it to the babel synset. Note that translations are sense-specific, as the context in which a term occurs is provided to the translation system.

3.4 Example

We now illustrate the execution of our methodology by way of an example. Let us focus on the Wikipage BALLOON (AIRCRAFT). The word is polysemous both in Wikipedia and WordNet. In the first phase of our methodology we aim to find a mapping μ(BALLOON (AIRCRAFT)) to an appropriate WordNet sense of the word. To

[4] We use the Google Translate API. An initial prototype used a statistical machine translation system based on Moses (Koehn et al., 2007) and trained on Europarl (Koehn, 2005). However, we found such system unable to cope with many technical names, such as in the domains of sciences, literature, history, etc.

this end we construct the disambiguation context for the Wikipage by including words from its label, links and categories (cf. Section 3.2.1). The context thus includes, among others, the following words: aircraft, wind, airship, lighter-than-air. We now construct the disambiguation context for the two WordNet senses of balloon (cf. Section 3.2.2), namely the aircraft (#1) and the toy (#2) senses. To do so, we include words from their synsets, hypernyms, hyponyms, sisters, and glosses. The context for balloon^1_n includes: aircraft, craft, airship, lighter-than-air. The context for balloon^2_n contains: toy, doll, hobby. The sense with the largest intersection is #1, so the following mapping is established: μ(BALLOON (AIRCRAFT)) = balloon^1_n. After the first phase, our babel synset includes the following English words from WordNet plus the Wikipedia inter-language links to other languages (we report German, Spanish and Italian): { $\text{balloon}_{\text{EN}}$, $\text{Ballon}_{\text{DE}}$, $\text{aerostato}_{\text{ES}}$, $\text{balón aerostático}_{\text{ES}}$, $\text{pallone aerostatico}_{\text{IT}}$ }.

In the second phase (see Section 3.3), we collect all the sentences in SemCor and Wikipedia in which the above English word sense occurs. We translate these sentences with the Google Translate API and select the most frequent translation in each language. As a result, we can enrich the initial babel synset with the following words: $\text{mongolfière}_{\text{FR}}$, $\text{globus}_{\text{CA}}$, globo_{ES}, $\text{mongolfiera}_{\text{IT}}$. Note that we had no translation for Catalan and French in the first phase, because the inter-language link was not available, and we also obtain new lexicalizations for the Spanish and Italian languages.

4 Experiment 1: Mapping Evaluation

Experimental setting. We first performed an evaluation of the quality of our mapping from Wikipedia to WordNet. To create a gold standard for evaluation we considered all lemmas whose senses are contained both in WordNet and Wikipedia: the intersection between the two resources contains 80,295 lemmas which correspond to 105,797 WordNet senses and 199,735 Wikipedia pages. The average polysemy is 1.3 and 2.5 for WordNet senses and Wikipages, respectively (2.8 and 4.7 when excluding monosemous words). We then selected a random sample of 1,000 Wikipages and asked an annotator with previous experience in lexicographic annotation to provide the correct WordNet sense for each page (an empty sense label was given, if no correct mapping was possible). The gold-standard dataset includes 505 non-empty mappings, i.e. Wikipages with a corresponding WordNet sense. In order to quantify the quality of the annotations and the difficulty of the task, a second annotator sense tagged a subset of 200 pages from the original sample. Our annotators achieved a κ inter-annotator agreement (Carletta, 1996) of 0.9, indicating almost perfect agreement.

	P	R	F_1	A
Mapping algorithm	81.9	77.5	79.6	84.4
MFS BL	24.3	47.8	32.2	24.3
Random BL	23.8	46.8	31.6	23.9

Table 1: Performance of the mapping algorithm.

Results and discussion. Table 1 summarizes the performance of our mapping algorithm against the manually annotated dataset. Evaluation is performed in terms of standard measures of precision, recall, and F_1-measure. In addition we calculate accuracy, which also takes into account empty sense labels. As baselines we use the most frequent WordNet sense (MFS), and a random sense assignment.

The results show that our method achieves almost 80% F_1 and it improves over the baselines by a large margin. The final mapping contains 81,533 pairs of Wikipages and word senses they map to, covering 55.7% of the noun senses in WordNet. As for the baselines, the most frequent sense is just 0.6% and 0.4% above the random baseline in terms of F_1 and accuracy, respectively. A χ^2 test reveals in fact no statistical significant difference at $p < 0.05$. This is related to the random distribution of senses in our dataset and the Wikipedia unbiased coverage of WordNet senses. So selecting the first WordNet sense rather than any other sense for each target page represents a choice as arbitrary as picking a sense at random.

5 Experiment 2: Translation Evaluation

We perform a second set of experiments concerning the quality of the acquired concepts. This is assessed in terms of coverage against gold-standard resources (Section 5.1) and against a manually-validated dataset of translations (Section 5.2).

Language	Word senses	Synsets
German	15,762	9,877
Spanish	83,114	55,365
Catalan	64,171	40,466
Italian	57,255	32,156
French	44,265	31,742

Table 2: Size of the gold-standard wordnets.

5.1 Automatic Evaluation

Datasets. We compare BabelNet against gold-standard resources for 5 languages, namely: the subset of GermaNet (Lemnitzer and Kunze, 2002) included in EuroWordNet for German, MultiWordNet (Pianta et al., 2002) for Italian, the Multilingual Central Repository for Spanish and Catalan (Atserias et al., 2004), and WOrdnet Libre du Français (Benoît and Fišer, 2008, WOLF) for French. In Table 2 we report the number of synsets and word senses available in the gold-standard resources for the 5 languages.

Measures. Let $\mathcal{B}$ be BabelNet, $\mathcal{F}$ our gold-standard non-English wordnet (e.g. GermaNet), and let $\mathcal{E}$ be the English WordNet. All the gold-standard non-English resources, as well as BabelNet, are linked to the English WordNet: given a synset $S_{\mathcal{F}} \in \mathcal{F}$, we denote its corresponding babel synset as $S_{\mathcal{B}}$ and its synset in the English WordNet as $S_{\mathcal{E}}$. We assess the coverage of BabelNet against our gold-standard wordnets both in terms of synsets and word senses. For synsets, we calculate coverage as follows:

$$\text{SynsetCov}(\mathcal{B},\mathcal{F}) = \frac{\sum_{S_{\mathcal{F}}\in\mathcal{F}} \delta(S_{\mathcal{B}}, S_{\mathcal{F}})}{|\{S_{\mathcal{F}} \in \mathcal{F}\}|},$$

where $\delta(S_{\mathcal{B}}, S_{\mathcal{F}}) = 1$ if the two synsets $S_{\mathcal{B}}$ and $S_{\mathcal{F}}$ have a synonym in common, 0 otherwise. That is, synset coverage is determined as the percentage of synsets of $\mathcal{F}$ that share a term with the corresponding babel synsets. For word senses we calculate a similar measure of coverage:

$$\text{WordCov}(\mathcal{B},\mathcal{F}) = \frac{\sum_{S_{\mathcal{F}}\in\mathcal{F}} \sum_{s_{\mathcal{F}}\in S_{\mathcal{F}}} \delta'(s_{\mathcal{F}}, S_{\mathcal{B}})}{|\{s_{\mathcal{F}} \in S_{\mathcal{F}} : S_{\mathcal{F}} \in \mathcal{F}\}|},$$

where $s_{\mathcal{F}}$ is a word sense in synset $S_{\mathcal{F}}$ and $\delta'(s_{\mathcal{F}}, S_{\mathcal{B}}) = 1$ if $s_{\mathcal{F}} \in S_{\mathcal{B}}$, 0 otherwise. That is we calculate the ratio of word senses in our gold-standard resource $\mathcal{F}$ that also occur in the corresponding synset $S_{\mathcal{B}}$ to the overall number of senses in $\mathcal{F}$.

However, our gold-standard resources cover only a portion of the English WordNet, whereas the overall coverage of BabelNet is much higher. We calculate extra coverage for synsets as follows:

$$\text{SynsetExtraCov}(\mathcal{B},\mathcal{F}) = \frac{\sum_{S_{\mathcal{E}}\in\mathcal{E}\setminus\mathcal{F}} \delta(S_{\mathcal{B}}, S_{\mathcal{E}})}{|\{S_{\mathcal{F}} \in \mathcal{F}\}|}.$$

Similarly, we calculate extra coverage for word senses in BabelNet corresponding to WordNet synsets not covered by the reference resource $\mathcal{F}$.

Results and discussion. We evaluate the coverage and extra coverage of word senses and synsets at different stages: (a) using only the inter-language links from Wikipedia (WIKI Links); (b) and (c) using only the automatic translations of the sentences from Wikipedia (WIKI Transl.) or SemCor (WN Transl.); (d) using all available translations, i.e. BABELNET.

Coverage results are reported in Table 3. The percentage of word senses covered by BabelNet ranges from 52.9% (Italian) to 66.4 (Spanish) and 86.0% (French). Synset coverage ranges from 73.3% (Catalan) to 76.6% (Spanish) and 92.9% (French). As expected, synset coverage is higher, because a synset in the reference resource is considered to be covered if it shares at least one word with the corresponding synset in BabelNet.

Numbers for the extra coverage, which provides information about the percentage of word senses and synsets in BabelNet but not in the gold-standard resources, are given in Figure 2. The results show that we provide for all languages a high extra coverage for both word senses – between 340.1% (Catalan) and 2,298% (German) – and synsets – between 102.8% (Spanish) and 902.6% (German).

Table 3 and Figure 2 show that the best results are obtained when combining *all* available translations, i.e. both from Wikipedia and the machine translation system. The performance figures suffer from the errors of the mapping phase (see Section 4). Nonetheless, the results are generally high, with a peak for French, since WOLF has been created semi-automatically by combining several resources, *including* Wikipedia. The relatively low word sense coverage for Italian (55.4%) is, instead, due to the lack of many common words in the Italian gold-standard synsets. Examples include whip$_{\text{EN}}$ translated as staffile$_{\text{IT}}$ but not as the more common frusta$_{\text{IT}}$, playboy$_{\text{EN}}$ translated as vitaiolo$_{\text{IT}}$ but not gigolò$_{\text{IT}}$, etc.

	BABELNET	All	**86.0**	**92.9**

Table 3: Coverage against gold-standard wordnets (we report percentages).

5.2 Manual Evaluation

Experimental setup. The automatic evaluation quantifies how much of the gold-standard resources is covered by BabelNet. However, it does not say anything about the precision of the *additional* lexicalizations provided by BabelNet. Given that our resource has displayed a remarkably high extra coverage – ranging from 340% to 2,298% of the national wordnets (see Figure 2) – we performed a second evaluation to assess its precision. For each of our 5 languages, we selected a random set of 600 babel synsets composed as follows: 200 synsets whose senses exist in WordNet only, 200 synsets in the intersection between WordNet and Wikipedia (i.e. those mapped with our method illustrated in Section 3.2), 200 synsets whose lexicalizations exist in Wikipedia only. Therefore, our dataset included $600 \times 5 = 3{,}000$ babel synsets. None of the synsets was covered by any of the five reference wordnets. The babel synsets were manually validated by expert annotators who decided which senses (i.e. lexicalizations) were appropriate given the corresponding WordNet gloss and/or Wikipage.

Results and discussion. We report the results in Table 4. For each language (rows) and for each of the three regions of BabelNet (columns), we report precision (i.e. the percentage of synonyms deemed correct) and, in parentheses, the overall number of synonyms evaluated. The results show that the different regions of BabelNet contain translations of different quality: while on average translations for WordNet-only synsets have a precision around 72%, when Wikipedia comes into play the performance increases considerably (around 80% in the intersection and 95% with Wikipedia-only translations). As can be seen from the figures in parentheses, the number of translations available in the presence of Wikipedia is higher. This quantitative difference is due to our method collecting many translations from the redirections in the Wikipedia of the target language (Section 3.3), as well as to the paucity of examples in SemCor for many synsets. In addition, some of the synsets in WordNet with no Wikipedia counterpart are very difficult to translate. Examples include terms like stammel, crape fern, baseball clinic, and many others for which we could

Language	WN	WN ∩ Wiki	Wiki
German	73.76 (282)	78.37 (777)	97.74 (709)
Spanish	69.45 (275)	78.53 (643)	92.46 (703)
Catalan	75.58 (258)	82.98 (517)	92.71 (398)
Italian	72.32 (271)	80.83 (574)	99.09 (552)
French	67.16 (268)	77.43 (709)	96.44 (758)

not find translations in major editions of bilingual dictionaries. In contrast, good translations were produced using our machine translation method when enough sentences were available. Examples are: chaudrée de poisson$_{\text{FR}}$ for fish chowder$_{\text{EN}}$, grano de café$_{\text{ES}}$ for coffee bean$_{\text{EN}}$, etc.

6 Related Work

Previous attempts to manually build multilingual resources have led to the creation of a multitude of wordnets such as EuroWordNet (Vossen, 1998), MultiWordNet (Pianta et al., 2002), BalkaNet (Tufiş et al., 2004), Arabic WordNet (Black et al., 2006), the Multilingual Central Repository (Atserias et al., 2004), bilingual electronic dictionaries such as EDR (Yokoi, 1995), and fully-fledged frameworks for the development of multilingual lexicons (Lenci et al., 2000). As it is often the case with manually assembled resources, these lexical knowledge repositories are hindered by high development costs and an insufficient coverage. This barrier has led to proposals that acquire multilingual lexicons from either parallel text (Gale and Church, 1993; Fung, 1995, *inter alia*) or monolingual corpora (Sammer and Soderland, 2007; Haghighi et al., 2008). The disambiguation of bilingual dictionary glosses has also been proposed to create a bilingual semantic network from a machine readable dictionary (Navigli, 2009a). Recently, Etzioni et al. (2007) and Mausam et al. (2009) presented methods to produce massive multilingual translation dictionaries from Web resources such as online lexicons and Wiktionaries. However, while providing lexical resources on a very large scale for hundreds of thousands of language pairs, these do not encode semantic relations between concepts denoted by their lexical entries.

The research closest to ours is presented by de Melo and Weikum (2009), who developed a Universal WordNet (UWN) by automatically acquiring a semantic network for languages other than English. UWN is bootstrapped from WordNet and is built by collecting evidence extracted from existing wordnets, translation dictionaries, and parallel corpora. The result is a graph containing 800,000 words from over 200 languages in a hierarchically structured semantic network with over 1.5 million links from words to word senses. Our work goes one step further by (1) developing an even larger multilingual resource including *both* lexical semantic and encyclopedic knowledge, (2) enriching the structure of the 'core' semantic network (i.e. the semantic pointers from WordNet) with topical, semantically unspecified relations from the link structure of Wikipedia. This result is essentially achieved by complementing WordNet with Wikipedia, as well as by leveraging the multilingual structure of the latter. Previous attempts at linking the two resources have been proposed. These include associating Wikipedia pages with the most frequent WordNet sense (Suchanek et al., 2008), extracting domain information from Wikipedia and providing a manual mapping to WordNet concepts (Auer et al., 2007), a model based on vector spaces (Ruiz-Casado et al., 2005), a supervised approach using keyword extraction (Reiter et al., 2008), as well as automatically linking Wikipedia categories to WordNet based on structural information (Ponzetto and Navigli, 2009). In contrast to previous work, BabelNet is the first proposal that integrates the relational structure of WordNet with the semi-structured information from Wikipedia into a unified, wide-coverage, multilingual semantic network.

7 Conclusions

In this paper we have presented a novel methodology for the automatic construction of a large multilingual lexical knowledge resource. Key to our approach is the establishment of a mapping between a multilingual encyclopedic knowledge repository (Wikipedia) and a computational lexicon of English (WordNet). This integration process has several advantages. Firstly, the two resources contribute different kinds of lexical knowledge, one is concerned mostly with named entities, the other with concepts. Secondly, while Wikipedia is less structured than WordNet, it provides large

amounts of semantic relations and can be leveraged to enable multilinguality. Thus, even when they overlap, the two resources provide complementary information about the same named entities or concepts. Further, we contribute a large set of sense occurrences harvested from Wikipedia and SemCor, a corpus that we input to a state-of-the-art machine translation system to fill in the gap between resource-rich languages – such as English – and resource-poorer ones. Our hope is that the availability of such a language-rich resource[5] will enable many non-English and multilingual NLP applications to be developed.

Our experiments show that our fully-automated approach produces a large-scale lexical resource with high accuracy. The resource includes millions of semantic relations, mainly from Wikipedia (however, WordNet relations are labeled), and contains almost 3 million concepts (6.7 labels per concept on average). As pointed out in Section 5, such coverage is much wider than that of existing wordnets in non-English languages. While BabelNet currently includes 6 languages, links to freely-available wordnets[6] can immediately be established by utilizing the English WordNet as an interlanguage index. Indeed, BabelNet can be extended to virtually any language of interest. In fact, our translation method allows it to cope with any resource-poor language.

As future work, we plan to apply our method to other languages, including Eastern European, Arabic, and Asian languages. We also intend to link missing concepts in WordNet, by establishing their most likely hypernyms – e.g., à la Snow et al. (2006). We will perform a semi-automatic validation of BabelNet, e.g. by exploiting Amazon's Mechanical Turk (Callison-Burch, 2009) or designing a collaborative game (von Ahn, 2006) to validate low-ranking mappings and translations. Finally, we aim to apply BabelNet to a variety of applications which are known to benefit from a wide-coverage knowledge resource. We have already shown that the English-only subset of BabelNet allows simple knowledge-based algorithms to compete with supervised systems in standard coarse-grained and domain-specific WSD settings (Ponzetto and Navigli, 2010). We plan in the near future to apply BabelNet to the challenging task of cross-lingual WSD (Lefever and Hoste, 2009).

arir@cs.huji.ac.il

Abstract

The core-adjunct argument distinction is a basic one in the theory of argument structure. The task of distinguishing between the two has strong relations to various basic NLP tasks such as syntactic parsing, semantic role labeling and subcategorization acquisition. This paper presents a novel unsupervised algorithm for the task that uses no supervised models, utilizing instead state-of-the-art syntactic induction algorithms. This is the first work to tackle this task in a fully unsupervised scenario.

1 Introduction

The distinction between core arguments (henceforth, cores) and adjuncts is included in most theories on argument structure (Dowty, 2000). The distinction can be viewed syntactically, as one between obligatory and optional arguments, or semantically, as one between arguments whose meanings are predicate dependent and independent. The latter (cores) are those whose function in the described event is to a large extent determined by the predicate, and are obligatory. Adjuncts are optional arguments which, like adverbs, modify the meaning of the described event in a predictable or predicate-independent manner.

Consider the following examples:

1. The surgeon operated [on his colleague].
2. Ron will drop by [after lunch].
3. Yuri played football [in the park].

The marked argument is a core in 1 and an adjunct in 2 and 3. Adjuncts form an independent semantic unit and their semantic role can often be inferred independently of the predicate (e.g., [after lunch] is usually a temporal modifier). Core roles are more predicate-specific, e.g., [on his colleague] has a different meaning with the verbs 'operate' and 'count'.

Sometimes the same argument plays a different role in different sentences. In (3), [in the park] places a well-defined situation (Yuri playing football) in a certain location. However, in "The troops are based [in the park]", the same argument is obligatory, since being based requires a place to be based in.

Distinguishing between the two argument types has been discussed extensively in various formulations in the NLP literature, notably in PP attachment, semantic role labeling (SRL) and subcategorization acquisition. However, no work has tackled it yet in a fully unsupervised scenario. Unsupervised models reduce reliance on the costly and error prone manual multi-layer annotation (POS tagging, parsing, core-adjunct tagging) commonly used for this task. They also allow to examine the nature of the distinction and to what extent it is accounted for in real data in a theory-independent manner.

In this paper we present a fully unsupervised algorithm for core-adjunct classification. We utilize leading fully unsupervised grammar induction and POS induction algorithms. We focus on prepositional arguments, since non-prepositional ones are generally cores. The algorithm uses three measures based on different characterizations of the core-adjunct distinction, and combines them using an ensemble method followed by self-training. The measures used are based on selectional preference, predicate-slot collocation and argument-slot collocation.

We evaluate against PropBank (Palmer et al., 2005), obtaining roughly 70% accuracy when evaluated on the prepositional arguments and more than 80% for the entire argument set. These results are substantially better than those obtained by a non-trivial baseline.

2 Core-Adjunct in Previous Work

PropBank. PropBank (PB) (Palmer et al., 2005) is a widely used corpus, providing SRL annotation for the entire WSJ Penn Treebank. Its core labels are predicate specific, while adjunct (or modifiers under their terminology) labels are shared across predicates. The adjuncts are subcategorized into several classes, the most frequent of which are locative, temporal and manner[1].

The organization of PropBank is based on the notion of diathesis alternations, which are (roughly) defined to be alternations between two subcategorization frames that preserve meaning or change it systematically. The frames in which each verb appears were collected and sets of alternating frames were defined. Each such set was assumed to have a unique set of roles, named 'role-set'. These roles include all roles appearing in any of the frames, except of those defined as adjuncts.

Adjuncts are defined to be optional arguments appearing with a wide variety of verbs and frames. They can be viewed as fixed points with respect to alternations, i.e., as arguments that do not change their place or slot when the frame undergoes an alternation. This follows the notions of optionality and compositionality that define adjuncts.

Detecting diathesis alternations automatically is difficult (McCarthy, 2001), requiring an initial acquisition of a subcategorization lexicon. This alone is a challenging task tackled in the past using supervised parsers (see below).

FrameNet. FrameNet (FN) (Baker et al., 1998) is a large-scale lexicon based on frame semantics. It takes a different approach from PB to semantic roles. Like PB, it distinguishes between core and non-core arguments, but it does so for each and every frame separately. It does not commit that a semantic role is consistently tagged as a core or a non-core across frames. For example, the semantic role 'path' is considered core in the 'Self Motion' frame, but as non-core in the 'Placing' frame. Another difference is that FN does not allow any type of non-core argument to attach to a given frame. For instance, while the 'Getting' frame allows a 'Duration' non-core argument, the 'Active Perception' frame does not.

PB and FN tend to agree in clear (prototypical) cases, but to differ in others. For instance, both schemes would tag "Yuri played football [in the park]" as an adjunct and "The commander placed a guard [in the park]" as a core. However, in "He walked [into his office]", the marked argument is tagged as a directional adjunct in PB but as a 'Direction' core in FN.

Under both schemes, non-cores are usually confined to a few specific semantic domains, notably time, place and manner, in contrast to cores that are not restricted in their scope of applicability. This approach is quite common, e.g., the COBUILD English grammar (Willis, 2004) categorizes adjuncts to be of manner, aspect, opinion, place, time, frequency, duration, degree, extent, emphasis, focus and probability.

Semantic Role Labeling. Work in SRL does not tackle the core-adjunct task separately but as part of general argument classification. Supervised approaches obtain an almost perfect score in distinguishing between the two in an in-domain scenario. For instance, the confusion matrix in (Toutanova et al., 2008) indicates that their model scores 99.5% accuracy on this task. However, adaptation results are lower, with the best two models in the CoNLL 2005 shared task (Carreras and Màrquez, 2005) achieving 95.3% (Pradhan et al., 2008) and 95.6% (Punyakanok et al., 2008) accuracy in an adaptation between the relatively similar corpora WSJ and Brown.

Despite the high performance in supervised scenarios, tackling the task in an unsupervised manner is not easy. The success of supervised methods stems from the fact that the predicate-slot combination (slot is represented in this paper by its preposition) strongly determines whether a given argument is an adjunct or a core (see Section 3.4). Supervised models are provided with an annotated corpus from which they can easily learn the mapping between predicate-slot pairs and their core/adjunct label. However, induction of the mapping in an unsupervised manner must be based on inherent core-adjunct properties. In addition, supervised models utilize supervised parsers and POS taggers, while the current state-of-the-art in unsupervised parsing and POS tagging is considerably worse than their supervised counterparts.

This challenge has some resemblance to un-

[1] PropBank annotates modals and negation words as modifiers. Since these are not arguments in the common usage of the term, we exclude them from the discussion in this paper.

supervised detection of multiword expressions (MWEs). An important MWE sub-class is that of phrasal verbs, which are also characterized by verb-preposition pairs (Li et al., 2003; Sporleder and Li, 2009) (see also (Boukobza and Rappoport, 2009)). Both tasks aim to determine semantic compositionality, which is a highly challenging task.

Few works addressed unsupervised SRL-related tasks. The setup of (Grenager and Manning, 2006), who presented a Bayesian Network model for argument classification, is perhaps closest to ours. Their work relied on a supervised parser and a rule-based argument identification (both during training and testing). Swier and Stevenson (2004, 2005), while addressing an unsupervised SRL task, greatly differ from us as their algorithm uses the VerbNet (Kipper et al., 2000) verb lexicon, in addition to supervised parses. Finally, Abend et al. (2009) tackled the argument identification task alone and did not perform argument classification of any sort.

PP attachment. PP attachment is the task of determining whether a prepositional phrase which immediately follows a noun phrase attaches to the latter or to the preceding verb. This task's relation to the core-adjunct distinction was addressed in several works. For instance, the results of (Hindle and Rooth, 1993) indicate that their PP attachment system works better for cores than for adjuncts.

Merlo and Esteve Ferrer (2006) suggest a system that jointly tackles the PP attachment and the core-adjunct distinction tasks. Unlike in this work, their classifier requires extensive supervision including WordNet, language-specific features and a supervised parser. Their features are generally motivated by common linguistic considerations. Features found adaptable to a completely unsupervised scenario are used in this work as well.

Syntactic Parsing. The core-adjunct distinction is included in many syntactic annotation schemes. Although the Penn Treebank does not explicitly annotate adjuncts and cores, a few works suggested mapping its annotation (including function tags) to core-adjunct labels. Such a mapping was presented in (Collins, 1999). In his Model 2, Collins modifies his parser to provide a core-adjunct prediction, thereby improving its performance.

The Combinatory Categorial Grammar (CCG) formulation models the core-adjunct distinction explicitly. Therefore, any CCG parser can be used as a core-adjunct classifier (Hockenmaier, 2003).

Subcategorization Acquisition. This task specifies for each predicate the number, type and order of obligatory arguments. Determining the allowable subcategorization frames for a given predicate necessarily involves separating its cores from its allowable adjuncts (which are not framed). Notable works in the field include (Briscoe and Carroll, 1997; Sarkar and Zeman, 2000; Korhonen, 2002). All these works used a parsed corpus in order to collect, for each predicate, a set of hypothesized subcategorization frames, to be filtered by hypothesis testing methods.

This line of work differs from ours in a few aspects. First, all works use manual or supervised syntactic annotations, usually including a POS tagger. Second, the common approach to the task focuses on syntax and tries to identify the entire frame, rather than to tag each argument separately. Finally, most works address the task at the verb type level, trying to detect the allowable frames for each type. Consequently, the common evaluation focuses on the quality of the allowable frames acquired for each verb type, and not on the classification of specific arguments in a given corpus. Such a token level evaluation was conducted in a few works (Briscoe and Carroll, 1997; Sarkar and Zeman, 2000), but often with a small number of verbs or a small number of frames. A discussion of the differences between type and token level evaluation can be found in (Reichart et al., 2010).

The core-adjunct distinction task was tackled in the context of child language acquisition. Villavicencio (2002) developed a classifier based on preposition selection and frequency information for modeling the distinction for locative prepositional phrases. Her approach is not entirely corpus based, as it assumes the input sentences are given in a basic logical form.

The study of prepositions is a vibrant research area in NLP. A special issue of *Computational Linguistics*, which includes an extensive survey of related work, was recently devoted to the field (Baldwin et al., 2009).

3 Algorithm

We are given a (predicate, argument) pair in a test sentence, and we need to determine whether the argument is a core or an adjunct. Test arguments are assumed to be correctly bracketed. We are allowed to utilize a training corpus of raw text.

3.1 Overview

Our algorithm utilizes statistics based on the (predicate, slot, argument head) (PSH) joint distribution (a slot is represented by its preposition). To estimate this joint distribution, PSH samples are extracted from the training corpus using unsupervised POS taggers (Clark, 2003; Abend et al., 2010) and an unsupervised parser (Seginer, 2007). As current performance of unsupervised parsers for long sentences is low, we use only short sentences (up to 10 words, excluding punctuation). The length of test sentences is not bounded. Our results will show that the training data accounts well for the argument realization phenomena in the test set, despite the length bound on its sentences. The sample extraction process is detailed in Section 3.2.

Our approach makes use of both aspects of the distinction – obligatoriness and compositionality. We define three measures, one quantifying the obligatoriness of the slot, another quantifying the selectional preference of the verb to the argument and a third that quantifies the association between the head word and the slot irrespective of the predicate (Section 3.3).

The measures' predictions are expected to coincide in clear cases, but may be less successful in others. Therefore, an ensemble-based method is used to combine the three measures into a single classifier. This results in a high accuracy classifier with relatively low coverage. A self-training step is now performed to increase coverage with only a minor deterioration in accuracy (Section 3.4).

We focus on prepositional arguments. Non-prepositional arguments in English tend to be cores (e.g., in more than 85% of the cases in PB sections 2–21), while prepositional arguments tend to be equally divided between cores and adjuncts. The difficulty of the task thus lies in the classification of prepositional arguments.

3.2 Data Collection

The statistical measures used by our classifier are based on the (predicate, slot, argument head) (PSH) joint distribution. This section details the process of extracting samples from this joint distribution given a raw text corpus.

We start by parsing the corpus using the Seginer parser (Seginer, 2007). This parser is unique in its ability to induce a bracketing (unlabeled parsing) from raw text (without even using POS tags) with strong results. Its high speed (thousands of words per second) allows us to use millions of sentences, a prohibitive number for other parsers.

We continue by tagging the corpus using Clark's unsupervised POS tagger (Clark, 2003) and the unsupervised Prototype Tagger (Abend et al., 2010)[2]. The classes corresponding to prepositions and to verbs are manually selected from the induced clusters[3]. A preposition is defined to be any word which is the first word of an argument and belongs to a prepositions cluster. A verb is any word belonging to a verb cluster. This manual selection requires only a minute, since the number of classes is very small (34 in our experiments). In addition, knowing what is considered a preposition is part of the task definition itself.

Argument identification is hard even for supervised models and is considerably more so for unsupervised ones (Abend et al., 2009). We therefore confine ourselves to sentences of length not greater than 10 (excluding punctuation) which contain a single verb. A sequence of words will be marked as an argument of the verb if it is a constituent that does not contain the verb (according to the unsupervised parse tree), whose parent is an ancestor of the verb. This follows the pruning heuristic of (Xue and Palmer, 2004) often used by SRL algorithms.

The corpus is now tagged using an unsupervised POS tagger. Since the sentences in question are short, we consider every word which does not belong to a closed class cluster as a head word (an argument can have several head words). A closed class is a class of function words with relatively few word types, each of which is very frequent. Typical examples include determiners, prepositions and conjunctions. A class which is not closed is open. In this paper, we define closed classes to be clusters in which the ratio between the number of word tokens and the number of word types ex-

[2]Clark's tagger was replaced by the Prototype Tagger where the latter gave a significant improvement. See Section 4.

[3]We also explore a scenario in which they are identified by a supervised tagger. See Section 4.

ceeds a threshold T[4].

Using these annotation layers, we traverse the corpus and extract every (predicate, slot, argument head) triplet. In case an argument has several head words, each of them is considered as an independent sample. We denote the number of times that a triplet occurred in the training corpus by $N(p, s, h)$.

3.3 Collocation Measures

In this section we present the three types of measures used by the algorithm and the rationale behind each of them. These measures are all based on the PSH joint distribution.

Given a (predicate, prepositional argument) pair from the test set, we first tag and parse the argument using the unsupervised tools above[5]. Each word in the argument is now represented by its word form (without lemmatization), its unsupervised POS tag and its depth in the parse tree of the argument. The last two will be used to determine which are the head words of the argument (see below). The head words themselves, once chosen, are represented by the lemma. We now compute the following measures.

Selectional Preference (SP). Since the semantics of cores is more predicate dependent than the semantics of adjuncts, we expect arguments for which the predicate has a strong preference (in a specific slot) to be cores.

Selectional preference induction is a well-established task in NLP. It aims to quantify the likelihood that a certain argument appears in a certain slot of a predicate. Several methods have been suggested (Resnik, 1996; Li and Abe, 1998; Schulte im Walde et al., 2008).

We use the paradigm of (Erk, 2007). For a given predicate slot pair (p, s), we define its preference to the argument head h to be:

$$SP(p, s, h) = \sum_{h' \in Heads} Pr(h'|p, s) \cdot sim(h, h')$$

$$Pr(h|p, s) = \frac{N(p, s, h)}{\Sigma_{h'} N(p, s, h')}$$

$sim(h, h')$ is a similarity measure between argument heads. $Heads$ is the set of all head words. This is a natural extension of the naive (and sparse) maximum likelihood estimator $Pr(h|p, s)$, which is obtained by taking $sim(h, h')$ to be 1 if $h = h'$ and 0 otherwise.

The similarity measure we use is based on the slot distributions of the arguments. That is, two arguments are considered similar if they tend to appear in the same slots. Each head word h is assigned a vector where each coordinate corresponds to a slot s. The value of the coordinate is the number of times h appeared in s, i.e. $\Sigma_{p'} N(p', s, h)$ (p' is summed over all predicates). The similarity measure between two head words is then defined as the cosine measure of their vectors.

Since arguments in the test set can be quite long, not every open class word in the argument is taken to be a head word. Instead, only those appearing in the top level (depth = 1) of the argument under its unsupervised parse tree are taken. In case there are no such open class words, we take those appearing in depth 2. The selectional preference of the whole argument is then defined to be the arithmetic mean of this measure over all of its head words. If the argument has no head words under this definition or if none of the head words appeared in the training corpus, the selectional preference is undefined.

Predicate-Slot Collocation. Since cores are obligatory, when a predicate persistently appears with an argument in a certain slot, the arguments in this slot tends to be cores. This notion can be captured by the $(predicate, slot)$ joint distribution. We use the Pointwise Mutual Information measure (PMI) to capture the slot and the predicate's collocation tendency. Let p be a predicate and s a slot, then:

$$PS(p, s) = PMI(p, s) = log \frac{Pr(p, s)}{Pr(s) \cdot Pr(p)} =$$

$$= log \frac{N(p, s) \Sigma_{p', s'} N(p', s')}{\Sigma_{s'} N(p, s') \Sigma_{p'} N(p', s)}$$

Since there is only a meager number of possible slots (that is, of prepositions), estimating the $(predicate, slot)$ distribution can be made by the maximum likelihood estimator with manageable sparsity.

In order not to bias the counts towards predicates which tend to take more arguments, we define here $N(p, s)$ to be the number of times the (p, s) pair occurred in the training corpus, irrespective of the number of head words the argument had (and not e.g., $\Sigma_h N(p, s, h)$). Argu-

[4] We use sections 2–21 of the PTB WSJ for these counts, containing 0.95M words. Our T was set to 50.

[5] Note that while current unsupervised parsers have low performance on long sentences, arguments, even in long sentences, are usually still short enough for them to operate well. Their average length in the test set is 5.1 words.

ments with no prepositions are included in these counts as well (with $s = NULL$), so not to bias against predicates which tend to have less non-prepositional arguments.

Argument-Slot Collocation. Adjuncts tend to belong to one of a few specific semantic domains (see Section 2). Therefore, if an argument tends to appear in a certain slot in many of its instances, it is an indication that this argument tends to have a consistent semantic flavor in most of its instances. In this case, the argument and the preposition can be viewed as forming a unit on their own, independent of the predicate with which they appear. We therefore expect such arguments to be adjuncts.

We formalize this notion using the following measure. Let p, s, h be a predicate, a slot and a head word respectively. We then use[6]:

$$AS(s,h) = 1 - Pr(s|h) = 1 - \frac{\Sigma_{p'} N(p', s, h)}{\Sigma_{p',s'} N(p', s', h)}$$

We select the head words of the argument as we did with the selectional preference measure. Again, the AS of the whole argument is defined to be the arithmetic mean of the measure over all of its head words.

Thresholding. In order to turn these measures into classifiers, we set a threshold below which arguments are marked as adjuncts and above which as cores. In order to avoid tuning a parameter for each of the measures, we set the threshold as the median value of this measure in the test set. That is, we find the threshold which tags half of the arguments as cores and half as adjuncts. This relies on the prior knowledge that prepositional arguments are roughly equally divided between cores and adjuncts[7].

3.4 Combination Model

The algorithm proceeds to integrate the predictions of the weak classifiers into a single classifier. We use an ensemble method (Breiman, 1996). Each of the classifiers may either classify an argument as an adjunct, classify it as a core, or abstain. In order to obtain a high accuracy classifier, to be used for self-training below, the ensemble classifier only tags arguments for which none of the classifiers abstained, i.e., when sufficient information was available to make all three predictions. The prediction is determined by the majority vote.

The ensemble classifier has high precision but low coverage. In order to increase its coverage, a self-training step is performed. We observe that a predicate and a slot generally determine whether the argument is a core or an adjunct. For instance, in our development data, a classifier which assigns all arguments that share a predicate and a slot their most common label, yields 94.3% accuracy on the pairs appearing at least 5 times. This property of the core-adjunct distinction greatly simplifies the task for supervised algorithms (see Section 2).

We therefore apply the following procedure: (1) tag the training data with the ensemble classifier; (2) for each test sample x, if more than a ratio of α of the training samples sharing the same predicate and slot with x are labeled as cores, tag x as core. Otherwise, tag x as adjunct.

Test samples which do not share a predicate and a slot with any training sample are considered out of coverage. The parameter α is chosen so half of the arguments are tagged as cores and half as adjuncts. In our experiments α was about 0.25.

4 Experimental Setup

Experiments were conducted in two scenarios. In the '*SID*' (supervised identification of prepositions and verbs) scenario, a gold standard list of prepositions was provided. The list was generated by taking every word tagged by the preposition tag ('*IN*') in at least one of its instances under the gold standard annotation of the WSJ sections 2–21. Verbs were identified using MXPOST (Ratnaparkhi, 1996). Words tagged with any of the verb tags, except of the auxiliary verbs ('have', 'be' and 'do') were considered predicates. This scenario decouples the accuracy of the algorithm from the quality of the unsupervised POS tagging.

In the '*Fully Unsupervised*' scenario, prepositions and verbs were identified using Clark's tagger (Clark, 2003). It was asked to produce a tagging into 34 classes. The classes corresponding to prepositions and to verbs were manually identified. Prepositions in the test set were detected with 84.2% precision and 91.6% recall.

The prediction of whether a word belongs to an open class or a closed was based on the output of the Prototype tagger (Abend et al., 2010). The Prototype tagger provided significantly more ac-

[6] The conditional probability is subtracted from 1 so that higher values correspond to cores, as with the other measures.

[7] In case the test data is small, we can use the median value on the training data instead.

curate predictions in this context than Clark's.

The 39832 sentences of PropBank's sections 2–21 were used as a test set without bounding their lengths[8]. Cores were defined to be any argument bearing the labels 'A0' – 'A5', 'C-A0' – 'C-A5' or 'R-A0' – 'R-A5'. Adjuncts were defined to be arguments bearing the labels 'AM', 'C-AM' or 'R-AM'. Modals ('AM-MOD') and negation modifiers ('AM-NEG') were omitted since they do not represent adjuncts.

The test set includes 213473 arguments, 45939 (21.5%) are prepositional. Of the latter, 22442 (48.9%) are cores and 23497 (51.1%) are adjuncts. The non-prepositional arguments include 145767 (87%) cores and 21767 (13%) adjuncts. The average number of words per argument is 5.1.

The NANC (Graff, 1995) corpus was used as a training set. Only sentences of length not greater than 10 excluding punctuation were used (see Section 3.2), totaling 4955181 sentences. 7673878 (5635810) arguments were identified in the '*SID*' ('*Fully Unsupervised*') scenario. The average number of words per argument is 1.6 (1.7).

Since this is the first work to tackle this task using neither manual nor supervised syntactic annotation, there is no previous work to compare to. However, we do compare against a non-trivial baseline, which closely follows the rationale of cores as obligatory arguments.

Our *Window Baseline* tags a corpus using MXPOST and computes, for each predicate and preposition, the ratio between the number of times that the preposition appeared in a window of W words after the verb and the total number of times that the verb appeared. If this number exceeds a certain threshold β, all arguments having that predicate and preposition are tagged as cores. Otherwise, they are tagged as adjuncts. We used 18.7M sentences from NANC of unbounded length for this baseline. W and β were fine-tuned against the test set[9].

We also report results for partial versions of the algorithm, starting with the three measures used (selectional preference, predicate-slot collocation and argument-slot collocation). Results for the ensemble classifier (prior to the bootstrapping stage) are presented in two variants: one in which the ensemble is used to tag arguments for which all three measures give a prediction (the '*Ensemble(Intersection)*' classifier) and one in which the ensemble tags all arguments for which at least one classifier gives a prediction (the '*Ensemble(Union)*' classifier). For the latter, a tie is broken in favor of the core label. The '*Ensemble(Union)*' classifier is not a part of our model and is evaluated only as a reference.

In order to provide a broader perspective on the task, we compare the measures in the basis of our algorithm to simplified or alternative measures. We experiment with the following measures:

1. *Simple SP* – a selectional preference measure defined to be $Pr(head|slot, predicate)$.

2. *Vast Corpus SP* – similar to '*Simple SP*' but with a much larger corpus. It uses roughly 100M arguments which were extracted from the web-crawling based corpus of (Gabrilovich and Markovitch, 2005) and the British National Corpus (Burnard, 2000).

3. *Thesaurus SP* – a selectional preference measure which follows the paradigm of (Erk, 2007) (Section 3.3) and defines the similarity between two heads to be the Jaccard affinity between their two entries in Lin's automatically compiled thesaurus (Lin, 1998)[10].

4. *Pr(slot|predicate)* – an alternative to the used predicate-slot collocation measure.

5. *PMI(slot, head)* – an alternative to the used argument-slot collocation measure.

6. *Head Dependence* – the entropy of the predicate distribution given the slot and the head (following (Merlo and Esteve Ferrer, 2006)):

$$HD(s,h) = -\Sigma_p Pr(p|s,h) \cdot log(Pr(p|s,h))$$

Low entropy implies a core.

For each of the scenarios and the algorithms, we report accuracy, coverage and effective accuracy. Effective accuracy is defined to be the accuracy obtained when all out of coverage arguments are tagged as adjuncts. This procedure always yields a classifier with 100% coverage and therefore provides an even ground for comparing the algorithms' performance.

We see accuracy as important on its own right since increasing coverage is often straightforward given easily obtainable larger training corpora.

[8]The first 15K arguments were used for the algorithm's development and therefore excluded from the evaluation.

[9]Their optimal value was found to be W=2, β=0.03. The low optimal value of β is an indication of the noisiness of this technique.

[10]Since we aim for a minimally supervised scenario, we used the proximity-based version of his thesaurus which does not require parsing as pre-processing. http://webdocs.cs.ualberta.ca/∼lindek/Downloads/sims.lsp.gz

		Collocation Measures				Ensemble + Cov.	
		Sel. Preference	Pred-Slot	Arg-Slot	Ensemble(I)	Ensemble(U)	E(I) + ST
SID Scenario	Accuracy	65.6	64.5	72.4	**74.1**	68.7	70.6
	Coverage	35.6	77.8	44.7	33.2	**88.1**	74.2
	Eff. Acc.	56.7	64.8	58.8	58.8	67.8	**68.4**
Fully Unsupervised Scenario	Accuracy	62.6	61.1	69.4	**70.6**	64.8	68.8
	Coverage	24.8	59.0	38.7	22.8	**74.2**	56.9
	Eff. Acc.	52.6	57.5	55.8	53.8	61.0	**61.4**

Table 1: Results for the various models. Accuracy, coverage and effective accuracy are presented in percents. Effective accuracy is defined to be the accuracy resulting from labeling each out of coverage argument with an adjunct label. The rows represent the following models (left to right): selectional preference, predicate-slot collocation, argument-slot collocation, '*Ensemble(Intersection)*', '*Ensemble(Union)*' and the '*Ensemble(Intersection)*' followed by self-training (see Section 3.4). '*Ensemble(Intersection)*' obtains the highest accuracy. The ensemble + self-training obtains the highest effective accuracy.

	Selectional Preference Measures				Pred-Slot Measures			Arg-Slot Measures		
	SP*	S. SP	V.C. SP	Lin SP	PS*	Pr(s|p)	Window	AS*	PMI(s, h)	HD
Acc.	**65.6**	41.6	44.8	49.9	**64.5**	58.9	64.1	**72.4**	67.5	67.4
Cov.	35.6	36.9	**45.3**	36.7	77.8	77.8	**92.6**	44.7	44.7	44.7
Eff. Acc.	**56.7**	48.2	47.7	51.3	64.8	60.5	**65.0**	**58.8**	56.6	56.6

Table 2: Comparison of the measures used by our model to alternative measures in the '*SID*' scenario. Results are in percents. The sections of the table are (from left to right): selectional preference measures, predicate-slot measures, argument-slot measures and head dependence. The measures are (left to right): SP*, Simple SP, Vast Corpus SP, Lin SP, PS*, Pr(slot|predicate), Window Baseline, AS*, PMI(slot, head) and Head Dependence. The measures marked with $*$ are the ones used by our model. See Section 4.

Another reason is that a high accuracy classifier may provide training data to be used by subsequent supervised algorithms.

For completeness, we also provide results for the entire set of arguments. The great majority of non-prepositional arguments are cores (87% in the test set). We therefore tag all non-prepositional as cores and tag prepositional arguments using our model. In order to minimize supervision, we distinguish between the prepositional and the non-prepositional arguments using Clark's tagger.

Finally, we experiment on a scenario where even argument identification on the test set is not provided, but performed by the algorithm of (Abend et al., 2009), which uses neither syntactic nor SRL annotation but does utilize a supervised POS tagger. We therefore run it in the '*SID*' scenario. We apply it to the sentences of length at most 10 contained in sections 2–21 of PB (11586 arguments in 6007 sentences). Non-prepositional arguments are invariably tagged as cores and out of coverage prepositional arguments as adjuncts.

We report labeled and unlabeled recall, precision and F-scores for this experiment. An unlabeled match is defined to be an argument that agrees in its boundaries with a gold standard argument and a labeled match requires in addition that the arguments agree in their core/adjunct label. We also report labeling accuracy which is the ratio between the number of labeled matches and the number of unlabeled matches[11].

5 Results

Table 1 presents the results of our main experiments. In both scenarios, the most accurate of the three basic classifiers was the argument-slot collocation classifier. This is an indication that the collocation between the argument and the preposition is more indicative of the core/adjunct label than the obligatoriness of the slot (as expressed by the predicate-slot collocation).

Indeed, we can find examples where adjuncts, although optional, appear very often with a certain verb. An example is 'meet', which often takes a temporal adjunct, as in 'Let's meet [in July]'. This is a semantic property of 'meet', whose syntactic expression is not obligatory.

All measures suffered from a comparable deterioration of accuracy when moving from the '*SID*' to the '*Fully Unsupervised*' scenario. The deterioration in coverage, however, was considerably lower for the argument-slot collocation.

The '*Ensemble(Intersection)*' model in both cases is more accurate than each of the basic classifiers alone. This is to be expected as it combines the predictions of all three. The self-training step significantly increases the ensemble model's cov-

[11] Note that the reported unlabeled scores are slightly lower than those reported in the 2009 paper, due to the exclusion of the modals and negation modifiers.

	Precision	Recall	F-score	lAcc.
Unlabeled	50.7	66.3	57.5	–
Labeled	42.4	55.4	48.0	83.6

Table 3: Unlabeled and labeled scores for the experiments using the unsupervised argument identification system of (Abend et al., 2009). Precision, recall, F-score and labeling accuracy are given in percents.

erage (with some loss in accuracy), thus obtaining the highest effective accuracy. It is also more accurate than the simpler classifier '*Ensemble(Union)*' (although the latter's coverage is higher).

Table 2 presents results for the comparison to simpler or alternative measures. Results indicate that the three measures used by our algorithm (leftmost column in each section) obtain superior results. The only case in which performance is comparable is the window baseline compared to the Pred-Slot measure. However, the baseline's score was obtained by using a much larger corpus and a careful hand-tuning of the parameters[12].

The poor performance of *Simple SP* can be ascribed to sparsity. This is demonstrated by the median value of 0, which this measure obtained on the test set. Accuracy is only somewhat better with a much larger corpus (*Vast Corpus SP*). The *Thesaurus SP* most probably failed due to insufficient coverage, despite its applicability in a similar supervised task (Zapirain et al., 2009).

The Head Dependence measure achieves a relatively high accuracy of 67.4%. We therefore attempted to incorporate it into our model, but failed to achieve a significant improvement to the overall result. We expect a further study of the relations between the measures will suggest better ways of combining their predictions.

The obtained effective accuracy for the entire set of arguments, where the prepositional arguments are automatically identified, was 81.6%.

Table 3 presents results of our experiments with the unsupervised argument identification model of (Abend et al., 2009). The unlabeled scores reflect performance on argument identification alone, while the labeled scores reflect the joint performance of both the 2009 and our algorithms. These results, albeit low, are potentially beneficial for unsupervised subcategorization acquisition. The accuracy of our model on the entire set (prepositional argument subset) of correctly identified arguments was 83.6% (71.7%). This is somewhat higher than the score on the entire test set ('*SID*' scenario), which was 83.0% (68.4%), probably due to the bounded length of the test sentences in this case.

[12]We tried about 150 parameter pairs for the baseline. The average of the five best effective accuracies was 64.3%.

6 Conclusion

We presented a fully unsupervised algorithm for the classification of arguments into cores and adjuncts. Since most non-prepositional arguments are cores, we focused on prepositional arguments, which are roughly equally divided between cores and adjuncts. The algorithm computes three statistical measures and utilizes ensemble-based and self-training methods to combine their predictions.

The algorithm applies state-of-the-art unsupervised parser and POS tagger to collect statistics from a large raw text corpus. It obtains an accuracy of roughly 70%. We also show that (somewhat surprisingly) an argument-slot collocation measure gives more accurate predictions than a predicate-slot collocation measure on this task. We speculate the reason is that the head word disambiguates the preposition and that this disambiguation generally determines whether a prepositional argument is a core or an adjunct (somewhat independently of the predicate). This calls for a future study into the semantics of prepositions and their relation to the core-adjunct distinction. In this context two recent projects, *The Preposition Project* (Litkowski and Hargraves, 2005) and *PrepNet* (Saint-Dizier, 2006), which attempt to characterize and categorize the complex syntactic and semantic behavior of prepositions, may be of relevance.

It is our hope that this work will provide a better understanding of core-adjunct phenomena. Current supervised SRL models tend to perform worse on adjuncts than on cores (Pradhan et al., 2008; Toutanova et al., 2008). We believe a better understanding of the differences between cores and adjuncts may contribute to the development of better SRL techniques, in both its supervised and unsupervised variants.

Abstract

Current Semantic Role Labeling technologies are based on inductive algorithms trained over large scale repositories of annotated examples. Frame-based systems currently make use of the FrameNet database but fail to show suitable generalization capabilities in out-of-domain scenarios. In this paper, a state-of-art system for frame-based SRL is extended through the encapsulation of a distributional model of semantic similarity. The resulting argument classification model promotes a simpler feature space that limits the potential overfitting effects. The large scale empirical study here discussed confirms that state-of-art accuracy can be obtained for out-of-domain evaluations.

1 Introduction

The availability of large scale semantic lexicons, such as FrameNet (Baker et al., 1998), allowed the adoption of a wide family of learning paradigms in the automation of semantic parsing. Building upon the so called *frame* semantic model (Fillmore, 1985), the Berkeley FrameNet project has developed a semantic lexicon for the core vocabulary of English, since 1997. A frame is evoked in texts through the occurrence of its *lexical units* (LU), i.e. predicate words such verbs, nouns, or adjectives, and specifies the participants and properties of the situation it describes, the so called *frame elements* (FEs).

Semantic Role Labeling (SRL) is the task of automatic recognition of individual predicates together with their major roles (e.g. frame elements) as they are grammatically realized in input sentences. It has been a popular task since the availability of the PropBank and FrameNet annotated corpora (Palmer et al., 2005), the seminal work of (Gildea and Jurafsky, 2002) and the successful CoNLL evaluation campaigns (Carreras and Màrquez, 2005). Statistical machine learning methods, ranging from joint probabilistic models to support vector machines, have been successfully adopted to provide very accurate semantic labeling, e.g. (Carreras and Màrquez, 2005).

SRL based on FrameNet is thus not a novel task, although very few systems are known capable of completing a general frame-based annotation process over raw texts, noticeable exceptions being discussed for example in (Erk and Pado, 2006), (Johansson and Nugues, 2008b) and (Coppola et al., 2009). Some critical limitations have been outlined in literature, some of them independent from the underlying semantic paradigm.

Parsing Accuracy. Most of the employed learning algorithms are based on complex sets of syntagmatic features, as deeply investigated in (Johansson and Nugues, 2008b). The resulting recognition *is thus highly dependent on the accuracy of the underlying parser*, whereas wrong structures returned by the parser usually imply large misclassification errors.

Annotation costs. Statistical learning approaches applied to SRL are *very demanding with respect to the amount and quality of the training material*. The complex SRL architectures proposed (usually combining local and global, i.e. joint, models of argument classification, e.g. (Toutanova et al., 2008)) require a large number of annotated examples. The amount and quality of the training data required to reach a significant accuracy is a serious limitation to the exploitation of SRL in many NLP applications.

Limited Linguistic Generalization. Several studies showed that even when large training sets exist *the corresponding learning exhibits poor generalization power*. Most of the CoNLL 2005 systems show a significant performance drop when the tested corpus, i.e. Brown, differs from

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 237–246,
Uppsala, Sweden, 11-16 July 2010.

the training one (i.e. Wall Street Journal), e.g. (Toutanova et al., 2008). More recently, the state-of-art frame-based semantic role labeling system discussed in (Johansson and Nugues, 2008b) reports a 19% drop in accuracy for the argument classification task when a different test domain is targeted (i.e. NTI corpus). Out-of-domain tests seem to suggest the models trained on BNC do not generalize well to novel grammatical and lexical phenomena. As also suggested in (Pradhan et al., 2008), the major drawback is the poor generalization power affecting lexical features. Notice how this is also a general problem of statistical learning processes, as large fine grain feature sets are more exposed to the risks of overfitting.

The above problems are particularly critical for frame-based shallow semantic parsing where, as opposed to more syntactic-oriented semantic labeling schemes (as Propbank (Palmer et al., 2005)), *a significant mismatch exists between the semantic descriptors and the underlying syntactic annotation level*. In (Johansson and Nugues, 2008b) an upper bound of about 83.9% for the accuracy of the argument identification task is reported, it is due to the complexity in projecting frame element boundaries out from the dependency graph: more than 16% of the roles in the annotated material lack of a clear grammatical status.

The limited level of linguistic generalization outlined above is still an open research problem. Existing solutions have been proposed in literature along different lines. Learning from richer linguistic descriptions of more complex structures is proposed in (Toutanova et al., 2008). Limiting the cost required for developing large domain-specific training data sets has been also studied, e.g., (Fürstenau and Lapata, 2009). Finally, the application of semi-supervised learning is attempted to increase the lexical expressiveness of the model, e.g. (Goldberg and Elhadad, 2009).

In this paper, this last direction is pursued. A semi-supervised statistical model exploiting useful lexical information from unlabeled corpora is proposed. The model adopts a simple feature space by relying on a limited set of grammatical properties, thus reducing its learning capacity. Moreover, it generalizes lexical information about the annotated examples by applying a geometrical model, in a Latent Semantic Analysis style, inspired by a distributional paradigm (Pado and Lapata, 2007). As we will see, the accuracy reachable through a restricted feature space is still quite close to the state-of-art, but interestingly the performance drops in out-of-domain tests are avoided.

In the following, after discussing existing approaches to SRL (Section 2), a distributional approach is defined in Section 3. Section 3.2 discusses the proposed HMM-based treatment of joint inferences in argument classification. The large scale experiments described in Section 4 will allow to draw the conclusions of Section 5.

2 Related Work

State-of-art approaches to frame-based SRL are based on Support Vector Machines, trained over linear models of syntactic features, e.g. (Johansson and Nugues, 2008b), or tree-kernels, e.g. (Coppola et al., 2009). SRL proceeds through two main steps: the localization of arguments in a sentence, called *boundary detection (BD)*, and the assignment of the proper role to the detected constituents, that is the *argument classification, (AC)* step. In (Toutanova et al., 2008) a SRL model over Propbank that effectively exploits the semantic argument frame as a joint structure, is presented. It incorporates strong dependencies within a comprehensive statistical joint model with a rich set of features over multiple argument phrases. This approach effectively introduces a new step in SRL, also called *Joint Re-ranking, (RR)*, e.g. (Toutanova et al., 2008) or (Moschitti et al., 2008). First local models are applied to produce role labels over individual arguments, then the joint model is used to decide the entire argument sequence among the set of the n-best competing solutions. While these approaches increase the expressive power of the models to capture more general linguistic properties, they rely on complex feature sets, are more demanding about the amount of training information and increase the overall exposure to overfitting effects.

In (Johansson and Nugues, 2008b) the impact of different grammatical representations on the task of frame-based shallow semantic parsing is studied and the poor lexical generalization problem is outlined. An argument classification accuracy of 89.9% over the FrameNet (i.e. BNC) dataset is shown to decrease to 71.1% when a different test domain is evaluated (i.e. the Nuclear Threat Initiative corpus). The argument classification

component is thus shown to be heavily domain-dependent whereas the inclusion of grammatical function features is just able to mitigate this sensitivity. In line with (Pradhan et al., 2008), it is suggested that lexical features are domain specific and their suitable generalization is not achieved.

The lack of suitable lexical information is also discussed in (Fürstenau and Lapata, 2009) through an approach aiming to support the creation of novel annotated resources. Accordingly a semi-supervised approach for reducing the costs of the manual annotation effort is proposed. Through a graph alignment algorithm triggered by annotated resources, the method acquires training instances from an unlabeled corpus also for verbs not listed as existing FrameNet predicates.

2.1 The role of Lexical Semantic Information

It is widely accepted that lexical information (as features directly derived from word forms) is crucial for training accurate systems in a number of NLP tasks. Indeed, all the best systems in the CoNLL shared task competitions (e.g. Chunking (Tjong Kim Sang and Buchholz, 2000)) make extensive use of lexical information. Also lexical features are beneficial in SRL usually either for systems on Propbank as well as for FrameNet-based annotation.

In (Goldberg and Elhadad, 2009), a different strategy to incorporate lexical features into classification models is proposed. A more expressive training algorithm (i.e. anchored SVM) coupled with an aggressive feature pruning strategy is shown to achieve high accuracy over a chunking and named entity recognition task. The suggested perspective here is that effective semantic knowledge can be collected from sources external to the annotated corpora (very large unannotated corpora or on manually constructed lexical resources) rather than learned from the raw lexical counts of the annotated corpus. Notice how this is also the strategy pursued in recent work on deep learning approaches to NLP tasks. In (Collobert and Weston, 2008) a unified architecture for Natural Language Processing that learns features relevant to the tasks at hand given very limited prior knowledge is presented. It embodies the idea that a multitask learning architecture coupled with semi-supervised learning can be effectively applied even to complex linguistic tasks such as SRL. In particular, (Collobert and Weston, 2008) proposes an embedding of lexical information using Wikipedia as source, and exploiting the resulting language model within the multitask learning process. The idea of (Collobert and Weston, 2008) to obtain an embedding of lexical information by acquiring a language model from unlabeled data is an interesting approach to the problem of performance degradation in out-of-domain tests, as already pursued by (Deschacht and Moens, 2009). The extensive use of unlabeled texts allows to achieve a significant level of lexical generalization that seems better capitalize the smaller annotated data sets.

3 A Distributional Model for Argument Classification

High quality lexical information is crucial for robust open-domain SRL, as semantic generalization highly depends on lexical information. For example, the following two sentences evoke the STATEMENT frame, through the LUs *say* and *state*, where the FEs, SPEAKER and MEDIUM, are shown.

[*President Kennedy*] SPEAKER said *to an astronaut, "Man is still the most extraordinary computer of all."* (1)

[*The report*] MEDIUM stated, *that some problems needed to be solved.* (2)

In sentence (1), for example, *President Kennedy* is the grammatical subject of the verb *say* and this justifies its role of SPEAKER. However, syntax does not entirely characterize argument semantics. In (1) and (2), the same syntactic relation is observed. It is the semantics of the grammatical heads, i.e. *report* and *Kennedy*, the main responsible for the difference between the two resulting proto-agentive roles, SPEAKER and MEDIUM.

In this work we explore two different aspects. First, we propose a model that does not depend on complex syntactic information in order to minimize the risk of overfitting. Second, we improve the lexical semantic information available to the learning algorithm. The proposed "minimalistic" approach will consider only two independent features:

- the *semantic head* (h) of a role, as it can be observed in the grammatical structure. In sentence (2), for example, the MEDIUM FE is realized as the logical subject, whose head is *report*.

- the *dependency relation* (r) connecting the semantic head to the predicate words. In (2), the semantic head *report* is connected to the LU *stated* through the subject (SBJ) relation.

In the rest of the section the distributional model for the argument classification step is presented. A lexicalized model for individual semantic roles is first defined in order to achieve robust semantic classification local to each argument. Then a Hidden Markov Model is introduced in order to exploit the local probability estimators, sensitive to lexical similarity, as well as the global information on the entire argument sequence.

3.1 Distributional Local Models

As the classification of semantic roles is strictly related to the lexical meaning of argument heads, we adopt a distributional perspective, where the meaning is described by the set of textual contexts in which words appear. In distributional models, words are thus represented through vectors built over these observable contexts: similar vectors suggest *semantic relatedness* as a function of the distance between two words, capturing paradigmatic (e.g. synonymy) or syntagmatic relations (Pado, 2007). Vectors $\overrightarrow{h}$ are described by an adjacency matrix M, whose rows describe target words (h) and whose columns describe their corpus contexts. Latent Semantic Analysis (LSA) (Landauer and Dumais, 1997), is then applied to M to acquire meaningful representations $\overrightarrow{h}$. LSA exploits the linear transformation called *Singular Value Decomposition* (SVD) and produces an approximation of the original matrix M, capturing (semantic) dependencies between context vectors. M is replaced by a lower dimensional matrix M_l, capturing the same statistical information in a new l-dimensional space, where each dimension is a linear combination of some of the original features (i.e. contexts). These derived features may be thought as artificial concepts, each one representing an emerging meaning component, as the linear combination of many different words.

In the argument classification task, the similarity between two argument heads h_1 and h_2 observed in FrameNet can be computed over $\overrightarrow{h_1}$ and $\overrightarrow{h_2}$. The model for a given frame element FE^k is built around the semantic heads h observed in the role FE^k: they form a set denoted by H^{FE^k}. These LSA vectors $\overrightarrow{h}$ express the individual annotated examples as they are immerse in the LSA space acquired from the unlabeled texts. Moreover, given FE^k, a model for each individual syntactic relation r (i.e. that links h labeled as FE^k to their corresponding predicates) is a partition of the set H^{FE^k} called $H_r^{FE^k}$, i.e. the subset of H^{FE^k} produced by examples of the relation r (e.g. Subj). Given the annotated sentence (2), we have that $report \in H^{\text{MEDIUM}}_{\text{SBJ}}$.

Role, FE^k	**Clusters of semantic heads**
MEDIUM	c_1: {*article, report, statement*} c_2: {*constitution, decree, rule*}
SPEAKER	c_3: {*brother, father, mother, sister* } c_4: {*biographer, philosopher, ...*} c_5: {*he, she, we, you*} c_6: {*friend*}
TOPIC	c_7: {*privilege, unresponsiveness*} c_8: {*pattern*}

Table 1: Clusters of semantic heads in the Subj position for the frame STATEMENT with σ = 0.5

As the LSA vectors $\overrightarrow{h}$ are available for the semantic heads h, a vector representation $\overrightarrow{FE^k}$ for the role FE^k can be obtained from the annotated data. However, one single vector is a too simplistic representation given the rich nature of semantic roles FE^k. In order to better represent FE^k, multiple regions in the semantic space are used. They are obtained by a clustering process applied to the set $H_r^{FE^k}$ according to the *Quality Threshold (QT)* algorithm (Heyer et al., 1999). QT is a generalization of k-mean where a variable number of clusters can be obtained. This number depends on the minimal value of intra-cluster similarity accepted by the algorithm and controlled by a parameter, σ: lower values of σ correspond to more heterogeneous (i.e. larger grain) clusters, while values close to 1 characterize stricter policies and more fine-grained results. Given a syntactic relation r, $C_r^{FE^k}$ denotes the clusters derived by QT clustering over $H_r^{FE^k}$. Each cluster $c \in C_r^{FE^k}$ is represented by a vector $\overrightarrow{c}$, computed as the geometric centroid of its semantic heads $h \in c$. For a frame F, clusters define a geometric model of every frame elements FE^k: it consists of centroids $\overrightarrow{c}$ with $c \subseteq H_r^{FE^k}$. Each c represents FE^k through a set of similar heads, as role fillers observed in FrameNet. Table 1 represents clusters for the heads $H^{FE^k}_{\text{Subj}}$ of the STATEMENT frame.

In argument classification we assume that the evoking predicate word for the frame F in an input sentence s is known. A sentence s can be seen as a sequence of role-relation pairs:

$s = \{(r_1, h_1), ..., (r_n, h_n)\}$ where the heads h_i are in the syntactic relation r_i with the underlying lexical unit of F.

For every head h in s, the vector $\overrightarrow{h}$ can be then used to estimate its similarity with the different candidate roles FE^k. Given the syntactic relation r, the clusters $c \in C_r^{FE^k}$ whose centroid vector $\vec{c}$ is closer to $\vec{h}$ are selected. $D_{r,h}$ is the set of the representations semantically related to h:

$$D_{r,h} = \bigcup_k \{c_{kj} \in C_r^{FE^k} | sim(h, c_{kj}) \geq \tau\} \quad (3)$$

where the similarity between the j-th cluster for the FE^k, i.e. $c_{kj} \in C_r^{FE^k}$, and h is the usual *cosine similarity*: $sim_{cos}(h, c_{kj}) = \frac{\overrightarrow{h} \cdot \overrightarrow{c}_{kj}}{\|\overrightarrow{h}\| \, \|\overrightarrow{c}_{kj}\|}$

Then, through a *k-nearest neighbours* (*k*-NN) strategy within $D_{r,h}$, the m clusters c_{kj} most similar to h are retained in the set $D_{r,h}^{(m)}$. A probabilistic preference for the role FE^k is estimated for h through a cluster-based voting scheme,

$$prob(FE^k | r, h) = \frac{|C_r^{FE^k} \cap D_{r,h}^{(m)}|}{|D_{r,h}^{(m)}|} \quad (4)$$

or, alternatively, an instance-based one over $D_{r,h}^{(m)}$:

$$prob(FE^k | r, h) = \frac{\sum_{c \in C_r^{FE^k} \cap D_{r,h}^{(m)}} |c|}{\sum_{c \in D_{r,h}^{(m)}} |c|} \quad (5)$$

In Fig. 1 the preference estimation for the incoming head $h = professor$ connected to a LU by the `Subj` relation is shown. Clusters for the heads in Table 1 are also reported. First, in the set of clusters whose similarity with $professor$ is higher than a threshold τ the $m = 5$ most similar clusters are selected. Accordingly, the preferences given by Eq. 4 are $prob(\text{SPEAKER}|\text{SBJ}, h) = 3/5$, $prob(\text{MEDIUM}|\text{SBJ}, h) = 2/5$ and $prob(\text{TOPIC}|\text{SBJ}, h) = 0$. The strategy modeled by Eq. 5 amplifies the role of larger clusters, e.g. $prob(\text{SPEAKER}|\text{SBJ}, h) = 9/14$ and $prob(\text{MEDIUM}|\text{SBJ}, h) = 5/14$. We call *Distributional*, the model that applies Eq. 5 to the source (r, h) arguments, by rejecting cases *only when* no information about the head h is available from the unlabeled corpus or no example of relation r for the role FE^k is available from the annotated corpus. Eq. 4 and 5 in fact do not cover all possible cases. Often the incoming head h or the relation r may be unavailable:

1. If the head h has never been met in the unlabeled corpus or the high grammatical ambiguity of the sentence does not allow to locate it reliably, Eq. 4 (or 5) should be backed off to a purely syntactic model, that is $prob(FE^k|r)$

2. If the relation r can not be properly located in s, h is also unknown: the prior probability of individual arguments, i.e. $prob(FE^k)$, is here employed.

Both $prob(FE^k|r)$ and $prob(FE^k)$ can be estimated from the training set and smoothing can be also applied[1]. A more robust argument preference function for all arguments $(r_i, h_i) \in s$ of the frame F is thus given by:

$$prob(FE^k | r_i, h_i) = \lambda_1 prob(FE^k | r_i, h_i) + \lambda_2 prob(FE^k | r_i) + \lambda_3 prob(FE^k) \quad (6)$$

where weights λ_1, λ_2, λ_3 can be heuristically assigned or estimated from the training set[2]. The resulting model is hereafter called *Backoff model*: although simply based on a single feature (i.e. the syntactic relation r), it accounts for information at different reliability degrees.

3.2 A Joint Model for Argument Classification

Eq. 6 defines roles preferences local to individual arguments (r_i, h_i). However, an argument frame is a joint structure, with strong dependencies between arguments. We thus propose to model the reranking phase (RR) as a HMM sequence labeling task. It defines a stochastic inference over multiple (locally justified) alternative sequences through a Hidden Markov Model (HMM). It infers the best sequence $FE^{(k_1,...,k_n)}$ over all the possible hidden state sequences (i.e. made by the target FE^{k_i}) given the observable emissions, i.e. the arguments (r_i, h_i). Viterbi inference is applied to build the best (role) interpretation for the input sentence.

Once Eq. 6 is available, the best frame element sequence $FE^{(\theta(1),...,\theta(n))}$ for the entire sentence s can be selected by defining the function $\theta(\cdot)$ that maps arguments $(r_i, h_i) \in s$ to frame elements FE^k:

$$\theta(i) = k \;\; s.t. \;\; FE^k \in F \quad (7)$$

[1] Lindstone smoothing was applied with $\delta = 1$.

[2] In each test discussed hereafter, λ_1, λ_2, λ_3 were assigned to .9,.09 and .01, in order to impose a strict priority to the model contributions.

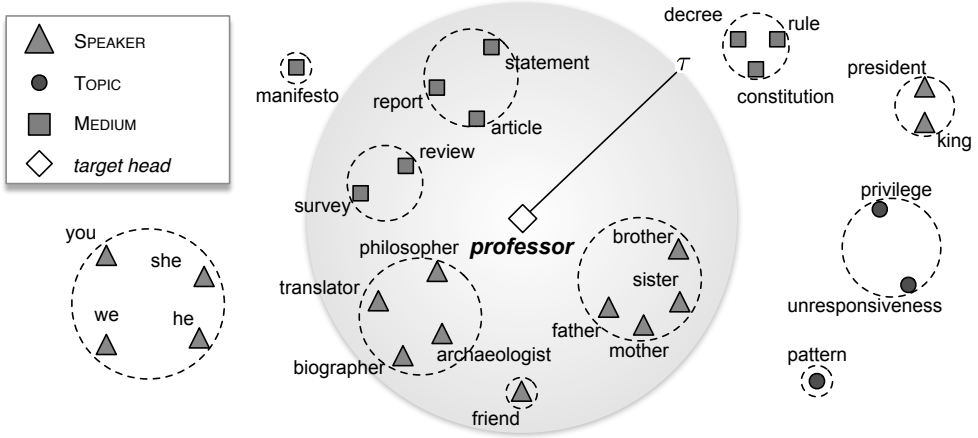

Figure 1: A k-NN approach to the role classification for $h_i = professor$

Notice that different transfer functions $\theta(\cdot)$ are usually possible. By computing their probability we can solve the SRL task by selecting the most likely interpretation, $\widehat{\theta}(\cdot)$, via $\text{argmax}_\theta\, P\big(\theta(\cdot) \mid s\big)$, as follows:

$$\widehat{\theta}(\cdot) = \underset{\theta}{\text{argmax}}\, P\big(s|\theta(\cdot)\big)P\big(\theta(\cdot)\big) \qquad (8)$$

In Eq. 8, the emission probability $P\big(s|\theta(\cdot)\big)$ and the transition probability $P\big(\theta(\cdot)\big)$ are explicit. Notice that the emission probability corresponds to an argument interpretation (e.g. Eq. 5) and it is assigned independently from the rest of the sentence. On the other hand, transition probabilities model role sequences and support the expectations about argument frames of a sentence.

The emission probability is approximated as:

$$P\big(s \mid \theta(1)\ldots\theta(n)\big) \approx \prod_{i=1}^{n} P(r_i, h_i \mid FE^{\theta(i)}) \qquad (9)$$

as it is made independent from previous states in a Viterbi path. Again the emission probability can be rewritten as:

$$P(r_i, h_i|FE^{\theta(i)}) = \frac{P(FE^{\theta(i)}|r_i, h_i)\; P(r_i, h_i)}{P(FE^{\theta(i)})} \qquad (10)$$

Since $P(r_i, h_i)$ does not depend on the role labeling, maximizing Eq. 10 corresponds to maximize:

$$\frac{P(FE^{\theta(i)}|r_i, h_i)}{P(FE^{\theta(i)})} \qquad (11)$$

whereas $P(FE^{\theta(i)}|r_i, h_i)$ is thus estimated through Eq. 6.

The transition probability, estimated through

$$P\big(\theta(1)\ldots\theta(n)\big) \approx \prod_{i=1}^{n} P\big(FE^{\theta(i)}|FE^{\theta(i-1)}, FE^{\theta(i-2)}\big) \qquad (12)$$

accounts FEs sequence via a *3*-gram model[3] .

4 Empirical Analysis

The aim of the evaluation is to measure the reachable accuracy of the simple model proposed and to compare its impact over in-domain and out-of-domain semantic role labeling tasks. In particular, we will evaluate the argument classification (AC) task in Section 4.2.

Experimental Set-Up. The in-domain test has been run over the FrameNet annotated corpus, derived from the British National Corpus (BNC). The splitting between train and test set is 90%-10% according to the same data set of (Johansson and Nugues, 2008b). In all experiments, the FrameNet 1.3 version and the dependency-based system using the LTH parser (Johansson and Nugues, 2008a) have been employed. Out-of-domain tests are run over the two training corpora as made available by the Semeval 2007 Task 19[4] (Baker et al., 2007): the Nuclear Threat Initiative (NTI) and the American National Corpus

[3]Two empty states are added at the beginning of any sequence. Moreover, Laplace smoothing was also applied to each estimator.

[4]The NTI and ANC annotated collections are downloadable at:
nlp.cs.swarthmore.edu/semeval/tasks/task19/data/train.tar.gz

	Corpus	Predicates	Arguments

(4) - .5	85.1	85.5	85.8	87.2	83.5	79.4
(4) - .1	84.5	84.8	85.1	86.5	83.0	78.7

Table 3: Accuracy on Arg classification tasks wrt different clustering policies

(ANC)[5]. Table 2 shows the predicates and arguments in each data set. All null-instantiated arguments were removed from the training and test sets.

Vectors $\vec{h}$ representing semantic heads have been computed according to the "dependency-based" vector space discussed in (Pado and Lapata, 2007). The entire BNC corpus has been parsed and the dependency graphs derived from individual sentences provided the basic observable contexts: every co-occurrence is thus syntactically justified by a dependency arc. The most frequent 30,000 basic features, i.e. (syntactic relation,lemma) pairs, have been used to build the matrix M, vector components corresponding to point-wise mutual information scores. Finally, the final space is obtained by applying the SVD reduction over M, with a dimensionality cut of $l = 250$.

In the evaluation of the AC task, accuracy is computed over the nodes of the dependency graph, in line with (Johansson and Nugues, 2008b) or (Coppola et al., 2009). Accordingly, also recall, precision and F-measure are reported on a *per node* basis, against the binary BD task or for the full $BD + AC$ chain.

4.1 The Role of Lexical Clustering

The first study aims at detecting the impact of different clustering policies on the resulting AC accuracy. Clustering, as discussed in Section 3.1, allows to generalize lexical information: similar heads within the latent semantic space are built from the annotated examples and they allow to predict the behavior of new unseen words as found in the test sentences. The system performances have been here measured under different clustering conditions, i.e. grains at which the clustering of annotated examples is applied. This grain is determined by the parameter σ of the applied Quality Threshold algorithm (Heyer et al., 1999). Notice that small values of σ imply large clusters, while if $\sigma \approx 1$ then many singleton clusters are promoted (i.e. one cluster for each example). By varying the threshold σ we thus account for prototype-based as well exemplar-based strategies, as discussed in (Erk, 2009).

We measured the performance on the argument classification tasks of different models obtained by combing different choices of σ with Eq. (4) or (5). Results are reported in Table 3. The leftmost column reports the different clustering settings, while in the remaining columns we see performances over test sentences related to different frames: we selected frames for which an increasing number of annotated examples are available: from all frames (for more than 0 examples) to the only frame (i.e. SELF_MOTION) that has more than 5,000 examples in our training data set.

The reported accuracies suggest that Eq. (5), promoting an example driven strategy, better captures the role preference, as it always outperforms alternative settings (i.e. more prototype oriented methods). It limits overgeneralization and promotes fine grained clusters. An interesting result is that a per-node accuracy of 86.3 (i.e. only 3 points under the state of-the art on the same data set, (Johansson and Nugues, 2008b)) is achieved. All the remaining tests have been run with the clustering configuration characterized by Eq. (5) and $\sigma = 0.85$.

4.2 Argument Classification Accuracy

In these experiments we evaluate the quality of the argument classification step against the lexical knowledge acquired from unlabeled texts and the reranking step. The accuracy reachable on the gold standard argument boundaries has been compared across several experimental settings. Two baseline systems have been obtained. The *Local Prior* model outputs the sequence that maximizes the prior probability locally to individual arguments. The *Global Prior* model is obtained by applying re-ranking (Section 3.2) to the best $n = 10$ candidates provided by the *Local Prior* model. Fi-

[5]Sentences whose arguments were not represented in the FrameNet training material were removed from all tests.

Model	FN-BNC	NTI	ANC
Local Prior	43.9	50.9	50.4
Global Prior	67.7 (+54.2%)	75.9 (+49.0%)	68.8 (+36.4%)
Distributional	81.1 (+19.8%)	82.3 (+8.4%)	69.7 (+1.3%)
Backoff	84.6 (+4.3%)	87.2 (+6.0%)	76.2 (+9.3%)
Backoff+HMMRR	86.3 (+2.0%)	90.5 (+3.8%)	79.9 (+5.0%)
(Johansson&Nugues, 2008)	89.9	71.1	-

Table 4: Accuracy of the Argument Classification task over the different corpora. In parenthesis the relative increment with respect to the immediately simpler model, previous row

nally, the application of the backoff strategies (as in Eq. 6) and the HMM-based reranking characterize the final two configurations. Table 4 reports the accuracy results obtained over the three corpora (defined as in Table 2): the accuracy scores are averaged over different values of m in Eq. 5, ranging from 3 to 30. In the in-domain scenario, i.e. the FN-BNC dataset reported in column 2, it is worth noticing that the proposed model, with backoff and global reranking, is quite effective with respect to the state-of-the-art.

Although results on the FN-BNC do not outperform the state-of-the-art for the FrameNet corpus, we still need to study the generalization capability of our SRL model in out-of-domain conditions. In a further experiment, we applied the same system, as trained over the FN-BNC data, to the other corpora, i.e. NTI and ANC, used entirely as test sets. Results, reported in column 3 and 4 of Table 4 and shown in Figure 2, confirm that no major drop in performance is observed. Notice how the positive impact of the backoff models and the HMM reranking policy is similarly reflected by all the collections. Moreover, the results on the NTI corpus are even better than those obtained on the BNC, with a resulting 90.5% accuracy on the AC task.

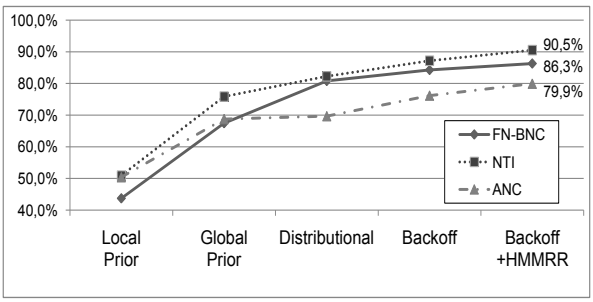

Figure 2: Accuracy of the AC task over different corpora

4.3 Discussion

The above empirical findings are relevant if compared with the outcome of a similar test on the NTI collection, discussed in (Johansson and Nugues, 2008b)[6]. There, under the same training conditions, a performance drop of about -19% is reported (from 89.9 to 71.1%) over gold standard argument boundaries. The model proposed in this paper exhibits no such drop in any collection (NTI and ANC). This seems to confirm the hypothesis that the model is able to properly generalize the required lexical information across different domains.

It is interesting to outline that the individual stages of the proposed model play different roles in the different domains, as Table 4 suggests. Although the positive contributions of the individual processing stages are uniformly confirmed, some differences can be outlined:

- The beneficial impact of the lexical information (i.e. the distributional model) applies differently across the different domains. The ANC domain seems not to significantly benefit when the distributional model (Eq. 5) is applied. Notice how Eq. 5 depends both from the evidence gathered in the corpus about lexical heads h as well as about the relation r. In ANC the percentage of times that the Eq. 5 is backed off against test instances (as h or r are not available from the training data) is twice as high as in the BNC-FN or in the NTI domain (i.e. 15.5 vs. 7.2 or 8.7, respectively). The different syntactic style of ANC seems thus the main responsible of the poor impact of distributional information, as it is often unapplicable to ANC test cases.

- The complexity of the three test sets is different, as the three plots show. The NTI col-

[6]Notice that in this paper only the training portion of the NTI data set is employed as reported in Table 2 and results are not directly comparable to (Johansson and Nugues, 2008b).

lections seems characterized by a lower level of complexity (see for example the accuracy of the *Local prior* model, that is about 51% as for the ANC). It then gets benefits from all the analysis stages, in particular the final HMM reranking. The BNC-FN test collection seems the most complex one, and the impact of the lexical information brought by the distributional model is here maximal. This is mainly due to the coherence between the distributions of lexical and grammatical phenomena in the test and training data.

- The role of HMM reranking is an effective way to compensate errors in the local argument classifications for all the three domains. However, it is particularly effective for the outside domain cases, while, in the BNC corpus, it produces just a small improvement instead (i.e. +2%, as shown in Table 4). It is worth noticing that the average length of the sentences in the BNC test collection is about 23 words per sentence, while it is higher for the NTI and ANC data sets (i.e. 34 and 31, respectively). It seems that the HMM model well captures some information on the global semantic structure of a sentence: this is helpful in cases where errors in the grammatical recognition (of individual arguments or at sentence level) are more frequent and afflict the local distributional model. The more complex is the syntax of a corpus (e.g. in the NTI and ANC data sets), the higher seems the impact of the reranking phase.

The significant performance of the AC model here presented suggest to test it when integrated within a full SRL architecture. Table 5 reports the results of the processing cascade over three collections. Results on the Boundary Detection BD task are obtained by training an SVM model on the same feature set presented in (Johansson and Nugues, 2008b) and are slightly below the state-of-the art BD accuracy reported in (Coppola et al., 2009). However, the accuracy of the complete $BD + AC + RR$ chain (i.e. 68%) improves the corresponding results of (Coppola et al., 2009). Given the relatively simple feature set adopted here, this result is very significant as for its resulting efficiency. The overall BD recognition process is, on a standard architecture, performed at about 6.74 sentences per second, that is basically the same as the time needed for applying the entire $BD + AC + RR$ chain, i.e. 6.21 sentence per second.

Corpus	Eval. Setting	Recall	Precision	F1
BNC	BD	72.6	85.1	78.4
	BD+AC+RR	62.6	74.5	**68.0**
NTI	BD	63.9	80.0	71.0
	BD+AC+RR	56.7	72.1	63.5
ANC	BD	64.0	81.5	71.7
	BD+AC+RR	47.4	62.5	53.9

Table 5: Accuracy of the full cascade of the SRL system over three domain

5 Conclusions

In this paper, a distributional approach for acquiring a semi-supervised model of argument classification (AC) preferences has been proposed. It aims at improving the generalization capability of the inductive SRL approach by reducing the complexity of the employed grammatical features and through a distributional representation of lexical features. The obtained results are close to the state-of-art in FrameNet semantic parsing. State of the art accuracy is obtained instead in out-of-domain experiments. The model seems to capitalize from simple methods of lexical modeling (i.e. the estimation of lexico-grammatical preferences through distributional analysis over unlabeled data), estimation (through syntactic or lexical back-off where necessary) and reranking. The result is an accurate and highly portable SRL cascade. Experiments on the integrated SRL architecture (i.e. $BD + AC + RR$ chain) show that state-of-art accuracy (i.e. 68%) can be obtained on raw texts. This result is also very significant as for the achieved efficiency. The system is able to apply the entire $BD + AC + RR$ chain at a speed of 6.21 sentences per second. This significant efficiency confirms the applicability of the SRL approach proposed here in large scale NLP applications. Future work will study the application of the flexible SRL method proposed to other languages, for which less resources are available and worst training conditions are the norm. Moreover, dimensionality reduction methods alternative to LSA, as currently studied on semi-supervised spectral learning (Johnson and Zhang, 2008), will be experimented.

Abstract

Existing word similarity measures are not robust to data sparseness since they rely only on the point estimation of words' context profiles obtained from a limited amount of data. This paper proposes a Bayesian method for robust distributional word similarities. The method uses a distribution of context profiles obtained by Bayesian estimation and takes the expectation of a base similarity measure under that distribution. When the context profiles are multinomial distributions, the priors are Dirichlet, and the base measure is the Bhattacharyya coefficient, we can derive an analytical form that allows efficient calculation. For the task of word similarity estimation using a large amount of Web data in Japanese, we show that the proposed measure gives better accuracies than other well-known similarity measures.

1 Introduction

The semantic similarity of words is a long-standing topic in computational linguistics because it is theoretically intriguing and has many applications in the field. Many researchers have conducted studies based on the distributional hypothesis (Harris, 1954), which states that words that occur in the same contexts tend to have similar meanings. A number of semantic similarity measures have been proposed based on this hypothesis (Hindle, 1990; Grefenstette, 1994; Dagan et al., 1994; Dagan et al., 1995; Lin, 1998; Dagan et al., 1999).

In general, most semantic similarity measures have the following form:

$$sim(w_1, w_2) = g(v(w_1), v(w_2)), \qquad (1)$$

where $v(w_i)$ is a vector that represents the contexts in which w_i appears, which we call a *context profile* of w_i. The function g is a function on these context profiles that is expected to produce good similarities. Each dimension of the vector corresponds to a context, f_k, which is typically a neighboring word or a word having dependency relations with w_i in a corpus. Its value, $v_k(w_i)$, is typically a co-occurrence frequency $c(w_i, f_k)$, a conditional probability $p(f_k|w_i)$, or point-wise mutual information (PMI) between w_i and f_k, which are all calculated from a corpus. For g, various works have used the cosine, the Jaccard coefficient, or the Jensen-Shannon divergence is utilized, to name only a few measures.

Previous studies have focused on how to devise good contexts and a good function g for semantic similarities. On the other hand, our approach in this paper is to estimate context profiles ($v(w_i)$) robustly and thus to estimate the similarity robustly. The problem here is that $v(w_i)$ is computed from a corpus of limited size, and thus inevitably contains uncertainty and sparseness. The guiding intuition behind our method is as follows. *All other things being equal, the similarity with a more frequent word should be larger, since it would be more reliable.* For example, if $p(f_k|w_1)$ and $p(f_k|w_2)$ for two given words w_1 and w_2 are equal, but w_1 is more frequent, we would expect that $sim(w_0, w_1) > sim(w_0, w_2)$.

In the NLP field, data sparseness has been recognized as a serious problem and tackled in the context of language modeling and supervised machine learning. However, to our knowledge, there

*The work was done while the author was at NICT.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 247–256,
Uppsala, Sweden, 11-16 July 2010.

has been no study that seriously dealt with data sparseness in the context of semantic similarity calculation. The data sparseness problem is usually solved by smoothing, regularization, margin maximization and so on (Chen and Goodman, 1998; Chen and Rosenfeld, 2000; Cortes and Vapnik, 1995). Recently, the Bayesian approach has emerged and achieved promising results with a clearer formulation (Teh, 2006; Mochihashi et al., 2009).

In this paper, we apply the Bayesian framework to the calculation of distributional similarity. The method is straightforward: Instead of using the point estimation of $v(w_i)$, we first estimate the distribution of the context profile, $p(v(w_i))$, by Bayesian estimation and then take the expectation of the original similarity under this distribution as follows:

$$\begin{aligned} & sim_b(w_1, w_2) \\ & = E[sim(w_1, w_2)]_{\{p(v(w_1)),p(v(w_2))\}} \\ & = E[g(v(w_1), v(w_2))]_{\{p(v(w_1)),p(v(w_2))\}}. \end{aligned} \quad (2)$$

The uncertainty due to data sparseness is represented by $p(v(w_i))$, and taking the expectation enables us to take this into account. The Bayesian estimation usually gives diverging distributions for infrequent observations and thus decreases the expectation value as expected.

The Bayesian estimation and the expectation calculation in Eq. 2 are generally difficult and usually require computationally expensive procedures. Since our motivation for this research is to calculate good semantic similarities for a large set of words (e.g., one million nouns) and apply them to a wide range of NLP tasks, such costs must be minimized.

Our technical contribution in this paper is to show that in the case where the context profiles are multinomial distributions, the priors are Dirichlet, and the base similarity measure is the Bhattacharyya coefficient (Bhattacharyya, 1943), we can derive an analytical form for Eq. 2, that enables efficient calculation (with some implementation tricks).

In experiments, we estimate semantic similarities using a large amount of Web data in Japanese and show that the proposed measure gives better word similarities than a non-Bayesian Bhattacharyya coefficient or other well-known similarity measures such as Jensen-Shannon divergence and the cosine with PMI weights.

The rest of the paper is organized as follows. In Section 2, we briefly introduce the Bayesian estimation and the Bhattacharyya coefficient. Section 3 proposes our new Bayesian Bhattacharyya coefficient for robust similarity calculation. Section 4 mentions some implementation issues and the solutions. Then, Section 5 reports the experimental results.

2 Background

2.1 Bayesian estimation with Dirichlet prior

Assume that we estimate a probabilistic model for the observed data D, $p(D|\phi)$, which is parameterized with parameters ϕ. In the maximum likelihood estimation (MLE), we find the point estimation $\phi^* = \mathrm{argmax}_\phi p(D|\phi)$. For example, we estimate $p(f_k|w_i)$ as follows with MLE:

$$p(f_k|w_i) = c(w_i, f_k) / \sum_k c(w_i, f_k). \quad (3)$$

On the other hand, the objective of the Bayesian estimation is to find the distribution of ϕ given the observed data D, i.e., $p(\phi|D)$, and use it in later processes. Using Bayes' rule, this can also be viewed as:

$$p(\phi|D) = \frac{p(D|\phi)p_{prior}(\phi)}{p(D)}. \quad (4)$$

$p_{prior}(\phi)$ is a prior distribution that represents the plausibility of each ϕ based on the prior knowledge. In this paper, we consider the case where ϕ is a multinomial distribution, i.e., $\sum_k \phi_k = 1$, that models the process of choosing one out of K choices. Estimating a conditional probability distribution $\phi_k = p(f_k|w_i)$ as a context profile for each w_i falls into this case. In this paper, we also assume that the prior is the Dirichlet distribution, $Dir(\alpha)$. The Dirichlet distribution is defined as follows.

$$Dir(\phi|\alpha) = \frac{\Gamma(\sum_{k=1}^K \alpha_k)}{\prod_{k=1}^K \Gamma(\alpha_k)} \prod_{k=1}^K \phi_k^{\alpha_k - 1}. \quad (5)$$

$\Gamma(.)$ is the Gamma function. The Dirichlet distribution is parametrized by hyperparameters $\alpha_k (> 0)$.

It is known that $p(\phi|D)$ is also a Dirichlet distribution for this simplest case, and it can be analytically calculated as follows.

$$p(\phi|D) = Dir(\phi|\{\alpha_k + c(k)\}), \quad (6)$$

where $c(k)$ is the frequency of choice k in data D. For example, $c(k) = c(w_i, f_k)$ in the estimation of $p(f_k|w_i)$. This is very simple: we just need to add the observed counts to the hyperparameters.

2.2 Bhattacharyya coefficient

When the context profiles are probability distributions, we usually utilize the measures on probability distributions such as the Jensen-Shannon (JS) divergence to calculate similarities (Dagan et al., 1994; Dagan et al., 1997). The JS divergence is defined as follows.

$$JS(p_1||p_2) = \frac{1}{2}(KL(p_1||p_{avg}) + KL(p_2||p_{avg})),$$

where $p_{avg} = \frac{p_1+p_2}{2}$ is a point-wise average of p_1 and p_2 and $KL(.)$ is the Kullback-Leibler divergence. Although we found that the JS divergence is a good measure, it is difficult to derive an efficient calculation of Eq. 2, even in the Dirichlet prior case.[1]

In this study, we employ the Bhattacharyya coefficient (Bhattacharyya, 1943) (BC for short), which is defined as follows:

$$BC(p_1, p_2) = \sum_{k=1}^{K} \sqrt{p_{1k} \times p_{2k}}.$$

The BC is also a similarity measure on probability distributions and is suitable for our purposes as we describe in the next section. Although BC has not been explored well in the literature on distributional word similarities, it is also a good similarity measure as the experiments show.

3 Method

In this section, we show that if our base similarity measure is BC and the distributions under which we take the expectation are Dirichlet distributions, then Eq. 2 also has an analytical form, allowing efficient calculation.

Here, we calculate the following value given two Dirichlet distributions:

$$BC_b(p_1, p_2) = E[BC(p_1, p_2)]_{\{Dir(p_1|\alpha'), Dir(p_2|\beta')\}}$$
$$= \iint_{\triangle\times\triangle} Dir(p_1|\alpha')Dir(p_2|\beta')BC(p_1, p_2)dp_1dp_2.$$

After several derivation steps (see Appendix A), we obtain the following analytical solution for the above:

$$= \frac{\Gamma(\alpha'_0)\Gamma(\beta'_0)}{\Gamma(\alpha'_0 + \frac{1}{2})\Gamma(\beta'_0 + \frac{1}{2})} \sum_{k=1}^{K} \frac{\Gamma(\alpha'_k + \frac{1}{2})\Gamma(\beta'_k + \frac{1}{2})}{\Gamma(\alpha'_k)\Gamma(\beta'_k)}, \quad (7)$$

where $\alpha'_0 = \sum_k \alpha'_k$ and $\beta'_0 = \sum_k \beta'_k$. Note that with the Dirichlet prior, $\alpha'_k = \alpha_k + c(w_1, f_k)$ and $\beta'_k = \beta_k + c(w_2, f_k)$, where α_k and β_k are the hyperparameters of the priors of w_1 and w_2, respectively.

To put it all together, we can obtain a new Bayesian similarity measure on words, which can be calculated only from the hyperparameters for the Dirichlet prior, α and β, and the observed counts $c(w_i, f_k)$. It is written as follows.

$$BC_b(w_1, w_2) = \quad (8)$$
$$\frac{\Gamma(\alpha_0 + a_0)\Gamma(\beta_0 + b_0)}{\Gamma(\alpha_0 + a_0 + \frac{1}{2})\Gamma(\beta_0 + b_0 + \frac{1}{2})} \times$$
$$\sum_{k=1}^{K} \frac{\Gamma(\alpha_k + c(w_1, f_k) + \frac{1}{2})\Gamma(\beta_k + c(w_2, f_k) + \frac{1}{2})}{\Gamma(\alpha_k + c(w_1, f_k))\Gamma(\beta_k + c(w_2, f_k))},$$

where $a_0 = \sum_k c(w_1, f_k)$ and $b_0 = \sum_k c(w_2, f_k)$. We call this new measure *the Bayesian Bhattacharyya coefficient* (BC_b for short). For simplicity, we assume $\alpha_k = \beta_k = \alpha$ in this paper.

We can see that BC_b actually encodes our guiding intuition. Consider four words, w_0, w_1, w_2, and w_4, for which we have $c(w_0, f_1) = 10$, $c(w_1, f_1) = 2$, $c(w_2, f_1) = 10$, and $c(w_3, f_1) = 20$. They have counts only for the first dimension, i.e., they have the same context profile: $p(f_1|w_i) = 1.0$, when we employ MLE. When $K = 10,000$ and $\alpha_k = 1.0$, the Bayesian similarity between these words is calculated as

$$BC_b(w_0, w_1) = 0.785368$$
$$BC_b(w_0, w_2) = 0.785421$$
$$BC_b(w_0, w_3) = 0.785463$$

We can see that similarities are different according to the number of observations, as expected. Note that the non-Bayesian BC will return the same value, 1.0, for all cases. Note also that $BC_b(w_0, w_0) = 0.78542$ if we use Eq. 8, meaning that the self-similarity might not be the maximum. This is conceptually strange, although not a serious problem since we hardly use $sim(w_i, w_i)$ in practice. If we want to fix this, we can use the special definition: $BC_b(w_i, w_i) \equiv 1$. This is equivalent to using $sim_b(w_i, w_i) = E[sim(w_i, w_i)]_{\{p(v(w_i))\}} = 1$ only for this case.

[1] A naive but general way might be to draw samples of $v(w_i)$ from $p(v(w_i))$ and approximate the expectation using these samples. However, such a method will be slow.

4 Implementation Issues

Although we have derived the analytical form (Eq. 8), there are several problems in implementing robust and efficient calculations.

First, the Gamma function in Eq. 8 overflows when the argument is larger than 170. In such cases, a commonly used way is to work in the logarithmic space. In this study, we utilize the "log Gamma" function: $ln\Gamma(x)$, which returns the logarithm of the Gamma function directly without the overflow problem.[2]

Second, the calculation of the log Gamma function is heavier than operations such as simple multiplication, which is used in existing measures. In fact, the log Gamma function is implemented using an iterative algorithm such as the Lanczos method. In addition, according to Eq. 8, it seems that we have to sum up the values for all k, because even if $c(w_i, f_k)$ is zero the value inside the summation will not be zero. In the existing measures, it is often the case that we only need to sum up for k where $c(w_i, f_k) > 0$. Because $c(w_i, f_k)$ is usually sparse, that technique speeds up the calculation of the existing measures drastically and makes it practical.

In this study, the above problem is solved by pre-computing the required log Gamma values, assuming that we calculate similarities for a large set of words, and pre-computing default values for cases where $c(w_i, f_k) = 0$. The following values are pre-computed once at the start-up time.

For each word:

(A) $ln\Gamma(\alpha_0 + a_0) - ln\Gamma(\alpha_0 + a_0 + \frac{1}{2})$

(B) $ln\Gamma(\alpha_k + c(w_i, f_k)) - ln\Gamma(\alpha_k + c(w_i, f_k) + \frac{1}{2})$ for all k where $c(w_i, f_k) > 0$

(C) $-\exp(2(ln\Gamma(\alpha_k + \frac{1}{2}) - ln\Gamma(\alpha_k)))) + \exp(ln\Gamma(\alpha_k + c(w_i, f_k)) - ln\Gamma(\alpha_k + c(w_i, f_k) + \frac{1}{2}) + ln\Gamma(\alpha_k + \frac{1}{2}) - ln\Gamma(\alpha_k))$ for all k where $c(w_i, f_k) > 0$;

For each k:
(D): $\exp(2(ln\Gamma(\alpha_k + \frac{1}{2}))$.

In the calculation of $BC_b(w_1, w_2)$, we first assume that all $c(w_i, f_k) = 0$ and set the output variable to the default value. Then, we iterate over the sparse vectors $c(w_1, f_k)$ and $c(w_2, f_k)$. If $c(w_1, f_k) > 0$ and $c(w_2, f_k) = 0$ (and vice versa), we update the output variable just by adding (C). If $c(w_1, f_k) > 0$ and $c(w_2, f_k) > 0$, we update the output value using (B), (D) and one additional $\exp(.)$ operation. With this implementation, we can make the computation of BC_b practically as fast as using other measures.

[2] We used the GNU Scientific Library (GSL) (www.gnu.org/software/gsl/), which implements this function.

5 Experiments

5.1 Evaluation setting

We evaluated our method in the calculation of similarities between nouns in Japanese.

Because human evaluation of word similarities is very difficult and costly, we conducted automatic evaluation in the set expansion setting, following previous studies such as Pantel et al. (2009).

Given a word set, which is expected to contain similar words, we assume that a good similarity measure should output, for each word in the set, the other words in the set as similar words. For given word sets, we can construct input-and-answers pairs, where the answers for each word are the other words in the set the word appears in.

We output a ranked list of 500 similar words for each word using a given similarity measure and checked whether they are included in the answers. This setting could be seen as document retrieval, and we can use an evaluation measure such as the mean of the precision at top T (MP@T) or the mean average precision (MAP). For each input word, P@T (precision at top T) and AP (average precision) are defined as follows.

$$\text{P@}T = \frac{1}{T}\sum_{i=1}^{T}\delta(w_i \in ans),$$

$$\text{AP} = \frac{1}{R}\sum_{i=1}^{N}\delta(w_i \in ans)\text{P@}i.$$

$\delta(w_i \in ans)$ returns 1 if the output word w_i is in the answers, and 0 otherwise. N is the number of outputs and R is the number of the answers. MP@T and MAP are the averages of these values over all input words.

5.2 Collecting context profiles

Dependency relations are used as context profiles as in Kazama and Torisawa (2008) and Kazama et al. (2009). From a large corpus of Japanese Web documents (Shinzato et al., 2008) (100 million

documents), where each sentence has a dependency parse, we extracted noun-verb and noun-noun dependencies with relation types and then calculated their frequencies in the corpus. If a noun, n, depends on a word, w, with a relation, r, we collect a dependency pair, $(n, \langle w, r \rangle)$. That is, a context f_k, is $\langle w, r \rangle$ here.

For noun-verb dependencies, postpositions in Japanese represent relation types. For example, we extract a dependency relation (ワイン, ⟨ 買う, を ⟩) from the sentence below, where a postposition "を (wo)" is used to mark the verb object.

ワイン (wine) を (wo) 買う (buy) (≈ buy a wine)

Note that we leave various auxiliary verb suffixes, such as "れる (reru)," which is for passivization, as a part of w, since these greatly change the type of n in the dependent position.

As for noun-noun dependencies, we considered expressions of type "n_1 の n_2" (≈ "n_2 of n_1") as dependencies $(n_1, \langle n_2, \text{の} \rangle)$.

We extracted about 470 million unique dependencies from the corpus, containing 31 million unique nouns (including compound nouns as determined by our filters) and 22 million unique contexts, f_k. We sorted the nouns according to the number of unique co-occurring contexts and the contexts according to the number of unique co-occurring nouns, and then we selected the top one million nouns and 100,000 contexts. We used only 260 million dependency pairs that contained both the selected nouns and the selected contexts.

5.3 Test sets

We prepared three test sets as follows.

Set "A" and "B": Thesaurus siblings We considered that words having a common hypernym (i.e., siblings) in a manually constructed thesaurus could constitute a similar word set. We extracted such sets from a Japanese dictionary, EDR (V3.0) (CRL, 2002), which contains concept hierarchies and the mapping between words and concepts. The dictionary contains 304,884 nouns. In all, 6,703 noun sibling sets were extracted with the average set size of 45.96. We randomly chose 200 sets each for sets "A" and "B." Set "A" is a development set to tune the value of the hyperparameters and "B" is for the validation of the parameter tuning.

Set "C": Closed sets Murata et al. (2004) constructed a dataset that contains several closed word sets such as the names of countries, rivers, sumo wrestlers, etc. We used all of the 45 sets that are marked as "complete" in the data, containing 12,827 unique words in total.

Note that we do not deal with ambiguities in the construction of these sets as well as in the calculation of similarities. That is, a word can be contained in several sets, and the answers for such a word is the union of the words in the sets it belongs to (excluding the word itself).

In addition, note that the words in these test sets are different from those of our one-million-word vocabulary. We filtered out the words that are not included in our vocabulary and removed the sets with size less than 2 after the filtering.

Set "A" contained 3,740 words that are actually evaluated, with about 115 answers on average, and "B" contained 3,657 words with about 65 answers on average. Set "C" contained 8,853 words with about 1,700 answers on average.

5.4 Compared similarity measures

We compared our Bayesian Bhattacharyya similarity measure, BC_b, with the following similarity measures.

JS Jensen-Shannon divergence between $p(f_k|w_1)$ and $p(f_k|w_2)$ (Dagan et al., 1994; Dagan et al., 1999).

PMI-cos The cosine of the context profile vectors, where the k-th dimension is the pointwise mutual information (PMI) between w_i and f_k defined as: $PMI(w_i, f_k) = \log \frac{p(w_i, f_k)}{p(w_i)p(f_k)}$ (Pantel and Lin, 2002; Pantel et al., 2009).[3]

Cls-JS Kazama et al. (2009) proposed using the Jensen-Shannon divergence between hidden class distributions, $p(c|w_1)$ and $p(c|w_2)$, which are obtained by using an EM-based clustering of dependency relations with a model $p(w_i, f_k) = \sum_c p(w_i|c)p(f_k|c)p(c)$ (Kazama and Torisawa, 2008). In order to

[3]We did not use the discounting of the PMI values described in Pantel and Lin (2002).

alleviate the effect of local minima of the EM clustering, they proposed averaging the similarities by several different clustering results, which can be obtained by using different initial parameters. In this study, we combined two clustering results (denoted as "s1+s2" in the results), each of which ("s1" and "s2") has 2,000 hidden classes.[4] We included this method since clustering can be regarded as another way of treating data sparseness.

BC The Bhattacharyya coefficient (Bhattacharyya, 1943) between $p(f_k|w_1)$ and $p(f_k|w_2)$. This is the baseline for BC$_b$.

BC$_a$ The Bhattacharyya coefficient with absolute discounting. In calculating $p(f_k|w_i)$, we subtract the discounting value, α, from $c(w_i, f_k)$ and equally distribute the residual probability mass to the contexts whose frequency is zero. This is included as an example of naive smoothing methods.

Since it is very costly to calculate the similarities with all of the other words (one million in our case), we used the following approximation method that exploits the sparseness of $c(w_i, f_k)$. Similar methods were used in Pantel and Lin (2002), Kazama et al. (2009), and Pantel et al. (2009) as well. For a given word, w_i, we sort the contexts in descending order according to $c(w_i, f_k)$ and retrieve the top-L contexts.[5] For each selected context, we sort the words in descending order according to $c(w_i, f_k)$ and retrieve the top-M words ($L = M = 1600$).[6] We merge all of the words above as candidate words and calculate the similarity only for the candidate words. Finally, the top 500 similar words are output.

Note also that we used modified counts, $log(c(w_i, f_k)) + 1$, instead of raw counts, $c(w_i, f_k)$, with the intention of alleviating the effect of strangely frequent dependencies, which can be found in the Web data. In preliminary experiments, we observed that this modification improves the quality of the top 500 similar words as reported in Terada et al. (2004) and Kazama et al. (2009).

[4] In the case of EM clustering, the number of unique contexts, f_k, was also set to one million instead of 100,000, following Kazama et al. (2009).

[5] It is possible that the number of contexts with non-zero counts is less than L. In that case, all of the contexts with non-zero counts are used.

[6] Sorting is performed only once in the initialization step.

BC	0.0296	0.201	0.118	0.0915	0.0721

As for BC$_b$, we assumed that all of the hyperparameters had the same value, i.e., $\alpha_k = \alpha$. It is apparent that an excessively large α is not appropriate because it means ignoring observations. Therefore, α must be tuned. The discounting value of BC$_a$ is also tuned.

5.5 Results

Table 1 shows the results for Set A. The MAP and the MPs at the top 1, 5, 10, and 20 are shown for each similarity measure. As for BC$_b$ and BC$_a$, the results for the tuned and several other values for α are shown. Figure 1 shows the parameter tuning for BC$_b$ with MAP as the y-axis (results for BC$_a$ are shown as well). Figure 2 shows the same results with MPs as the y-axis. The MAP and MPs showed a correlation here. From these results, we can see that BC$_b$ surely improves upon BC, with 6.6% improvement in MAP and 14.7% improvement in MP@1 when $\alpha = 0.0016$. BC$_b$ achieved the best performance among the compared measures with this setting. The absolute discounting, BC$_a$, improved upon BC as well, but the improvement was smaller than with BC$_b$. Table 1 also shows the results for the case where we did not use the log-modified counts. We can see that this modification gives improvements (though slight or unclear for PMI-cos).

Because tuning hyperparameters involves the possibility of overfitting, its robustness should be assessed. We checked whether the tuned α with Set A works well for Set B. The results are shown in Table 2. We can see that the best α ($= 0.0016$) found for Set A works well for Set B as well. That is, the tuning of α as above is not unrealistic in

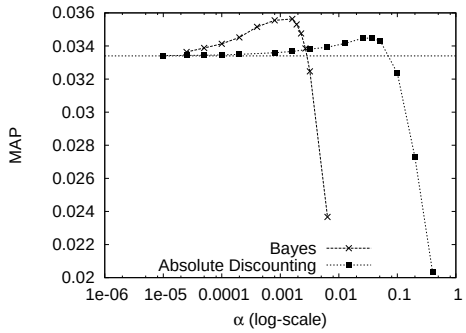

Figure 1: Tuning of α (MAP). The dashed horizontal line indicates the score of BC.

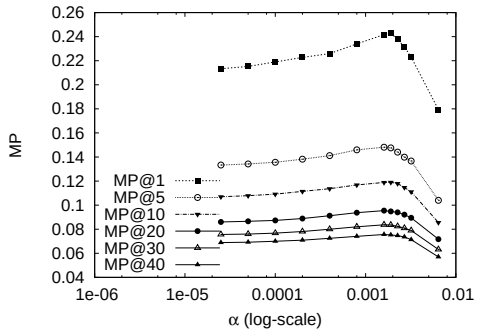

Figure 2: Tuning of α (MP).

practice because it seems that we can tune it robustly using a small subset of the vocabulary as shown by this experiment.

Next, we evaluated the measures on Set C, i.e., the closed set data. The results are shown in Table 3. For this set, we observed a tendency that is different from Sets A and B. Cls-JS showed a particularly good performance. BC_b surely improves upon BC. For example, the improvement was 7.5% for MP@1. However, the improvement in MAP was slight, and MAP did not correlate well with MPs, unlike in the case of Sets A and B.

We thought one possible reason is that the number of outputs, 500, for each word was not large enough to assess MAP values correctly because the average number of answers is 1,700 for this dataset. In fact, we could output more than 500 words if we ignored the cost of storage. Therefore, we also included the results for the case where $L = M = 3600$ and $N = 2,000$. Even with this setting, however, MAP did not correlate well with MPs.

Although Cls-JS showed very good performance for Set C, note that the EM clustering is very time-consuming (Kazama and Torisawa, 2008), and it took about one week with 24 CPU cores to get one clustering result in our computing environment. On the other hand, the preparation for our method requires just an hour with a single core.

6 Discussion

We should note that the improvement by using our method is just "on average," as in many other NLP tasks, and observing clear qualitative change is relatively difficult, for example, by just showing examples of similar word lists here. Comparing the results of BC_b and BC, Table 4 lists the numbers of improved, unchanged, and degraded words in terms of MP@20 for each evaluation set. As can be seen, there are a number of degraded words, although they are fewer than the improved words. Next, Figure 3 shows the averaged differences of MP@20 in each 40,000 word-ID range.[7] We can observe that the advantage of BC_b is lessened es-

[7] Word IDs are assigned in ascending order when we chose the top one million words as described in Section 5.2, and they roughly correlate with frequencies. So, frequent words tend to have low-IDs.

Table 4: The numbers of improved, unchanged, and degraded words in terms of MP@20 for each evaluation set.

	# improved	# unchanged	# degraded
Set A	755	2,585	400
Set B	643	2,610	404
Set C	3,153	3,962	1,738

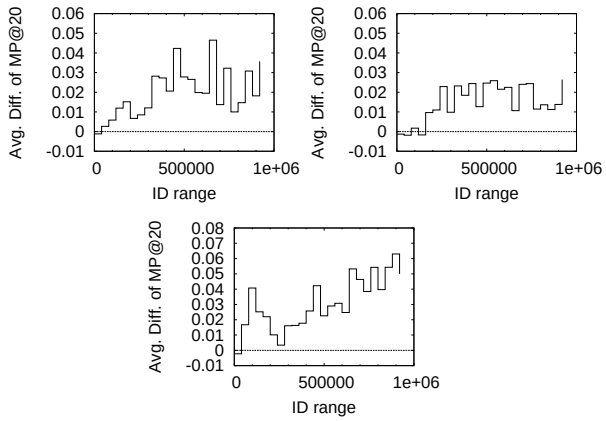

Figure 3: Averaged Differences of MP@20 between BC_b (0.0016) and BC within each 40,000 ID range (Left: Set A. Right: Set B. Bottom: Set C).

pecially for low-ID words (as expected) with on-average degradation.[8] The improvement is "on average" in this sense as well.

One might suspect that the answer words tended to be low-ID words, and the proposed method is simply biased towards low-ID words because of its nature. Then, the observed improvement is a trivial consequence. Table 5 lists some interesting statistics about the IDs. We can see that BC_b surely outputs more low-ID words than BC, and BC more than Cls-JS and JS.[9] However, the average ID of the outputs of BC is already lower than the average ID of the answer words. Therefore, even if BC_b preferred lower-ID words than BC, it should not have the effect of improving the accuracy. That is, the improvement by BC_b is not superficial. From BC/BC_b, we can also see that the IDs of the correct outputs did not become smaller compared to the IDs of the system outputs. Clearly, we need more analysis on what caused the improvement by the proposed method and how that affects the efficacy in real applications of similarity measures.

The proposed Bayesian similarity measure outperformed the baseline Bhattacharyya coefficient

[8]This suggests the use of different αs depending on ID ranges (e.g., smaller α for low-ID words) in practice.

[9]The outputs of Cls-JS are well-balanced in the ID space.

Table 5: Statistics on IDs. (A): Avg. ID of answers. (B): Avg. ID of system outputs. (C): Avg. ID of correct system outputs.

	Set A		Set C	
(A)	238,483		255,248	
	(B)	(C)	(B)	(C)

BC/BC_b	2.91	1.80	2.14	1.48

and other well-known similarity measures. As a smoothing method, it also outperformed a naive absolute discounting. Of course, we cannot say that the proposed method is better than any other sophisticated smoothing method at this point. However, as noted above, there has been no serious attempt to assess the effect of smoothing in the context of word similarity calculation. Recent studies have pointed out that the Bayesian framework derives state-of-the-art smoothing methods such as Kneser-Ney smoothing as a special case (Teh, 2006; Mochihashi et al., 2009). Consequently, it is reasonable to resort to the Bayesian framework. Conceptually, our method is equivalent to modifying $p(f_k|w_i)$ as $p(f_k|w_i) = \left\{\frac{\Gamma(\alpha_0+a_0)\Gamma(\alpha_k+c(w_i,f_k)+\frac{1}{2})}{\Gamma(\alpha_0+a_0+\frac{1}{2})\Gamma(\alpha_k+c(w_i,f_k))}\right\}^2$ and taking the Bhattacharyya coefficient. However, the implication of this form has not yet been investigated, and so we leave it for future research.

Our method is the simplest one as a Bayesian method. We did not employ any numerical optimization or sampling iterations, as in a more complete use of the Bayesian framework (Teh, 2006; Mochihashi et al., 2009). Instead, we used the obtained analytical form directly with the assumption that $\alpha_k = \alpha$ and α can be tuned directly by using a simple grid search with a small subset of the vocabulary as the development set. If substantial additional costs are allowed, we can fine-tune each α_k using more complete Bayesian methods. We also leave this for future research.

In terms of calculation procedure, BC_b has the same form as other similarity measures, which is basically the same as the inner product of sparse vectors. Thus, it can be as fast as other similarity measures with some effort as we described in Section 4 when our aim is to calculate similarities between words in a fixed large vocabulary. For example, BC_b took about 100 hours to calculate the

top 500 similar nouns for all of the one million nouns (using 16 CPU cores), while JS took about 57 hours. We think this is an acceptable additional cost.

The limitation of our method is that it cannot be used efficiently with similarity measures other than the Bhattacharyya coefficient, although that choice seems good as shown in the experiments. For example, it seems difficult to use the Jensen-Shannon divergence as the base similarity because the analytical form cannot be derived. One way we are considering to give more flexibility to our method is to adjust α_k depending on external knowledge such as the importance of a context (e.g., PMIs). In another direction, we will be able to use a "weighted" Bhattacharyya coefficient: $\sum_k \mu(w_1, f_k)\mu(w_2, f_k)\sqrt{p_{1k} \times p_{2k}}$, where the weights, $\mu(w_i, f_k)$, do not depend on p_{ik}, as the base similarity measure. The analytical form for it will be a weighted version of BC_b.

BC_b can also be generalized to the case where the base similarity is $BC^d(p_1, p_2) = \sum_{k=1}^{K} p_{1k}^d \times p_{2k}^d$, where $d > 0$. The Bayesian analytical form becomes as follows.

$$BC_b^d(w_1, w_2) = \frac{\Gamma(\alpha_0 + a_0)\Gamma(\beta_0 + b_0)}{\Gamma(\alpha_0 + a_0 + d)\Gamma(\beta_0 + b_0 + d)} \times \sum_{k=1}^{K} \frac{\Gamma(\alpha_k + c(w_1, f_k) + d)\Gamma(\beta_k + c(w_2, f_k) + d)}{\Gamma(\alpha_k + c(w_1, f_k))\Gamma(\beta_k + c(w_2, f_k))}.$$

See Appendix A for the derivation. However, we restricted ourselves to the case of $d = \frac{1}{2}$ in this study.

Finally, note that our BC_b is different from the Bhattacharyya distance measure on Dirichlet distributions of the following form described in Rauber et al. (2008) in its motivation and analytical form:

$$\frac{\sqrt{\Gamma(\alpha_0')\Gamma(\beta_0')}}{\sqrt{\prod_k \Gamma(\alpha_k')}\sqrt{\prod_k \Gamma(\beta_k')}} \times \frac{\prod_k \Gamma((\alpha_k' + \beta_k')/2)}{\Gamma(\frac{1}{2}\sum_k^K (\alpha_k' + \beta_k'))}. \quad (9)$$

Empirical and theoretical comparisons with this measure also form one of the future directions.[10]

7 Conclusion

We proposed a Bayesian method for robust distributional word similarities. Our method uses a distribution of context profiles obtained by Bayesian estimation and takes the expectation of a base similarity measure under that distribution. We showed that, in the case where the context profiles are multinomial distributions, the priors are Dirichlet, and the base measure is the Bhattacharyya coefficient, we can derive an analytical form, permitting efficient calculation. Experimental results show that the proposed measure gives better word similarities than a non-Bayesian Bhattacharyya coefficient, other well-known similarity measures such as Jensen-Shannon divergence and the cosine with PMI weights, and the Bhattacharyya coefficient with absolute discounting.

[10] Our preliminary experiments show that calculating similarity using Eq. 9 for the Dirichlet distributions obtained by Eq. 6 does not produce meaningful similarity (i.e., the accuracy is very low).

Appendix A

Here, we give the analytical form for the generalized case (BC_b^d) in Section 6. Recall the following relation, which is used to derive the normalization factor of the Dirichlet distribution:

$$\int_{\triangle} \prod_k \phi_k^{\alpha_k' - 1} d\phi = \frac{\prod_k \Gamma(\alpha_k')}{\Gamma(\alpha_0')} = Z(\alpha')^{-1}. \quad (10)$$

Then, $BC_b^d(w_1, w_2)$

$$= \iint_{\triangle \times \triangle} Dir(\phi_1|\alpha') Dir(\phi_2|\beta') \sum_k \phi_{1k}^d \phi_{2k}^d \, d\phi_1 \, d\phi_2$$
$$= Z(\alpha')Z(\beta') \times \underbrace{\iint_{\triangle \times \triangle} \prod_l \phi_{1l}^{\alpha_l' - 1} \prod_m \phi_{2m}^{\beta_m' - 1} \sum_k \phi_{1k}^d \phi_{2k}^d \, d\phi_1 \, d\phi_2}_{A}.$$

Using Eq. 10, A in the above can be calculated as follows:

$$= \int_{\triangle} \prod_m \phi_{2m}^{\beta_m' - 1} \left[\sum_k \phi_{2k}^d \int_{\triangle} \phi_{1k}^{\alpha_k' + d - 1} \prod_{l \neq k} \phi_{1l}^{\alpha_l' - 1} \, d\phi_1 \right] d\phi_2$$
$$= \int_{\triangle} \prod_m \phi_{2m}^{\beta_m' - 1} \left[\sum_k \phi_{2k}^d \frac{\Gamma(\alpha_k' + d) \prod_{l \neq k} \Gamma(\alpha_l')}{\Gamma(\alpha_0' + d)} \right] d\phi_2$$
$$= \sum_k \frac{\Gamma(\alpha_k' + d) \prod_{l \neq k} \Gamma(\alpha_l')}{\Gamma(\alpha_0' + d)} \int_{\triangle} \phi_{2k}^{\beta_k' + d - 1} \prod_{m \neq k} \phi_{2m}^{\beta_m' - 1} \, d\phi_2$$
$$= \sum_k \frac{\Gamma(\alpha_k' + d) \prod_{l \neq k} \Gamma(\alpha_l')}{\Gamma(\alpha_0' + d)} \frac{\Gamma(\beta_k' + d) \prod_{m \neq k} \Gamma(\beta_m')}{\Gamma(\beta_0' + d)}$$
$$= \frac{\prod \Gamma(\alpha_l') \prod \Gamma(\beta_m')}{\Gamma(\alpha_0' + d)\Gamma(\beta_0' + d)} \sum_k \frac{\Gamma(\alpha_k' + d)}{\Gamma(\alpha_k')} \frac{\Gamma(\beta_k' + d)}{\Gamma(\beta_k')}.$$

This will give:

$$BC_b^d(w_1, w_2) = \frac{\Gamma(\alpha_0')\Gamma(\beta_0')}{\Gamma(\alpha_0' + d)\Gamma(\beta_0' + d)} \sum_{k=1}^{K} \frac{\Gamma(\alpha_k' + d)\Gamma(\beta_k' + d)}{\Gamma(\alpha_k')\Gamma(\beta_k')}.$$

Abstract

The variety of engaging interactions among users in social medial distinguishes it from traditional Web media. Such a feature should be utilized while attempting to provide intelligent services to social media participants. In this article, we present a framework to recommend relevant information in Internet forums and blogs using user comments, one of the most representative of user behaviors in online discussion. When incorporating user comments, we consider structural, semantic, and authority information carried by them. One of the most important observation from this work is that semantic contents of user comments can play a fairly different role in a different form of social media. When designing a recommendation system for this purpose, such a difference must be considered with caution.

1 Introduction

In the past twenty years, the Web has evolved from a framework of information dissemination to a social interaction facilitator for its users. From the initial dominance of static pages or sites, with addition of dynamic content generation and provision of client-side computation and event handling, Web applications have become a prevalent framework for distributed GUI applications. Such technological advancement has fertilized vibrant creation, sharing, and collaboration among the users (Ahn et al., 2007). As a result, the role of Computer Science is not as much of designing or implementing certain data communication techniques, but more of enabling a variety of creative uses of the Web.

In a more general context, Web is one of the most important carriers for "social media", e.g. Internet forums, blogs, wikis, podcasts, instant messaging, and social networking. Various engaging interactions among users in social media differentiate it from traditional Web sites. Such characteristics should be utilized in attempt to provide intelligent services to social media users. One form of such interactions of particular interest here is *user comments*. In *self-publication*, or *customer-generated media*, a user can publish an article or post news to share with others. Other users can read and comment on the posting and these comments can, in turn, be read and commented on. Digg (www.digg.com), Yahoo!Buzz (buzz.yahoo.com) and various kinds of blogs are commercial examples of self-publication. Therefore, reader responses to earlier discussion provide a valuable source of information for effective recommendation.

Currently, self-publishing media are becoming increasingly popular. For instance, at this point of writing, Technorati is indexing over 133 million blogs, and about 900,000 new blogs are created worldwide daily[1]. With such a large scale, information in the *blogosphere* follows a Long Tail Distribution (Agarwal et al., 2010). That is, in aggregate, the not-so-well-known blogs can have more valuable information than the popular ones. This gives us an incentive to develop a recommender to provide a set of relevant articles, which are expected to be of interest to the current reader. The user experience with the system can be immensely enhanced with the recommended articles. In this work, we focus on recommendation in Internet forums and blogs with discussion threads.

Here, a fundamental challenge is to account for topic divergence, i.e. the change of gist during the process of discussion. In a discussion thread, the original posting is typically followed by other readers' opinions, in the form of comments. Inten-

Uppsala, Sweden, 11-16 July 2010.

tion and concerns of active users may change as the discussion goes on. Therefore, recommendation, if it were only based on the original posting, can not benefit the potentially evolving interests of the users. Apparently, there is a need to consider topic evolution in adaptive content-based recommendation and this requires novel techniques in order to capture topic evolution precisely and to prevent drastic topic shifting which returns completely irrelevant articles to users.

In this work, we present a framework to recommend relevant information in Internet forums and blogs using user comments, one of the most representative recordings of user behaviors in these forms of social media.

It has the following contributions.

> The relevant information is recommended based on a balanced perspective of both the authors and readers.
>
> We model the relationship among comments and that relative to the original posting using graphs in order to evaluate their combined impact. In addition, the weight of a comment is further enhanced with its content and with the authority of its poster.

2 Related Work

In a broader context, a related problem is content-based information recommendation (or filtering). Most information recommender systems select articles based on the contents of the original postings. For instance, Chiang and Chen (Chiang and Chen, 2004) study a few classifiers for agent-based news recommendations. The relevant news selections of these work are determined by the textual similarity between the recommended news and the original news posting. A number of later proposals incorporate additional metadata, such as user behaviors and timestamps. For example, Claypool et al. (Claypool et al., 1999) combine the news content with numerical user ratings. Del Corso, Gullí, and Romani (Del Corso et al., 2005) use timestamps to favor more recent news. Cantador, Bellogin, and Castells (Cantador et al., 2008) utilize domain ontology. Lee and Park (Lee and Park, 2007) consider matching between news article attributes and user preferences. Anh et al. (Ahn et al., 2007) and Lai, Liang, and Ku (Lai et al., 2003) construct explicit user profiles, respectively. Lavrenko et al. (Lavrenko et al., 2000) propose the e-Analyst system which combines news stories with trends in financial time series. Some go even further by ignoring the news contents and only using browsing behaviors of the readers with similar interests (Das et al., 2007).

Another related problem is topic detection and tracking (TDT), i.e. automated categorization of news stories by their themes. TDT consists of breaking the stream of news into individual news stories, monitoring the stories for events that have not been seen before, and categorizing them (Lavrenko and Croft, 2001). A topic is modeled with a language profile deduced by the news. Most existing TDT schemes calculate the similarity between a piece of news and a topic profile to determine its topic relevance (Lavrenko and Croft, 2001) (Yang et al., 1999). Qiu (Qiu et al., 2009) apply TDT techniques to group news for collaborative news recommendation. Some work on TDT takes one step further in that they update the topic profiles as part of the learning process during its operation (Allan et al., 2002) (Leek et al., 2002).

Most recent researches on information recommendation in social media focus on the blogosphere. Various types of user interactions in the blogosphere have been observed. A prominent feature of the blogosphere is the *collective wisdom* (Agarwal et al., 2010). That is, the knowledge in the blogosphere is enriched by such engaging interactions among bloggers and readers as posting, commenting and tagging. Prior to this work, the linking structure and user tagging mechanisms in the blogosphere are the most widely adopted ones to model such collective wisdom. For example, Esmaili et al. (Esmaili et al., 2006) focus on the linking structure among blogs. Hayes, Avesani, and Bojars (Hayes et al., 2007) explore measures based on blog authorship and reader tagging to improve recommendation. Li and Chen further integrate trust, social relation and semantic analysis (Li and Chen, 2009). These approaches attempt to capture accurate similarities between postings without using reader comments. Due to the interactions between bloggers and readers, blog recommendation should not limit its input to only blog postings themselves but also incorporate feedbacks from the readers.

The rest of this article is organized as follows. We first describe the design of our recommendation framework in Section 3. We then evaluate the performance of such a recommender using two

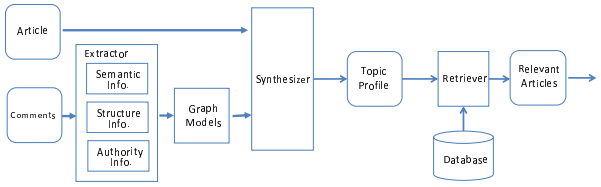

Figure 1: Design scheme

different social media corpora (Section 4). This paper is concluded with speculation on how the current prototype can be further improved in Section 5.

3 System Design

In this section, we present a mechanism for recommendation in Internet forums and blogs. The framework is sketched in Figure 1. Essentially, it builds a topic profile for each original posting along with the comments from readers, and uses this profile to retrieve relevant articles. In particular, we first extract structural, semantic, and authority information carried by the comments. Then, with such collective wisdom, we use a graph to model the relationship among comments and that relative to the original posting in order to evaluate the impact of each comment. The graph is weighted with postings' contents and the authors' authority. This information along with the original posting and its comments are fed into a synthesizer. The synthesizer balances views from both authors and readers to construct a topic profile to retrieve relevant articles.

3.1 Incorporating Comments

In a discussion thread, comments made at different levels reflect the variation of focus of readers. Therefore, recommended articles should reflect their concerns to complement the author's opinion. The degree of contribution from each comment, however, is different. In the extreme case, some of them are even advertisements which are completely irrelevant to the discussion topics. In this work, we use a graph model to differentiate the importance of each comment. That is, we model the authority, semantic, structural relations of comments to determine their combined impact.

3.1.1 Authority Scoring Comments

Intuitively, each comment may have a different degree of authority determined by the status of its author (Hu et al., 2007). Assume we have users in a forum, denoted by . We calculate the authority for user . To do that, we employ a variant of the PageRank algorithm (Brin and Page, 1998). We consider the cases that a user replies to a previous posting and that a user quotes a previous posting separately. For user , we use to denote the number of times that has replied to user . Similarly, we use to denote the number of times that has quoted user . We combine them linearly:

Further, we normalize the above quantity to record how frequently a user refers to another:

Inline with the PageRank algorithm, we define the authority of user as

–

3.1.2 Differentiating comments with Semantic and Structural relations

Next, we construct a similar model in terms of the comments themselves. In this model, we treat the original posting and the comments each as a text node. This model considers both the content similarity between text nodes and the logic relationship among them.

On the one hand, the semantic similarity between two nodes can be measured with any commonly adopted metric, such as cosine similarity and Jaccard coefficient (Baeza-Yates and Ribeiro-Neto, 1999). On the other hand, the structural relation between a pair of nodes takes two forms as we have discussed earlier. First, a comment can be made in response to the original posting or at most one earlier comment. In graph theoretic terms, the hierarchy can be represented as a tree , where is the set of all text nodes and is the edge set. In particular, the original posting is the root and all the comments are ordinary nodes. There is an arc (directed edge) from node to node , denoted , if the corresponding comment is made in response to comment (or original posting) . Second, a comment can quote from one or more earlier comments. From this perspective, the hierarchy can be modeled using a directed acyclic graph (DAG),

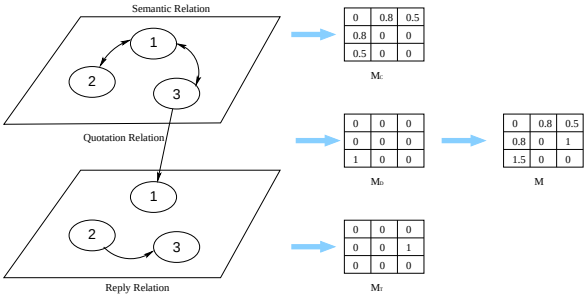

Figure 2: Multi-relation graph of comments based on the structural and semantic information

denoted . There is an arc from node to node , denoted , if the corresponding comment quotes comment (or original posting) . As shown in Figure 2, for either graph or , we can use a adjacency matrix, denoted and , respectively, to record them. Similarly, we can also use a matrix defined on to record the content similarity between nodes and denote it by . Thus, we combine these three aspects linearly:

The importance of a text node can be quantized by the times it has been referred to. Considering the semantic similarity between nodes, we use another variant of the PageRank algorithm to calculate the weight of comment :

—

where is a damping factor, and is the normalized weight of comment referring to defined as

———————

where is an entry in the graph adjacency matrix M and is a constant to avoid division by zero.

In some social networking media, a user may have a subset of other users as "friends". This can be captured by a matrix of , whose entries are denoted by . Thus, with this information and assuming poster has made a comment k for user 's posting, the final weight of this comment is defined as

————————

3.2 Topic Profile Construction

Once the weight of comments on one posting is quantified by our models, this information along with the entire discussion thread is fed into a synthesizer to construct a topic profile. As such, the perspectives of both authors and readers are balanced for recommendation.

The profile is a weight vector of terms to model the language used in the discussion thread. Consider a posting and its comment sequence . For each term , a compound weight is calculated. It is a linear combination of the contribution by the posting itself, , and that by the comments, . We assume that each term is associated with an "inverted document frequency", denoted by —, where is the corpus size and is the number of documents in corpus containing term . We use a function to denote the number of occurrences of term in document , i.e. "term frequency". Thus, when the original posting and comments are each considered as a document, this term frequency can be calculated for any term in any document. We thus define the weight of term in document , be the posting itself or a comment, using the standard TF/IDF definition (Baeza-Yates and Ribeiro-Neto, 1999):

———————

The weight contributed by the posting itself, , is thus:

———————

The weight contribution from the comments incorporates not only the language features of these documents but also their importance in the discussion thread. That is, the contribution of comment score is incorporated into weight calculation of the words in a comment.

——————— ————————

Such a treatment of compounded weight is essentially to recognize that readers' impact on selecting relevant articles and the difference of their influence. For each profile, we select the top- highest weighted words to represent the topic.

With the topic profile thus constructed, the retriever returns an ordered list of articles with decreasing relevance to the topic. Note that our approach to differentiate the importance of each comment can be easily incorporated into any generic retrieval model. In this work, our retriever is adopted from (Lavrenko et al., 2000).

3.3 Interpretation of Recommendation

Since interpreting recommended items enhances users' trusting beliefs (Wang and Benbasat, 2007), we design a creative approach to generate hints to indicate the relationship (generalization, specialization and duplication) between the recommended articles and the original posting based on our previous work (Candan et al., 2009).

Article being more general than can be interpreted as being less constrained than by the keywords they contain. Let us consider two articles, and , where contains keywords, and , and only contains .

> If is said to be more general than , then the additional keyword, , of article must render less constrained than . Therefore, the content of can be interpreted as .
>
> If, on the other hand, is said to be more specific than , then the additional keyword, , must render more constrained than . Therefore, the content of can be interpreted as .

Note that, in the two-keyword space , can be denoted by a vector and can be denoted by . The origin corresponds to the case where an article does contain neither nor . That is, corresponds to an article which can be interpreted as . Therefore, if is said to be more general than , should be greater than . This allows us to measure the degrees of generalization and specialization of two articles. Given two articles, and , *of the same topic*, they will have a common keyword base, while both articles will also have their own content, different from their common base. Let us denote the common part of by and common part of by . Note that and are usually unequal because the same words in the common part have different term weights in article and respectively. Given these and the generalization concept introduced above for two similar articles and , we can define the degree of generalization ( ) and specialization ( ) of with respect to as

To alleviate the effect of document length, we revise the definition as

The relative specialization and generalization values can be used to reveal the relationships between recommended articles and the original posting. Given original posting and recommended article , if , for a given generalization threshold , then B is marked as a generalization. When this is not the case, if , for a given specialization threshold, , then is marked as a specialization. If neither of these cases is true, then is duplicate of .

Such an interpretation provides a control on delivering recommended articles. In particular, we can filter the duplicate articles to avoid recommending the same information.

4 Experimental Evaluation

To evaluate the effectiveness of our proposed recommendation mechanism, we carry out a series of experiments on two synthetic data sets, collected from Internet forums and blogs, respectively. The first data set is called Forum. This data set is constructed by randomly selecting 20 news articles with corresponding reader comments from the Digg Web site and 16,718 news articles from the Reuters news Web site. This simulates the scenario of recommending relevant news from traditional media to social media users for their further reading. The second one is the Blog data set containing 15 blog articles with user comments and 15,110 articles obtained from the Myhome Web site [2]. Details of these two data sets are shown in Table 1. For evaluation purposes, we adopt the traditional pooling strategy (Zobel, 1998) and apply to the TREC data set to mark the relevant articles for each topic.

[2] http://blogs.myhome.ie

Table 1: Evaluation data set

Synthetic Data Set		Forum	Blog
Topics	No. of postings	20	15
	Ave. length of postings	676	236
	No. of comments per posting	81.4	46
	Ave. length of comments	45	150
Target	No. of articles	16718	15110
	Ave. length of articles	583	317

The recommendation engine may return a set of essentially the same articles re-posted at different sites. Therefore, we introduce a metric of novelty to measure the topic diversity of returned suggestions. In our experiments, we define precision and novelty metrics as

——— and ———

where is the subset of the top- articles returned by the recommender, is the set of manually tagged relevant articles, and is the set of manually tagged relevant articles excluding duplicate ones to the original posting. We select the top 10 articles for evaluation assuming most readers only browse up to 10 recommended articles (Karypis, 2001). Meanwhile, we also utilize mean average precision (MAP) and mean average novelty (MAN) to evaluate the entire set of returned article.

We test our proposal in four aspects. First, we compare our work to two baseline works. We then present results for some preliminary tests to find out the optimal values for two critical parameters. Next, we study the effect of user authority and its integration to comment weighting. Fourth, we evaluate the performance gain obtained from interpreting recommendation. In addition, we provide a significance test to show that the observed differences in effectiveness for different approaches are not incidental. In particular, we use the -test here, which is commonly used for significance tests in information retrieval experiments (Hull, 1993).

4.1 Overall Performance

As baseline proposals, we also implement two well-known content-based recommendation methods (Bogers and Bosch, 2007). The first method, Okapi, is commonly applied as a representative of the classic probabilistic model for relevant information retrieval (Robertson and Walker, 1994). The second one, LM, is based on statistical language models for relevant information retrieval (Ponte and Croft, 1998). It builds a probabilistic language model for each article, and ranks them on query likelihood, i.e. the probability of the model generating the query. Following the strategy of Bogers and Bosch, relevant articles are selected based on the title and the first 10 sentences of the original postings. This is because articles are organized in the so-called *inverted pyramid* style, meaning that the most important information is usually placed at the beginning. Trimming the rest of an article would usually remove relatively less crucial information, which speeds up the recommendation process.

Table 2: Overall performance

Data	Method	Precision		Novelty	
Forum	**Okapi**	0.827	0.833	0.807	0.751
	LM	0.804	0.833	0.807	0.731
	Our	0.967	0.967	0.9	0.85
Blog	**Okapi**	0.733	0.651	0.667	0.466
	LM	0.767	0.718	0.70	0.524
	Our	0.933	0.894	0.867	0.756

A paired -test shows that using and as performance measures, our approach performs significantly better than the baseline methods for both Forum and Blog data sets as shown in Table 2. In addition, we conduct -tests using MAP and MAN as performance measures, respectively, and the -values of these tests are all less than 0.05, meaning that the results of experiments are statistically significant. We believe that such gains are introduced by the additional information from the collective wisdom, i.e. user authority and comments. Note that the retrieval precision for Blog of two baseline methods is not as good as that for Forum. Our explanation is that blog articles may not be organized in the inverted pyramid style as strictly as news forum articles.

4.2 Parameters of Topic Profile

There are two important parameters to be considered to construct topic profiles for recommendation. 1) the number of the most weighted words to represent the topic, and 2) combination coefficient to determine the contribution of original posting and comments in selecting relevant articles.We conduct a series of experiments and find out that the optimal performance is obtained when the number of words is between 50 and 70, and is between 0.65 and 0.75. When is set to 0, the recommended articles only reflect the author's opinion. When , the suggested articles represent the concerns of readers exclusively. In the

Table 3: Performance of four runs

	Method	Precision		Novelty	
Forum	RUN1	0.88	0.869	0.853	0.794
	RUN2	0.933	0.911	0.9	0.814
	RUN3	0.94	0.932	0.9	0.848
	RUN4	0.967	0.967	0.9	0.85
Blog	RUN1	0.767	0.758	0.7	0.574
	RUN2	0.867	0.828	0.833	0.739
	RUN3	0.9	0.858	0.833	0.728
	RUN4	0.933	0.894	0.867	0.756

following experiments, we set topic word number to 60 and combination coefficient to 0.7.

4.3 Effect of Authority and Comments

In this part, we explore the contribution of user authority and comments in social media recommender. In particular, we study the following scenarios with increasing system capabilities. Note that, lacking friend information (Section 3.1.2) in the Forum data set, is set to zero.

RUN 1 (Posting): the topic profile is constructed only based on the original posting itself. This is analogous to traditional recommenders which only consider the focus of authors for suggesting further readings.

RUN 2 (Posting+Authority): the topic profile is constructed based on the original posting and participant authority.

RUN 3 (Posting+Comment): the topic profile is constructed based on the original posting and its comments.

RUN 4 (All): the topic profile is constructed based on the original posting, user authority, and its comments.

Here, we set . Our -test shows that using and as performance measures, RUN4 performs best in both Forum and Blog data sets as shown in Table 3. There is a stepwise performance improvement while integrating user authority, comments and both. With the assistance of user authority and comments, the recommendation precision is improved up to 9.8% and 21.6% for Forum and Blog, respectively. The opinion of readers is an effective complementarity to the authors' view in suggesting relevant information for further reading.

Moreover, we investigate the effect of the semantic and structural relations among comments, i.e. semantic similarity, reply, and quotation. For this purpose, we carry out a series of experiments based on different combinations of these relations.

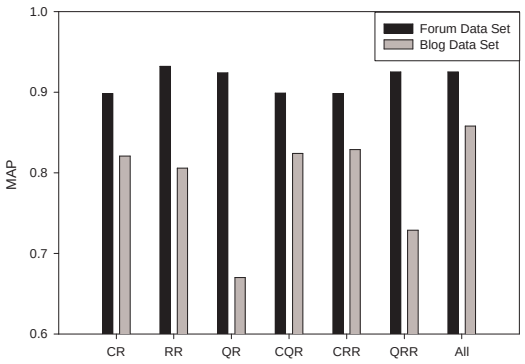

Figure 3: Effect of content, quotation and reply relation

Content Relation (CR): only the content relation matrix is used in scoring the comments.

Quotation Relation (QR): only the quotation relation matrix is used in scoring the comments.

Reply Relation (RR): only the reply relation matrix is used in scoring the comments.

Content+Quotation Relation (CQR): both the content and quotation relation matrices is used in scoring the comments.

Content+Reply Relation(CRR): both the content and reply relation matrices are used in scoring the comments.

Quotation+Reply Relation (QRR): both the quotation and reply relation matrices are used in scoring the comments.

All: all three matrices are used.

The MAP yielded by these combinations for both data sets is plotted in Figure 3. For the case of Forum, we observe that incorporating content information adversely affects recommendation precision. This concurs with what we saw in our previous work (Wang et al., 2010). On the other hand, when we test the Blog data set, the trend is the opposite, i.e. content similarity does contribute to retrieval performance positively. This is attributed by the text characteristics of these two forms of social media. Specifically, comments in news forums usually carry much richer structural information than blogs where comments are usually "flat" among themselves.

4.4 Recommendation Interpretation

To evaluate the precision of interpreting the relationship between recommended articles and the

original posting, the evaluation metric of success rate is defined as

where is the number of recommended articles, is the error weight of recommended article . Here, the error weight is set to one if the result interpretation is mis-labelled.

From our studies, we observe that the success rate at top-10 is around 89.3% and 87.5% for the Forum and Blog data sets, respectively. Note that these rates include the errors introduced by the irrelevant articles returned by the retrieval module. To estimate optimal thresholds of generalization and specialization, we calculate the success rate at different threshold values and find that neither too small nor too large a value is appropriate for interpretation. In our experiments, we set generalization threshold to 3.2 and specialization threshold to 1.8 for the Forum data set, and to 3.5 and to 2.0 for Blog. Ideally, threshold values would need to be set through a machine learning process, which identifies proper values based on a given training sample.

5 Conclusion and Future Work

The Web has become a platform for social networking, in addition to information dissemination at its earlier stage. Many of its applications are also being extended in this fashion. Traditional recommendation is essentially a push service to provide information according to the profile of individual or groups of users. Its niche at the Web 2.0 era lies in its ability to enable online discussion by serving up relevant references to the participants. In this work, we present a framework for information recommendation in such social media as Internet forums and blogs. This model incorporates information of user status and comment semantics and structures within the entire discussion thread. This framework models the logic connections among readers and the innovativeness of comments. By combining such information with traditional statistical language models, it is capable of suggesting relevant articles that meet the dynamic nature of a discussion in social media. One important discovery from this work is that, when integrating comment contents, the structural information among comments, and reader relationship, it is crucial to distinguish the characteristics of various forms of social media. The reason is that the role that the semantic content of a comment plays can differ from one form to another.

This study can be extended in a few interesting ways. For example, we can also evaluate its effectiveness and costs during the operation of a discussion forum, where the discussion thread is continually updated by new comments and votes. Indeed, its power is yet to be further improved and investigated.

Abstract

This paper explores the use of clickthrough data for query spelling correction. First, large amounts of query-correction pairs are derived by analyzing users' query reformulation behavior encoded in the clickthrough data. Then, a phrase-based error model that accounts for the transformation probability between multi-term phrases is trained and integrated into a query speller system. Experiments are carried out on a human-labeled data set. Results show that the system using the phrase-based error model outperforms significantly its baseline systems.

1 Introduction

Search queries present a particular challenge for traditional spelling correction methods for three main reasons (Ahmad and Kondrak, 2004). First, spelling errors are more common in search queries than in regular written text: roughly 10-15% of queries contain misspelled terms (Cucerzan and Brill, 2004). Second, most search queries consist of a few key words rather than grammatical sentences, making a grammar-based approach inappropriate. Most importantly, many queries contain search terms, such as proper nouns and names, which are not well established in the language. For example, Chen et al. (2007) reported that 16.5% of valid search terms do not occur in their 200K-entry spelling lexicon.

Therefore, recent research has focused on the use of Web corpora and query logs, rather than human-compiled lexicons, to infer knowledge about misspellings and word usage in search queries (e.g., Whitelaw et al., 2009). Another important data source that would be useful for this purpose is clickthrough data. Although it is well-known that clickthrough data contain rich information about users' search behavior, e.g., how a user (re-) formulates a query in order to find the relevant document, there has been little research on exploiting the data for the development of a query speller system.

In this paper we present a novel method of extracting large amounts of query-correction pairs from the clickthrough data. These pairs, implicitly judged by millions of users, are used to train a set of spelling error models. Among these models, the most effective one is a phrase-based error model that captures the probability of transforming one multi-term phrase into another multi-term phrase. Comparing to traditional error models that account for transformation probabilities between single characters (Kernighan et al., 1990) or sub-word strings (Brill and Moore, 2000), the phrase-based model is more powerful in that it captures some contextual information by retaining inter-term dependencies. We show that this information is crucial to detect the correction of a query term, because unlike in regular written text, any query word can be a valid search term and in many cases the only way for a speller system to make the judgment is to explore its usage according to the contextual information.

We conduct a set of experiments on a large data set, consisting of human-labeled

query-correction pairs. Results show that the error models learned from clickthrough data lead to significant improvements on the task of query spelling correction. In particular, the speller system incorporating a phrase-based error model significantly outperforms its baseline systems.

To the best of our knowledge, this is the first extensive study of learning phase-based error models from clickthrough data for query spelling correction. The rest of the paper is structured as follows. Section 2 reviews related work. Section 3 presents the way query-correction pairs are extracted from the clickthrough data. Section 4 presents the baseline speller system used in this study. Section 5 describes in detail the phrase-based error model. Section 6 presents the experiments. Section 7 concludes the paper.

2 Related Work

Spelling correction for regular written text is a long standing research topic. Previous researches can be roughly grouped into two categories: correcting non-word errors and real-word errors.

In non-word error spelling correction, any word that is not found in a pre-compiled lexicon is considered to be misspelled. Then, a list of lexical words that are *similar* to the misspelled word are proposed as candidate spelling corrections. Most traditional systems use a manually tuned similarity function (e.g., edit distance function) to rank the candidates, as reviewed by Kukich (1992). During the last two decades, statistical error models learned on training data (i.e., query-correction pairs) have become increasingly popular, and have proven more effective (Kernighan et al., 1990; Brill and Moore, 2000; Toutanova and Moore, 2002; Okazaki et al., 2008).

Real-word spelling correction is also referred to as context sensitive spelling correction (CSSC). It tries to detect incorrect usages of a valid word based on its context, such as "peace" and "piece" in the context "a _ of cake". A common strategy in CSSC is as follows. First, a pre-defined confusion set is used to generate candidate corrections, then a scoring model, such as a trigram language model or naïve Bayes classifier, is used to rank the candidates according to their context (e.g., Golding and Roth, 1996; Mangu and Brill, 1997; Church et al., 2007).

When designed to handle regular written text, both CSSC and non-word error speller systems rely on a pre-defined vocabulary (i.e., either a lexicon or a confusion set). However, in query spelling correction, it is impossible to compile such a vocabulary, and the boundary between the non-word and real-word errors is quite vague. Therefore, recent research on query spelling correction has focused on exploiting noisy Web data and query logs to infer knowledge about misspellings and word usage in search queries. Cucerzan and Brill (2004) discuss in detail the challenges of query spelling correction, and suggest the use of query logs. Ahmad and Kondrak (2005) propose a method of estimating an error model from query logs using the EM algorithm. Li et al. (2006) extend the error model by capturing word-level similarities learned from query logs. Chen et al. (2007) suggest using web search results to improve spelling correction. Whitelaw et al. (2009) present a query speller system in which both the error model and the language model are trained using Web data.

Compared to Web corpora and query logs, clickthrough data contain much richer information about users' search behavior. Although there has been a lot of research on using clickthrough data to improve Web document retrieval (e.g., Joachims, 2002; Agichtein et al., 2006; Gao et al., 2009), the data have not been fully explored for query spelling correction. This study tries to learn error models from clickthrough data. To our knowledge, this is the first such attempt using clickthrough data.

Most of the speller systems reviewed above are based on the framework of the source channel model. Typically, a language model (source model) is used to capture contextual information, while an error model (channel model) is considered to be *context free* in that it does not take into account any contextual information in modeling word transformation probabilities. In this study we argue that it is beneficial to capture contextual information in the error model. To this end, inspired by the phrase-based statistical machine translation (SMT) systems (Koehn et al., 2003; Och and Ney, 2004), we propose a phrase-based error model where we assume that query spelling correction is performed at the phrase level.

In what follows, before presenting the phrase-based error model, we will first describe the clickthrough data and the query speller system we used in this study.

3 Clickthrough Data and Spelling Correction

This section describes the way the query-correction pairs are extracted from click-

through data. Two types of clickthrough data are explored in our experiment.

The clickthrough data of the first type has been widely used in previous research and proved to be useful for Web search (Joachims, 2002; Agichtein et al., 2006; Gao et al., 2009) and query reformulation (Wang and Zhai, 2008; Suzuki et al., 2009). We start with this same data with the hope of achieving similar improvements in our task. The data consist of a set of query sessions that were extracted from one year of log files from a commercial Web search engine. A query session contains a query issued by a user and a ranked list of links (i.e., URLs) returned to that same user along with records of which URLs were clicked. Following Suzuki et al. (2009), we extract query-correction pairs as follows. First, we extract pairs of queries Q_1 and Q_2 such that (1) they are issued by the same user; (2) Q_2 was issued within 3 minutes of Q_1; and (3) Q_2 contained at least one clicked URL in the result page while Q_1 did not result in any clicks. We then scored each query pair (Q_1, Q_2) using the edit distance between Q_1 and Q_2, and retained those with an edit distance score lower than a pre-set threshold as query correction pairs.

Unfortunately, we found in our experiments that the pairs extracted using the method are too noisy for reliable error model training, even with a very tight threshold, and we did not see any significant improvement. Therefore, in Section 6 we will not report results using this dataset.

The clickthrough data of the second type consists of a set of *query reformulation sessions* extracted from 3 months of log files from a commercial Web browser. A query reformulation session contains a list of URLs that record user behaviors that relate to the query reformulation functions, provided by a Web search engine. For example, almost all commercial search engines offer the "did you mean" function, suggesting a possible alternate interpretation or spelling of a user-issued query. Figure 1 shows a sample of the query reformulation sessions that record the "did you mean" sessions from three of the most popular search engines. These sessions encode the same user behavior: A user first queries for "harrypotter sheme park", and then clicks on the resulting spelling suggestion "harry potter theme park". In our experiments, we "reverse-engineer" the parameters from the URLs of these sessions, and deduce how each search engine encodes both a query and the fact that a user arrived at a URL by clicking on the spelling suggestion of the query – an important indication that the spelling suggestion is desired. From these three months of query reformulation sessions, we extracted about 3 million query-correction pairs. Compared to the pairs extracted from the clickthrough data of the first type (query sessions), this data set is much cleaner because all these spelling corrections are actually clicked, and thus judged implicitly, by many users.

Figure 1. A sample of query reformulation sessions from three popular search engines. These sessions show that a user first issues the query "harrypotter sheme park", and then clicks on the resulting spell suggestion "harry potter theme park".

In addition to the "did you mean" function, recently some search engines have introduced two new spelling suggestion functions. One is the "auto-correction" function, where the search engine is confident enough to automatically apply the spelling correction to the query and execute it to produce search results for the user. The other is the "split pane" result page, where one half portion of the search results are produced using the original query, while the other half, usually visually separate portion of results are produced using the auto-corrected query.

In neither of these functions does the user ever receive an opportunity to approve or disapprove of the correction. Since our extraction approach focuses on user-approved spelling suggestions,

we ignore the query reformulation sessions recording either of the two functions. Although by doing so we could miss some basic, obvious spelling corrections, our experiments show that the negative impact on error model training is negligible. One possible reason is that our baseline system, which does not use any error model learned from the clickthrough data, is already able to correct these basic, obvious spelling mistakes. Thus, including these data for training is unlikely to bring any further improvement.

We found that the error models trained using the data directly extracted from the query reformulation sessions suffer from the problem of underestimating the self-transformation probability of a query $P(Q_2=Q_1|Q_1)$, because we only included in the training data the pairs where the query is different from the correction. To deal with this problem, we augmented the training data by including correctly spelled queries, i.e., the pairs (Q_1, Q_2) where $Q_1 = Q_2$. First, we extracted a set of queries from the sessions where no spell suggestion is presented or clicked on. Second, we removed from the set those queries that were recognized as being auto-corrected by a search engine. We do so by running a sanity check of the queries against our baseline spelling correction system, which will be described in Section 6. If the system thinks an input query is misspelled, we assumed it was an obvious misspelling, and removed it. The remaining queries were assumed to be correctly spelled and were added to the training data.

4 The Baseline Speller System

The spelling correction problem is typically formulated under the framework of the source channel model. Given an input query $Q = q_1 \dots q_I$, we want to find the best spelling correction $C = c_1 \dots c_J$ among all candidate spelling corrections:

$$C^* = \underset{C}{\operatorname{argmax}}\, P(C|Q) \quad (1)$$

Applying Bayes' Rule and dropping the constant denominator, we have

$$C^* = \underset{C}{\operatorname{argmax}}\, P(Q|C)P(C) \quad (2)$$

where the error model $P(Q|C)$ models the transformation probability from C to Q, and the language model $P(C)$ models how likely C is a correctly spelled query.

The speller system used in our experiments is based on a ranking model (or ranker), which can be viewed as a generalization of the source channel model. The system consists of two components: (1) a candidate generator, and (2) a ranker.

In candidate generation, an input query is first tokenized into a sequence of terms. Then we scan the query from left to right, and each query term q is looked up in lexicon to generate a list of spelling suggestions c whose edit distance from q is lower than a preset threshold. The lexicon we used contains around 430,000 entries; these are high frequency query terms collected from one year of search query logs. The lexicon is stored using a trie-based data structure that allows efficient search for all terms within a maximum edit distance.

The set of all the generated spelling suggestions is stored using a lattice data structure, which is a compact representation of exponentially many possible candidate spelling corrections. We then use a decoder to identify the top twenty candidates from the lattice according to the source channel model of Equation (2). The language model (the second factor) is a backoff bigram model trained on the tokenized form of one year of query logs, using maximum likelihood estimation with absolute discounting smoothing. The error model (the first factor) is approximated by the edit distance function as

$$-\log P(Q|C) \propto \text{EditDist}(Q, C) \quad (3)$$

The decoder uses a standard two-pass algorithm to generate 20-best candidates. The first pass uses the Viterbi algorithm to find the best C according to the model of Equations (2) and (3). In the second pass, the A-Star algorithm is used to find the 20-best corrections, using the Viterbi scores computed at each state in the first pass as heuristics. Notice that we always include the input query Q in the 20-best candidate list.

The core of the second component of the speller system is a ranker, which re-ranks the 20-best candidate spelling corrections. If the top C after re-ranking is different than the original query Q, the system returns C as the correction.

Let $\mathbf{f}$ be a feature vector extracted from a query and candidate spelling correction pair (Q, C). The ranker maps $\mathbf{f}$ to a real value y that indicates how likely C is a desired correction of Q. For example, a linear ranker simply maps $\mathbf{f}$ to y with a learned weight vector $\mathbf{w}$ such as $y = \mathbf{w} \cdot \mathbf{f}$, where $\mathbf{w}$ is optimized w.r.t. accuracy on a set of hu-

C:	"disney theme park"	*correct query*
S:	["disney", "theme park"]	*segmentation*
T:	["disnee", "theme part"]	*translation*
M:	(1 → 2, 2→ 1)	*permutation*
Q:	"theme part disnee"	*misspelled query*

Figure 2: Example demonstrating the generative procedure behind the phrase-based error model.

man-labeled (Q, C) pairs. The features in $\mathbf{f}$ are arbitrary functions that map (Q, C) to a real value. Since we define the logarithm of the probabilities of the language model and the error model (i.e., the edit distance function) as features, the ranker can be viewed as a more general framework, subsuming the source channel model as a special case. In our experiments we used 96 features and a non-linear model, implemented as a two-layer neural net, though the details of the ranker and the features are beyond the scope of this paper.

5 A Phrase-Based Error Model

The goal of the phrase-based error model is to transform a correctly spelled query C into a misspelled query Q. Rather than replacing single words in isolation, this model replaces sequences of words with sequences of words, thus incorporating contextual information. For instance, we might learn that "*theme part*" can be replaced by "*theme park*" with relatively high probability, even though "*part*" is not a misspelled word. We assume the following generative story: first the correctly spelled query C is broken into K non-empty word sequences $\mathbf{c}_1, \ldots, \mathbf{c}_k$, then each is replaced with a new non-empty word sequence $\mathbf{q}_1, \ldots, \mathbf{q}_k$, and finally these phrases are permuted and concatenated to form the misspelled Q. Here, $\mathbf{c}$ and $\mathbf{q}$ denote consecutive sequences of words.

To formalize this generative process, let S denote the segmentation of C into K phrases $\mathbf{c}_{1\ldots}\mathbf{c}_K$, and let T denote the K replacement phrases $\mathbf{q}_1\ldots\mathbf{q}_K$ – we refer to these ($\mathbf{c}_i$, $\mathbf{q}_i$) pairs as *bi-phrases*. Finally, let M denote a permutation of K elements representing the final reordering step. Figure 2 demonstrates the generative procedure.

Next let us place a probability distribution over rewrite pairs. Let $B(C, Q)$ denote the set of S, T, M triples that transform C into Q. If we assume a uniform probability over segmentations, then the phrase-based probability can be defined as:

$$P(Q|C) \propto \sum_{\substack{(S,T,M)\in \\ B(C,Q)}} P(T|C,S) \cdot P(M|C,S,T) \quad (4)$$

As is common practice in SMT, we use the maximum approximation to the sum:

$$P(Q|C) \approx \max_{\substack{(S,T,M)\in \\ B(C,Q)}} P(T|C,S) \cdot P(M|C,S,T) \quad (5)$$

5.1 Forced Alignments

Although we have defined a generative model for transforming queries, our goal is not to propose new queries, but rather to provide scores over existing Q and C pairs which act as features for the ranker. Furthermore, the word-level alignments between Q and C can most often be identified with little ambiguity. Thus we restrict our attention to those phrase transformations consistent with a good word-level alignment.

Let J be the length of Q, L be the length of C, and $A = a_1, \ldots, a_J$ be a hidden variable representing the word alignment. Each a_i takes on a value ranging from 1 to L indicating its corresponding word position in C, or 0 if the ith word in Q is unaligned. The cost of assigning k to a_i is equal to the Levenshtein edit distance (Levenshtein, 1966) between the i^{th} word in Q and the k^{th} word in C, and the cost of assigning 0 to a_i is equal to the length of the i^{th} word in Q. We can determine the least cost alignment A^* between Q and C efficiently using the A-star algorithm.

When scoring a given candidate pair, we further restrict our attention to those S, T, M triples that are consistent with the word alignment, which we denote as $B(C, Q, A^*)$. Here, consistency requires that if two words are aligned in A^*, then they must appear in the same bi-phrase ($\mathbf{c}_i$, $\mathbf{q}_i$). Once the word alignment is fixed, the final permutation is uniquely determined, so we can safely discard that factor. Thus we have:

$$P(Q|C) \approx \max_{\substack{(S,T,M)\in \\ \mathcal{B}(C,Q,A^*)}} P(T|C,S) \quad (6)$$

For the sole remaining factor $P(T|C, S)$, we make the assumption that a segmented query $T = \mathbf{q}_1\ldots\ \mathbf{q}_K$ is generated from left to right by transforming each phrase $\mathbf{c}_1\ldots\mathbf{c}_K$ independently:

```
Input: biPhraseLattice "PL" with length = K & height = L;
Initialization: biPhrase.maxProb = 0;
for (x = 0; x <= K – 1; x++)
    for (y = 1; y <= L; y++)
        for (yPre = 1; yPre <= L; yPre++)
        {
            xPre = x – y;
            biPhrasePre = PL.get(xPre, yPre);
            biPhrase = PL.get(x, y);
            if (!biPhrasePre || !biPhrase)
                continue;
            probIncrs = PL.getProbIncrease(biPhrasePre,
                                           biPhrase);
            maxProbPre = biPhrasePre.maxProb;
            totalProb = probIncrs + maxProbPre;
            if (totalProb > biPhrase.maxProb)
            {
                biPhrase.maxProb = totalProb;
                biPhrase.yPre = yPre;
            }
        }
Result: record at each bi-phrase boundary its maximum probability (biPhrase.maxProb) and optimal back-tracking biPhrases (biPhrase.yPre).
```

Figure 3: The dynamic programming algorithm for Viterbi bi-phrase segmentation.

$$P(T|C,S) = \prod_{k=1}^{K} P(\mathbf{q}_k|\mathbf{c}_k), \quad (7)$$

where $P(\mathbf{q}_k|\mathbf{c}_k)$ is a phrase transformation probability, the estimation of which will be described in Section 5.2.

To find the maximum probability assignment efficiently, we can use a dynamic programming approach, somewhat similar to the monotone decoding algorithm described in Och (2002). Here, though, both the input and the output word sequences are specified as the input to the algorithm, as is the word alignment. We define the quantity α_j to be the probability of the most likely sequence of bi-phrases that produce the first j terms of Q and are consistent with the word alignment and C. It can be calculated using the following algorithm:

1. Initialization:

$$\alpha_0 = 1 \quad (8)$$

2. Induction:

$$\alpha_j = \max_{j' < j, \mathbf{q} = q_{j'+1} \ldots q_j} \left\{ \alpha_{j'} P(\mathbf{q}|\mathbf{c}_\mathbf{q}) \right\} \quad (9)$$

3. Total:

$$P(Q|C) = \alpha_J \quad (10)$$

	A	B	C	D	E	F
a	#					
d				#		
c			#			
f						#

a	A
adc	ABCD
d	D
dc	CD
dcf	CDEF
c	C
f	F

Figure 4: Toy example of (left) a word alignment between two strings "adcf" and "ABCDEF"; and (right) the bi-phrases containing up to four words that are consistent with the word alignment.

The pseudo-code of the above algorithm is shown in Figure 3. After generating Q from left to right according to Equations (8) to (10), we record at each possible bi-phrase boundary its maximum probability, and we obtain the total probability at the end-position of Q. Then, by back-tracking the most probable bi-phrase boundaries, we obtain B^*. The algorithm takes a complexity of $O(KL^2)$, where K is the total number of word alignments in A^* which does not contain empty words, and L is the maximum length of a bi-phrase, which is a hyper-parameter of the algorithm. Notice that when we set L=1, the phrase-based error model is reduced to a word-based error model which assumes that words are transformed independently from C to Q, without taking into account any contextual information.

5.2 Model Estimation

We follow a method commonly used in SMT (Koehn et al., 2003) to extract bi-phrases and estimate their replacement probabilities. From each query-correction pair with its word alignment (Q, C, A^*), all bi-phrases consistent with the word alignment are identified. Consistency here implies two things. First, there must be at least one aligned word pair in the bi-phrase. Second, there must not be any word alignments from words inside the bi-phrase to words outside the bi-phrase. That is, we do not extract a phrase pair if there is an alignment from within the phrase pair to outside the phrase pair. The toy example shown in Figure 4 illustrates the bilingual phrases we can generate by this process.

After gathering all such bi-phrases from the full training data, we can estimate conditional relative frequency estimates without smoothing. For example, the phrase transformation probability $P(\mathbf{q}|\mathbf{c})$ in Equation (7) can be estimated approximately as

$$P(\mathbf{q}|\mathbf{c}) = \frac{N(\mathbf{c},\mathbf{q})}{\sum_{\mathbf{q}'} N(\mathbf{c},\mathbf{q}')} \quad (11)$$

where $N(\mathbf{c},\mathbf{q})$ is the number of times that **c** is aligned to **q** in training data. These estimates are useful for contextual lexical selection with sufficient training data, but can be subject to data sparsity issues.

An alternate translation probability estimate not subject to data sparsity issues is the so-called *lexical weight* estimate (Koehn et al., 2003). Assume we have a word translation distribution $t(q|c)$ (defined over individual words, not phrases), and a word alignment A between **q** and **c**; here, the word alignment contains (i, j) pairs, where $i \in 1..|\boldsymbol{q}|$ and $j \in 0..|\mathbf{c}|$, with 0 indicating an inserted word. Then we can use the following estimate:

$$P_w(\mathbf{q}|\mathbf{c},A) = \prod_{i=1}^{|\mathbf{q}|} \frac{1}{|\{j|(j,i)\in A\}|} \sum_{\forall(i,j)\in A} t(q_i|c_j) \quad (12)$$

We assume that for every position in **q**, there is either a single alignment to 0, or multiple alignments to non-zero positions in **c**. In effect, this computes a product of per-word translation scores; the per-word scores are averages of all the translations for the alignment links of that word. We estimate the word translation probabilities using counts from the word aligned corpus: $t(q|c) = \frac{N(c,q)}{\sum_{q'} N(c,q')}$. Here $N(c,q)$ is the number of times that the words (not phrases as in Equation 11) c and q are aligned in the training data. These word based scores of bi-phrases, though not as effective in contextual selection, are more robust to noise and sparsity.

Throughout this section, we have approached this model in a noisy channel approach, finding probabilities of the misspelled query given the corrected query. However, the method can be run in both directions, and in practice SMT systems benefit from also including the direct probability of the corrected query given this misspelled query (Och, 2002).

5.3 Phrase-Based Error Model Features

To use the phrase-based error model for spelling correction, we derive five features and integrate them into the ranker-based query speller system, described in Section 4. These features are as follows.

- **Two phrase transformation features:** These are the phrase transformation scores based on relative frequency estimates in two directions. In the correction-to-query direction, we define the feature as $f_{PT}(Q,C,A) = \log P(Q|C)$, where $P(Q|C)$ is computed by Equations (8) to (10), and $P(\mathbf{q}|\mathbf{c_q})$ is the relative frequency estimate of Equation (11).
- **Two lexical weight features:** These are the phrase transformation scores based on the lexical weighting models in two directions. For example, in the correction-to-query direction, we define the feature as $f_{LW}(Q,C,A) = \log P(Q|C)$, where $P(Q|C)$ is computed by Equations (8) to (10), and the phrase transformation probability is the computed as lexical weight according to Equation (12).
- **Unaligned word penalty feature:** the feature is defined as the ratio between the number of unaligned query words and the total number of query words.

6 Experiments

We evaluate the spelling error models on a large scale real world data set containing 24,172 queries sampled from one year's worth of query logs from a commercial search engine. The spelling of each query is judged and corrected by four annotators.

We divided the data set into training and test data sets. The two data sets do not overlap. The training data contains 8,515 query-correction pairs, among which 1,743 queries are misspelled (i.e., in these pairs, the corrections are different from the queries). The test data contains 15,657 query-correction pairs, among which 2,960 queries are misspelled. The average length of queries in the training and test data is 2.7 words.

The speller systems we developed in this study are evaluated using the following three metrics.

- **Accuracy:** The number of correct outputs generated by the system divided by the total number of queries in the test set.
- **Precision:** The number of correct spelling corrections for misspelled queries generated by the system divided by the total number of corrections generated by the system.
- **Recall:** The number of correct spelling corrections for misspelled queries generated by the system divided by the total number of misspelled queries in the test set.

We also perform a significance test, i.e., a t-test with a significance level of 0.05. A significant difference should be read as significant at the 95% level.

#	System	Accuracy	Precision	Recall
1	Source-channel	0.8526	0.7213	0.3586
2	Ranker-based	0.8904	0.7414	0.4964
3	Word model	0.8994	0.7709	0.5413
4	Phrase model (L=3)	0.9043	0.7814	0.5732

Table 1. Summary of spelling correction results.

#	System	Accuracy	Precision	Recall
5	Phrase model (L=1)	0.8994	0.7709	0.5413
6	Phrase model (L=2)	0.9014	0.7795	0.5605
7	Phrase model (L=3)	0.9043	0.7814	0.5732
8	Phrase model (L=5)	0.9035	0.7834	0.5698
9	Phrase model (L=8)	0.9033	0.7821	0.5713

Table 2. Variations of spelling performance as a function of phrase length.

#	System	Accuracy	Precision	Recall
10	L=3; 0 month data	0.8904	0.7414	0.4964
11	L=3; 0.5 month data	0.8959	0.7701	0.5234
12	L=3; 1.5 month data	0.9023	0.7787	0.5667
13	L=3; 3 month data	0.9043	0.7814	0.5732

Table 3. Variations of spelling performance as a function of the size of clickthrough data used for training.

In our experiments, all the speller systems are ranker-based. In most cases, other than the baseline system (a linear neural net), the ranker is a two-layer neural net with 5 hidden nodes. The free parameters of the neural net are trained to optimize accuracy on the training data using the back propagation algorithm, running for 500 iterations with a very small learning rate (0.1) to avoid overfitting. We did not adjust the neural net structure (e.g., the number of hidden nodes) or any training parameters for different speller systems. Neither did we try to seek the best tradeoff between precision and recall. Since all the systems are optimized for accuracy, we use accuracy as the primary metric for comparison.

Table 1 summarizes the main spelling correction results. Row 1 is the baseline speller system where the source-channel model of Equations (2) and (3) is used. In our implementation, we use a linear ranker with only two features, derived respectively from the language model and the error model models. The error model is based on the edit distance function. Row 2 is the ranker-based spelling system that uses all 96 ranking features, as described in Section 4. Note that the system uses the features derived from two error models. One is the edit distance model used for candidate generation. The other is a phonetic model that measures the edit distance between the metaphones (Philips, 1990) of a query word and its aligned correction word. Row 3 is the same system as Row 2, with an additional set of features derived from a word-based error model. This model is a special case of the phrase-based error model described in Section 5 with the maximum phrase length set to one. Row 4 is the system that uses the additional 5 features derived from the phrase-based error models with a maximum bi-phrase length of 3.

In phrase based error model, L is the maximum length of a bi-phrase (Figure 3). This value is important for the spelling performance. We perform experiments to study the impact of L; the results are displayed in Table 2. Moreover, since we proposed to use clickthrough data for spelling correction, it is interesting to study the impact on spelling performance from the size of clickthrough data used for training. We varied the size of clickthrough data and the experimental results are presented in Table 3.

The results show first and foremost that the ranker-based system significantly outperforms the spelling system based solely on the source-channel model, largely due to the richer set of features used (Row 1 vs. Row 2). Second, the error model learned from clickthrough data leads to significant improvements (Rows 3 and 4 vs. Row 2). The phrase-based error model, due to its capability of capturing contextual information, outperforms the word-based model with a small but statistically significant margin (Row 4 vs. Row 3), though using phrases longer ($L > 3$) does not lead to further significant improvement (Rows 6 and 7 vs. Rows 8 and 9). Finally, using more clickthrough data leads to significant improvement (Row 13 vs. Rows 10 to 12). The benefit does not appear to have peaked – further improvements are likely given a larger data set.

7 Conclusions

Unlike conventional textual documents, most search queries consist of a sequence of key words, many of which are valid search terms but are not stored in any compiled lexicon. This presents a challenge to any speller system that is based on a dictionary.

This paper extends the recent research on using Web data and query logs for query spelling correction in two aspects. First, we show that a large amount of training data (i.e. query-correction pairs) can be extracted from clickthrough data, focusing on query reformulation sessions. The resulting data are very clean and effective for error model training. Second, we argue that it is critical to capture contextual information for query spelling correction. To this end, we propose

a new phrase-based error model, which leads to significant improvement in our spelling correction experiments.

There is additional potentially useful information that can be exploited in this type of model. For example, in future work we plan to investigate the combination of the clickthrough data collected from a Web browser with the noisy but large query sessions collected from a commercial search engine.

Inducing Domain-specific Semantic Class Taggers from (Almost) Nothing

Ruihong Huang and Ellen Riloff
School of Computing
University of Utah
Salt Lake City, UT 84112
{huangrh,riloff}@cs.utah.edu

Abstract

This research explores the idea of inducing domain-specific semantic class taggers using only a domain-specific text collection and seed words. The learning process begins by inducing a classifier that only has access to contextual features, forcing it to generalize beyond the seeds. The contextual classifier then labels new instances, to expand and diversify the training set. Next, a *cross-category bootstrapping process* simultaneously trains a suite of classifiers for multiple semantic classes. The positive instances for one class are used as negative instances for the others in an iterative bootstrapping cycle. We also explore a one-semantic-class-per-discourse heuristic, and use the classifiers to dynamically create semantic features. We evaluate our approach by inducing six semantic taggers from a collection of veterinary medicine message board posts.

1 Introduction

The goal of our research is to create semantic class taggers that can assign a semantic class label to every noun phrase in a sentence. For example, consider the sentence: *"The lab mix was diagnosed with parvo and given abx"*. A semantic tagger should identify the *"the lab mix"* as an ANIMAL, *"parvo"* as a DISEASE, and *"abx"* (antibiotics) as a DRUG. Accurate semantic tagging could be beneficial for many NLP tasks, including coreference resolution and word sense disambiguation, and many NLP applications, such as event extraction systems and question answering technology.

Semantic class tagging has been the subject of previous research, primarily under the guises of *named entity recognition* (NER) and *mention detection*. Named entity recognizers perform semantic tagging on proper name noun phrases, and sometimes temporal and numeric expressions as well. The *mention detection* task was introduced in recent ACE evaluations (e.g., (ACE, 2007; ACE, 2008)) and requires systems to identify all noun phrases (proper names, nominals, and pronouns) that correspond to 5-7 semantic classes.

Despite widespread interest in semantic tagging, nearly all semantic taggers for comprehensive NP tagging still rely on supervised learning, which requires annotated data for training. A few annotated corpora exist, but they are relatively small and most were developed for broad-coverage NLP. Many domains, however, are replete with specialized terminology and jargon that cannot be adequately handled by general-purpose systems. Domains such as biology, medicine, and law are teeming with specialized vocabulary that necessitates training on domain-specific corpora.

Our research explores the idea of inducing domain-specific semantic taggers using a small set of seed words as the only form of human supervision. Given an (unannotated) collection of domain-specific text, we automatically generate training instances by labelling every instance of a seed word with its designated semantic class. We then train a classifier to do semantic tagging using these seed-based annotations, using bootstrapping to iteratively improve performance.

On the surface, this approach appears to be a contradiction. The classifier must learn how to assign different semantic tags to different instances of the same word based on context (e.g., *"lab"* may refer to an animal in one context but a laboratory in another). And yet, we plan to train the classifier using stand-alone seed words, making the assumption that every instance of the seed belongs to the same semantic class. We resolve this apparent contradiction by using semantically unambiguous seeds and by introducing an initial context-only training phase before bootstrapping begins. First, we train a *strictly contextual* classifier that only

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 275–285,
Uppsala, Sweden, 11-16 July 2010.

has access to contextual features and cannot see the seed. Then we apply the classifier to the corpus to automatically label new instances, and combine these new instances with the seed-based instances. This process expands and diversifies the training set to fuel subsequent bootstrapping.

Another challenge is that we want to use a *small* set of seeds to minimize the amount of human effort, and then use bootstrapping to fully exploit the domain-specific corpus. Iterative self-training, however, often has difficulty sustaining momentum or it succumbs to semantic drift (Komachi et al., 2008; McIntosh and Curran, 2009). To address these issues, we simultaneously induce a suite of classifiers for multiple semantic categories, using the positive instances of one semantic category as negative instances for the others. As bootstrapping progresses, the classifiers gradually improve themselves, and each other, over many iterations. We also explore a *one-semantic-class-per-discourse* (OSCPD) heuristic that infuses the learning process with fresh training instances, which may be substantially different from the ones seen previously, and we use the labels produced by the classifiers to dynamically create semantic features.

We evaluate our approach by creating six semantic taggers using a collection of message board posts in the domain of veterinary medicine. Our results show this approach produces high-quality semantic taggers after a sustained bootstrapping cycle that maintains good precision while steadily increasing recall over many iterations.

2 Related Work

Semantic class tagging is most closely related to *named entity recognition* (NER), *mention detection*, and *semantic lexicon induction*. NER systems (e.g., (Bikel et al., 1997; Collins and Singer, 1999; Cucerzan and Yarowsky, 1999; Fleischman and Hovy, 2002) identify proper named entities, such as people, organizations, and locations. Several bootstrapping methods for NER have been previously developed (e.g., (Collins and Singer, 1999; Niu et al., 2003)). NER systems, however, do not identify nominal NP instances (e.g., "a software manufacturer" or "the beach"), or handle semantic classes that are not associated with proper named entities (e.g., symptoms).[1] ACE mention detection systems (e.g., see (ACE, 2005; ACE, 2007; ACE, 2008)) require tagging of NPs that correspond to 5-7 general semantic classes. These systems are typically trained with supervised learning using annotated corpora, although techniques have been developed to use resources for one language to train systems for different languages (e.g., (Zitouni and Florian, 2009)).

Another line of relevant work is *semantic class induction* (e.g., (Riloff and Shepherd, 1997; Roark and Charniak, 1998; Thelen and Riloff, 2002; Ng, 2007; McIntosh and Curran, 2009), where the goal is to induce a stand-alone dictionary of words with semantic class labels. These techniques are often designed to learn specialized terminology from unannotated domain-specific texts via bootstrapping. Our work, however, focuses on classification of NP *instances* in context, so the same phrase may be assigned to different semantic classes in different contexts. Consequently, our classifier can also assign semantic class labels to pronouns.

There has also been work on extracting semantically related terms or category members from the Web (e.g., (Paşca, 2004; Etzioni et al., 2005; Kozareva et al., 2008; Carlson et al., 2009)). These techniques harvest broad-coverage semantic information from the Web using patterns and statistics, typically for the purpose of knowledge acquisition. Importantly, our goal is to classify instances in context, rather than generate lists of terms. In addition, the goal of our research is to learn specialized terms and jargon that may not be common on the Web, as well as domain-specific usages that may differ from the norm (e.g., *"mix"* and *"lab"* are usually ANIMALS in our domain).

The idea of simulataneously learning multiple semantic categories to prevent semantic drift has been explored for other tasks, such as semantic lexicon induction (Thelen and Riloff, 2002; McIntosh and Curran, 2009) and pattern learning (Yangarber, 2003). Our bootstrapping model can be viewed as a form of self-training (e.g., (Ng and Cardie, 2003; Mihalcea, 2004; McClosky et al., 2006)), and cross-category training is similar in spirit to co-training (e.g., (Blum and Mitchell, 1998; Collins and Singer, 1999; Riloff and Jones, 1999; Mueller et al., 2002; Phillips and Riloff, 2002)). But, importantly, our classifiers all use the same feature set so they do not represent independent views of the data. They do, however, offer slightly different perspectives because each is at-

[1] Some NER systems also handle specialized constructs such as dates and monetary amounts.

tempting to recognize a different semantic class.

3 Bootstrapping an Instance-based Semantic Class Tagger from Seeds

3.1 Motivation

Our goal is to create a bootstrapping model that can rapidly create semantic class taggers using just a small set of seed words and an unannotated domain-specific corpus. Our motivation comes from specialized domains that cannot be adequately handled by general-purpose NLP systems. As an example of such a domain, we have been working with a collection of message board posts in the field of veterinary medicine. Given a document, we want a semantic class tagger to label every NP with a semantic category, for example:

> [A 14yo doxy]$_{ANIMAL}$ owned by [a reputable breeder]$_{HUMAN}$ is being treated for [IBD]$_{DISEASE}$ with [pred]$_{DRUG}$.

When we began working with these texts, we were immediately confronted by a dizzying array of non-standard words and word uses. In addition to formal veterinary vocabulary (e.g., animal diseases), veterinarians often use informal, shorthand terms when posting on-line. For example, they frequently refer to breeds using "nicknames" or shortened terms (e.g., *gshep* for German shepherd, *doxy* for dachsund, *bxr* for boxer, *labx* for labrador cross). Often, they refer to animals based solely on their physical characteristics, for example *"a dlh"* (domestic long hair), *"a m/n"* (male, neutered), or *"a 2yo"* (2 year old). This phenomenon occurs with other semantic categories as well, such as drugs and medical tests (e.g., *pred* for prednisone, and *rads* for radiographs).

Nearly all semantic class taggers are trained using supervised learning with manually annotated data. However, annotated data is rarely available for specialized domains, and it is expensive to obtain because domain experts must do the annotation work. So we set out to create a bootstrapping model that can rapidly create domain-specific semantic taggers using just a few seed words and a domain-specific text collection.

Our bootstrapping model consists of two distinct phases. First, we train *strictly contextual classifiers* from the seed annotations. We then apply the classifiers to the unlabeled data to generate new annotated instances that are added to the training set. Second, we employ a *cross-category bootstrapping* process that simultaneously trains a suite of classifiers for multiple semantic categories, using the positive instances for one semantic class as negative instances for the others. This cross-category training process gives the learner sustained momentum over many bootstrapping iterations. Finally, we explore two additional enhancements: (1) a *one-semantic-class-per-discourse* heuristic to automatically generate new training instances, and (2) dynamically created semantic features produced by the classifiers themselves. In the following sections, we explain each of these steps in detail.

3.2 Phase 1: Inducing a Contextual Classifier

The main challenge that we faced was how to train an instance-based classifier using seed words as the only form of human supervision. First, the user must provide a small set of seed words that are relatively unambiguous (e.g., *"dog"* will nearly always refer to an animal in our domain). But even so, training a traditional classifier from seed-based instances would likely produce a classifier that learns to recognize the seeds but is unable to classify new examples. We needed to force the classifier to generalize beyond the seed words.

Our solution was to introduce an initial training step that induces a *strictly contextual classifier*. First, we generate training instances by automatically labeling each instance of a seed word with its designated semantic class. However, when we create feature vectors for the classifier, the seeds themselves are hidden and only contextual features are used to represent each training instance. By essentially "masking" the seed words so the classifier can only see the contexts around them, we force the classifier to generalize.

We create a suite of *strictly contextual classifiers*, one for each semantic category. Each classifier makes a binary decision as to whether a noun phrase belongs to its semantic category. We use the seed words for category C_k to generate positive training instances for the C_k classifier, and the seed words for all other categories to generate the negative training instances for C_k.

We use an in-house sentence segmenter and NP chunker to identify the base NPs in each sentence and create feature vectors that represent each constituent in the sentence as either an NP or an individual word. For each seed word, the feature

vector captures a context window of 3 constituents (word or NP) to its left and 3 constituents (word or NP) to its right. Each constituent is represented with a lexical feature: for NPs, we use its head noun; for individual words, we use the word itself. The seed word, however, is discarded so that the classifier is essentially blind-folded and cannot see the seed that produced the training instance. We also create a feature for every modifier that precedes the head noun in the target NP, except for articles which are discarded. As an example, consider the following sentence:

> *Fluffy was diagnosed with FELV after a blood test showed that he tested positive.*

Suppose that "*FELV*" is a seed for the DISEASE category and "*test*" is a seed for the TEST category. Two training instances would be created, with feature vectors that look like this, where M represents a modifier inside the target NP:

was_{-3} $diagnosed_{-2}$ $with_{-1}$ $after_1$ $test_2$ $showed_3$ $\Rightarrow$ DISEASE

$with_{-3}$ $FELV_{-2}$ $after_{-1}$ $blood_M$ $showed_1$ $that_2$ $he_3 \Rightarrow$ TEST

The contextual classifiers are then applied to the corpus to automatically label new instances. We use a confidence score to label only the instances that the classifiers are most certain about. We compute a confidence score for instance i with respect to semantic class C_k by considering both the score of the C_k classifier as well as the scores of the competing classifiers. Intuitively, we have confidence in labeling an instance as category C_k if the C_k classifier gave it a positive score, and its score is much higher than the score of any other classifier. We use the following scoring function:

Confidence(i,C_k) =
score(i,C_k) - max($\forall_{j \neq k}$ score(i,C_j))

We employ support vector machines (SVMs) (Joachims, 1999) with a linear kernel as our classifiers, using the SVMlin software (Keerthi and DeCoste, 2005). We use the value produced by the decision function (essentially the distance from the hyperplane) as the score for a classifier. We specify a threshold θ_{cf} and only assign a semantic tag C_k to an instance i if Confidence(i,C_k) $\geq \theta_{cf}$.

All instances that pass the confidence threshold are labeled and added to the training set. This process greatly enhances the diversity of the training data. In this initial learning step, the strictly contextual classifiers substantially increase the number of training instances for each semantic category, producing a more diverse mix of seed-generated instances and context-generated instances.

3.3 Phase 2: Cross-Category Bootstrapping

The next phase of the learning process is an iterative bootstrapping procedure. The key challenge was to design a bootstrapping model that would not succumb to semantic drift and would have sustained momentum to continue learning over many iterations.

Figure 1 shows the design of our *cross-category bootstrapping* model.[2] We simultaneously train a suite of binary classifiers, one for each semantic category, $C_1 \ldots C_n$. After each training cycle, all of the classifiers are applied to the remaining unlabeled instances and each classifier labels the (positive) instances that it is most confident about (i.e., the instances that it classifies with a confidence score $\geq \theta_{cf}$). The set of instances positively labeled by classifier C_k are shown as C_k^+ in Figure 1. All of the new instances produced by classifier C_k are then added to the set of positive training instances for C_k and to the set of negative training instances for all of the other classifiers.

One potential problem with this scheme is that some categories are more prolific than others, plus we are collecting negative instances from a set of competing classifiers. Consequently, this approach can produce highly imbalanced training sets. Therefore we enforced a 3:1 ratio of negatives to positives by randomly selecting a subset of the possible negative instances. We discuss this issue further in Section 4.4.

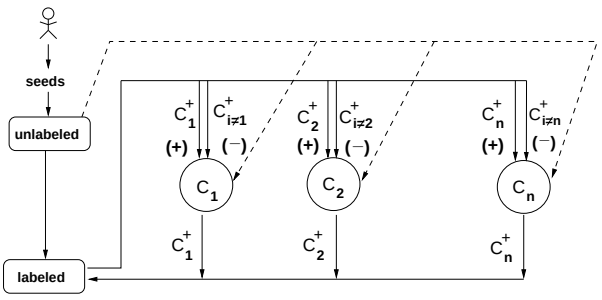

Figure 1: Cross-Category Bootstrapping

[2] For simplicity, this picture does not depict the initial contextual training step, but that can be viewed as the first iteration in this general framework.

Cross-category training has two advantages over independent self-training. First, as others have shown for pattern learning and lexicon induction (Thelen and Riloff, 2002; Yangarber, 2003; McIntosh and Curran, 2009), simultaneously training classifiers for multiple categories reduces semantic drift because each classifier is deterred from encroaching on another one's territory (i.e., claiming the instances from a competing class as its own). Second, similar in spirit to co-training[3], this approach allows each classifier to obtain new training instances from an outside source that has a slightly different perspective. While independent self-training can quickly run out of steam, cross-category training supplies each classifier with a constant stream of new (negative) instances produced by competing classifiers. In Section 4, we will show that cross-category bootstrapping performs substantially better than an independent self-training model, where each classifier is bootstrapped separately.

The feature set for these classifiers is exactly the same as described in Section 3.2, except that we add a new lexical feature that represents the head noun of the target NP (i.e., the NP that needs to be tagged). This allows the classifiers to consider the local context as well as the target word itself when making decisions.

3.4 One Semantic Class Per Discourse

We also explored the idea of using a *one semantic class per discourse (OSCPD)* heuristic to generate additional training instances during bootstrapping. Inspired by Yarowsky's *one sense per discourse* heuristic for word sense disambiguation (Yarowsky, 1995), we make the assumption that multiple instances of a word in the same discourse will nearly always correspond to the same semantic class. Since our data set consists of message board posts organized as threads, we consider all posts in the same thread to be a single discourse.

After each training step, we apply the classifiers to the unlabeled data to label some new instances. For each newly labeled instance, the OSCPD heuristic collects all instances with the same head noun in the same discourse (thread) and unilaterally labels them with the same semantic class. This heuristic serves as meta-knowledge to label instances that (potentially) occur in very different contexts, thereby infusing the bootstrapping process with "fresh" training examples.

In early experiments, we found that OSCPD can be aggressive, pulling in many new instances. If the classifier labels a word incorrectly, however, then the OSCPD heuristic will compound the error and mislabel even more instances incorrectly. Therefore we only apply this heuristic to instances that are labeled with extremely high confidence ($\theta_{cf} \geq 2.5$) and that pass a global sanity check, $gsc(w) \geq 0.2$, which ensures that a relatively high proportion of labeled instances with the same head noun have been assigned to the same semantic class. Specifically, $gsc(w) = 0.1 * \frac{w_{l/c}}{w_l} + 0.9 * \frac{w_{u/c}}{w_u}$ where w_l and w_u are the # of labeled and unlabeled instances, respectively, $w_{l/c}$ is the # of instances labeled as c, and $w_{u/c}$ is the # of unlabeled instances that receive a positive confidence score for c when given to the classifier. The intuition behind the second term is that most instances are initially unlabeled and we want to make sure that many of the unlabeled instances are likely to belong to the same semantic class (even though the classifier isn't ready to commit to them yet).

3.5 Dynamic Semantic Features

For many NLP tasks, classifiers use semantic features to represent the semantic class of words. These features are typically obtained from external resources such as Wordnet (Miller, 1990). Our bootstrapping model incrementally trains semantic class taggers, so we explored the idea of using the labels assigned by the classifiers to create enhanced feature vectors by dynamically adding semantic features. This process allows later stages of bootstrapping to directly benefit from earlier stages. For example, consider the sentence:

He started the doxy on Vetsulin today.

If *"Vetsulin"* was labeled as a DRUG in a previous bootstrapping iteration, then the feature vector representing the context around *"doxy"* can be enhanced to include an additional semantic feature identifying Vetsulin as a DRUG, which would look like this:

$$He_{-2}\ started_{-1}\ on_{1}\ Vetsulin_{2}\ DRUG_{2}\ today_{3}$$

Intuitively, the semantic features should help the classifier identify more general contextual patterns, such as *"started <X> on DRUG"*. To create semantic features, we use the semantic tags that

[3]But technically this is not co-training because our feature sets are all the same.

have been assigned to the current set of labeled instances. When a feature vector is created for a target NP, we check every noun instance in its context window to see if it has been assigned a semantic tag, and if so, then we add a semantic feature. In the early stages of bootstrapping, however, relatively few nouns will be assigned semantic tags, so these features are often missing.

3.6 Thresholds and Stopping Criterion

When new instances are automatically labeled during bootstrapping, it is critically important that most of the labels are correct or performance rapidly deteriorates. This suggests that we should only label instances in which the classifier has high confidence. On the other hand, a high threshold often yields few new instances, which can cause the bootstrapping process to sputter and halt. To balance these competing demands, we used a *sliding threshold* that begins conservatively but gradually loosens the reins as bootstrapping progresses. Initially, we set $\theta_{cf} = 2.0$, which only labels instances that the classifier is highly confident about. When fewer than min new instances can be labeled, we automatically decrease θ_{cf} by 0.2, allowing another batch of new instances to be labeled, albeit with slightly less confidence. We continue decreasing the threshold, as needed, until $\theta_{cf} < 1.0$, when we end the bootstrapping process. In Section 4, we show that this sliding threshold outperforms fixed threshold values.

4 Evaluation

4.1 Data

Our data set consists of message board posts from the Veterinary Information Network (VIN), which is a web site (www.vin.com) for professionals in veterinary medicine. Among other things, VIN hosts forums where veterinarians engage in discussions about medical issues, cases in their practices, etc. Over half of the small animal veterinarians in the U.S. and Canada use VIN. Analysis of veterinary data could not only improve pet health care, but also provide early warning signs of infectious disease outbreaks, emerging zoonotic diseases, exposures to environmental toxins, and contamination in the food chain.

We obtained over 15,000 VIN message board threads representing three topics: cardiology, endocrinology, and feline internal medicine. We did basic cleaning, removing html tags and tokenizing numbers. For training, we used 4,629 threads, consisting of 25,944 individual posts. We developed classifiers to identify six semantic categories: ANIMAL, DISEASE/SYMPTOM[4], DRUG, HUMAN, TEST, and OTHER.

The message board posts contain an abundance of veterinary terminology and jargon, so two domain experts[5] from VIN created a test set (answer key) for our evaluation. We defined annotation guidelines[6] for each semantic category and conducted an inter-annotator agreement study to measure the consistency of the two domain experts on 30 message board posts, which contained 1,473 noun phrases. The annotators achieved a relatively high κ score of .80. Each annotator then labeled an additional 35 documents, which gave us a *test set* containing 100 manually annotated message board posts. The table below shows the distribution of semantic classes in the test set.

Animal	Dis/Sym	Drug	Test	Human	Other
612	900	369	404	818	1723

To select seed words, we used the procedure proposed by Roark and Charniak (1998), ranking all of the head nouns in the training corpus by frequency and manually selecting the first 10 nouns that *unambiguously* belong to each category.[7] This process is fast, relatively objective, and guaranteed to yield high-frequency terms, which is important for bootstrapping. We used the Stanford part-of-speech tagger (Toutanova et al., 2003) to identify nouns, and our own simple rule-based NP chunker.

4.2 Baselines

To assess the difficulty of our data set and task, we evaluated several baselines. The first baseline searches for each head noun in WordNet and labels the noun as category C_k if it has a hypernym synset corresponding to that category. We manually identified the WordNet synsets that, to the best of our ability, seem to most closely correspond

[4]We used a single category for diseases and symptoms because our domain experts had difficulty distinguishing between them. A veterinary consultant explained that the same term (e.g., diabetes) may be considered a symptom in one context if it is secondary to another condition (e.g., pancreatitis) and a disease in a different context if it is the primary diagnosis.

[5]One annotator is a veterinarian and the other is a veterinary technician.

[6]The annotators were also allowed to label an NP as *POS_Error* if it was clearly misparsed. These cases were not used in the evaluation.

[7]We used 20 seeds for DIS/SYM because we merged two categories and for OTHER because it is a broad catch-all class.

Method	Animal	Dis/Sym	Drug	Test	Human	Other	Avg
BASELINES							
WordNet	32/80/46	21/81/34	25/35/29	NA	62/66/64	NA	35/66/45.8

XCat+OSCPD+SF I.39	86/70/77	60/81/69	69/81/75	73/69/71	86/91/89	50/81/62	75/78/76.6

Table 1: Experimental results, reported as Recall/Precision/F score

to each semantic class. We do not report WordNet results for TEST because there did not seem be an appropriate synset, or for the OTHER category because that is a catch-all class. The first row of Table 1 shows the results, which are reported as Recall/Precision/F score[8]. The WordNet baseline yields low recall (21-32%) for every category except HUMAN, which confirms that many veterinary terms are not present in WordNet. The surprisingly low precision for some categories is due to atypical word uses (e.g., *patient*, *boy*, and *girl* are HUMAN in WordNet but nearly always ANIMALS in our domain), and overgeneralities (e.g., WordNet lists *calcium* as a DRUG).

The second baseline simply labels every instance of a seed with its designated semantic class. All non-seed instances remain unlabeled. As expected, the seeds produce high precision but low recall. The exception is HUMAN, where 80% of the instances match a seed word, undoubtedly because five of the ten HUMAN seeds are 1st and 2nd person pronouns, which are extremely common.

A third baseline trains semantic classifiers using supervised learning by performing 10-fold cross-validation on the test set. The feature set and classifier settings are exactly the same as with our bootstrapped classifiers.[9] Supervised learning achieves good precision but low recall for all categories except ANIMAL and HUMAN. In the next section, we present the experimental results for our bootstrapped classifiers.

4.3 Results for Bootstrapped Classifiers

The bottom section of Table 1 displays the results for our bootstrapped classifiers. The **Contextual I.1** row shows results after just the first iteration, which trains only the *strictly contextual classifiers*. The average F score improved from 53.1 for the seeds alone to 64.3 with the contextual classifiers. The next row, **XCategory I.45**, shows the results after cross-category bootstrapping, which ended after 45 iterations. (We indicate the number of iterations until bootstrapping ended using the notation **I.#**.) With cross-category bootstrapping, the average F score increased from 64.3 to 76.1. A closer inspection reveals that all of the semantic categories except HUMAN achieved large recall gains. And importantly, these recall gains were obtained with relatively little loss of precision, with the exception of TEST.

Next, we measured the impact of the *one-semantic-class-per-discourse* heuristic, shown as **XCat+OSCPD I.40**. From Table 1, it appears that OSCPD produced mixed results: recall increased by 1-4 points for DIS/SYM, DRUG, HUMAN, and OTHER, but precision was inconsistent, improving by +4 for TEST but dropping by -8 for DRUG. However, this single snapshot in time does not tell the full story. Figure 2 shows the performance of the classifiers during the course of bootstrapping. The OSCPD heuristic produced a steeper learning curve, and consistently improved performance until the last few iterations when its performance dipped. This is probably due to the fact that noise gradually increases during bootstrapping, so incorrect labels are more likely and OSCPD will compound any mistakes by the classifier. A good future strategy might be to use the OSCPD heuristic only during the early stages of bootstrapping when the classifier's decisions are most reliable.

We also evaluated the effect of dynamically created semantic features. When added to the basic XCategory system, they had almost no effect. We suspect this is because the semantic features are sparse during most of the bootstrapping process. However, the semantic features did im-

[8]We use an F(1) score, where recall and precision are equally weighted.

[9]For all of our classifiers, supervised and bootstrapped, we label all instances of the seed words first and then apply the classifiers to the unlabeled (non-seed) instances.

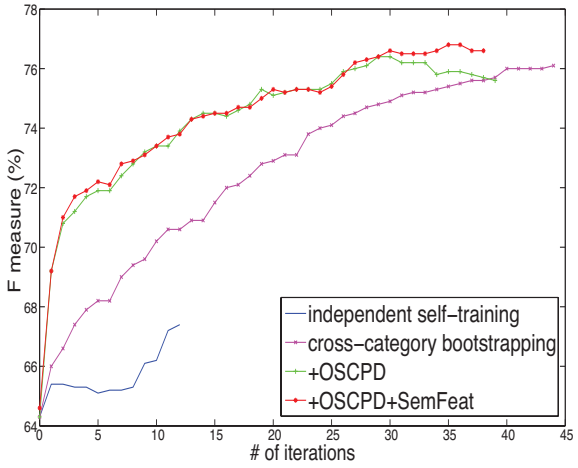

Figure 2: Average F scores after each iteration

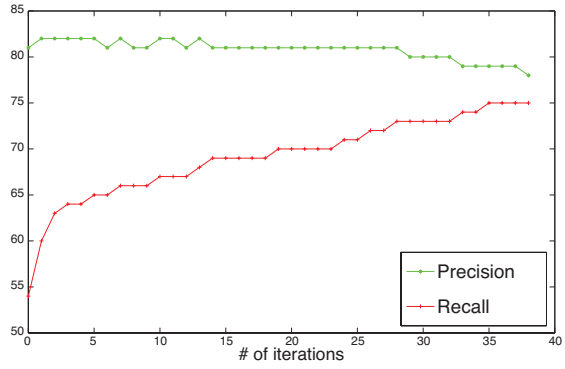

Figure 3: Recall and Precision scores during cross-category bootstrapping

prove performance when coupled with the OSCPD heuristic, presumably because the OSCPD heuristic aggressively labels more instances in the earlier stages of bootstrapping, increasing the prevalence of semantic class tags. The **XCat+OSCPD+SF I.39** row in Table 1 shows that the semantic features coupled with OSCPD dramatically increased the precision for DRUG, yielding the best overall F score of 76.6.

We conducted one additional experiment to assess the benefits of cross-category bootstrapping. We created an analogous suite of classifiers using self-training, where each classifier independently labels the instances that it is most confident about, adds them only to its own training set, and then retrains itself. The **Ind. Self-Train I.13** row in Table 1 shows that these classifiers achieved only 58% recall (compared to 75% for **XCategory**) and an average F score of 67.4 (compared to 76.1 for **XCategory**). One reason for the disparity is that the self-training model ended after just 13 bootstrapping cycles (**I.13**), given the same threshold values. To see if we could push it further, we lowered the confidence threshold to 0 and it continued learning through 35 iterations. Even so, its final score was 65% recall with 79% precision, which is still well below the 75% recall with 78% precision produced by the **XCategory** model. These results support our claim that cross-category bootstrapping is more effective than independently self-trained models.

Figure 3 tracks the recall and precision scores of the **XCat+OSCPD+SF** system as bootstrapping progresses. This graph shows the sustained momentum of cross-category bootstrapping: recall steadily improves while precision stays consistently high with only a slight dropoff at the end.

4.4 Analysis

To assess the impact of corpus size, we generated a learning curve with randomly selected subsets of the training texts. Figure 4 shows the average F score of our best system using $\frac{1}{16}$, $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, and all of the data. With just $\frac{1}{16}$th of the training set, the system has about 1,600 message board posts to use for training, which yields a similar F score (roughly 61%) as the supervised baseline that used 100 manually annotated posts via 10-fold cross-validation. So with 16 times more text, seed-based bootstrapping achieves roughly the same results as supervised learning. This result reflects the natural trade-off between supervised learning and seed-based bootstrapping. Supervised learning exploits manually annotated data, but must make do with a relatively small amount of training text because manual annotations are expensive. In contrast, seed-based bootstrapping exploits a small number of human-provided seeds, but needs a larger set of (unannotated) texts for training because the seeds produce relatively sparse annotations of the texts.

An additional advantage of seed-based bootstrapping methods is that they can easily exploit unlimited amounts of training text. For many domains, large text collections are readily available. Figure 4 shows a steady improvement in performance as the amount of training text grows. Overall, the F score improves from roughly 61% to nearly 77% simply by giving the system access to more unannotated text during bootstrapping.

We also evaluated the effectiveness of our sliding confidence threshold (Section 3.6). The table below shows the results using fixed thresholds

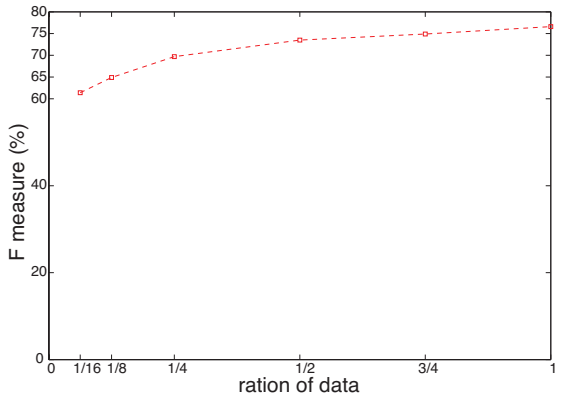

Figure 4: Learning Curve

of 1.0, 1.5, 2.0, as well as the sliding threshold (which begins at 2.0 and ends at 1.0 decreasing by 0.2 when the number of newly labeled instances falls below 3000 (i.e., < 500 per category, on average). This table depicts the expected trade-off between recall and precision for the fixed thresholds, with higher thresholds producing higher precision but lower recall. The sliding threshold produces the best F score, achieving the best balance of high recall and precision.

θ_{cf}	R/P/F
1.0	71/77/74.1
1.5	69/81/74.7
2.0	65/82/72.4
Sliding	75/78/76.6

As mentioned in Section 3.3, we used 3 times as many negative instances as positive instances for every semantic category during bootstrapping. This ratio was based on early experiments where we needed to limit the number of negative instances per category because the cross-category framework naturally produces an extremely skewed negative/positive training set. We revisited this issue to empirically assess the impact of the negative/positive ratio on performance. The table below shows recall, precision, and F score results when we vary the ratio from 1:1 to 5:1. A 1:1 ratio seems to be too conservative, improving precision a bit but lowering recall. However the difference in performance between the other ratios is small. Our conclusion is that a 1:1 ratio is too restrictive but, in general, the cross-category bootstrapping process is relatively insensitive to the specific negative/positive ratio used. Our observation from preliminary experiments, however, is that the negative/positive ratio does need to be controlled, or else the dominant categories overwhelm the less frequent categories with negative instances.

Neg:Pos	R/P/F
1:1	72/79/75.2
2:1	74/78/76.1
3:1	75/78/76.6
4:1	75/77/76.0
5:1	76/77/76.4

Finally, we examined performance on gendered pronouns (he/she/him/her), which can refer to either animals or people in the veterinary domain. 84% (220/261) of the gendered pronouns were annotated as ANIMAL in the test set. Our classifier achieved 95% recall (209/220) and 90% precision (209/232) for ANIMAL and 15% recall (6/41) and 100% precision (6/6) for HUMAN. So while it failed to recognize most of the (relatively few) gendered pronouns that refer to a person, it was highly effective at identifying the ANIMAL references and it was always correct when it did assign a HUMAN tag to a pronoun.

5 Conclusions

We presented a novel technique for inducing domain-specific semantic class taggers from a handful of seed words and an unannotated text collection. Our results showed that the induced taggers achieve good performance on six semantic categories associated with the domain of veterinary medicine. Our technique allows semantic class taggers to be rapidly created for specialized domains with minimal human effort. In future work, we plan to investigate whether these semantic taggers can be used to improve other tasks.

Acknowledgments

We are very grateful to the people at the Veterinary Information Network for providing us access to their resources. Special thanks to Paul Pion, DVM and Nicky Mastin, DVM for making their data available to us, and to Sherri Lofing and Becky Lundgren, DVM for their time and expertise in creating the gold standard annotations. Abstract

Many researchers are trying to use information extraction (IE) to create large-scale knowledge bases from natural language text on the Web. However, the primary approach (supervised learning of relation-specific extractors) requires manually-labeled training data for each relation and doesn't scale to the thousands of relations encoded in Web text.

This paper presents LUCHS, a self-supervised, relation-specific IE system which learns 5025 relations — more than an order of magnitude greater than any previous approach — with an average F1 score of 61%. Crucial to LUCHS's performance is an automated system for *dynamic lexicon learning*, which allows it to learn accurately from heuristically-generated training data, which is often noisy and sparse.

1 Introduction

Information extraction (IE), the process of generating relational data from natural-language text, has gained popularity for its potential applications in Web search, question answering and other tasks. Two main approaches have been attempted:

- Supervised learning of relation-specific extractors (*e.g.*, (Freitag, 1998)), and
- "Open" IE — self-supervised learning of unlexicalized, relation-independent extractors (*e.g.*, Textrunner (Banko et al., 2007)).

Unfortunately, both methods have problems. Supervised approaches require manually-labeled training data for each relation and hence can't scale to handle the thousands of relations encoded in Web text. Open extraction is more scalable, but has lower precision and recall. Furthermore, open extraction doesn't canonicalize relations, so any application using the output must deal with homonymy and synonymy.

A third approach, sometimes refered to as weak supervision, is to heuristically match values from a database to text, thus generating a set of training data for self-supervised learning of relation-specific extractors (Craven and Kumlien, 1999). With the Kylin system (Wu and Weld, 2007) applied this idea to Wikipedia by matching values of an article's infobox[1] attributes to corresponding sentences in the article, and suggested that their approach could extract thousands of relations (Wu et al., 2008). Unfortunately, however, they never tested the idea on more than a dozen relations. Indeed, no one has demonstrated a practical way to extract more than about one hundred relations.

We note that Wikipedia's infobox 'ontology' is a particularly interesting target for extraction. As a by-product of thousands of contributors, it is broad in coverage and growing quickly. Unfortunately, the schemata are surprisingly noisy and most are sparsely populated; challenging conditions for extraction.

This paper presents LUCHS, an autonomous, self-supervised system, which learns 5025 relational extractors — an order of magnitude greater than any previous effort. Like Kylin, LUCHS creates training data by matching Wikipedia attribute values with corresponding sentences, but by itself, this method was insufficient for accurate extraction of most relations. Thus, LUCHS introduces a new technique, *dynamic lexicon features*, which dramatically improves performance when learning from sparse data and that way enables scalability.

1.1 Dynamic Lexicon Features

Figure 1 summarizes the architecture of LUCHS. At the highest level, LUCHS's offline training process resembles that of Kylin. Wikipedia pages

[1] A sizable fraction of Wikipedia articles have associated infoboxes — relational summaries of the key aspects of the subject of the article. For example, the infobox for Alan Turing's Wikipedia page lists the values of 10 attributes, including his birthdate, nationality and doctoral advisor.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 286–295,
Uppsala, Sweden, 11-16 July 2010.

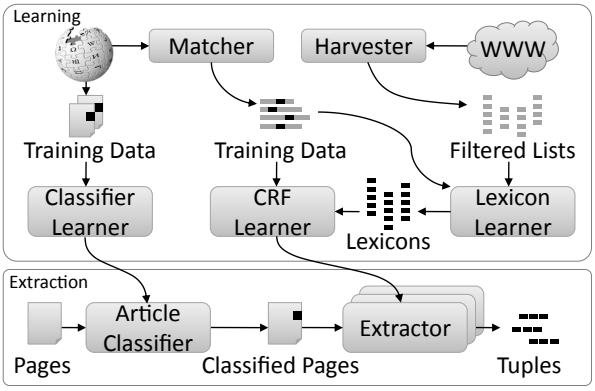

Figure 1: Architecture of LUCHS. In order to handle sparsity in its heuristically-generated training data, LUCHS generates custom lexicon features when learning each relational extractor.

containing infoboxes are used to train a classifier that can predict the appropriate schema for pages missing infoboxes. Additionally, the values of infobox attributes are compared with article sentences to heuristically generate training data. LUCHS's major innovation is a feature-generation process, which starts by harvesting HTML lists from a 5B document Web crawl, discarding 98% to create a set of 49M semantically-relevant lists. When learning an extractor for relation R, LUCHS extracts seed phrases from R's training data and uses a semi-supervised learning algorithm to create several relation-specific lexicons at different points on a precision-recall spectrum. These lexicons form Boolean features which, along with lexical and dependency parser-based features, are used to produce a CRF extractor for each relation — one which performs much better than lexicon-free extraction on sparse training data.

At runtime, LUCHS feeds pages to the article classfier, which predicts which infobox schema is most appropriate for extraction. Then a small set of relation-specific extractors are applied to each sentence, outputting tuples. Our experiments demonstrate a high F1 score, 61%, across the 5025 relational extractors learned.

1.2 Summary

This paper makes several contributions:

- We present LUCHS, a self-supervised IE system capable of learning more than an order of magnitude more relation-specific extractors than previous systems.
- We describe the construction and use of *dynamic lexicon features*, a novel technique, that enables hyper-lexicalized extractors which cope effectively with sparse training data.
- We evaluate the overall end-to-end performance of LUCHS, showing an F1 score of 61% when extracting relations from randomly selected Wikipedia pages.
- We present a comprehensive set of additional experiments, evaluating LUCHS's individual components, measuring the effect of dynamic lexicon features, testing sensitivity to varying amounts of training data, and categorizing the types of relations LUCHS can extract.

2 Heuristic Generation of Training Data

Wikipedia is an ideal starting point for our long-term goal of creating a massive knowledge base of extracted facts for two reasons. First, it is comprehensive, containing a diverse body of content with significant depth. Perhaps more importantly, Wikipedia's structure facilitates self-supervised extraction. Infoboxes are short, manually-created tabular summaries of many articles' key facts — effectively defining a relational schema for that class of entity. Since the same facts are often expressed in both article and ontology, matching values of the ontology to the article can deliver valuable, though noisy, training data.

For example, the Wikipedia article on "Jerry Seinfeld" contains the sentence "Seinfeld was born in Brooklyn, New York." and the article's infobox contains the attribute "birth_place = Brooklyn". By matching the attribute's value "Brooklyn" to the sentence, we can heuristically generate training data for a birth_place extractor. This data is noisy; some attributes will not find matches, while others will find many co-incidental matches.

3 Learning Extractors

We first assume that each Wikipedia infobox attribute corresponds to a unique relation (but see Section 5.6) for which we would like to learn a specific extractor. A major challenge with such an approach is scalability. Running a relation-specific extractor for each of Wikipedia's 34,000 unique infobox attributes on each of Wikipedia's 50 million sentences would require 1.7 trillion extractor executions.

We therefore choose a *hierarchical* approach that combines both article classifiers and relation extractors. For each infobox schema, LUCHS trains a classifier that predicts if an article is likely to contain that schema. Only when an article

is likely to contain a schema, does LUCHS run that schema's relation extractors. To extract infobox attributes from all of Wikipedia, LUCHS now needs orders of magnitude fewer executions.

While this approach does not propagate information from extractors back to article classifiers, experiments confirm that our article classifiers nonetheless deliver accurate results (Section 5.2), reducing the potential benefit of joint inference. In addition, our approach reduces the need for extractors to keep track of the larger context, thus simplifying the extraction problem.

We briefly summarize article classification: We use a linear, multi-class classifier with six kinds of features: words in the article title, words in the first sentence, words in the first sentence which are direct objects to the verb 'to be', article section headers, Wikipedia categories, and their ancestor categories. We use the voted perceptron algorithm (Freund and Schapire, 1999) for training.

More challenging are the attribute extractors, which we wish to be simple, fast, and able to well capture local dependencies. We use a linear-chain conditional random field (CRF) — an undirected graphical model connecting a sequence of input and output random variables, $x = (x_0, \ldots, x_T)$ and $y = (y_0, \ldots, y_T)$ (Lafferty et al., 2001). Input variables are assigned words w. The states of output variables represent discrete labels l, e.g. $\mathsf{Arg}_i\text{-of-}\mathsf{Rel}_j$ and Other. In our case, variables are connected in a chain, following the first-order Markov assumption. We train to maximize conditional likelihood of output variables given an input probability distribution. The CRF models $p(y|x)$ are represented with a log-linear distribution

$$p(y|x) = \frac{1}{Z(x)} \exp \sum_{t=1}^{T} \sum_{k=1}^{K} \lambda_k f_k(y_{t-1}, y_t, x, t)$$

where feature functions, f, encode sufficient statistics of (x, y), T is the length of the sequence, K is the number of feature functions, and λ_k are parameters representing feature weights, which we learn during training. $Z(x)$ is a partition function used to normalize the probabilities to 1. Feature functions allow complex, overlapping global features with lookahead.

Common techniques for learning the weights λ_k include numeric optimization algorithms such as stochastic gradient descent or L-BFGS. In our experiments, we again use the simpler and more efficient voted-perceptron algorithm (Collins, 2002). The linear-chain layout enables efficient interence using the dynamic programming-based Viterbi algorithm (Lafferty et al., 2001).

We evaluate nine kinds of Boolean features:

Words For each input word w we introduce feature $f_w^{\mathbf{w}}(y_{t-1}, y_t, x, t) := \mathbb{1}_{[x_t=w]}$.

State Transitions For each transition between output labels l_i, l_j we add feature $f_{l_i,l_j}^{\mathbf{tran}}(y_{t-1}, y_t, x, t) := \mathbb{1}_{[y_{t-1}=l_i \wedge y_t=l_j]}$.

Word Contextualization For parameters p and s we add features $f_w^{\mathbf{prev}}(y_{t-1}, y_t, x, t) := \mathbb{1}_{[w \in \{x_{t-p}, \ldots, x_{t-1}\}]}$ and $f_w^{\mathbf{sub}}(y_{t-1}, y_t, x, t) := \mathbb{1}_{[w \in \{x_{t+1}, \ldots, x_{t+s}\}]}$ which capture a window of words appearing before and after each position t.

Capitalization We add feature $f^{\mathbf{cap}}(y_{t-1}, y_t, x, t) := \mathbb{1}_{[x_t \text{is capitalized}]}$.

Digits We add feature $f^{\mathbf{dig}}(y_{t-1}, y_t, x, t) := \mathbb{1}_{[x_t \text{is digits}]}$.

Dependencies We set $f^{\mathbf{dep}}(y_{t-1}, y_t, x, t)$ to the lemmatized sequence of words from x_t to the root of the dependency tree, computed using the Stanford parser (Marneffe et al., 2006).

First Sentence We set $f^{\mathbf{fs}}(y_{t-1}, y_t, x, t) := \mathbb{1}_{[x_t \text{in first sentence of article}]}$.

Gaussians For numeric attributes, we fit a Gaussian (μ, σ) and add feature $f_i^{\mathbf{gau}}(y_{t-1}, y_t, x, t) := \mathbb{1}_{[|x_t - \mu| < i\sigma]}$ for parameters i.

Lexicons For non-numeric attributes, and for a lexicon l, *i.e.* a set of related words, we add feature $f_l^{\mathbf{lex}}(y_{t-1}, y_t, x, t) := \mathbb{1}_{[x_t \in l]}$. Lexicons are explained in the following section.

4 Extraction with Lexicons

It is often possible to group words that are likely to be assigned similar labels, even if many of these words do not appear in our training set. The obtained lexicons then provide an elegant way to improve the generalization ability of an extractor, especially when only little training data is available. However, there is a danger of overfitting, which we discuss in Section 4.2.4.

The next section explains how we mine the Web to obtain a large corpus of quality lists. Then Section 4.2 presents our semi-supervised algorithm for learning semantic lexicons from these lists.

4.1 Harvesting Lists from the Web

Domain-independence requires access to an extremely large number of lists, but our tight integration of lexicon acquisition and CRF learning requires that relevant lists be accessed instantaneously. Approaches using search engines or wrappers at query time (Etzioni et al., 2004; Wang and Cohen, 2008) are too slow; we must extract and index lists prior to learning.

We begin with a 5 billion page Web crawl. LUCHS can be combined with any list harvesting technique, but we choose a simple approach, extracting lists defined by HTML `<ul>` or `<ol>` tags. The set of lists obtained in this way is extremely noisy — many lists comprise navigation bars, tag sets, spam links, or a series of long text paragraphs. This is consistent with the observation that less than 2% of Web tables are relational (Cafarella et al., 2008).

We therefore apply a series of filtering steps. We remove lists of only one or two items, lists containing long phrases, and duplicate lists from the same host. After filtering we obtain 49 million lists, containing 56 million unique phrases.

4.2 Semi-Supervised Learning of Lexicons

While training a CRF extractor for a given relation, LUCHS uses its corpus of lists to automatically generate a set of semantic lexicons — *specific to that relation*. The technique proceeds in three steps, which have been engineered to run extremely quickly:

1. Seed phrases are extracted from the labeled training set.
2. A learning algorithm expands the seed phrases into a set of lexicons.
3. The semantic lexicons are added as features to the CRF learning algorithm.

4.2.1 Extracting Seed Phrases

For each training sentence LUCHS first identifies subsequences of labeled words, and for each such labeled subsequence, LUCHS creates one or more seed phrases p. Typically, a set of seeds consists precisely of the labeled subsequences. However, if the labeled subsequences are long and have substructure, *e.g.*, 'San Remo, Italy', our system splits at the separator token, and creates additional seed sets from prefixes and postfixes.

4.2.2 From Seeds to Lexicons

To expand a set of seeds into a lexicon, LUCHS must identify relevant lists in the corpus. Relevancy can be computed by defining a similarity between lists using the vector-space model. Specifically, let $\mathcal{L}$ denote the corpus of lists, and $\mathcal{P}$ be the set of unique phrases from $\mathcal{L}$. Each list $l^0 \in \mathcal{L}$ can be represented as a vector of weighted phrases $p \in \mathcal{P}$ appearing on the list, $l^0 = (l^0_{p_1} l^0_{p_2} \ldots l^0_{p_{|\mathcal{P}|}})$. Following the notion of *inverse document frequency,* a phrase's weight is inversely proportional to the number of lists containing the phrase. Popular phrases which appear on many lists thus receive a small weight, whereas rare phrases are weighted higher:

$$l^0_{p_i} = \frac{1}{|\{l \in \mathcal{L} | p \in l\}|}$$

Unlike the vector space model for documents, we ignore term frequency, since the vast majority of lists in our corpus don't contain duplicates. This vector representation supports the simple cosine definition of *list similarity*, which for lists $l^0, l^1 \in \mathcal{L}$ is defined as

$$sim_{cos} := \frac{l^0 \cdot l^1}{\|l^0\| \|l^1\|}.$$

Intuitively, two lists are similar if they have many overlapping phrases, the phrases are not too common, and the lists don't contain many other phrases. By representing the seed set as another vector, we can find similar lists, hopefully containing related phrases. We then create a semantic lexicon by collecting phrases from a range of related lists.

For example, one lexicon may be created as the union of all phrases on lists that have non-zero similarity to the seed list. Unfortunately, due to the noisy nature of the Web lists such a lexicon may be very large and may contain many irrelevant phrases. We expect that lists with higher similarity are more likely to contain phrases which are related to our seeds; hence, by varying the similarity threshold one may produce lexicons representing different compromises between lexicon precision and recall. Not knowing which lexicon will be most useful to the extractors, LUCHS generates several and lets the extractors learn appropriate weights.

However, since list similarities vary depending on the seeds, fixed thresholds are not an option. If *#similarlists* denotes the number of lists that have non-zero similarity to the seed list and *#lexicons*

the total number of lexicons we want to generate, LUCHS sets lexicon $i \in \{0, \ldots, \#lexicons - 1\}$ to be the union of prases on the

$$\#similarlists^{i/\#lexicons}$$

most similar lists.[2]

4.2.3 Efficiently Creating Lexicons

We create lexicons from lists that are *similar* to our seed vector, so we only consider lists that have at least one phrase in common. Importantly, our index structures allow LUCHS to select the relevant lists efficiently. For each seed, LUCHS retrieves the set of containing lists as a sorted sequence of list identifiers. These sequences are then merged yielding a sequence of list identifiers with associated seed-hit counts. Precomputed list lengths and inverse document frequencies are also retrieved from indices, allowing efficient computation of similarity. The worst case complexity is $O(\log(S)SK)$ where S is the number of seeds and K the maximum number of lists to consider per seed.

4.2.4 Preventing Lexicon Overfitting

Finally, we integrate the acquired semantic lexicons as features into the CRF. Although Section 3 discussed how to use lexicons as CRF features, there are some subtleties. Recall that the lexicons were created from seeds extracted from the training set. If we now train the CRF on the *same* examples that generated the lexicon features, then the CRF will likely overfit, and weight the lexicon features too highly!

Before training, we therefore split the training set into k partitions. For each example in a partition we assign features based on lexicons generated from only the $k-1$ *remaining partitions*. This avoids overfitting and ensures that we will not perform much worse than without lexicon features. When we apply the CRF to our test set, we use the lexicons based on all k partitions. We refer to this technique as *cross-training*.

5 Experiments

We start by evaluating end-to-end performance of LUCHS when applied to Wikipedia text, then analyze the characteristics of its components. Our experiments use the 10/2008 English Wikipedia dump.

[2]For practical reasons, we exclude the case $i =$ #lexicons in our experiments.

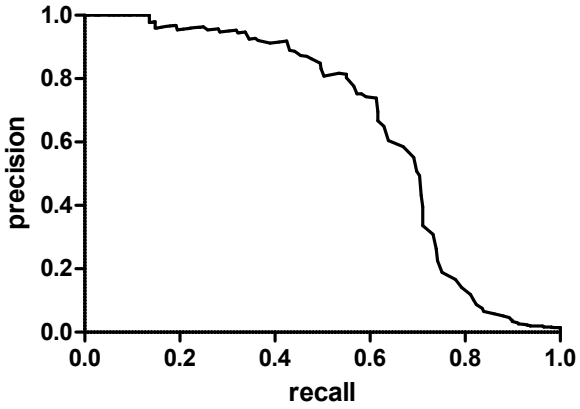

Figure 2: Precision / recall curve for end-to-end system performance on 100 random articles.

5.1 Overall Extraction Performance

To evaluate the end-to-end performance of LUCHS, we test the pipeline which first classifies incoming pages, activating a small set of extractors on the text. To ensure adequate training and test data, we limit ourselves to infobox classes with at least ten instances; there exist 1,583 such classes, together comprising 981,387 articles. We only consider the first ten sentences for each article, and we only consider 5025 attributes.[3] We create a test set by sampling 100 articles randomly; these articles are not used to train article classifiers or extractors. Each test article is then automatically classified, and a random attribute of the predicted schema is selected for extraction. Gold labels for the selected attribute and article are created manually by a human judge and compared to the token-level predictions from the extractors which are trainined on the remaining articles with heuristic matches.

Overall, LUCHS reaches a precision of .55 at a recall of .68, giving an F1-score of .61 (Figure 2). Analyzing the errors in more detail, we find that in 11 of 100 cases an article was incorrectly classified. We note that in at least two of these cases the predicted class could also be considered correct. For example, instead of *Infobox Minor Planet* the extractor predicted *Infobox Planet*.

On five of the selected attributes the extractor failed because the attributes could be considered unlearnable: The flexibility of Wikipedia's infobox system allows contributors to introduce attributes for formatting, for example defining el-

[3]Attributes were selected to have at least 10 heuristic matches, to have 10% of values covered by matches, and 10% of articles with attribute in infobox covered by matches.

ement order. In the future we wish to train LUCHS to ignore this type of attribute.

We also compared the heuristic matches contained in the selected 100 articles to the gold standard: The matches reach a precision of .90 at a recall of .33, giving an F1-score of .48. So while most heuristic matches hit mentions of attribute values, many other mentions go unmatched. Manual analysis shows that these values are often missing from an infobox, are formatted differently, or are inconsistent to what is stated in the article.

So why did the low recall of the heuristic matches not adversely affect recall of our extractors? For most articles, an attribute can be assigned a single unique value. When training an attribute extractor, only articles that contained a heuristic match for that attribute were considered, thus avoiding many cases of unmatched mentions.

Subsequent experiments evaluate the performance of LUCHS components in more detail.

5.2 Article Classification

The first step in LUCHS's run-time pipeline is determining which infobox schemata are most likely to be found in a given article. To test this, we randomly split our 981,387 articles into 4/5 for training and 1/5 for testing, and train a single multi-class classifier. For this experiment, we use the original infobox class of an article as its gold label. We compute the accuracy of the prediction at .92. Since some classes can be considered interchangeable, this number represents a lower bound on performance.

5.3 Factors Affecting Extraction Accuracy

We now evaluate attribute extraction assuming perfect article classification. To keep training time manageable, we sample 100 articles for training and 100 articles for testing[4] for each of 100 random attributes. We again only consider the first ten sentences of each article, and we only consider articles that have heuristic matches with the attribute. We measure F1-score at a token-level, taking the heuristic matches as ground-truth.

We first test the performance of extractors trained using our basic features (Section 3)[5], not including lexicons and Gaussians. We begin using word features and obtain a token-level F1-score of .311 for text and .311 for numeric attributes. Adding any of our additional features improves these scores, but the relative improvements vary: For both text and numeric attributes, contextualization and dependency features deliver the largest improvement. We then iteratively add the feature with largest improvement until no further improvement is observed. We finally obtain an F1-score of .491 for text and .586 for numeric attributes. For text attributes the extractor uses word, contextualization, first sentence, capitalization, and digit features; for numeric attributes the extractor uses word, contextualization, digit, first sentence, and dependency features. We use these extractors as a baseline to evaluate our lexicon and Gaussian features.

Features	F1-Score
Text attributes	
Baseline	.491
Baseline + Lexicons w/o CT	.367
Baseline + Lexicons	.545
Numeric attributes	
Baseline	.586
Baseline + Gaussians w/o CT	.623
Baseline + Gaussians	.627

Table 1: Impact of Lexicon and Gaussian features. Cross-Training (CT) is essential to improve performance.

Varying the size of the training sets affects results: Taking more articles raises the F1-score, but taking more sentences per article reduces it. This is because Wikipedia articles often summarize a topic in the first few paragraphs and later discuss related topics, necessitating reference resolution which we plan to add in future work.

5.4 Lexicon and Gaussian Features

We next study how our distribution features[6] impact the quality of the baseline extractors (Table 1). Without cross-training we observe a reduction in performance, due to overfitting. Cross-training avoids this, and substantially improves results over the baseline. While cross-training is particularly critical for lexicon features, it is less needed for Gaussians where only two parameters, mean and deviation, are fitted to the training set.

The relative improvements depend on the number of available training examples (Table 2). Lexicon and Gaussian features especially benefit extractors for sparse attributes. Here we can also see that the improvements are mainly due to increases in recall.

[4]These numbers are smaller for attributes with less training data available, but the same split is maintained.

[5]For contextualization features we choose $p, s = 5$.

[6]We set the number of lexicon and Gaussian features to 4.

# Train	F1-B	F1-LUCHS	ΔF1	ΔPr	ΔRe
Text attributes					
10	.379	.439	+16%	+10%	+20%
25	.447	.504	+13%	+7%	+20%
100	.491	.545	+11%	+5%	+17%
Numeric attributes					
10	.484	.531	+10%	+4%	+13%
25	.552	.596	+8%	+4%	+10%
100	.586	.627	+7%	+5%	+8%

Table 2: Lexicon and Gaussian features greatly expand F1 score (F1-LUCHS) over the baseline (F1-B), in particular for attributes with few training examples. Gains are mainly due to increased recall.

5.5 Scaling to All of Wikipedia

Finally, we take our best extractors and run them on all 5025 attributes, again assuming perfect article classification and using heuristic matches as gold-standard. Figure 3 shows the distribution of obtained F1 scores. 810 text attributes and 328 numeric attributes reach a score of 0.80 or higher.

The performance depends on the number of available training examples, and that number is governed by a long-tailed distribution. For example, 61% of the attributes in our set have 50 or fewer examples, 36% have 20 or fewer. Interestingly, the number of training examples had a smaller effect on performance than expected. Figure 4 shows the correlation between these variables. Lexicon and Gaussian features enables acceptable performance even for sparse attributes.

Averaging across all attributes we obtain F1 scores of 0.56 and 0.60 for textual and numeric values respectively. We note that these scores assume that all attributes are equally important, weighting rare attributes just like common ones. If we weight scores by the number of attribute instances, we obtain F1 scores of 0.64 (textual) and 0.78 (numeric). In each case, precision is slightly higher than recall.

5.6 Towards an Attribute Ontology

The true promise of relation-specific extractors comes when an ontology ties the system together. By learning a probabilistic model of selectional preferences, one can use joint inference to improve extraction accuracy. One can also answer scientific questions, such as "How many of the learned Wikipedia attributes are distinct?" It is clear that many duplicates exist due to collaborative sloppiness, but semantic similarity is a matter of opinion and an exact answer is impossible.

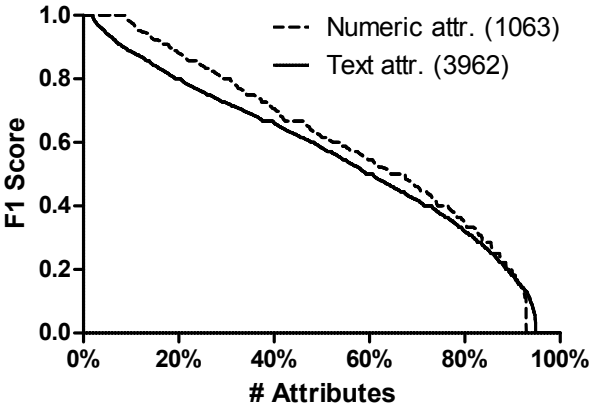

Figure 3: F1 scores among attributes, ranked by score. 810 text attributes (20%) and 328 numeric attributes (31%) had an F1-score of .80 or higher.

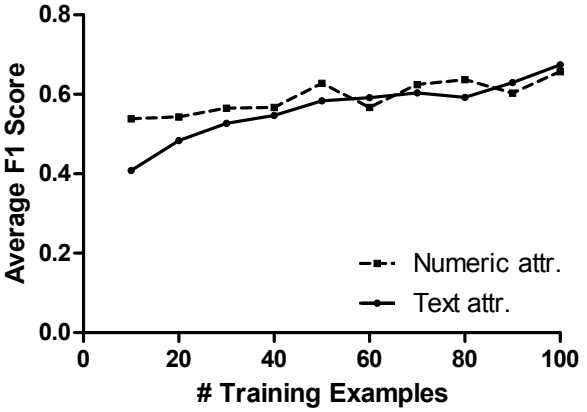

Figure 4: Average F1 score by number of training examples. While more training data helps, even sparse attributes reach acceptable performance.

Nevertheless, we clustered the textual attributes in several ways. First, we cleaned the attribute names heuristically and performed spell check. The "distance" between two attributes was calculated with a combination of edit distance and IR metrics with Wordnet synonyms; then hierarchical agglomerative clustering was performed. We manually assigned names to the clusters and cleaned them, splitting and joining as needed. The result is too crude to be called an ontology, but we continue its elaboration. There are a total of 3962 attributes grouped in about 1282 clusters (not yet counting attributes with numerical values); the largest cluster, *location*, has 115 similar attributes. Figure 5 shows the confusion matrix between attributes in the biggest clusters; the shade of the i, j^{th} pixel indicates the F1 score achieved by training on instances of attribute i and testing on attribute j.

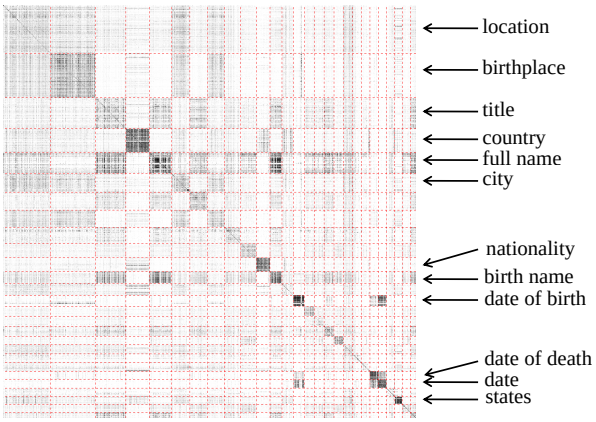

Figure 5: Confusion matrix for extractor accuracy training on one attribute then testing on another. Note the extraction similarity between title and full-name, as well as between dates of birth and death. Space constraints allow us to show only 1000 of LUCHS's 5025 extracted attributes, those in the largest clusters.

6 Related Work

Large-scale extraction A popular approach to IE is supervised learning of relation-specific extractors (Freitag, 1998). Open IE, self-supervised learning of unlexicalized, relation-independent extractors (Banko et al., 2007), is a more scalable approach, but suffers from lower precision and recall, and doesn't canonicalize the relations. A third approach, weak supervision, performs self-supervised learning of relation-specific extractors from noisy training data, heuristically generated by matching database values to text. (Craven and Kumlien, 1999; Hirschman et al., 2002) apply this technique to the biological domain, and (Mintz et al., 2009) apply it to 102 relations from Freebase. LUCHS differs from these approaches in that its "database" – the set of infobox values – itself is noisy, contains many more relations, and has few instances per relation. Whereas the existing approaches focus on *syntactic* extraction patterns, LUCHS focuses on *lexical* information enhanced by dynamic lexicon learning.

Extraction from Wikipedia Wikipedia has become an interesting target for extraction. (Suchanek et al., 2008) build a knowledgebase from Wikipedia's semi-structured data. (Wang et al., 2007) propose a semisupervised positive-only learning technique. Although that extracts from text, its reliance on hyperlinks and other semi-structured data limits extraction. (Wu and Weld, 2007; Wu et al., 2008)'s systems generate training data similar to LUCHS, but were only on a few infobox classes. In contrast, LUCHS shows that the idea scales to more than 5000 relations, but that additional techniques, such as dynamic lexicon learning, are necessary to deal with sparsity.

Extraction with lexicons While lexicons have been commonly used for IE (Cohen and Sarawagi, 2004; Agichtein and Ganti, 2004; Bellare and McCallum, 2007), many approaches assume that lexicons are clean and are supplied by a user *before* training. Other approaches (Talukdar et al., 2006; Miller et al., 2004; Riloff, 1993) learn lexicons automatically from distributional patterns in text. (Wang et al., 2009) learns lexicons from Web lists for query tagging. LUCHS differs from these approaches in that it is not limited to a small set of well-defined relations. Rather than creating large lexicons of common entities, LUCHS attempts to efficiently instantiate a series of lexicons from a small set of seeds to bias extractors of sparse attributes. Crucual to LUCHS's different setting is also the need to avoid overfitting.

Set expansion A large amount of work has looked at automatically generating sets of related items. Starting with a set of seed terms, (Etzioni et al., 2004) extract lists by learning wrappers for Web pages containing those terms. (Wang and Cohen, 2007; Wang and Cohen, 2008) extend the idea, computing term relatedness through a random walk algorithm that takes into account seeds, documents, wrappers and mentions. Other approaches include Bayesian methods (Ghahramani and Heller, 2005) and graph label propagation algorithms (Talukdar et al., 2008; Bengio et al., 2006). The goal of set expansion techniques is to generate high precision sets of related items; hence, these techniques are evaluated based on *lexicon* precision and recall. For LUCHS, which is evaluated based on the quality of an *extractor* using the lexicons, lexicon precision is not important – as long as it does not confuse the extractor.

7 Future Work

We envision a Web-scale machine reading system which simultaneously learns ontologies and extractors, and we believe that LUCHS's approach of leveraging noisy semi-structured information (such as lists or formatting templates) is a key towards this goal. For future work, we plan to enhance LUCHS in two major ways.

First, we note that a big weakness is that the system currently only works for Wikipedia pages.

For example, LUCHS assumes that each page corresponds to exactly one schema and that the subject of relations on a page are the same. Also, LUCHS makes predictions on a token basis, thus sometimes failing to recognize larger segments. To remove these limitations we plan to add a deeper linguistic analysis, making better use of parse and dependency information and including coreference resolution. We also plan to employ relation-independent Open extraction techniques, e.g. as suggested in (Wu and Weld, 2008) (retraining).

Second, we note that LUCHS's performance may benefit substantially from an attribute ontology. As we showed in Section 5.6, LUCHS's current extractors can also greatly facilitate learning a full attribute ontology. We therefore plan to interleave extractor learning and ontology inference, hence jointly learning ontology and extractors.

8 Conclusion

Many researchers are trying to use IE to create large-scale knowledge bases from natural language text on the Web, but existing relation-specific techniques do not scale to the thousands of relations encoded in Web text – while relation-independent techniques suffer from lower precision and recall, and do not canonicalize the relations. This paper shows that – with new techniques – *self-supervised* learning of relation-specific extractors from Wikipedia infoboxes *does* scale.

In particular, we present LUCHS, a self-supervised IE system capable of learning more than an order of magnitude more relation-specific extractors than previous systems. LUCHS uses *dynamic lexicon features* that enable hyper-lexicalized extractors which cope effectively with sparse training data. We show an overall performance of 61% F1 score, and present experiments evaluating LUCHS's individual components.

Datasets generated in this work are available to the community[7].

Unsupervised Ontology Induction from Text

Hoifung Poon and **Pedro Domingos**

Abstract

Extracting knowledge from unstructured text is a long-standing goal of NLP. Although learning approaches to many of its subtasks have been developed (e.g., parsing, taxonomy induction, information extraction), all end-to-end solutions to date require heavy supervision and/or manual engineering, limiting their scope and scalability. We present OntoUSP, a system that induces and populates a probabilistic ontology using only dependency-parsed text as input. OntoUSP builds on the USP unsupervised semantic parser by jointly forming ISA and IS-PART hierarchies of lambda-form clusters. The ISA hierarchy allows more general knowledge to be learned, and the use of smoothing for parameter estimation. We evaluate OntoUSP by using it to extract a knowledge base from biomedical abstracts and answer questions. OntoUSP improves on the recall of USP by 47% and greatly outperforms previous state-of-the-art approaches.

1 Introduction

Knowledge acquisition has been a major goal of NLP since its early days. We would like computers to be able to read text and express the knowledge it contains in a formal representation, suitable for answering questions and solving problems. However, progress has been difficult. The earliest approaches were manual, but the sheer amount of coding and knowledge engineering needed makes them very costly and limits them to well-circumscribed domains. More recently, machine learning approaches to a number of key subproblems have been developed (e.g., Snow et al. (2006)), but to date there is no sufficiently automatic end-to-end solution. Most saliently, supervised learning requires labeled data, which itself is costly and infeasible for large-scale, open-domain knowledge acquisition.

Ideally, we would like to have an end-to-end unsupervised (or lightly supervised) solution to the problem of knowledge acquisition from text. The TextRunner system (Banko et al., 2007) can extract a large number of ground atoms from the Web using only a small number of seed patterns as guidance, but it is unable to extract non-atomic formulas, and the mass of facts it extracts is unstructured and very noisy. The USP system (Poon and Domingos, 2009) can extract formulas and appears to be fairly robust to noise. However, it is still limited to extractions for which there is substantial evidence in the corpus, and in most corpora most pieces of knowledge are stated only once or a few times, making them very difficult to extract without supervision. Also, the knowledge extracted is simply a large set of formulas without ontological structure, and the latter is essential for compact representation and efficient reasoning (Staab and Studer, 2004).

We propose OntoUSP (Ontological USP), a system that learns an ISA hierarchy over clusters of logical expressions, and populates it by translating sentences to logical form. OntoUSP is encoded in a few formulas of higher-order Markov logic (Domingos and Lowd, 2009), and can be viewed as extending USP with the capability to perform hierarchical (as opposed to flat) clustering. This clustering is then used to perform hierarchical smoothing (a.k.a. shrinkage), greatly increasing the system's capability to generalize from

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 296–305,
Uppsala, Sweden, 11-16 July 2010.

sparse data.

We begin by reviewing the necessary background. We then present the OntoUSP Markov logic network and the inference and learning algorithms used with it. Finally, experiments on a biomedical knowledge acquisition and question answering task show that OntoUSP can greatly outperform USP and previous systems.

2 Background

2.1 Ontology Learning

In general, ontology induction (constructing an ontology) and ontology population (mapping textual expressions to concepts and relations in the ontology) remain difficult open problems (Staab and Studer, 2004). Recently, ontology learning has attracted increasing interest in both NLP and semantic Web communities (Cimiano, 2006; Maedche, 2002), and a number of machine learning approaches have been developed (e.g., Snow et al. (2006), Cimiano (2006), Suchanek et al. (2008,2009), Wu & Weld (2008)). However, they are still limited in several aspects. Most approaches induce and populate a deterministic ontology, which does not capture the inherent uncertainty among the entities and relations. Besides, many of them either bootstrap from heuristic patterns (e.g., Hearst patterns (Hearst, 1992)) or build on existing structured or semi-structured knowledge bases (e.g., WordNet (Fellbaum, 1998) and Wikipedia[1]), thus are limited in coverage. Moreover, they often focus on inducing ontology over individual words rather than arbitrarily large meaning units (e.g., idioms, phrasal verbs, etc.). Most importantly, existing approaches typically separate ontology induction from population and knowledge extraction, and pursue each task in a standalone fashion. While computationally efficient, this is suboptimal. The resulted ontology is disconnected from text and requires additional effort to map between the two (Tsujii, 2004). In addition, this fails to leverage the intimate connections between the three tasks for joint inference and mutual disambiguiation.

Our approach differs from existing ones in two main aspects: we induce a probabilistic ontology from text, and we do so by jointly conducting ontology induction, population, and knowledge extraction. Probabilistic modeling handles uncertainty and noise. A joint approach propagates information among the three tasks, uncovers more implicit information from text, and can potentially work well even in domains not well covered by existing resources like WordNet and Wikipedia. Furthermore, we leverage the ontology for hierarchical smoothing and incorporate this smoothing into the induction process. This facilitates more accurate parameter estimation and better generalization.

Our approach can also leverage existing ontologies and knowledge bases to conduct semi-supervised ontology induction (e.g., by incorporating existing structures as hard constraints or penalizing deviation from them).

2.2 Markov Logic

Combining uncertainty handling and joint inference is the hallmark of the emerging field of statistical relational learning (a.k.a. structured prediction), where a plethora of approaches have been developed (Getoor and Taskar, 2007; Bakir et al., 2007). In this paper, we use Markov logic (Domingos and Lowd, 2009), which is the leading unifying framework, but other approaches can be used as well. Markov logic is a probabilistic extension of first-order logic and can compactly specify probability distributions over complex relational domains. It has been successfully applied to unsupervised learning for various NLP tasks such as coreference resolution (Poon and Domingos, 2008) and semantic parsing (Poon and Domingos, 2009). A *Markov logic network (MLN)* is a set of weighted first-order clauses. Together with a set of constants, it defines a Markov network with one node per ground atom and one feature per ground clause. The weight of a feature is the weight of the first-order clause that originated it. The probability of a state x in such a network is given by the log-linear model $P(x) = \frac{1}{Z} \exp\left(\sum_i w_i n_i(x)\right)$, where Z is a normalization constant, w_i is the weight of the ith formula, and n_i is the number of satisfied groundings.

2.3 Unsupervised Semantic Parsing

Semantic parsing aims to obtain a complete canonical meaning representation for input sentences. It can be viewed as a structured prediction problem, where a semantic parse is formed by partitioning the input sentence (or a syntactic analysis such as a dependency tree) into meaning units and assigning each unit to the logical form representing an entity or relation (Figure 1). In effect, a semantic

[1] `http://www.wikipedia.org`

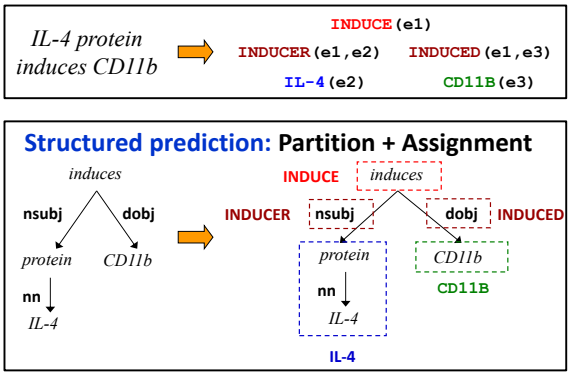

Figure 1: An example of semantic parsing. Top: semantic parsing converts an input sentence into logical form in Davidsonian semantics. Bottom: a semantic parse consists of a partition of the dependency tree and an assignment of its parts.

parser extracts knowledge from input text and converts them into logical form (the semantic parse), which can then be used in logical and probabilistic inference and support end tasks such as question answering.

A major challenge to semantic parsing is syntactic and lexical variations of the same meaning, which abound in natural languages. For example, the fact that IL-4 protein induces CD11b can be expressed in a variety of ways, such as, "Interleukin-4 enhances the expression of CD11b", "CD11b is upregulated by IL-4", etc. Past approaches either manually construct a grammar or require example sentences with meaning annotation, and do not scale beyond restricted domains.

Recently, we developed the USP system (Poon and Domingos, 2009), the first unsupervised approach for semantic parsing.[2] USP inputs dependency trees of sentences and first transforms them into quasi-logical forms (QLFs) by converting each node to a unary atom and each dependency edge to a binary atom (e.g., the node for "induces" becomes $\texttt{induces}(\texttt{e}_1)$ and the subject dependency becomes $\texttt{nsubj}(\texttt{e}_1, \texttt{e}_2)$, where $\texttt{e}_\texttt{i}$'s are Skolem constants indexed by the nodes.).[3] For each sentence, a semantic parse comprises of a partition of its QLF into subexpressions, each of which has a naturally corresponding lambda

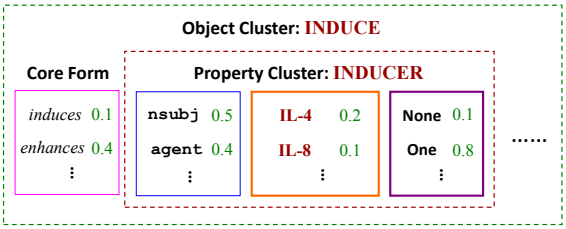

Figure 2: An example of object/property clusters: INDUCE contains the core-form property cluster and others, such as the agent argument INDUCER.

form,[4] and an assignment of each subexpression to a lambda-form cluster.

The lambda-form clusters naturally form an IS-PART hierarchy (Figure 2). An *object cluster* corresponds to semantic concepts or relations such as INDUCE, and contains a variable number of *property clusters*. A special property cluster of *core forms* maintains a distribution over variations in lambda forms for expressing this concept or relation. Other property clusters correspond to modifiers or arguments such as INDUCER (the agent argument of INDUCE), each of which in turn contains three subclusters of property values: the argument-object subcluster maintains a distribution over object clusters that may occur in this argument (e.g., IL − 4), the argument-form subcluster maintains a distribution over lambda forms that corresponds to syntactic variations for this argument (e.g., nsubj in active voice and agent in passive voice), and the argument-number subcluster maintains a distribution over total numbers of this argument that may occur in a sentence (e.g., zero if the argument is not mentioned).

Effectively, USP simultaneously discovers the lambda-form clusters and an IS-PART hierarchy among them. It does so by recursively combining subexpressions that are composed with or by similar subexpressions. The partition breaks a sentence into subexpressions that are meaning units, and the clustering abstracts away syntactic and lexical variations for the same meaning. This novel form of relational clustering is governed by a joint probability distribution $P(T, L)$ defined in higher-order[5] Markov logic, where T are the input dependency trees, and L the semantic parses. The

[2] In this paper, we use a slightly different formulation of USP and its MLN to facilitate the exposition of OntoUSP.

[3] We call these QLFs because they are not true logical form (the ambiguities are not yet resolved). This is related to but not identical with the definition in Alshawi (1990).

[4] The lambda form is derived by replacing every Skolem constant $\texttt{e}_\texttt{i}$ that does not appear in any unary atom in the subexpression with a lambda variable $\texttt{x}_\texttt{i}$ that is uniquely indexed by the corresponding node i. For example, the lambda form for $\texttt{nsubj}(\texttt{e}_1, \texttt{e}_2)$ is $\lambda\texttt{x}_1\lambda\texttt{x}_2.\texttt{nsubj}(\texttt{x}_1, \texttt{x}_2)$.

[5] Variables can range over arbitrary lambda forms.

main predicates are:

$\texttt{e} \in \texttt{c}$: expression e is assigned to cluster c;

$\texttt{SubExpr}(\texttt{s}, \texttt{e})$: s is a subexpression of e;

$\texttt{HasValue}(\texttt{s}, \texttt{v})$: s is of value v;

$\texttt{IsPart}(\texttt{c}, \texttt{i}, \texttt{p})$: p is the property cluster in object cluster c uniquely indexed by i.

In USP, property clusters in different object clusters use distinct index i's. As we will see later, in OntoUSP, property clusters with ISA relation share the same index i, which corresponds to a generic semantic frame such as agent and patient.

The probability model of USP can be captured by two formulas:

$$\begin{aligned} &\texttt{x} \in +\texttt{p} \wedge \texttt{HasValue}(\texttt{x}, +\texttt{v}) \\ &\texttt{e} \in \texttt{c} \wedge \texttt{SubExpr}(\texttt{x}, \texttt{e}) \wedge \texttt{x} \in \texttt{p} \\ &\quad \Rightarrow \exists^1 \texttt{i}.\texttt{IsPart}(\texttt{c}, \texttt{i}, \texttt{p}). \end{aligned}$$

All free variables are implicitly universally quantified. The "+" notation signifies that the MLN contains an instance of the formula, with a separate weight, for each value combination of the variables with a plus sign. The first formula is the core of the model and represents the mixture of property values given the cluster. The second formula ensures that a property cluster must be a part in the corresponding object cluster; it is a hard constraint, as signified by the period at the end.

To encourage clustering, USP imposes an exponential prior over the number of parameters.

To parse a new sentence, USP starts by partitioning the QLF into atomic forms, and then hill-climbs on the probability using a search operator based on lambda reduction until it finds the maximum a posteriori (MAP) parse. During learning, USP starts with clusters of atomic forms, maintains the optimal semantic parses according to current parameters, and hill-climbs on the log-likelihood of observed QLFs using two search operators:

$\texttt{MERGE}(\texttt{c}_1, \texttt{c}_2)$ merges clusters $\texttt{c}_1, \texttt{c}_2$ into a larger cluster c by merging the core-form clusters and argument clusters of $\texttt{c}_1, \texttt{c}_2$, respectively. E.g., $\texttt{c}_1 = \{\text{“}\textit{induce}\text{”}\}$, $\texttt{c}_2 = \{\text{“}\textit{enhance}\text{”}\}$, and $\texttt{c} = \{\text{“}\textit{induce}\text{”}, \text{“}\textit{enhance}\text{”}\}$.

$\texttt{COMPOSE}(\texttt{c}_1, \texttt{c}_2)$ creates a new lambda-form cluster c formed by composing the lambda forms in $\texttt{c}_1, \texttt{c}_2$ into larger ones. E.g., $\texttt{c}_1 = \{\text{“}\textit{amino}\text{”}\}$, $\texttt{c}_2 = \{\text{“}\textit{acid}\text{”}\}$, and $\texttt{c} = \{\text{“}\textit{amino acid}\text{”}\}$.

Each time, USP executes the highest-scored operator and reparses affected sentences using the new parameters. The output contains the optimal lambda-form clusters and parameters, as well as the MAP semantic parses of input sentences.

3 Unsupervised Ontology Induction with Markov Logic

A major limitation of USP is that it either merges two object clusters into one, or leaves them separate. This is suboptimal, because different object clusters may still possess substantial commonalities. Modeling these can help extract more general knowledge and answer many more questions. The best way to capture such commonalities is by forming an ISA hierarchy among the clusters. For example, INDUCE and INHIBIT are both subconcepts of REGULATE. Learning these ISA relations helps answer questions like "What regulates CD11b?", when the text states that "IL-4 induces CD11b" or "AP-1 suppresses CD11b".

For parameter learning, this is also undesirable. Without the hierarchical structure, each cluster estimates its parameters solely based on its own observations, which can be extremely sparse. The better solution is to leverage the hierarchical structure for smoothing (a.k.a. shrinkage (McCallum et al., 1998; Gelman and Hill, 2006)). For example, if we learn that "super-induce" is a verb and that in general verbs have active and passive voices, then even though "super-induce" only shows up once in the corpus as in "AP-1 is super-induced by IL-4", by smoothing we can still infer that this probably means the same as "IL-4 super-induces AP-1", which in turn helps answer questions like "What super-induces AP-1".

OntoUSP overcomes the limitations of USP by replacing the flat clustering process with a hierarchical clustering one, and learns an ISA hierarchy of lambda-form clusters in addition to the IS-PART one. The output of OntoUSP consists of an ontology, a semantic parser, and the MAP parses. In effect, OntoUSP conducts ontology induction, population, and knowledge extraction in a single integrated process. Specifically, given clusters $\texttt{c}_1, \texttt{c}_2$, in addition to merge vs. separate, OntoUSP evaluates a third option called *abstraction*, in which a new object cluster c is created, and ISA links are added from $\texttt{c}_\texttt{i}$ to c; the argument clusters in c are formed by merging that of $\texttt{c}_\texttt{i}$'s.

In the remainder of the section, we describe the

details of OntoUSP. We start by presenting the OntoUSP MLN. We then describe our inference algorithm and how to parse a new sentence using OntoUSP. Finally, we describe the learning algorithm and how OntoUSP induces the ontology while learning the semantic parser.

3.1 The OntoUSP MLN

The OntoUSP MLN can be obtained by modifying the USP MLN with three simple changes. First, we introduce a new predicate $\texttt{IsA}(\texttt{c}_1, \texttt{c}_2)$, which is true if cluster $\texttt{c}_1$ is a subconcept of $\texttt{c}_2$. For convenience, we stipulate that IsA is reflexive (i.e., $\texttt{IsA}(\texttt{c}, \texttt{c})$ is true for any c). Second, we add two formulas to the MLN:

$$\texttt{IsA}(\texttt{c}_1, \texttt{c}_2) \wedge \texttt{IsA}(\texttt{c}_2, \texttt{c}_3) \Rightarrow \texttt{IsA}(\texttt{c}_1, \texttt{c}_3).$$
$$\texttt{IsPart}(\texttt{c}_1, \texttt{i}_1, \texttt{p}_1) \wedge \texttt{IsPart}(\texttt{c}_2, \texttt{i}_2, \texttt{p}_2) \wedge \texttt{IsA}(\texttt{c}_1, \texttt{c}_2) \Rightarrow (\texttt{i}_1 = \texttt{i}_2 \Leftrightarrow \texttt{IsA}(\texttt{p}_1, \texttt{p}_2)).$$

The first formula simply enforces the transitivity of ISA relation. The second formula states that if the ISA relation holds for a pair of object clusters, it also holds between their corresponding property clusters. Both are hard constraints. Third, we introduce hierarchical smoothing into the model by replacing the USP mixture formula

$$\texttt{x} \in +\texttt{p} \wedge \texttt{HasValue}(\texttt{x}, +\texttt{v})$$

with a new formula

$$\texttt{ISA}(\texttt{p}_1, +\texttt{p}_2) \ \wedge \ \texttt{x} \in \texttt{p}_1 \ \wedge \texttt{HasValue}(\texttt{x}, +\texttt{v})$$

Intuitively, for each $\texttt{p}_2$, the weight corresponds to the delta in log-probability of v comparing to the prediction according to all ancestors of $\texttt{p}_2$. The effect of this change is that now the value v of a subexpression x is not solely determined by its property cluster $\texttt{p}_1$, but is also smoothed by statistics of all $\texttt{p}_2$ that are super clusters of $\texttt{p}_1$.

Shrinkage takes place via interaction among the weights of the ISA mixture formula. In particular, if the weights for some property cluster p are all zero, it means that values in p are completely predicted by p's ancestors. In effect, p is backed off to its parent.

3.2 Inference

Given the dependency tree T of a sentence, the conditional probability of a semantic parse L is given by $Pr(L|T) \propto \exp\left(\sum_i w_i n_i(T, L)\right)$. The MAP semantic parse is simply $\arg\max_L \sum_i w_i n_i(T, L)$. Directly enumerating all L's is intractable. OntoUSP uses the same inference algorithm as USP by hill-climbing on the probability of L; in each step, OntoUSP evaluates the alternative semantic parses that can be formed by lambda-reducing a current subexpression with one of its arguments. The only difference is that OntoUSP uses a different MLN and so the probabilities and resulting semantic parses may be different. Algorithm 1 gives pseudo-code for OntoUSP's inference algorithm.

Algorithm 1 OntoUSP-Parse(*MLN, T*)

```
Initialize semantic parse L with individual atoms in the QLF of T
repeat
  for all subexpressions e in L do
    Evaluate all semantic parses that are lambda-reducible from e
  end for
  L ← the new semantic parse with the highest gain in probability
until none of these improve the probability
return L
```

3.3 Learning

OntoUSP uses the same learning objective as USP, i.e., to find parameters θ that maximizes the log-likelihood of observing the dependency trees T, summing out the unobserved semantic parses L:

$$\begin{aligned} L_\theta(T) &= \log P_\theta(L) \\ &= \log \textstyle\sum_L P_\theta(T, L) \end{aligned}$$

However, the learning problem in OntoUSP is distinct in two important aspects. First, OntoUSP learns in addition an ISA hierarchy among the lambda-form clusters. Second and more importantly, OntoUSP leverages this hierarchy during learning to smooth the parameter estimation of individual clusters, as embodied by the new ISA mixture formula in the OntoUSP MLN.

OntoUSP faces several new challenges unseen in previous hierarchical-smoothing approaches. The ISA hierarchy in OntoUSP is not known in advance, but needs to be learned as well. Similarly, OntoUSP has no known examples of populated facts and rules in the ontology, but has to infer that in the same joint learning process. Finally, OntoUSP does not start from well-formed structured input like relational tuples, but rather directly from raw text. In sum, OntoUSP tackles a

Algorithm 2 OntoUSP-Learn(*MLN, T's*)

```
Initialize with a flat ontology, along with clusters and semantic parses
Merge clusters with the same core form
Agenda ← ∅
repeat
  for all candidate operations O do
    Score O by log-likelihood improvement
    if score is above a threshold then
      Add O to agenda
    end if
  end for
  Execute the highest scoring operation O* in the agenda
  Regenerate MAP parses for affected trees and update agenda and candidate operations
until agenda is empty
return the learned ontology and MLN, and the semantic parses
```

very hard problem with exceedingly little aid from user supervision.

To combat these challenges, OntoUSP adopts a novel form of hierarchical smoothing by integrating it with the search process for identifying the hierarchy. Algorithm 2 gives pseudocode for OntoUSP's learning algorithm. Like USP, OntoUSP approximates the sum over all semantic parses with the most probable parse, and searches for both θ and the MAP semantic parses L that maximize $P_\theta(T, L)$. In addition to MERGE and COMPOSE, OntoUSP uses a new operator $\texttt{ABSTRACT}(\texttt{c}_1, \texttt{c}_2)$, which does the following:

1. Create an *abstract* cluster $\texttt{c}$;
2. Create ISA links from $\texttt{c}_1, \texttt{c}_2$ to $\texttt{c}$;
3. Align property clusters of $\texttt{c}_1$ and $\texttt{c}_2$; for each aligned pair $\texttt{p}_1$ and $\texttt{p}_2$, either merge them into a single property cluster, or create an *abstract* property cluster $\texttt{p}$ in $\texttt{c}$ and create ISA links from $\texttt{p}_\texttt{i}$ to $\texttt{p}$, so as to maximize log-likelihood.

Intuitively, $\texttt{c}$ corresponds to a more abstract concept that summarizes similar properties in $\texttt{c}_\texttt{i}$'s.

To add a child cluster $\texttt{c}_2$ to an existing abstract cluster $\texttt{c}_1$, OntoUSP also uses an operator $\texttt{ADDCHILD}(\texttt{c}_1, \texttt{c}_2)$ that does the following:

1. Create an ISA link from $\texttt{c}_2$ to $\texttt{c}_1$;
2. For each property cluster of $\texttt{c}_2$, maximize the log-likelihood by doing one of the following: merge it with a property cluster in an existing child of $\texttt{c}_1$; create ISA link from it to an abstract property cluster in $\texttt{c}$; leave it unchanged.

For efficiency, in both operators, the best option is chosen greedily for each property cluster in $\texttt{c}_2$, in descending order of cluster size.

Notice that once an abstract cluster is created, it could be merged with an existing cluster using MERGE. Thus with the new operators, OntoUSP is capable of inducing any ISA hierarchy among abstract and existing clusters. (Of course, the ISA hierarchy it actually induces depends on the data.)

Learning the shrinkage weights has been approached in a variety of ways; examples include EM and cross-validation (McCallum et al., 1998), hierarchical Bayesian methods (Gelman and Hill, 2006), and maximum entropy with L_1 priors (Dudik et al., 2007). The past methods either only learn parameters with one or two levels (e.g., in hierarchical Bayes), or requires significant amount of computation (e.g., in EM and in L_1-regularized maxent), while also typically assuming a given hierarchy. In contrast, OntoUSP has to both induce the hierarchy and populate it, with potentially many levels in the induced hierarchy, starting from raw text with little user supervision.

Therefore, OntoUSP simplifies the weight learning problem by adopting standard m-estimation for smoothing. Namely, the weights for cluster $\texttt{c}$ are set by counting its observations plus m fractional samples from its parent distribution. When $\texttt{c}$ has few observations, its unreliable statistics can be significantly augmented via the smoothing by its parent (and in turn to a gradually smaller degree by its ancestors). m is a hyperparameter that can be used to trade off bias towards statistics for parent vs oneself.

OntoUSP also needs to balance between two conflicting aspects during learning. On one hand, it should encourage creating abstract clusters to summarize intrinsic commonalities among the children. On the other hand, this needs to be heavily regularized to avoid mistaking noise for the signal. OntoUSP does this by a combination of priors and thresholding. To encourage the induction of higher-level nodes and inheritance, OntoUSP imposes an exponential prior β on the number of *parameter slots*. Each slot corresponds to a distinct property value. A child cluster inherits its parent's slots (and thus avoids the penalty on them). On-

toUSP also stipulates that, in an ABSTRACT operation, a new property cluster can be created either as a *concrete* cluster with full parameterization, or as an *abstract* cluster that merely serves for smoothing purposes. To discourage overproposing clusters and ISA links, OntoUSP imposes a large exponential prior γ on the number of concrete clusters created by ABSTRACT. For *abstract* cluster, it sets a cut-off t_p and only allows storing a probability value no less than t_p. Like USP, it also rejects MERGE and COMPOSE operations that improve log-likelihood by less than t_o. These priors and cut-off values can be tuned to control the granularity of the induced ontology and clusters.

Concretely, given semantic parses L, OntoUSP computes the optimal parameters and evaluates the regularized log-likelihood as follows. Let $w_{p_2,v}$ denote the weight of the ISA mixture formula $\texttt{ISA}(\texttt{p}_1, +\texttt{p}_2) \wedge \texttt{x} \in \texttt{p}_1 \wedge \texttt{HasValue}(\texttt{x}, +\texttt{v})$. For convenience, for each pair of property cluster c and value v, OntoUSP instead computes and stores $w'_{\texttt{c,v}} = \sum_{\texttt{ISA}(\texttt{c},\texttt{a})} w_{\texttt{a,v}}$, which sums over all weights for c and its ancestors. (Thus $w_{\texttt{c,v}} = w'_{\texttt{c,v}} - w'_{\texttt{p,v}}$, where p is the parent of c.) Like USP, OntoUSP imposes local normalization constraints that enable closed-form estimation of the optimal parameters and likelihood. Specifically, using m-estimation, the optimal $w'_{\texttt{c,v}}$ is $\log((m \cdot e^{w'_{\texttt{p,v}}} + n_{\texttt{c,v}})/(m + n_{\texttt{c}}))$, where p is the parent of c and n is the count. The log-likelihood is $\sum_{\texttt{c,v}} w'_{\texttt{c,v}} \cdot n_{\texttt{c,v}}$, which is then augmented by the priors.

4 Experiments

4.1 Methodology

Evaluating unsupervised ontology induction is difficult, because there is no gold ontology for comparison. Moreover, our ultimate goal is to aid knowledge acquisition, rather than just inducing an ontology for its own sake. Therefore, we used the same methodology and dataset as the USP paper to evaluate OntoUSP on its capability in knowledge acquisition. Specifically, we applied OntoUSP to extract knowledge from the GENIA dataset (Kim et al., 2003) and answer questions, and we evaluated it on the number of extracted answers and accuracy. GENIA contains 1999 PubMed abstracts.[6] The question set contains 2000 questions which were created by sampling verbs and entities according to their frequencies in GENIA. Sample questions include "What regulates MIP-1alpha?", "What does anti-STAT 1 inhibit?". These simple question types were used to focus the evaluation on the knowledge extraction aspect, rather than engineering for handling special question types and/or reasoning.

4.2 Systems

OntoUSP is the first unsupervised approach that synergistically conducts ontology induction, population, and knowledge extraction. The system closest in aim and capability is USP. We thus compared OntoUSP with USP and all other systems evaluated in the USP paper (Poon and Domingos, 2009). Below is a brief description of the systems. (For more details, see Poon & Domingos (2009).)

Keyword is a baseline system based on keyword matching. It directly matches the question substring containing the verb and the available argument with the input text, ignoring case and morphology. Given a match, two ways to derive the answer were considered: KW simply returns the rest of sentence on the other side of the verb, whereas KW-SYN is informed by syntax and extracts the answer from the subject or object of the verb, depending on the question (if the expected argument is absent, the sentence is ignored).

TextRunner (Banko et al., 2007) is the state-of-the-art system for open-domain information extraction. It inputs text and outputs relational triples in the form (R, A_1, A_2), where R is the relation string, and A_1, A_2 the argument strings. To answer questions, each triple-question pair is considered in turn by first matching their relation strings, and then the available argument strings. If both match, the remaining argument string in the triple is returned as an answer. Results were reported when exact match is used (TR-EXACT), or when the triple strings may contain the question ones as substrings (TR-SUB).

RESOLVER (Yates and Etzioni, 2009) inputs TextRunner triples and collectively resolves coreferent relation and argument strings. To answer questions, the only difference from TextRunner is that a question string can match any string in its cluster. As in TextRunner, results were reported for both exact match (RS-EXACT) and substring (RS-SUB).

DIRT (Lin and Pantel, 2001) resolves binary rela-

Table 1: Comparison of question answering results on the GENIA dataset. Results for systems other than OntoUSP are from Poon & Domingos (2009).

	# Total	# Correct	Accuracy
KW	150	67	45%
KW-SYN	87	67	77%
TR-EXACT	29	23	79%
TR-SUB	152	81	53%
RS-EXACT	53	24	45%
RS-SUB	196	81	41%
DIRT	159	94	59%
USP	334	295	88%
OntoUSP	**480**	**435**	**91%**

tions by inputting a dependency path that signifies the relation and returns a set of similar paths. To use DIRT in question answering, it was queried to obtain similar paths for the relation of the question, which were then used to match sentences.

USP (Poon and Domingos, 2009) parses the input text using the Stanford dependency parser (Klein and Manning, 2003; de Marneffe et al., 2006), learns an MLN for semantic parsing from the dependency trees, and outputs this MLN and the MAP semantic parses of the input sentences. These MAP parses formed the knowledge base (KB). To answer questions, USP first parses the questions (with the question slot replaced by a dummy word), and then matches the question parse to parses in the KB by testing subsumption.

OntoUSP uses a similar procedure as USP for extracting knowledge and answering questions, except for two changes. First, USP's learning and parsing algorithms are replaced with OntoUSP-Learn and OntoUSP-Parse, respectively. Second, when OntoUSP matches a question to its KB, it not only considers the lambda-form cluster of the question relation, but also all its sub-clusters.[7]

4.3 Results

Table 1 shows the results comparing OntoUSP with other systems. While USP already greatly outperformed other systems in both precision and recall, OntoUSP further substantially improved on the recall of USP, without any loss in precision. In particular, OntoUSP extracted 140 more correct answers than USP, for a gain of 47% in absolute

[7] Additional details are available at `http://alchemy.cs.washington.edu/papers/poon10`.

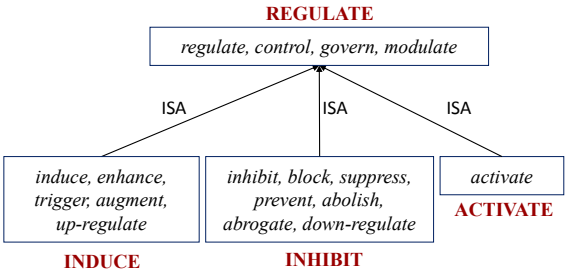

Figure 3: A fragment of the induced ISA hierarchy, showing the core forms for each cluster (the cluster labels are added by the authors for illustration purpose).

recall. Compared to TextRunner (TR-SUB), OntoUSP gained on precision by 38 points and extracted more than five times of correct answers.

Manual inspection shows that the induced ISA hierarchy is the key for the recall gain. Like USP, OntoUSP discovered the following clusters (in core forms) that represent some of the core concepts in biomedical research:

{regulate, control, govern, modulate}

{induce, enhance, trigger, augment, up-regulate}

{inhibit, block, suppress, prevent, abolish, abrogate, down-regulate}

However, USP formed these as separate clusters, whereas OntoUSP in addition induces ISA relations from the `INDUCE` and `INHIBIT` clusters to the `REGULATE` cluster (Figure 3). This allows OntoUSP to answer many more questions that are asked about general regulation events, even though the text states them with specific regulation directions like "induce" or "inhibit". Below is an example question-answer pair output by OntoUSP; neither USP nor any other system were able to extract the necessary knowledge.

Q: What does IL-2 control?

A: The DEX-mediated IkappaBalpha induction.

Sentence: Interestingly, the DEX-mediated IkappaBalpha induction was completely inhibited by IL-2, but not IL-4, in Th1 cells, while the reverse profile was seen in Th2 cells.

OntoUSP also discovered other interesting commonalities among the clusters. For example, both USP and OntoUSP formed a singleton cluster with core form "activate". Although this cluster may appear similar to the `INDUCE` cluster, the data in GENIA does not support merging the two. However, OntoUSP discovered that

the ACTIVATE cluster, while not completely resolvent with INDUCE, shared very similar distributions in their agent arguments. In fact, they are so similar that OntoUSP merges them into a single property cluster. It found that the patient arguments of INDUCE and INHIBIT are very similar and merged them. In turn, OntoUSP formed ISA links from these three object clusters to REGULATE, as well as among their property clusters. Intuitively, this makes sense. The positive- and negative-regulation events, as signified by INDUCE and INHIBIT, often target similar object entities or processes. However, their agents tend to differ since in one case they are inducers, and in the other they are inhibitors. On the other hand, ACTIVATE and INDUCE share similar agents since they both signify positive regulation. However, "activate" tends to be used more often when the patient argument is a concrete entity (e.g., cells, genes, proteins), whereas "induce" and others are also used with processes and events (e.g., expressions, inhibition, pathways).

USP was able to resolve common syntactic differences such as active vs. passive voice. However, it does so on the basis of individual verbs, and there is no generalization beyond their clusters. OntoUSP, on the other hand, formed a high-level cluster with two abstract property clusters, corresponding to general agent argument and patient argument. The active-passive alternation is captured in these clusters, and is inherited by all descendant clusters, including many rare verbs like "super-induce" which only occur once in GENIA and for which there is no way that USP could have learned about their active-passive alternations. This illustrates the importance of discovering ISA relations and performing hierarchical smoothing.

4.4 Discussion

OntoUSP is a first step towards joint ontology induction and knowledge extraction. The experimental results demonstrate the promise in this direction. However, we also notice some limitations in the current system. While OntoUSP induced meaningful ISA relations among relation clusters like REGULATE, INDUCE, etc., it was less successful in inducing ISA relations among entity clusters such as specific genes and proteins. This is probably due to the fact that our model only considers local features such as the parent and arguments. A relation is often manifested as verbs and has several arguments, whereas an entity typically appears as an argument of others and has few arguments of its own. As a result, in average, there is less information available for entities than relations. Presumably, we can address this limitation by modeling longer-ranged dependencies such as grandparents, siblings, etc. This is straightforward to do in Markov logic.

OntoUSP also uses a rather elaborate scheme for regularization. We hypothesize that this can be much simplified and improved by adopting a principled framework such as Dudik et al. (2007).

5 Conclusion

This paper introduced OntoUSP, the first unsupervised end-to-end system for ontology induction and knowledge extraction from text. OntoUSP builds on the USP semantic parser by adding the capability to form hierarchical clusterings of logical expressions, linked by ISA relations, and using them for hierarchical smoothing. OntoUSP greatly outperformed USP and other state-of-the-art systems in a biomedical knowledge acquisition task.

Directions for future work include: exploiting the ontological structure for principled handling of antonyms and (more generally) expressions with opposite meanings; developing and testing alternate methods for hierarchical modeling in OntoUSP; scaling up learning and inference to larger corpora; investigating the theoretical properties of OntoUSP's learning approach and generalizing it to other tasks; answering questions that require inference over multiple extractions; etc.

Exploring Syntactic Structural Features for Sub-Tree Alignment using Bilingual Tree Kernels

sunjun@comp.nus.edu.sg mzhang@i2r.a-star.edu.sg tancl@comp.nus.edu.sg

Abstract

We propose Bilingual Tree Kernels (BTKs) to capture the structural similarities across a pair of syntactic translational equivalences and apply BTKs to sub-tree alignment along with some plain features. Our study reveals that the structural features embedded in a bilingual parse tree pair are very effective for sub-tree alignment and the bilingual tree kernels can well capture such features. The experimental results show that our approach achieves a significant improvement on both gold standard tree bank and automatically parsed tree pairs against a heuristic similarity based method. We further apply the sub-tree alignment in machine translation with two methods. It is suggested that the sub-tree alignment benefits both phrase and syntax based systems by relaxing the constraint of the word alignment.

1 Introduction

Syntax based Statistical Machine Translation (SMT) systems allow the translation process to be more grammatically performed, which provides decent reordering capability. However, most of the syntax based systems construct the syntactic translation rules based on *word alignment*, which not only suffers from the pipeline errors, but also fails to effectively utilize the syntactic structural features. To address those deficiencies, Tinsley et al. (2007) attempt to directly capture the syntactic translational equivalences by automatically conducting sub-tree alignment, which can be defined as follows:

A sub-tree alignment process pairs up sub-tree pairs across bilingual parse trees whose contexts are semantically translational equivalent. According to Tinsley et al. (2007), a sub-tree aligned parse tree pair follows the following criteria:

(i) a node can only be linked once;

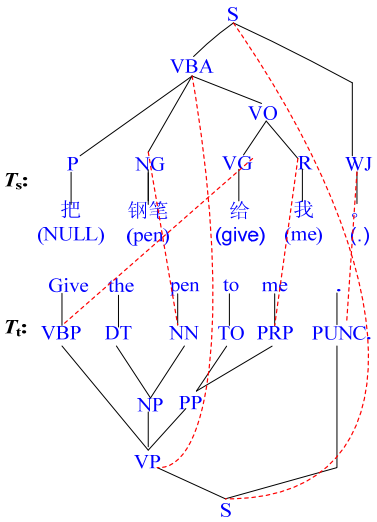

Figure 1: Sub-tree alignment as referred to Node alignment

(ii) descendants of a source linked node may only link to descendants of its target linked counterpart;

(iii) ancestors of a source linked node may only link to ancestors of its target linked counterpart.

By sub-tree alignment, translational equivalent sub-tree pairs are coupled as aligned counterparts. Each pair consists of both the lexical constituents and their maximum tree structures generated over the lexical sequences in the original parse trees. Due to the 1-to-1 mapping between sub-trees and tree nodes, sub-tree alignment can also be considered as node alignment by conducting multiple links across the internal nodes as shown in Fig. 1.

Previous studies conduct sub-tree alignments by either using a rule based method or conducting some similarity measurement only based on lexical features. Groves et al. (2004) conduct sub-tree alignment by using some heuristic rules, lack of extensibility and generality. Tinsley et al. (2007)

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 306–315,
Uppsala, Sweden, 11-16 July 2010.

and Imamura (2001) propose some score functions based on the lexical similarity and co-occurrence. These works fail to utilize the structural features, rendering the syntactic rich task of sub-tree alignment less convincing and attractive. This may be due to the fact that the syntactic structures in a parse tree pair are hard to describe using plain features. In addition, explicitly utilizing syntactic tree fragments results in exponentially high dimensional feature vectors, which is hard to compute. Alternatively, convolution parse tree kernels (Collins and Duffy, 2001), which implicitly explore the tree structure information, have been successfully applied in many NLP tasks, such as Semantic parsing (Moschitti, 2004) and Relation Extraction (Zhang et al. 2006). However, all those studies are carried out in monolingual tasks. In multilingual tasks such as machine translation, tree kernels are seldom applied.

In this paper, we propose Bilingual Tree Kernels (BTKs) to model the bilingual translational equivalences, in our case, to conduct sub-tree alignment. This is motivated by the decent effectiveness of tree kernels in expressing the similarity between tree structures. We propose two kinds of BTKs named dependent Bilingual Tree Kernel (dBTK), which takes the sub-tree pair as a whole and independent Bilingual Tree Kernel (iBTK), which individually models the source and the target sub-trees. Both kernels can be utilized within different feature spaces using various representations of the sub-structures.

Along with BTKs, various lexical and syntactic structural features are proposed to capture the correspondence between bilingual sub-trees using a polynomial kernel. We then attempt to combine the polynomial kernel and BTKs to construct a composite kernel. The sub-tree alignment task is considered as a binary classification problem. We employ a kernel based classifier with the composite kernel to classify each candidate of sub-tree pair as *aligned* or *unaligned*. Then a greedy search algorithm is performed according to the three criteria of sub-tree alignment within the space of candidates classified as *aligned*.

We evaluate the sub-tree alignment on both the gold standard tree bank and an automatically parsed corpus. Experimental results show that the proposed BTKs benefit sub-tree alignment on both corpora, along with the lexical features and the plain structural features. Further experiments in machine translation also suggest that the obtained sub-tree alignment can improve the performance of both phrase and syntax based SMT systems.

2 Bilingual Tree Kernels

In this section, we propose the two BTKs and study their capability and complexity in modeling the bilingual structural similarity. Before elaborating the concepts of BTKs, we first illustrate some notations to facilitate further understanding.

Each sub-tree pair $(S \cdot T)$ can be explicitly decomposed into multiple sub-structures which belong to the given sub-structure spaces. $\mathcal{S}_I = \{s_1, \dots, s_i, \dots, s_I\}$ refers to the *source* tree sub-structure space; while $\mathcal{T}_J = \{t_1, \dots, t_j, \dots, t_J\}$ refers to the *target* sub-structure space. A sub-structure pair (s_i, t_j) refers to an element in the set of the Cartesian product of the two sub-structure spaces: $(s_i, t_j) \in \mathcal{S}_I \times \mathcal{T}_J$.

2.1 Independent Bilingual Tree Kernel (iBTK)

Given the sub-structure spaces $\mathcal{S}_I$ and $\mathcal{T}_J$, we construct two vectors using the integer counts of the source and target sub-structures:

$$\phi(S) = \left(\#(s_1), \dots, \#(s_k), \dots, \#(s_{|\mathcal{S}_I|})\right)$$
$$\phi(T) = \left(\#(t_1), \dots, \#(t_k), \dots, \#(t_{|\mathcal{T}_J|})\right)$$

where $\#(s_k)$ and $\#(t_k)$ are the numbers of occurrences of the sub-structures s_k and t_k. In order to compute the dot product of the feature vectors in the exponentially high dimensional feature space, we introduce the tree kernel functions as follows:

$$\mathcal{K}_{iBTK}(S \cdot T, S' \cdot T') = \mathcal{K}(S, S') + \mathcal{K}(T, T')$$

The iBTK is defined as a composite kernel consisting of a source tree kernel and a target tree kernel which measures the source and the target structural similarity respectively. Therefore, the composite kernel can be computed using the ordinary monolingual tree kernels (Collins and Duffy, 2001).

$$\begin{aligned}&\mathcal{K}(S, S') = <\phi(S), \phi(S')> \\ &= \sum_{i=1}^{|\mathcal{S}_I|}\left(\sum_{n_s \in N_S} I_i(n_s) \cdot \sum_{n'_s \in N'_S} I_i(n'_s)\right) \\ &= \sum_{n_s \in N_S}\sum_{n'_s \in N'_S} \Delta(n_s, n'_s)\end{aligned}$$

where N_S and N'_S refer to the node sets of the source sub-tree S and S' respectvely. $I_i(n_s)$ is an indicator function which equals to 1 iff the sub-structure s_i is rooted at the node n_s and 0 otherwise. $\Delta(n_s, n'_s) = \sum_{i=1}^{|\mathcal{S}_I|}\left(I_i(n_s) \cdot I_i(n'_s)\right)$ is the number of identical sub-structures rooted at n_s and n'_s. Then we compute the $\Delta(n_s, n'_s)$ function as follows:

(1) If the production rule at n_s and n'_s are different, $\Delta(n_s, n'_s) = 0$;
(2)else if both $n_s$and $n'_s$are POS tags, $\Delta(n_s, n'_s) = \lambda$;
(3)else, $\Delta(n_s, n'_s) = \lambda \prod_{l=1}^{nc(n_s)} \left(1 + \Delta\left(c(n_s, l), c(n'_s, l)\right)\right)$.

where $nc(n_s)$ is the child number of n_s, $c(n_s, l)$ is the l^{th} child of n_s, λ is the decay factor used to make the kernel value less variable with respect to the number of sub-structures.

Similarly, we can decompose the target kernel as $\mathcal{K}(T, T') = \sum_{n_t \in N_T} \sum_{n'_t \in N'_T} \Delta(n_t, n'_t)$ and run the algorithm above as well.

The disadvantage of the iBTK is that it fails to capture the correspondence across the sub-structure pairs. However, the composite style of constructing the iBTK helps keep the computational complexity comparable to the monolingual tree kernel, which is $O(|N_S| \cdot |N'_S| + |N_T| \cdot |N'_T|)$.

2.2 Dependent Bilingual Tree Kernel (dBTK)

The iBTK explores the structural similarity of the source and the target sub-trees respectively. As an alternative, we further define a kernel to capture the relationship across the counterparts without increasing the computational complexity. As a result, we propose the dependent Bilingual Tree kernel (dBTK) to jointly evaluate the similarity across sub-tree pairs by enlarging the feature space to the Cartesian product of the two sub-structure sets.

A dBTK takes the source and the target sub-structure pair as a whole and recursively calculate over the joint sub-structures of the given sub-tree pair. We define the dBTK as follows:

Given the sub-structure space $\mathcal{S}_I \times \mathcal{T}_J$, we construct a vector using the integer counts of the sub-structure pairs to represent a sub-tree pair:

$$\phi(S \cdot T) = \begin{pmatrix} \#(s_1, t_1), \dots, \#(s_1, t_{|\mathcal{T}_J|}), \#(s_2, t_1), \\ \dots, \#(s_{|\mathcal{S}_I|}, t_1), \dots, \#(s_{|\mathcal{S}_I|}, t_{|\mathcal{T}_J|}) \end{pmatrix}$$

where $\#(s_i, t_j)$ is the number of occurrences of the sub-structure pair (s_i, t_j).

$$\begin{aligned}
&\mathcal{K}_{dBTK}(S \cdot T, S' \cdot T') \\
&= < \phi(S \cdot T), \phi(S' \cdot T') > \\
&= \sum_{k=1}^{|\mathcal{S}_I \times \mathcal{T}_J|} \begin{pmatrix} \sum_{n_s \in N_S} \sum_{n_t \in N_T} I_k(n_s, n_t) \cdot \\ \sum_{n'_s \in N'_S} \sum_{n'_t \in N'_T} I_k(n'_s, n'_t) \end{pmatrix} \\
&= \sum_{n_s \in N_S} \sum_{n_t \in N_T} \sum_{n'_s \in N'_S} \sum_{n'_t \in N'_T} \Delta \begin{pmatrix} (n_s, n_t), \\ (n'_s, n'_t) \end{pmatrix} \quad (1) \\

&= \sum_{n_s \in N_S} \sum_{n'_s \in N'_S} \Delta(n_s, n'_s) \sum_{n_t \in N_T} \sum_{n'_t \in N'_T} \Delta(n_t, n'_t) \\
&= \mathcal{K}(S, S') \cdot \mathcal{K}(T, T')
\end{aligned}$$

It is infeasible to explicitly compute the kernel function by expressing the sub-trees as feature vectors. In order to achieve convenient computation, we deduce the kernel function as the above.

The deduction from (1) to (2) is derived according to the fact that the number of identical sub-structure pairs rooted in the node pairs (n_s, n_t) and (n'_s, n'_t) equals to the product of the respective counts. As a result, the dBTK can be evaluated as a product of two monolingual tree kernels. Here we verify the correctness of the kernel by directly constructing the feature space for the inner product. Alternatively, Cristianini and Shawe-Taylor (2000) prove the positive semi-definite characteristic of the tensor product of two kernels. The decomposition benefits the efficient computation to use the algorithm for the monolingual tree kernel in Section 2.1.

The computational complexity of the dBTK is still $O(|N_S| \cdot |N'_S| + |N_T| \cdot |N'_T|)$.

3 Sub-structure Spaces for BTKs

The syntactic translational equivalences under BTKs are evaluated with respective to the sub-structures factorized from the candidate sub-tree pairs. In this section, we propose different sub-structures to facilitate the measurement of syntactic similarity for sub-tree alignment. Since the proposed BTKs can be computed by individually evaluating the source and target monolingual tree kernels, the definition of the sub-structure can be simplified to base only on monolingual sub-trees.

3.1 Subset Tree

Motivated from Collins and Duffy (2002) in monolingual tree kernels, the Subset Tree (SST) can be employed as sub-structures. An SST is any sub-graph, which includes more than one non-terminal node, with the constraint that the entire rule productions are included. Fig. 2 shows an example of the SSTs decomposed from the source sub-tree rooted at VP*.

3.2 Root directed Subset Tree

Monolingual Tree kernels achieve decent performance using the SSTs due to the rich exploration of syntactic information. However, the sub-tree alignment task requires strong capability of discriminating the sub-trees with their roots across adjacent generations, because those candidates share many identical SSTs. As illustrated in Fig 2, the source sub-tree rooted at VP*, which should be aligned to the target sub-tree rooted at NP*, may be likely aligned to the sub-tree rooted at PP*,

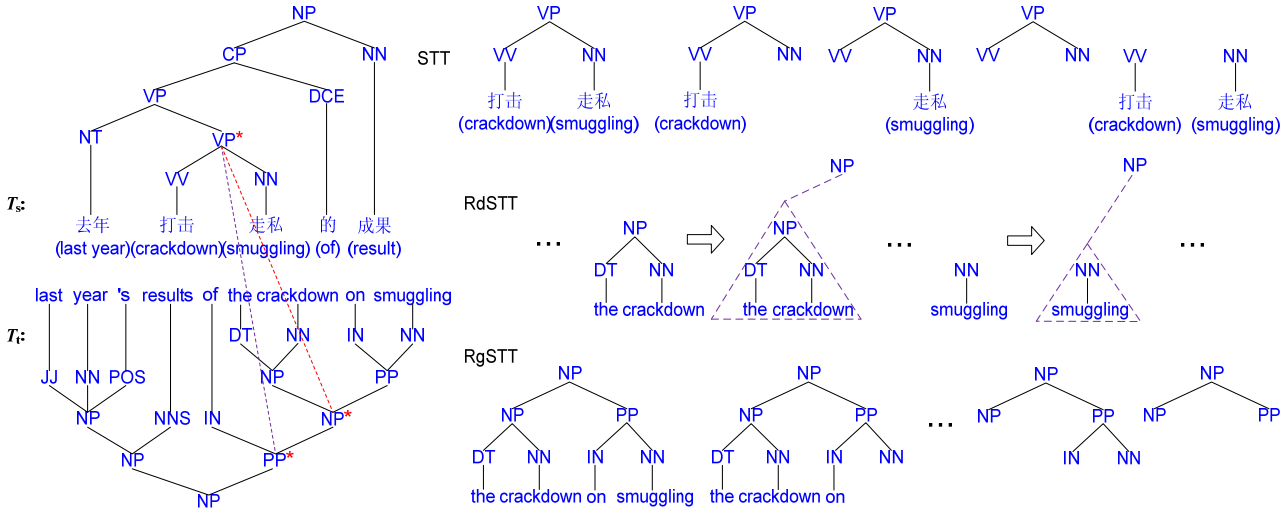

Figure 2: Illustration of SST, RdSST and RgSST

which shares quite a similar context with NP*. It is also easy to show that the latter shares all the SSTs that the former obtains. In consequence, the values of the SST based kernel function are quite similar between the candidate sub-tree pair rooted at (VP*,NP*) and (VP*,PP*).

In order to effectively differentiate the candidates like the above, we propose the Root directed Subset Tree (RdSST) by encapsulating each SST with the root of the given sub-tree. As shown in Fig 2, a sub-structure is considered identical to the given examples, when the SST is identical and the root tag of the given sub-tree is NP. As a result, the kernel function in Section 2.1 is re-defined as:

$$\mathcal{K}(S,S') = \sum_{n_s \in N_S} \sum_{n'_s \in N'_S} \Delta(n_s, n'_s) I(r_s, r'_s) = I(r_s, r'_s) \sum_{n_s \in N_S} \sum_{n'_s \in N'_S} \Delta(n_s, n'_s)$$

where r_s and r'_s are the root nodes of the sub-tree S and S' respectively. The indicator function $I(r_s, r'_s)$ equals to 1 if r_s and r'_s are identical, and 0 otherwise. Although defined for individual SST, the indicator function can be evaluated outside the summation, without increasing the computational complexity of the kernel function.

3.3 Root generated Subset Tree

Some grammatical tags (NP/VP) may have identical tags as their parents or children which may make RdSST less effective. Consequently, we step further to propose the sub-structure of Root generated Subset Tree (RgSST). An RgSST requires the root node of the given sub-tree to be part of the sub-structure. In other words, all sub-structures should be generated from the root of the given sub-tree as presented in Fig. 2. Therefore the kernel function can be simplified to only capture the sub-structure rooted at the root of the sub-tree.

$$\mathcal{K}(S,S') = \Delta(r_s, r'_s)$$

where r_s and r'_s are the root nodes of the sub-tree S and S' respectively. The time complexity is reduced to $O(|N_S| + |N'_S| + |N_T| + |N'_T|)$.

3.4 Root only

More aggressively, we can simplify the kernel to only measure the common root node without considering the complex tree structures. Therefore the kernel function is simplified to be a binary function with time complexity $O(1)$.

$$\mathcal{K}(S,S') = I(r_s, r'_s)$$

4 Plain features

Besides BTKs, we introduce various plain lexical features and structural features which can be expressed as feature functions. The lexical features with directions are defined as conditional feature functions based on the conditional lexical translation probabilities. The plain syntactic structural features can deal with the structural divergence of bilingual parse trees in a more general perspective.

4.1 Lexical and Word Alignment Features

In this section, we define seven lexical features to measure semantic similarity of a given sub-tree pair.

Internal Lexical Features: We define two lexical features with respective to the internal span of the sub-tree pair.

$$\phi_1(S|T) = \left(\prod_{v \in in(T)} \sum_{u \in in(S)} P(u|v)\right)^{\frac{1}{|in(T)|}}$$

$$\phi_2(T|S) = \left(\prod_{u\in in(S)} \sum_{v\in in(T)} P(v|u)\right)^{\frac{1}{|in(S)|}}$$

where $P(v|u)$ refers to the lexical translation probability from the source word u to the target word v within the sub-tree spans, while $P(u|v)$ refers to that from target to source; $in(S)$ refers to the word set for the internal span of the source sub-tree S, while $in(T)$ refers to that of the target sub-tree T.

Internal-External Lexical Features: These features are motivated by the fact that lexical translation probabilities within the translational equivalence tend to be high, and that of the non-equivalent counterparts tend to be low.

$$\phi_3(S|T) = \left(\prod_{v\in in(T)} \sum_{u\in out(S)} P(u|v)\right)^{\frac{1}{|in(T)|}}$$

$$\phi_4(T|S) = \left(\prod_{u\in in(S)} \sum_{v\in out(T)} P(v|u)\right)^{\frac{1}{|in(S)|}}$$

where $out(S)$ refers to the word set for the external span of the source sub-tree S, while $out(T)$ refers to that of the target sub-tree T.

Internal Word Alignment Features: The word alignment links account much for the co-occurrence of the aligned terms. We define the internal word alignment features as follows:

$$\phi_5(S,T) = \frac{\sum_{v\in in(T)} \sum_{u\in in(S)} \delta(u,v) \cdot \left(P(u|v) \cdot P(v|u)\right)^{\frac{1}{2}}}{(|in(S)| \cdot |in(T)|)^{\frac{1}{2}}}$$

where

$$\delta(u,v) = \begin{cases} 1 & \text{if } (u,v) \text{ is aligned} \\ 0 & \text{otherwise} \end{cases}$$

The binary function $\delta(u,v)$ is employed to trigger the computation only when a word aligned link exists for the two words (u,v) within the sub-tree span.

Internal-External Word Alignment Features: Similar to the lexical features, we also introduce the internal-external word alignment features as follows:

$$\phi_6(S,T) = \frac{\sum_{v\in in(T)} \sum_{u\in out(S)} \delta(u,v) \cdot \left(P(u|v) \cdot P(v|u)\right)^{\frac{1}{2}}}{(|out(S)| \cdot |in(T)|)^{\frac{1}{2}}}$$

$$\phi_7(S,T) = \frac{\sum_{v\in out(T)} \sum_{u\in in(S)} \delta(u,v) \cdot \left(P(u|v) \cdot P(v|u)\right)^{\frac{1}{2}}}{(|in(S)| \cdot |out(T)|)^{\frac{1}{2}}}$$

where

$$\delta(u,v) = \begin{cases} 1 & \text{if } (u,v) \text{ is aligned} \\ 0 & \text{otherwise} \end{cases}$$

4.2 Online Structural Features

In addition to the lexical correspondence, we also capture the structural divergence by introducing the following tree structural features.

Span difference: Translational equivalent sub-tree pairs tend to share similar length of spans. Thus the model will penalize the candidate sub-tree pairs with largely different length of spans.

$$\varphi_1(S,T) = \left|\frac{|in(S)|}{|in(\mathbf{S})|} - \frac{|in(T)|}{|in(\mathbf{T})|}\right|$$

S and **T** refer to the entire source and target parse trees respectively. Therefore, $|in(\mathbf{S})|$ and $|in(\mathbf{T})|$ are the respective span length of the parse tree used for normalization.

Number of Descendants: Similarly, the number of the root's descendants of the aligned sub-trees should also correspond.

$$\varphi_2(S,T) = \left|\frac{|R(S)|}{|R(\mathbf{S})|} - \frac{|R(T)|}{|R(\mathbf{T})|}\right|$$

where $R(.)$ refers to the descendant set of the root to a sub-tree.

Tree Depth difference: Intuitively, translational equivalent sub-tree pairs tend to have similar depth from the root of the parse tree. We allow the model to penalize the candidate sub-tree pairs with quite different distance of path from the root of the parse tree to the root of the sub-tree.

$$\varphi_3(S,T) = \left|\frac{Depth(S)}{Height(\mathbf{S})} - \frac{Depth(T)}{Height(\mathbf{T})}\right|$$

5 Alignment Model

Given feature spaces defined in the last two sections, we propose a 2-phase sub-tree alignment model as follows:

In the 1st phase, a kernel based classifier, SVM in our study, is employed to classify each candidate sub-tree pair as *aligned* or *unaligned*. The feature vector of the classifier is computed using a composite kernel:

$$\mathcal{K}(S\cdot T, S'\cdot T') =$$

$$\theta_0 \widehat{\mathcal{K}}_p(S\cdot T, S'\cdot T') + \sum_{\mathrm{i}=1}^{\mathrm{K}} \theta_{\mathrm{i}} \widehat{\mathcal{K}}_{BTK}^{i}(S\cdot T, S'\cdot T')$$

$\widehat{\mathcal{K}}_p(\cdot,\cdot)$ is the normalized form of the polynomial kennel $\mathcal{K}_p(\cdot,\cdot)$, which is a polynomial kernel with the degree of 2, utilizing the plain features. $\widehat{\mathcal{K}}_{BTK}^{i}(\cdot,\cdot)$ is the normalized form of the BTK $\mathcal{K}_{BTK}^{i}(\cdot,\cdot)$, exploring the corresponding sub-structure space. The composite kernel can be constructed using the polynomial kernel for plain features and various BTKs for tree structure by linear combination with coefficient θ_{i}, where $\sum_{\mathrm{i}=0}^{\mathrm{K}} \theta_{\mathrm{i}} = 1$.

In the 2nd phase, we adopt a greedy search with respect to the alignment probabilities. Since SVM is a large margin based discriminative classifier rather than a probabilistic model, we introduce a sigmoid function to convert the distance against the hyperplane to a posterior alignment probability as follows:

$$P(a_+|S,T) = \frac{1}{1+e^{-D_+}}$$

$$P(a_-|S,T) = \frac{1}{1+e^{-D_-}}$$

where D_+ is the distance for the instances classified as *aligned* and D_- is that for the *unaligned*. We use $P(a_+|S,T)$ as the confidence to conduct the *sure* links for those classified as *aligned*. On this perspective, the alignment probability is suitable as a searching metric. The search space is reduced to that of the candidates classified as *aligned* after the 1st phase.

6 Experiments on Sub-Tree Alignments

In order to evaluate the effectiveness of the alignment model and its capability in the applications requiring syntactic translational equivalences, we employ two corpora to carry out the sub-tree alignment evaluation. The first is HIT gold standard English Chinese parallel tree bank referred as HIT corpus[1]. The other is the automatically parsed bilingual tree pairs selected from FBIS corpus (allowing minor parsing errors) with human annotated sub-tree alignment.

6.1 Data preparation

HIT corpus, which is collected from English learning text books in China as well as example sentences in dictionaries, is used for the gold standard corpus evaluation. The word segmentation, tokenization and parse-tree in the corpus are manually constructed or checked. The corpus is constructed with manually annotated sub-tree alignment. The annotation strictly reserves the semantic equivalence of the aligned sub-tree pair. Only *sure* links are conducted in the internal node level, without considering *possible* links adopted in word alignment. A different annotation criterion of the Chinese parse tree, designed by the annotator, is employed. Compared with the widely used Penn TreeBank annotation, the new criterion utilizes some different grammar tags and is able to effectively describe some rare language phenomena in Chinese. The annotator still uses Penn TreeBank annotation on the English side. The statistics of HIT corpus used in our experiment is shown in Table 1. We use 5000 sentences for experiment and divide them into three parts, with 3k for training, 1k for testing and 1k for tuning the parameters of kernels and thresholds of pruning the negative instances.

[1]HIT corpus is designed and constructed by HIT-MITLAB. http://mitlab.hit.edu.cn/index.php/resources.html .

	Chinese	English
# of Sentence pair	5000	
Avg. Sentence Length	12.93	12.92
Avg. # of sub-tree	21.40	23.58
Avg. # of alignment	11.60	

Table 1. Corpus Statistics for HIT corpus

Most linguistically motivated syntax based SMT systems require an automatic parser to perform the rule induction. Thus, it is important to evaluate the sub-tree alignment on the automatically parsed corpus with parsing errors. In addition, HIT corpus is not applicable for MT experiment due to the problems of domain divergence, annotation discrepancy (Chinese parse tree employs a different grammar from Penn Treebank annotations) and degree of tolerance for parsing errors.

Due to the above issues, we annotate a new data set to apply the sub-tree alignment in machine translation. We randomly select 300 bilingual sentence pairs from the Chinese-English FBIS corpus with the length ≤ 30 in both the source and target sides. The selected plain sentence pairs are further parsed by Stanford parser (Klein and Manning, 2003) on both the English and Chinese sides. We manually annotate the sub-tree alignment for the automatically parsed tree pairs according to the definition in Section 1. To be fully consistent with the definition, we strictly reserve the semantic equivalence for the aligned sub-trees to keep a high precision. In other words, we do not conduct any doubtful links. The corpus is further divided into 200 aligned tree pairs for training and 100 for testing as shown in Table 2.

	Chinese	English
# of Sentence pair	300	
Avg. Sentence Length	16.94	20.81
Avg. # of sub-tree	28.97	34.39
Avg. # of alignment	17.07	

Table 2. Statistics of FBIS selected Corpus

6.2 Baseline approach

We implement the work in Tinsley et al. (2007) as our baseline methodology.

Given a tree pair $< \mathbf{S}, \mathbf{T} >$, the baseline approach first takes all the links between the sub-tree pairs as alignment hypotheses, i.e., the Cartesian product of the two sub-tree sets:

$$\{S_1, \dots, S_i, \dots, S_I\} \times \{T_1, \dots, T_j, \dots, T_J\}$$

By using the lexical translation probabilities, each hypothesis is assigned an alignment score. All hypotheses with zero score are pruned out.

Baseline	70.48	78.70	74.36

Table 4. Structure feature contribution for FBIS test set

Then the algorithm iteratively selects the link of the sub-tree pairs with the maximum score as a *sure* link, and blocks all hypotheses that contradict with this link and itself, until no non-blocked hypotheses remain.

The baseline system uses many heuristics in searching the optimal solutions with alternative score functions. Heuristic *skip1* skips the tied hypotheses with the same score, until it finds the highest-scoring hypothesis with no competitors of the same score. Heuristic *skip2* deals with the same problem. Initially, it skips over the tied hypotheses. When a hypothesis sub-tree pair (S_i, T_j) without any competitor of the same score is found, where neither S_i nor T_j has been skipped over, the hypothesis is chosen as a *sure* link. Heuristic *span1* postpones the selection of the hypotheses on the POS level. Since the highest-scoring hypotheses tend to appear on the leaf nodes, it may introduce ambiguity when conducting the alignment for a POS node whose child word appears twice in a sentence.

The baseline method proposes two score functions based on the lexical translation probability. They also compute the score function by splitting the tree into the internal and external components.

Tinsley et al. (2007) adopt the lexical translation probabilities dumped by GIZA++ (Och and Ney, 2003) to compute the span based scores for each pair of sub-trees. Although all of their heuristics combinations are re-implemented in our study, we only present the best result among them with the highest Recall and F-value as our baseline, denoted as *skip2_s1_span1*[2].

[2] s1 denotes score function 1 in Tinsley et al. (2007), skip2_s1_span1 denotes the utilization of heuristics skip2 and span1 while using score function 1

6.3 Experimental settings

We use SVM with binary classes as the classifier. In case of the implementation, we modify the Tree Kernel tool (Moschitti, 2004) and SVMLight (Joachims, 1999). The coefficient θ_i for the composite kernel are tuned with respect to F-measure (**F**) on the development set of HIT corpus. We empirically set C=2.4 for SVM and use $\alpha = 0.23$, the default parameter $\lambda = 0.4$ for BTKs.

Since the negative training instances largely overwhelm the positive instances, we prune the negative instances using the thresholds according to the lexical feature functions $(\phi_1, \phi_2, \phi_3, \phi_4)$ and online structural feature functions $(\varphi_1, \varphi_2, \varphi_3)$. Those thresholds are also tuned on the development set of HIT corpus with respect to F-measure.

To learn the lexical and word alignment features for both the proposed model and the baseline method, we train GIZA++ on the entire FBIS bilingual corpus (240k). The evaluation is conducted by means of Precision (**P**), Recall (**R**) and F-measure (**F**).

6.4 Experimental results

In Tables 3 and 4, we incrementally enlarge the feature spaces in certain order for both corpora and examine the feature contribution to the alignment results. In detail, the iBTKs and dBTKs are firstly combined with the polynomial kernel for plain features individually, then the best iBTK and dBTK are chosen to construct a more complex composite kernel along with the polynomial kernel for both corpora. The experimental results show that:

- All the settings with structural features of the proposed approach achieve better performance than the baseline method. This is because the

baseline only assesses semantic similarity using the lexical features. The improvement suggests that the proposed framework with syntactic structural features is more effective in modeling the bilingual syntactic correspondence.

- By introducing BTKs to construct a composite kernel, the performance in both corpora is significantly improved against only using the polynomial kernel for plain features. This suggests that the structural features captured by BTKs are quite useful for the sub-tree alignment task. We also try to use BTKs alone without the polynomial kernel for plain features; however, the performance is rather low. This suggests that the structure correspondence cannot be used to measure the semantically equivalent tree structures alone, since the same syntactic structure tends to be reused in the same parse tree and lose the ability of disambiguation to some extent. In other words, to capture the semantic similarity, structure features requires lexical features to cooperate.
- After comparing iBTKs with the corresponding dBTKs, we find that for *FBIS* corpus, iBTK greatly outperforms dBTK in any feature space except the Root space. However, when it comes the *HIT* corpus, the gaps between the corresponding iBTKs and dBTKs are much closer, while on the Root space, dBTK outperforms iBTK to a large amount. This finding can be explained by the relationship between the amount of training data and the high dimensional feature space. Since dBTKs are constructed in a joint manner which obtains a much larger high dimensional feature space than those of iBTKs, dBTKs require more training data to excel its capability, otherwise it will suffer from the data sparseness problem. The reason that dBTK outperforms iBTK in the feature space of Root in *FBIS* corpus is that although it is a joint feature space, the Root node pairs can be constructed from a close set of grammar tags and to form a relatively low dimensional space.

  As a result, when applying to *FBIS* corpus, which only contains limited amount of training data, dBTKs will suffer more from the data sparseness problem, and therefore, a relatively low performance. When enlarging the amount of training corpus to the *HIT* corpus, the ability of dBTKs excels and the benefit from data increasing of dBTKs is more significant than iBTKs.
- We also find that the introduction of BTKs gains more improvement in HIT gold standard corpus than in FBIS corpus. Other than the factor of the amount of training data, this is also because the plain features in Table 3 are not as effective as those in Table 4, since they are trained on FBIS corpus which facilitates Table 4 more with respect to the domains. On the other hand, the grammatical tags and syntactic tree structures are more accurate in HIT corpus, which facilitates the performance of BTKs in Table 3.
- On the comparison across the different feature spaces of BTKs, we find that STT, RdSTT and TgSTT are rather selective, since **Recall**s of those feature spaces are relatively low, exp. for HIT corpus. However, the Root sub-structure obtains a satisfactory **Recall** for both corpora. That's why we attempt to construct a more complex composite kernel in adoption of the kernel of dBTK-Root as below.
- To gain an extra performance boosting, we further construct a composite kernel which includes the best iBTK and the best dBTK for each corpus along with the polynomial kernel for plain features. In the HIT corpus, we use dBTK in the Root space and iBTK in the RgSST space; while for FBIS corpus, we use dBTK in the Root space and iBTK in the RdSST space. The experimental results suggest that by combining iBTK and dBTK together, we can achieve more improvement.

7 Experiments on Machine Translation

In addition to the intrinsic alignment evaluation, we further conduct the extrinsic MT evaluation. We explore the effectiveness of sub-tree alignment for both phrase based and linguistically motivated syntax based SMT systems.

7.1 Experimental configuration

In the experiments, we train the translation model on FBIS corpus (7.2M (Chinese) + 9.2M (English) words in 240,000 sentence pairs) and train a 4-gram language model on the Xinhua portion of the English Gigaword corpus (181M words) using the SRILM Toolkits (Stolcke, 2002). We use these sentences with less than 50 characters from the NIST MT-2002 test set as the development set (to speed up tuning for syntax based system) and the NIST MT-2005 test set as our test set. We use the Stanford parser (Klein and Manning, 2003) to parse bilingual sentences on the training set and Chinese sentences on the development and test set. The evaluation metric is case-sensitive BLEU-4.

System	Model	BLEU
Moses	BP*	23.86
	DirC	23.98
	EWoS	24.48
Syntax STSG	STSG	24.71
	DirC	25.16
	EWoS	25.38
Syntax STSSG	STSSG	25.92
	DirC	25.95
	EWoS	26.45

Table 5. MT evaluation on various systems
*BP denotes bilingual phrases

For the phrase based system, we use Moses (Koehn et al., 2007) with its default settings. For the syntax based system, since sub-tree alignment can directly benefit Tree-2-Tree based systems, we apply the sub-tree alignment in a syntax system based on Synchronous Tree Substitution Grammar (STSG) (Zhang et al., 2007). The STSG based decoder uses a pair of *elementary tree*[3] as a basic translation unit. Recent research on tree based systems shows that relaxing the restriction from tree structure to tree sequence structure (Synchronous Tree Sequence Substitution Grammar: STSSG) significantly improves the translation performance (Zhang et al., 2008). We implement the STSG/STSSG based model in the Pisces decoder with the identical features and settings in Sun et al. (2009). In the Pisces decoder, the STSSG based decoder translates each span iteratively in a bottom up manner which guarantees that when translating a source span, any of its sub-spans is already translated. The STSG based decoding can be easily performed with the STSSG decoder by restricting the translation rule set to be elementary tree pairs only.

As for the alignment setting, we use the word alignment trained on the entire FBIS (240k) corpus by GIZA++ with heuristic grow-diag-final for both Moses and the syntax system. For sub-tree-alignment, we use the above word alignment to learn lexical/word alignment feature, and train with the FBIS training corpus (200) using the composite kernel of Plain+dBTK-Root+iBTK-RdSTT.

7.2 Experimental results

Compared with the adoption of word alignment, translational equivalences generated from structural alignment tend to be more grammatically aware and syntactically meaningful. However, utilizing syntactic translational equivalences alone for machine translation loses the capability of modeling non-syntactic phrases (Koehn et al., 2003). Consequently, instead of using phrases constraint by sub-tree alignment alone, we attempt to combine word alignment and sub-tree alignment and deploy the capability of both with two methods.

- *Directly Concatenate* (DirC) is operated by directly concatenating the rule set genereted from sub-tree alignment and the original rule set generated from word alignment (Tinsley et al., 2009). As shown in Table 5, we gain minor improvement in the Bleu score for all configurations.
- Alternatively, we proposed a new approach to generate the rule set from the scratch. We constrain the bilingual phrases to be consistent with *Either Word alignment or Sub-tree alignment* (EWoS) instead of being originally consistent with the word alignment only. The method helps tailoring the rule set decently without redundant counts for syntactic rules. The performance is further improved compared to DirC in all systems.

The findings suggest that with the modeling of non-syntactic phrases maintained, more emphasis on syntactic phrases can benefit both the phrase and syntax based SMT systems.

8 Conclusion

In this paper, we explore syntactic structure features by means of Bilingual Tree Kernels and apply them to bilingual sub-tree alignment along with various lexical and plain structural features. We use both gold standard tree bank and the automatically parsed corpus for the sub-tree alignment evaluation. Experimental results show that our model significantly outperforms the baseline method and the proposed Bilingual Tree Kernels are very effective in capturing the cross-lingual structural similarity. Further experiment shows that the obtained sub-tree alignment benefits both phrase and syntax based MT systems by delivering more weight on syntactic phrases.

Acknowledgments
We thank MITLAB[4] in Harbin Institute of Technology for licensing us their sub-tree alignment corpus for our research.

[3] An elementary tree is a fragment whose leaf nodes can be either non-terminal symbols or terminal symbols.

Abstract

While Inversion Transduction Grammar (ITG) has regained more and more attention in recent years, it still suffers from the major obstacle of speed. We propose a discriminative ITG pruning framework using Minimum Error Rate Training and various features from previous work on ITG alignment. Experiment results show that it is superior to all existing heuristics in ITG pruning. On top of the pruning framework, we also propose a discriminative ITG alignment model using hierarchical phrase pairs, which improves both F-score and Bleu score over the baseline alignment system of GIZA++.

1 Introduction

Inversion transduction grammar (ITG) (Wu, 1997) is an adaptation of SCFG to bilingual parsing. It does synchronous parsing of two languages with phrasal and word-level alignment as by-product. For this reason ITG has gained more and more attention recently in the word alignment community (Zhang and Gildea, 2005; Cherry and Lin, 2006; Haghighi *et al.*, 2009).

A major obstacle in ITG alignment is speed. The original (unsupervised) ITG algorithm has complexity of $O(n^6)$. When extended to supervised/discriminative framework, ITG runs even more slowly. Therefore all attempts to ITG alignment come with some pruning method. For example, Haghighi *et al.* (2009) do pruning based on the probabilities of links from a simpler alignment model (viz. HMM); Zhang and Gildea (2005) propose Tic-tac-toe pruning, which is based on the Model 1 probabilities of word pairs inside and outside a pair of spans.

As all the principles behind these techniques have certain contribution in making good pruning decision, it is tempting to incorporate all these features in ITG pruning. In this paper, we propose a novel discriminative pruning framework for discriminative ITG. The pruning model uses no more training data than the discriminative ITG parser itself, and it uses a log-linear model to integrate all features that help identify the correct span pair (like Model 1 probability and HMM posterior). On top of the discriminative pruning method, we also propose a discriminative ITG alignment system using hierarchical phrase pairs.

In the following, some basic details on the ITG formalism and ITG parsing are first reviewed (Sections 2 and 3), followed by the definition of pruning in ITG (Section 4). The "Discriminative Pruning for Discriminative ITG" model (DPDI) and our discriminative ITG (DITG) parsers will be elaborated in Sections 5 and 6 respectively. The merits of DPDI and DITG are illustrated with the experiments described in Section 7.

2 Basics of ITG

The simplest formulation of ITG contains three types of rules: terminal unary rules $X \rightarrow e/f$, where e and f represent words (possibly a null word, ε) in the English and foreign language respectively, and the binary rules $X \rightarrow [X, X]$ and $X \rightarrow \langle X, X \rangle$, which refer to that the component English and foreign phrases are combined in the same and inverted order respectively.

From the viewpoint of word alignment, the terminal unary rules provide the links of word pairs, whereas the binary rules represent the reordering factor. One of the merits of ITG is that it is less biased towards short-distance reordering.

Such a formulation has two drawbacks. First of all, it imposes a 1-to-1 constraint in word alignment. That is, a word is not allowed to align to more than one word. This is a strong limitation as no idiom or multi-word expression is allowed to align to a single word on the other side. In fact there have been various attempts in relaxing the 1-to-1 constraint. Both ITG alignment

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 316–324,
Uppsala, Sweden, 11-16 July 2010.

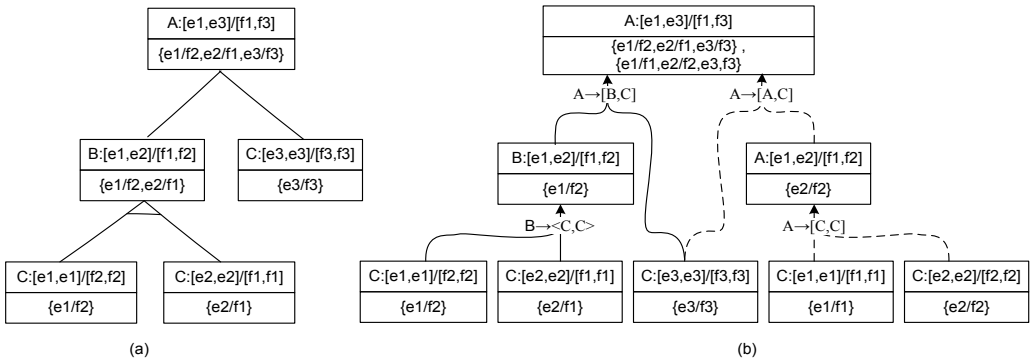

Figure 1: Example ITG parses in graph (a) and hypergraph (b).

approaches with and without this constraint will be elaborated in Section 6.

Secondly, the simple ITG leads to redundancy if word alignment is the sole purpose of applying ITG. For instance, there are two parses for three consecutive word pairs, viz. $[a/a'\,[b/b'\,c/c']\,]$ and $[[a/a'\,b/b']\,c/c']$. The problem of redundancy is fixed by adopting ITG normal form. In fact, normal form is the very first key to speeding up ITG. The ITG normal form grammar as used in this paper is described in Appendix A.

3 Basics of ITG Parsing

Based on the rules in normal form, ITG word alignment is done in a similar way to chart parsing (Wu, 1997). The base step applies all relevant terminal unary rules to establish the links of word pairs. The word pairs are then combined into span pairs in all possible ways. Larger and larger span pairs are recursively built until the sentence pair is built.

Figure 1(a) shows one possible derivation for a toy example sentence pair with three words in each sentence. Each node (rectangle) represents a pair, marked with certain phrase category, of foreign span (F-span) and English span (E-span) (the upper half of the rectangle) and the associated alignment hypothesis (the lower half). Each graph like Figure 1(a) shows only one derivation and also only one alignment hypothesis.

The various derivations in ITG parsing can be compactly represented in hypergraph (Klein and Manning, 2001) like Figure 1(b). Each hypernode (rectangle) comprises both a span pair (upper half) and the list of possible alignment hypotheses (lower half) for that span pair. The hyperedges show how larger span pairs are derived from smaller span pairs. Note that a hypernode may have more than one alignment hypothesis, since a hypernode may be derived through more than one hyperedge (e.g. the topmost hypernode in Figure 1(b)). Due to the use of normal form, the hypotheses of a span pair are different from each other.

4 Pruning in ITG Parsing

The ITG parsing framework has three levels of pruning:

1) To discard some unpromising span pairs;
2) To discard some unpromising F-spans and/or E-spans;
3) To discard some unpromising alignment hypotheses for a particular span pair.

The second type of pruning (used in Zhang *et. al.* (2008)) is very radical as it implies discarding too many span pairs. It is empirically found to be highly harmful to alignment performance and therefore not adopted in this paper.

The third type of pruning is equivalent to minimizing the beam size of alignment hypotheses in each hypernode. It is found to be well handled by the K-Best parsing method in Huang and Chiang (2005). That is, during the bottom-up construction of the span pair repertoire, each span pair keeps only the best alignment hypothesis. Once the complete parse tree is built, the k-best list of the topmost span is obtained by minimally expanding the list of alignment hypotheses of minimal number of span pairs.

The first type of pruning is equivalent to minimizing the number of hypernodes in a hypergraph. The task of ITG pruning is defined in this paper as the first type of pruning; i.e. the search for, given an F-span, the minimal number of E-spans which are the most likely counterpart of that F-span.[1] The pruning method should maintain a balance between efficiency (run as quickly as possible) and performance (keep as many correct span pairs as possible).

[1] Alternatively it can be defined as the search of the minimal number of E-spans per F-span. That is simply an arbitrary decision on how the data are organized in the ITG parser.

A naïve approach is that the required pruning method outputs a score given a span pair. This score is used to rank all E-spans for a particular F-span, and the score of the correct E-span should be in general higher than most of the incorrect ones.

5 The DPDI Framework

DPDI, the discriminative pruning model proposed in this paper, assigns score to a span pair $(\bar{f}, \bar{e})$ as probability from a log-linear model:

$$P(\bar{e}|\bar{f}) = \frac{exp(\sum_i \lambda_i \Psi_i(\bar{f}, \bar{e}))}{\sum_{\bar{e}' \in E} exp(\sum_i \lambda_i \Psi_i(\bar{f}, \bar{e}'))} \quad (1)$$

where each $\Psi_i(\bar{f}, \bar{e})$ is some feature about the span pair, and each λ is the weight of the corresponding feature. There are three major questions to this model:

1) How to acquire training samples? (Section 5.1)
2) How to train the parameters λ ? (Section 5.2)
3) What are the features? (Section 5.3)

5.1 Training Samples

Discriminative approaches to word alignment use manually annotated alignment for sentence pairs. Discriminative pruning, however, handles not only a sentence pair but every possible span pair. The required training samples consist of various F-spans and their corresponding E-spans.

Rather than recruiting annotators for marking span pairs, we modify the parsing algorithm in Section 3 so as to produce span pair annotation out of sentence-level annotation. In the base step, only the word pairs listed in sentence-level annotation are inserted in the hypergraph, and the recursive steps are just the same as usual.

If the sentence-level annotation satisfies the alignment constraints of ITG, then each F-span will have only one E-span in the parse tree. However, in reality there are often the cases where a foreign word aligns to more than one English word. In such cases the F-span covering that foreign word has more than one corresponding E-spans. Consider the example in Figure 2, where the golden links in the alignment annotation are $e1/f1$, $e2/f1$, and $e3/f2$; i.e. the foreign word $f1$ aligns to both the English words $e1$ and $e2$. Therefore the F-span $[f1, f1]$ aligns to the E-span $[e1, e1]$ in one hypernode and to the E-span $[e2, e2]$ in another hypernode. When such situation happens, we calculate the product of the inside and outside probability of each alignment hypothesis of the span pair, based on the probabilities of the links from some simpler alignment model[2]. The E-span with the most probable hypothesis is selected as the alignment of the F-span.

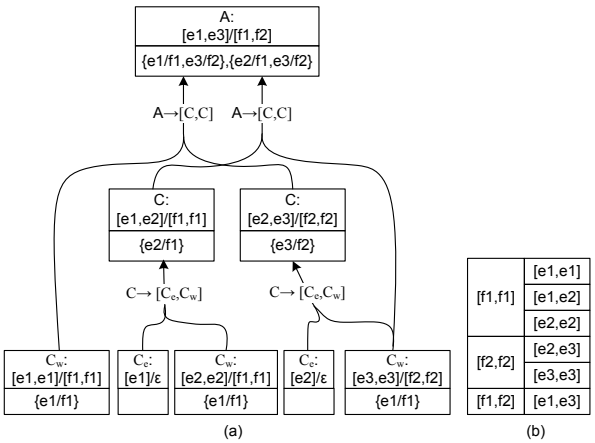

Figure 2: Training sample collection.

Table (b) lists, for the hypergraph in (a), the candidate E-spans for each F-span.

It should be noted that this automatic span pair annotation may violate some of the links in the original sentence-level alignment annotation. We have already seen how the 1-to-1 constraint in ITG leads to the violation. Another situation is the 'inside-out' alignment pattern (c.f. Figure 3). The ITG reordering constraint cannot be satisfied unless one of the links in this pattern is removed.

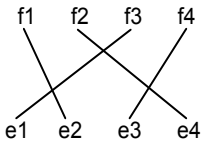

Figure 3: An example of inside-out alignment

The training samples thus obtained are positive training samples. If we apply some classifier for parameter training, then negative samples are also needed. Fortunately, our parameter training does not rely on any negative samples.

5.2 MERT for Pruning

Parameter training of DPDI is based on Minimum Error Rate Training (MERT) (Och, 2003), a widely used method in SMT. MERT for SMT estimates model parameters with the objective of minimizing certain measure of translation errors (or maximizing certain performance measure of translation quality) for a development corpus. Given an SMT system which produces, with

[2] The formulae of the inside and outside probability of a span pair will be elaborated in Section 5.3. The simpler alignment model we used is HMM.

model parameters λ_1^M, the K-best candidate translations $\hat{e}(f_s; \lambda_1^M)$ for a source sentence f_s, and an error measure $E(r_s, e_{s,k})$ of a particular candidate $e_{s,k}$ with respect to the reference translation r_s, the optimal parameter values will be:

$$\hat{\lambda}_1^M = \underset{\lambda_1^M}{argmin}\left\{\sum_{s=1}^{S} E\left(r_s, \hat{e}(f_s; \lambda_1^M)\right)\right\}$$

$$= \underset{\lambda_1^M}{argmin}\left\{\sum_{s=1}^{S}\sum_{k=1}^{K} E\left(r_s, e_{s,k}\right)\delta(\hat{e}(f_s; \lambda_1^M), e_{s,k})\right\}$$

DPDI applies the same equation for parameter tuning, with different interpretation of the components in the equation. Instead of a development corpus with reference translations, we have a collection of training samples, each of which is a pair of F-span (f_s) and its corresponding E-span (r_s). These samples are acquired from some manually aligned dataset by the method elaborated in Section 5.1. The ITG parser outputs for each f_s a K-best list of E-spans $\hat{e}(f_s; \lambda_1^M)$ based on the current parameter values λ_1^M.

The error function is based on the presence and the rank of the correct E-span in the K-best list:

$$E\left(r_s, \hat{e}(f_s; \lambda_1^M)\right) = \begin{cases} -rank(r_s) \; if \; r_s \in \hat{e}(f_s; \lambda_1^M) \\ penalty \quad otherwise \end{cases} \tag{2}$$

where $rank(r_s)$ is the (0-based) rank of the correct E-span r_s in the K-best list $\hat{e}(f_s; \lambda_1^M)$. If r_s is not in the K-best list at all, then the error is defined to be $penalty$, which is set as *-100000* in our experiments. The rationale underlying this error function is to keep as many correct E-spans as possible in the K-best lists of E-spans, and push the correct E-spans upward as much as possible in the K-best lists.

This new error measure leads to a change in details of the training algorithm. In MERT for SMT, the interval boundaries at which the performance or error measure changes are defined by the *upper envelope* (illustrated by the dash line in Figure 4(a)), since the performance/error measure depends on the best candidate translation. In MERT for DPDI, however, the error measure depends on the correct E-span rather than the E-span leading to the highest system score. Thus the interval boundaries are the intersections between the correct E-span and all other candidate E-spans (as shown in Figure 4(b)). The rank of the correct E-span in each interval can then be figured out as shown in Figure 4(c). Finally, the error measure in each interval can be calculated by Equation (2) (as shown in Figure 4(d)). All other steps in MERT for DPDI are the same as that for SMT.

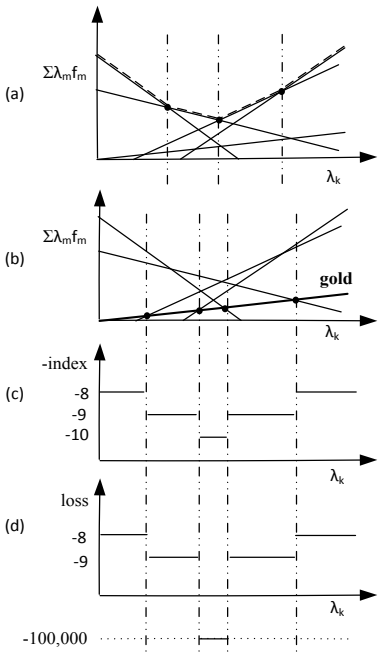

Figure 4: MERT for DPDI

Part (a) shows how intervals are defined for SMT and part (b) for DPDI. Part (c) obtains the rank of correct E-spans in each interval and part (d) the error measure. Note that the beam size (max number of E-spans) for each F-span is 10.

5.3 Features

The features used in DPDI are divided into three categories:

1) Model 1-based probabilities. Zhang and Gildea (2005) show that Model 1 (Brown *et al.*, 1993; Och and Ney., 2000) probabilities of the word pairs inside and outside a span pair ($[e_{i1}, e_{i2}]/[f_{j1}, f_{j2}]$) are useful. Hence these two features:
   a) Inside probability (i.e. probability of word pairs within the span pair):

$$p_{inc}\left(e_{i1,i2}|f_{j1,j2}\right) = \prod_{i\in(i1,i2)}\sum_{j\in(j1,j2)}\frac{1}{(j2-j1)}p_{M1}(e_i|f_j)$$

   b) Outside probability (i.e. probability of the word pairs outside the span pair):

$$p_{out}\left(e_{i1,i2}|f_{j1,j2}\right) = \prod_{i\notin(i1,i2)}\sum_{j\notin(j1,j2)}\frac{1}{(J-j2+j1)}p_{M1}(e_i|f_j)$$

   where J is the length of the foreign sentence.
2) Heuristics. There are four features in this category. The features are explained with the

example of Figure 5, in which the span pair in interest is $[e2, e3]/[f1, f2]$. The four links are produced by some simpler alignment model like HMM. The word pair $e2/f1$ is the only link in the span pair. The links $e4/f2$ and $e3/f3$ are inconsistent with the span pair.[3]

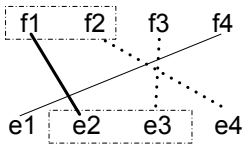

Figure 5: Example for heuristic features

a) Link ratio: $\frac{2\times\#links}{flen+elen}$
where $\#links$ is the number of links in the span pair, and $flen$ and $elen$ are the length of the foreign and English spans respectively. The feature value of the example span pair is (2*1)/(2+2)=0.5.

b) inconsistent link ratio: $\frac{2\times\#links_{incon}}{flen+elen}$
where $\#links_{incon}$ is the number of links which are inconsistent with the phrase pair according to some simpler alignment model (e.g. HMM). The feature value of the example is (2*2)/(2+2) =1.0.

c) Length ratio: $\left|\frac{flen}{elen} - ratio_{avg}\right|$
where $ratio_{avg}$ is defined as the average ratio of foreign sentence length to English sentence length, and it is estimated to be around 1.15 in our training dataset. The rationale underlying this feature is that the ratio of span length should not be too deviated from the average ratio of sentence length. The feature value for the example is |2/2-1.15|=0.15.

d) Position Deviation: $\left|pos_{\bar{f}} - pos_{\bar{e}}\right|$
where $pos_{\bar{f}}$ refers to the position of the F-span in the entire foreign sentence, and it is defined as $\frac{1}{2J}\left(start_{\bar{f}} + end_{\bar{f}}\right)$, $start_{\bar{f}}$ /$end_{\bar{f}}$ being the position of the first/last word of the F-span in the foreign sentence. $pos_{\bar{e}}$ is defined similarly. The rationale behind this feature is the monotonic assumption, i.e. a phrase of the foreign sentence usually occupies roughly the same position of the equivalent English phrase. The feature value for the example is |(1+2)/(2*4)-(2+3)/(2*4)| =0.25.

3) HMM-based probabilities. Haghighi *et al.* (2009) show that posterior probabilities from the HMM alignment model is useful for pruning. Therefore, we design two new features by replacing the link count in link ratio and inconsistent link ratio with the sum of the link's posterior probability.

6 The DITG Models

The discriminative ITG alignment can be conceived as a two-staged process. In the first stage DPDI selects good span pairs. In the second stage good alignment hypotheses are assigned to the span pairs selected by DPDI. Two discriminative ITG (DITG) models are investigated. One is word-to-word DITG (henceforth W-DITG), which observes the 1-to-1 constraint on alignment. Another is DITG with hierarchical phrase pairs (henceforth HP-DITG), which relaxes the 1-to-1 constraint by adopting hierarchical phrase pairs in Chiang (2007).

Each model selects the best alignment hypotheses of each span pair, given a set of features. The contributions of these features are integrated through a log linear model (similar to Liu *et al.*, 2005; Moore, 2005) like Equation (1). The discriminative training of the feature weights is again MERT (Och, 2003). The MERT module for DITG takes alignment F-score of a sentence pair as the performance measure. Given an input sentence pair and the reference annotated alignment, MERT aims to maximize the F-score of DITG-produced alignment. Like SMT (and unlike DPDI), it is the upper envelope which defines the intervals where the performance measure changes.

6.1 Word-to-word DITG

The following features about alignment link are used in W-DITG:

1) Word pair translation probabilities trained from HMM model (Vogel, *et.al.*, 1996) and IBM model 4 (Brown *et.al.*, 1993; Och and Ney, 2000).
2) Conditional link probability (Moore, 2005).
3) Association score rank features (Moore *et al.*, 2006).
4) Distortion features: counts of inversion and concatenation.
5) Difference between the relative positions of the words. The relative position of a word in a sentence is defined as the posi-

[3] An inconsistent link connects a word within the phrase pair to some word outside the phrase pair. C.f. Deng *et al.* (2008)

tion of the word divided by sentence length.

6) Boolean features like whether a word in the word pair is a stop word.

6.2 DITG with Hierarchical Phrase Pairs

The 1-to-1 assumption in ITG is a serious limitation as in reality there are always segmentation or tokenization errors as well as idiomatic expressions. Wu (1997) proposes a bilingual segmentation grammar extending the terminal rules by including phrase pairs. Cherry and Lin (2007) incorporate phrase pairs in phrase-based SMT into ITG, and Haghighi *et al.* (2009) introduce Block ITG (BITG), which adds 1-to-many or many-to-1 terminal unary rules.

It is interesting to see if DPDI can benefit the parsing of a more realistic ITG. HP-DITG extends Cherry and Lin's approach by not only employing simple phrase pairs but also hierarchical phrase pairs (Chiang, 2007). The grammar is enriched with rules of the format: $X \rightarrow \bar{e}_i / \bar{f}_i$ where $\bar{e}_i$ and $\bar{f}_i$ refer to the English and foreign side of the *i*-th (simple/hierarchical) phrase pair respectively.

As example, if there is a simple phrase pair $X \rightarrow \langle North\ Korea, 北\ 朝鲜 \rangle$, then it is transformed into the ITG rule $C \rightarrow$ "*North Korea*"/"北 朝鲜". During parsing, each span pair does not only examine all possible combinations of sub-span pairs using binary rules, but also checks if the yield of that span pair is exactly the same as that phrase pair. If so, then the alignment links within the phrase pair (which are obtained in standard phrase pair extraction procedure) are taken as an alternative alignment hypothesis of that span pair.

For a hierarchical phrase pair like $X \rightarrow \langle X_1\ of\ X_2, X_2\ 的\ X_1 \rangle$, it is transformed into the ITG rule $C \rightarrow$ "X_1 *of* X_2"/"X_2 的 X_1" during parsing, each span pair checks if it contains the lexical anchors *"of"* and "的", and if the remaining words in its yield can form two sub-span pairs which fit the reordering constraint among X_1 and X_2. (Note that span pairs of any category in the ITG normal form grammar can substitute for X_1 or X_2.) If both conditions hold, then the span pair is assigned an alignment hypothesis which combines the alignment links among the lexical anchors ($like\ of$/的) and those links among the sub-span pairs.

HP-ITG acquires the rules from HMM-based word-aligned corpus using standard phrase pair extraction as stated in Chiang (2007). The rule probabilities and lexical weights in both English-to-foreign and foreign-to-English directions are estimated and taken as features, in addition to those features in W-DITG, in the discriminative model of alignment hypothesis selection.

7 Evaluation

DPDI is evaluated against the baselines of Tic-tac-toe (TTT) pruning (Zhang and Gildea, 2005) and Dynamic Program (DP) pruning (Haghighi *et al.*, 2009; DeNero *et al.*, 2009) with respect to Chinese-to-English alignment and translation. Based on DPDI, HP-DITG is evaluated against the alignment systems GIZA++ and BITG.

7.1 Evaluation Criteria

Four evaluation criteria are used in addition to the time spent on ITG parsing. We will first evaluate pruning regarding the pruning decisions themselves. That is, the first evaluation metric, pruning error rate (henceforth PER), measures how many correct E-spans are discarded. The major drawback of PER is that not all decisions in pruning would impact on alignment quality, since certain F-spans are of little use to the entire ITG parse tree.

An alternative criterion is the upper bound on alignment F-score, which essentially measures how many links in annotated alignment can be kept in ITG parse. The calculation of F-score upper bound is done in a bottom-up way like ITG parsing. All leaf hypernodes which contain a correct link are assigned a score (known as hit) of 1. The hit of a non-leaf hypernode is based on the sum of hits of its daughter hypernodes. The maximal sum among all hyperedges of a hypernode is assigned to that hypernode. Formally,

$$hit\big(X[\bar{f}, \bar{e}]\big) = \max_{Y,Z,\bar{f}_1,\bar{e}_1,\bar{f}_2,\bar{e}_2} \big(hit\big(Y[\bar{f}_1, \bar{e}_1]\big) + hit[\bar{f}_2, \bar{e}_2]\big)$$

$$hit(C_w[u, v]) = \begin{cases} 1 & if\ \langle u, v \rangle \in R \\ 0 & otherwise \end{cases}$$

$$hit(C_e) = 0; hit\big(C_f\big) = 0$$

where X, Y, Z are variables for the categories in ITG grammar, and R comprises the golden links in annotated alignment. C_w, C_e, C_f are defined in Appendix A.

Figure 6 illustrates the calculation of the hit score for the example in Section 5.1/Figure 2. The upper bound of recall is the hit score divided by the total number of golden links. The upper

ID	pruning	beam size	pruning/total time cost	PER	F-UB	F-score

2	TTT	10	**58''/4'51''**	8.6%	93.0%	84.8%
3	TTT	20	53''/12'5''	5.2%	**94.0%**	86.5%
4	DP	--	11''/15'39''	12.1%	91.4%	83.6%

Table 2: Evaluation of DPDI against TTT (Tic-tac-toe) and DP (Dynamic Program) for HP-DITG.

bound of precision, which should be defined as the hit score divided by the number of links produced by the system, is almost always 1.0 in practice. The upper bound of alignment F-score can thus be calculated as well.

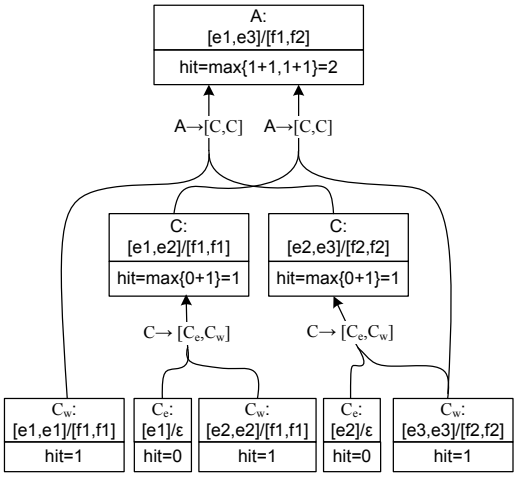

Figure 6: Recall Upper Bound Calculation

Finally, we also do end-to-end evaluation using both F-score in alignment and Bleu score in translation. We use our implementation of hierarchical phrase-based SMT (Chiang, 2007), with standard features, for the SMT experiments.

7.2 Experiment Data

Both discriminative pruning and alignment need training data and test data. We use the manually aligned Chinese-English dataset as used in Haghighi *et al.* (2009). The 491 sentence pairs in this dataset are adapted to our own Chinese word segmentation standard. 250 sentence pairs are used as training data and the other 241 are test data. The corresponding numbers of F-spans in training and test data are 4590 and 3951 respectively.

In SMT experiments, the bilingual training dataset is the NIST training set excluding the Hong Kong Law and Hong Kong Hansard, and our 5-gram language model is trained from the Xinhua section of the Gigaword corpus. The NIST'03 test set is used as our development corpus and the NIST'05 and NIST'08 test sets are our test sets.

7.3 Small-scale Evaluation

The first set of experiments evaluates the performance of the three pruning methods using the small 241-sentence set. Each pruning method is plugged in both W-DITG and HP-DITG. IBM Model 1 and HMM alignment model are re-implemented as they are required by the three ITG pruning methods.

The results for W-DITG are listed in Table 1. Tests 1 and 2 show that with the same beam size (i.e. number of E-spans per F-span), although DPDI spends a bit more time (due to the more complicated model), DPDI makes far less incorrect pruning decisions than the TTT. In terms of F-score upper bound, DPDI is 1 percent higher. DPDI achieves even larger improvement in actual F-score.

To enable TTT achieving similar F-score or F-score upper bound, the beam size has to be doubled and the time cost is more than twice the original (c.f. Tests 1 and 3 in Table 1) .

The DP pruning in Haghighi *et.al.* (2009) performs much poorer than the other two pruning methods. In fact, we fail to enable DP achieve the same F-score upper bound as the other two methods before DP leads to intolerable memory consumption. This may be due to the use of different HMM model implementations between our work and Haghighi *et.al.* (2009).

Table 2 lists the results for HP-DITG. Roughly the same observation as in W-DITG can be made. In addition to the superiority of DPDI, it can also be noted that HP-DITG achieves much higher F-score and F-score upper bound. This shows that

hierarchical phrase is a powerful tool in rectifying the 1-to-1 constraint in ITG.

Note also that while TTT in Test 3 gets roughly the same F-score upper bound as DPDI in Test 1, the corresponding F-score is slightly worse. A possible explanation is that better pruning not only speeds up the parsing/alignment process but also guides the search process to focus on the most promising region of the search space.

7.4 Large-scale End-to-End Experiment

ID	Pruning	beam size	time cost	Bleu-05	Bleu-08
1	DPDI	10	1092h	**38.57**	**28.31**
2	TTT	10	**972h**	37.96	27.37
3	TTT	20	2376h	38.13	27.58
4	DP	--	2068h	37.43	27.12

Table 3: Evaluation of DPDI against TTT and DP for HP-DITG

ID	WA-Model	F-Score	Bleu-05	Bleu-08
1	HMM	80.1%	36.91	26.86
2	Giza++	84.2%	37.70	27.33
3	BITG	85.9%	37.92	27.85
4	HP-DITG	**87.0%**	**38.57**	**28.31**

Table 4: Evaluation of DPDI against HMM, Giza++ and BITG

Table 3 lists the word alignment time cost and SMT performance of different pruning methods. HP-DITG using DPDI achieves the best Bleu score with acceptable time cost. Table 4 compares HP-DITG to HMM (Vogel, et al., 1996), GIZA++ (Och and Ney, 2000) and BITG (Haghighi *et al.*, 2009). It shows that HP-DITG (with DPDI) is better than the three baselines both in alignment F-score and Bleu score. Note that the Bleu score differences between HP-DITG and the three baselines are statistically significant (Koehn, 2004).

An explanation of the better performance by HP-DITG is the better phrase pair extraction due to DPDI. On the one hand, a good phrase pair often fails to be extracted due to a link inconsistent with the pair. On the other hand, ITG pruning can be considered as phrase pair selection, and good ITG pruning like DPDI guides the subsequent ITG alignment process so that less links inconsistent to good phrase pairs are produced. This also explains (in Tables 2 and 3) why DPDI with beam size 10 leads to higher Bleu than TTT with beam size 20, even though both pruning methods lead to roughly the same alignment F-score.

8 Conclusion and Future Work

This paper reviews word alignment through ITG parsing, and clarifies the problem of ITG pruning. A discriminative pruning model and two discriminative ITG alignments systems are proposed. The pruning model is shown to be superior to all existing ITG pruning methods, and the HP-DITG alignment system is shown to improve state-of-the-art alignment and translation quality.

The current DPDI model employs a very limited set of features. Many features are related only to probabilities of word pairs. As the success of HP-DITG illustrates the merit of hierarchical phrase pair, in future we should investigate more features on the relationship between span pair and hierarchical phrase pair.

Appendix A. The Normal Form Grammar

Table 5 lists the ITG rules in normal form as used in this paper, which extend the normal form in Wu (1997) so as to handle the case of alignment to null.

1	$S \rightarrow A \mid B \mid C$
2	$A \rightarrow [A\ B] \mid [A\ C] \mid [B\ B] \mid [BC] \mid [C\ B] \mid [C\ C]$
3	$B \rightarrow \langle A\ A\rangle \mid \langle A\ C\rangle \mid \langle B\ A\rangle \mid \langle B\ C\rangle$
	$B \rightarrow \langle C\ A\rangle \mid \langle C\ C\rangle$
4	$C \rightarrow C_w \mid C_{fw} \mid C_{ew}$
5	$C \rightarrow [C_{ew}\ C_{fw}]$
6	$C_w \rightarrow u/v$
7	$C_e \rightarrow \varepsilon/v; C_f \rightarrow u/\varepsilon$
8	$C_{em} \rightarrow C_e \mid [C_{em}\ C_e]; C_{fm} \rightarrow C_f \mid [C_{fm}\ C_f]$
9	$C_{ew} \rightarrow [C_{em}\ C_w]; C_{fw} \rightarrow [C_{fm}\ C_w]$

Table 5: ITG Rules in Normal Form

In these rules, S is the Start symbol; A is the category for concatenating combination whereas B for inverted combination. Rules (2) and (3) are inherited from Wu (1997). Rules (4) divide the terminal category C into subcategories. Rule schema (6) subsumes all terminal unary rules for some English word u and foreign word v, and rule schemas (7) are unary rules for alignment to null. Rules (8) ensure all words linked to null are combined in left branching manner, while rules (9) ensure those words linked to null combine with some following, rather than preceding, word pair. (Note: Accordingly, all sentences must be ended by a special token $\langle end\rangle$, otherwise the last word(s) of a sentence cannot be linked to null.) If there are both English and foreign words linked to null, rule (5) ensures that those English

words linked to null precede those foreign words linked to null.

Abstract

Tree-to-string translation rules are widely used in linguistically syntax-based statistical machine translation systems. In this paper, we propose to use *deep syntactic information* for obtaining fine-grained translation rules. A head-driven phrase structure grammar (HPSG) parser is used to obtain the deep syntactic information, which includes a fine-grained description of the syntactic property and a semantic representation of a sentence. We extract fine-grained rules from aligned HPSG tree/forest-string pairs and use them in our tree-to-string and string-to-tree systems. Extensive experiments on large-scale bidirectional Japanese-English translations testified the effectiveness of our approach.

1 Introduction

Tree-to-string translation rules are generic and applicable to numerous *linguistically syntax-based* Statistical Machine Translation (SMT) systems, such as string-to-tree translation (Galley et al., 2004; Galley et al., 2006; Chiang et al., 2009), tree-to-string translation (Liu et al., 2006; Huang et al., 2006), and forest-to-string translation (Mi et al., 2008; Mi and Huang, 2008). The algorithms proposed by Galley et al. (2004; 2006) are frequently used for extracting minimal and composed rules from aligned 1-best tree-string pairs. Dealing with the parse error problem and rule sparseness problem, Mi and Huang (2008) replaced the 1-best parse tree with a packed forest which compactly encodes exponentially many parses for tree-to-string rule extraction.

However, current tree-to-string rules only make use of Probabilistic Context-Free Grammar tree fragments, in which part-of-speech (POS) or phrasal tags are used as the tree node labels. As will be testified by our experiments, we argue that the simple POS/phrasal tags are too coarse to reflect the accurate translation probabilities of the translation rules.

	koroshita (active)	*korosareta* (passive)
VBN(*killed*)	**6** (6/10,6/6)	4 (4/10,4/4)
VBN(*killed*:active)	**5** (5/6,5/6)	1 (1/6,1/4)
VBN(*killed*:passive)	1 (1/4,1/6)	**3** (3/4,3/4)

Table 1: Bidirectional translation probabilities of rules, denoted in the brackets, change when *voice* is attached to "*killed*".

For example, as shown in Table 1, suppose a simple tree fragment "VBN(*killed*)" appears 6 times with "*koroshita*", which is a Japanese translation of an *active* form of "*killed*", and 4 times with "*korosareta*", which is a Japanese translation of a *passive* form of "*killed*". Then, without larger tree fragments, we will more frequently translate "VBN(*killed*)" into "*koroshita*" (with a probability of 0.6). But, "VBN(*killed*)" is indeed separable into two fine-grained tree fragments of "VBN(*killed*:active)" and "VBN(*killed*:passive)"[1]. Consequently, "VBN(*killed*:active)" appears 5 times with "*koroshita*" and 1 time with "*korosareta*"; and "VBN(*killed*:passive)" appears 1 time with "*koroshita*" and 3 times with "*korosareta*". Now, by attaching the *voice* information to "*killed*", we are gaining a rule set that is more appropriate to reflect the real translation situations.

This motivates our proposal of using deep syntactic information to obtain a fine-grained translation rule set. We name the information such as the voice of a verb in a tree fragment as deep syntactic information. We use a head-driven phrase structure grammar (HPSG) parser to obtain the

[1]For example, "*John has killed Mary.*" versus "*John was killed by Mary.*"

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 325–334,
Uppsala, Sweden, 11-16 July 2010.

deep syntactic information of an English sentence, which includes a fine-grained description of the syntactic property and a semantic representation of the sentence. We extract fine-grained translation rules from aligned HPSG tree/forest-string pairs. We localize an HPSG tree/forest to make it segmentable at any nodes to fit the extraction algorithms described in (Galley et al., 2006; Mi and Huang, 2008). We also propose a linear-time algorithm for extracting composed rules guided by predicate-argument structures. The effectiveness of the rules are testified in our tree-to-string and string-to-tree systems, taking bidirectional Japanese-English translations as our test cases.

This paper is organized as follows. In Section 2, we briefly review the tree-to-string and string-to-tree translation frameworks, tree-to-string rule extraction algorithms, and rich syntactic information previously used for SMT. The HPSG grammar and our proposal of fine-grained rule extraction algorithms are described in Section 3. Section 4 gives the experiments for applying fine-grained translation rules to large-scale Japanese-English translation tasks. Finally, we conclude in Section 5.

2 Related Work

2.1 Tree-to-string and string-to-tree translations

Tree-to-string translation (Liu et al., 2006; Huang et al., 2006) first uses a parser to parse a source sentence into a 1-best tree and then searches for the best derivation that segments and converts the tree into a target string. In contrast, string-to-tree translation (Galley et al., 2004; Galley et al., 2006; Chiang et al., 2009) is like *bilingual* parsing. That is, giving a (bilingual) translation grammar and a source sentence, we are trying to construct a parse forest in the target language. Consequently, the translation results can be collected from the leaves of the parse forest.

Figure 1 illustrates the training and decoding processes of bidirectional Japanese-English translations. The English sentence is "*John killed Mary*" and the Japanese sentence is "*jyon ha mari wo koroshita*", in which the function words "*ha*" and "*wo*" are not aligned with any English word.

2.2 Tree/forest-based rule extraction

Galley et al. (2004) proposed the GHKM algorithm for extracting (minimal) tree-to-string translation rules from a tuple of $\langle F, E_t, A\rangle$, where $F =$

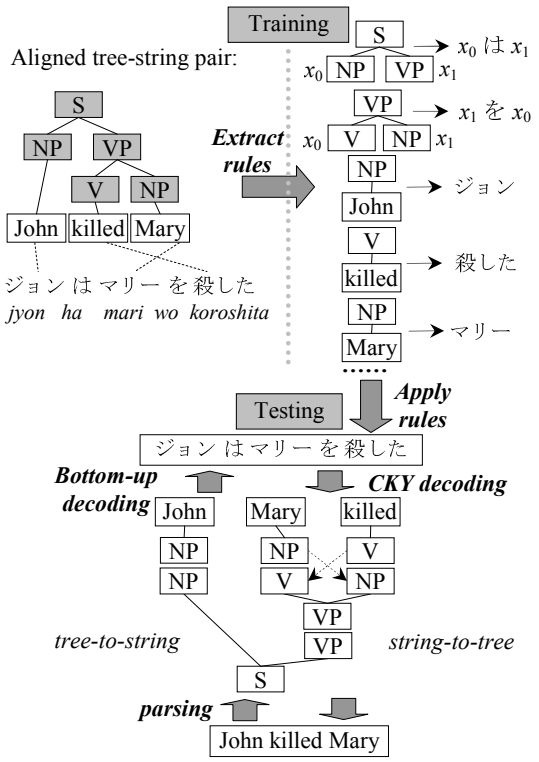

Figure 1: Illustration of the training and decoding processes for tree-to-string and string-to-tree translations.

f_1^J is a sentence of a foreign language other than English, E_t is a 1-best parse tree of an English sentence $E = e_1^I$, and $A = \{(j, i)\}$ is an alignment between the words in F and E.

The basic idea of GHKM algorithm is to decompose E_t into a series of tree fragments, each of which will form a rule with its corresponding translation in the foreign language. A is used as a constraint to guide the segmentation procedure, so that the root node of every tree fragment of E_t exactly corresponds to a *contiguous* span on the foreign language side. Based on this consideration, a *frontier set* (*fs*) is defined to be a set of nodes n in E_t that satisfies the following constraint:

$$fs = \{n | span(n) \cap comp\_span(n) = \phi\}. \quad (1)$$

Here, $span(n)$ is defined by the indices of the first and last word in F that are reachable from a node n, and $comp\_span(n)$ is defined to be the complement set of $span(n)$, i.e., the union of the spans of all nodes n' in E_t that are neither descendants nor ancestors of n. $span(n)$ and $comp\_span(n)$ of each n can be computed by first a bottom-up exploration and then a top-down traversal of E_t.

By restricting each fragment so that it only takes

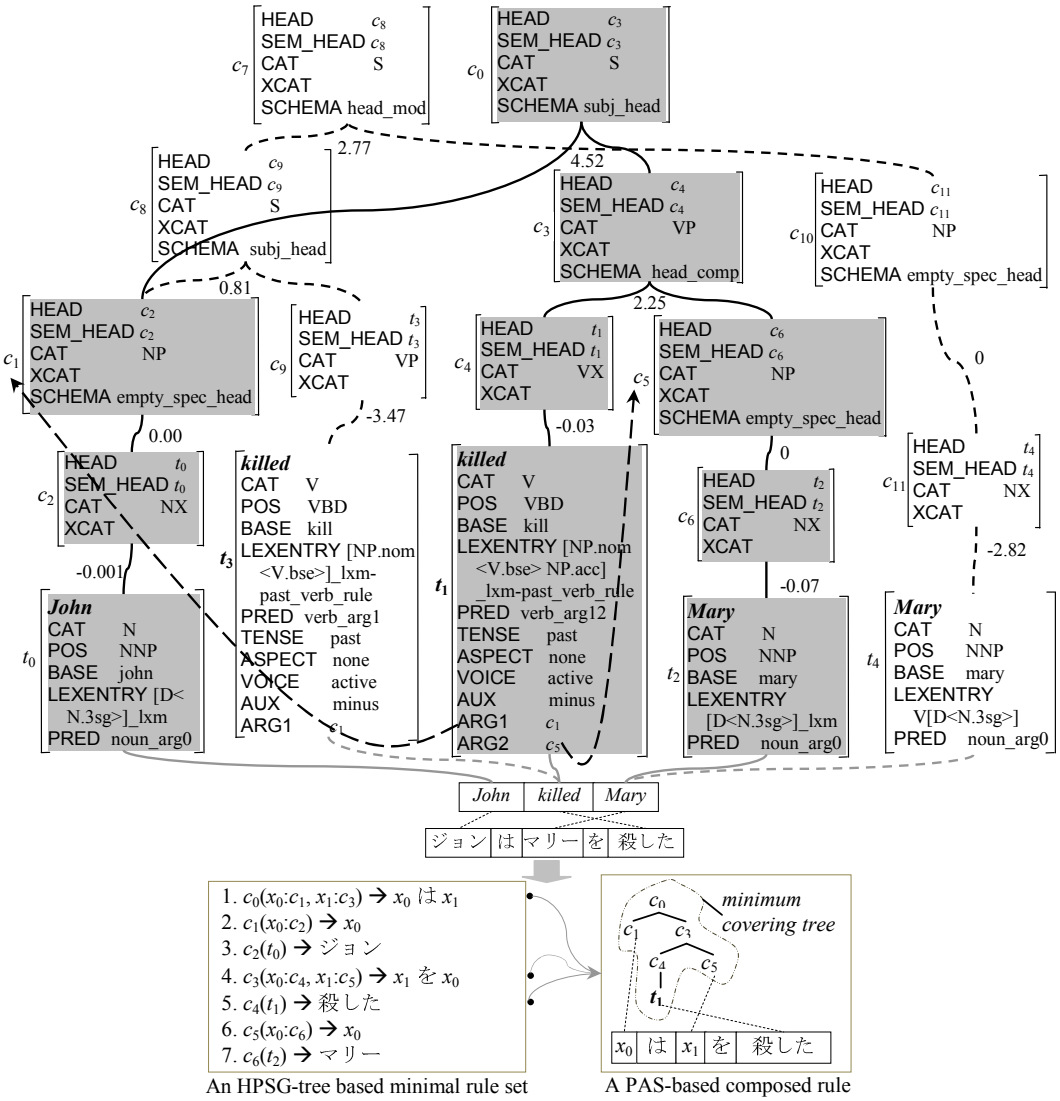

Figure 2: Illustration of an aligned HPSG forest-string pair. The forest includes two parse trees by taking "*Mary*" as a modifier (t_3, t_4) or an argument (t_1, t_2) of "*killed*". Arrows with broken lines denote the PAS dependencies from the terminal node t_1 to its argument nodes (c_1 and c_5). The scores of the hyperedges are attached to the forest as well.

the nodes in *fs* as the root and leaf nodes, a well-formed fragmentation of E_t is generated. With *fs* computed, rules are extracted through a depth-first traversal of E_t: we cut E_t at all nodes in *fs* to form tree fragments and extract a rule for each fragment. These extracted rules are called *minimal rules* (Galley et al., 2004). For example, the 1-best tree (with gray nodes) in Figure 2 is cut into 7 pieces, each of which corresponds to the tree fragment in a rule (bottom-left corner of the figure).

In order to include richer context information and account for multiple interpretations of unaligned words of foreign language, minimal rules which share adjacent tree fragments are connected together to form composed rules (Galley et al., 2006). For each aligned tree-string pair, Galley et al. (2006) constructed a derivation-forest, in which composed rules were generated, unaligned words of foreign language were consistently attached, and the translation probabilities of rules were estimated by using Expectation-Maximization (EM) (Dempster et al., 1977) training. For example, by combining the minimal rules of 1, 4, and 5, we obtain a composed rule, as shown in the bottom-right corner of Figure 2.

Considering the parse error problem in the 1-best or k-best parse trees, Mi and Huang (2008) extracted tree-to-string translation rules from aligned packed forest-string pairs. A forest compactly encodes exponentially many trees

rather than the 1-best tree used by Galley et al. (2004; 2006). Two problems were managed to be tackled during extracting rules from an aligned forest-string pair: where to cut and how to cut. Equation 1 was used again to compute a frontier node set to determine where to cut the packed forest into a number of tree-fragments. The difference with tree-based rule extraction is that the nodes in a packed forest (which is a hypergraph) now are hypernodes, which can take a set of incoming hyperedges. Then, by limiting each fragment to be a tree and whose root/leaf hypernodes all appearing in the frontier set, the packed forest can be segmented properly into a set of tree fragments, each of which can be used to generate a tree-to-string translation rule.

2.3 Rich syntactic information for SMT

Before describing our approaches of applying deep syntactic information yielded by an HPSG parser for fine-grained rule extraction, we would like to briefly review what kinds of deep syntactic information have been employed for SMT.

Two kinds of supertags, from Lexicalized Tree-Adjoining Grammar and Combinatory Categorial Grammar (CCG), have been used as lexical syntactic descriptions (Hassan et al., 2007) for phrase-based SMT (Koehn et al., 2007). By introducing supertags into the target language side, i.e., the target language model and the target side of the phrase table, significant improvement was achieved for Arabic-to-English translation. Birch et al. (2007) also reported a significant improvement for Dutch-English translation by applying CCG supertags at a word level to a factorized SMT system (Koehn et al., 2007).

In this paper, we also make use of supertags on the English language side. In an HPSG parse tree, these lexical syntactic descriptions are included in the LEXENTRY feature (refer to Table 2) of a lexical node (Matsuzaki et al., 2007). For example, the LEXENTRY feature of "t_1*:killed*" takes the value of `[NP.nom<V.bse>NP.acc]_lxm-past_verb_rule` in Figure 2. In which, `[NP.nom<V.bse>NP.acc]` is an HPSG style supertag, which tells us that the base form of "*killed*" needs a nominative NP in the left hand side and an accessorial NP in the right hand side. The major differences are that, we use a larger feature set (Table 2) including the supertags for fine-grained tree-to-string rule extraction, rather than string-to-string translation (Hassan et al., 2007; Birch et al., 2007).

The Logon project[2] (Oepen et al., 2007) for Norwegian-English translation integrates in-depth grammatical analysis of Norwegian (using lexical functional grammar, similar to (Riezler and Maxwell, 2006)) with semantic representations in the minimal recursion semantics framework, and fully grammar-based generation for English using HPSG. A hybrid (of rule-based and data-driven) architecture with a semantic transfer backbone is taken as the vantage point of this project. In contrast, the fine-grained tree-to-string translation rule extraction approaches in this paper are totally data-driven, and easily applicable to numerous language pairs by taking English as the source or target language.

3 Fine-grained rule extraction

We now introduce the deep syntactic information generated by an HPSG parser and then describe our approaches for fine-grained tree-to-string rule extraction. Especially, we localize an HPSG tree/forest to fit the extraction algorithms described in (Galley et al., 2006; Mi and Huang, 2008). Also, we propose a linear-time composed rule extraction algorithm by making use of predicate-argument structures.

3.1 Deep syntactic information by HPSG parsing

Head-driven phrase structure grammar (HPSG) is a lexicalist grammar framework. In HPSG, linguistic entities such as words and phrases are represented by a data structure called a *sign*. A sign gives a factored representation of the syntactic features of a word/phrase, as well as a representation of their semantic content. Phrases and words represented by signs are composed into larger phrases by applications of *schemata*. The semantic representation of the new phrase is calculated at the same time. As such, an HPSG parse tree/forest can be considered as a tree/forest of signs (c.f. the HPSG forest in Figure 2).

An HPSG parse tree/forest has two attractive properties as a representation of an English sentence in syntax-based SMT. First, we can carefully control the condition of the application of a translation rule by exploiting the fine-grained syntactic

[2] http://www.emmtee.net/

Feature	Description
CAT	phrasal category
XCAT	fine-grained phrasal category
SCHEMA	name of the schema applied in the node
HEAD	*pointer* to the head daughter
SEM_HEAD	*pointer* to the semantic head daughter
CAT	syntactic category
POS	Penn Treebank-style part-of-speech tag
BASE	base form
TENSE	tense of a verb (past, present, untensed)
ASPECT	aspect of a verb (none, perfect, progressive, perfect-progressive)
VOICE	voice of a verb (passive, active)
AUX	auxiliary verb or not (minus, modal, have, be, do, to, copular)
LEXENTRY	lexical entry, with supertags embedded
PRED	type of a predicate
ARG$\langle x \rangle$	*pointer* to semantic arguments, $x = 1..4$

Table 2: Syntactic/semantic features extracted from HPSG signs that are included in the output of Enju. Features in phrasal nodes (top) and lexical nodes (bottom) are listed separately.

description in the English parse tree/forest, as well as those in the translation rules. Second, we can identify sub-trees in a parse tree/forest that correspond to basic units of the semantics, namely sub-trees covering a predicate and its arguments, by using the semantic representation given in the signs. We expect that extraction of translation rules based on such *semantically-connected* subtrees will give a compact and effective set of translation rules.

A sign in the HPSG tree/forest is represented by a typed feature structure (TFS) (Carpenter, 1992). A TFS is a directed-acyclic graph (DAG) wherein the edges are labeled with feature names and the nodes (feature values) are typed. In the original HPSG formalism, the types are defined in a hierarchy and the DAG can have arbitrary shape (e.g., it can be of any depth). We however use a simplified form of TFS, for simplicity of the algorithms. In the simplified form, a TFS is converted to a (flat) set of pairs of feature names and their values. Table 2 lists the features used in this paper, which are a subset of those in the original output from an HPSG parser, Enju[3]. The HPSG forest shown in Figure 2 is in this simplified format. An important detail is that we allow a feature value to be a pointer to another (simplified) TFS. Such pointer-valued features are necessary for denoting the semantics, as explained shortly.

In the Enju English HPSG grammar (Miyao et al., 2003) used in this paper, the semantic content of a sentence/phrase is represented by a predicate-argument structure (PAS). Figure 3 shows the PAS of the example sentence in Figure 2, "*John killed Mary*", and a more complex PAS for another sentence, "*She ignored the fact that I wanted to dispute*", which is adopted from (Miyao et al., 2003). In an HPSG tree/forest, each leaf node generally introduces a predicate, which is represented by the pair of LEXENTRY (lexical entry) feature and PRED (predicate type) feature. The arguments of a predicate are designated by the pointers from the ARG$\langle x \rangle$ features in a leaf node to non-terminal nodes.

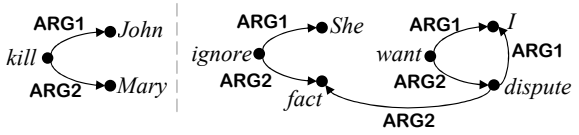

Figure 3: Predicate argument structures for the sentences of "*John killed Mary*" and "*She ignored the fact that I wanted to dispute*".

3.2 Localize HPSG forest

Our fine-grained translation rule extraction algorithm is sketched in Algorithm 1. Considering that a parse tree is a trivial packed forest, we only use the term forest to expand our discussion, hereafter. Recall that there are pointer-valued features in the TFSs (Table 2) which prevent arbitrary segmentation of a packed forest. Hence, we have to localize an HPSG forest.

For example, there are ARG pointers from t_1 to c_1 and c_5 in the HPSG forest of Figure 2. However, the three nodes are not included in one (minimal) translation rule. This problem is caused by not considering the predicate argument dependency among t_1, c_1, and c_5 while performing the GHKM algorithm. We can combine several minimal rules (Galley et al., 2006) together to address this dependency. Yet we have a faster way to tackle PASs, as will be described in the next subsection.

Even if we omit ARG, there are still two kinds of pointer-valued features in TFSs, HEAD and SEM_HEAD. Localizing these pointer-valued features is straightforward, since during parsing, the HEAD and SEM_HEAD of a node are automatically transferred to its mother node. That is, the syntactic and semantic head of a node only take

1: **if** E_f is an HPSG tree **then**
2: $E_f^{'}$ = localize_Tree(E_f)
3: $\mathcal{R}_1$ = PASR_extraction($E_f^{'}$, F, A) ▷ Algorithm 2
4: $E_f^{''}$ = ignore_PAS($E_f^{'}$)
5: $\mathcal{R}_2$ = TR_extraction($E_f^{''}$, F, A) ▷ composed rule extraction algorithm in (Galley et al., 2006)
6: **else if** E_f is an HPSG forest **then**
7: $E_f^{'}$ = localize_Forest(E_f);
8: $\mathcal{R}_2$ = forest_based_rule_extraction($E_f^{'}$, F, A) ▷ Algorithm 1 in (Mi and Huang, 2008)
9: **end if**

the identifier of the daughter node as the values. For example, HEAD and SEM_HEAD of node c_0 take the identical value to be c_3 in Figure 2.

To extract tree-to-string rules from the tree structures of an HPSG forest, our solution is to pre-process an HPSG forest in the following way:

- for a phrasal hypernode, replace its HEAD and SEM_HEAD value with L, R, or S, which respectively represent left daughter, right daughter, or single daughter (line 2 and 7); and,
- for a lexical node, ARG⟨x⟩ and PRED features are ignored (line 4).

A pure syntactic-based HPSG forest without any pointer-valued features can be yielded through this pre-processing for the consequent execution of the extraction algorithms (Galley et al., 2006; Mi and Huang, 2008).

3.3 Predicate-argument structures

In order to extract translation rules from PASs, we want to localize a predicate word and its arguments into one tree fragment. For example, in Figure 2, we can use a tree fragment which takes c_0 as its root node and c_1, t_1, and c_5 on its yield (= leaf nodes of a tree fragment) to cover "*killed*" and its subject and direct object arguments. We define this kind of tree fragment to be a *minimum covering tree*. For example, the minimum covering tree of $\{t_1, c_1, c_5\}$ is shown in the bottom-right corner of Figure 2. The definition supplies us a linear-time algorithm to directly find the tree fragment that covers a PAS during both rule extracting and rule matching when decoding an HPSG tree.

Algorithm 2 PASR extraction

Input: HPSG tree E_t, foreign sentence F, and alignment A
Output: a PAS-based rule set $\mathcal{R}$

1: $\mathcal{R}$ = {}
2: **for** node $n \in$ Leaves(E_t) **do**
3: **if** Open(n.ARG) **then**
4: T_c = MinimumCoveringTree(E_t, n, n.ARGs)
5: **if** root and leaf nodes of T_c are in *fs* **then**
6: generate a rule r using fragment T_c
7: $\mathcal{R}$.append(r)
8: **end if**
9: **end if**
10: **end for**

See (Wu, 2010) for more examples of minimum covering trees.

Taking a minimum covering tree as the tree fragment, we can easily build a tree-to-string translation rule that reflects the semantic dependency of a PAS. The algorithm of PAS-based rule (PASR) extraction is sketched in Algorithm 2. Suppose we are given a tuple of $\langle F, E_t, A\rangle$. E_t is pre-processed by replacing HEAD and SEM_HEAD to be L, R, or S, and computing the $span$ and $comp\_span$ of each node.

We extract PAS-based rules through one-time traversal of the leaf nodes in E_t (line 2). For each leaf node n, we extract a minimum covering tree T_c if n contains at least one argument. That is, at least one ARG⟨x⟩ takes the value of some node identifier, where x ranges 1 over 4 (line 3). Then, we require the root and yield nodes of T_c being in the frontier set of E_t (line 5). Based on T_c, we can easily build a tree-to-string translation rule by further completing the right-hand-side string by sorting the spans of T_c's leaf nodes, lexicalizing the terminal node's span(s), and assigning a variable to each non-terminal node's span. Maximum likelihood estimation is used to calculate the translation probabilities of each rule.

An example of PAS-based rule is shown in the bottom-right corner of Figure 2. In the rule, the subject and direct-object of "*killed*" are generalized into two variables, x_0 and x_1.

4 Experiments

4.1 Translation models

We use a tree-to-string model and a string-to-tree model for bidirectional Japanese-English translations. Both models use a phrase translation table (PTT), an HPSG tree-based rule set (TRS), and a PAS-based rule set (PRS). Since the three rule sets are independently extracted and estimated, we

use Minimum Error Rate Training (MERT) (Och, 2003) to tune the weights of the features from the three rule sets on the development set.

Given a 1-best (localized) HPSG tree E_t, the tree-to-string decoder searches for the optimal derivation d^* that transforms E_t into a Japanese string among the set of all possible derivations D:

$$d^* = \arg\max_{d \in D} \{\lambda_1 \log p_{LM}(\tau(d)) + \lambda_2 |\tau(d)| + \log s(d|E_t)\}. \quad (2)$$

Here, the first item is the language model (LM) probability where $\tau(d)$ is the target string of derivation d; the second item is the translation length penalty; and the third item is the translation score, which is decomposed into a product of feature values of rules:

$$s(d|E_t) = \prod_{r \in d} f(r_{\in PTT}) f(r_{\in TRS}) f(r_{\in PRS}).$$

This equation reflects that the translation rules in one d come from three sets. Inspired by (Liu et al., 2009b), it is appealing to combine these rule sets together in one decoder because PTT provides excellent rule coverages while TRS and PRS offer linguistically motivated phrase selections and non-local reorderings. Each $f(r)$ is in turn a product of five features:

$$f(r) = p(s|t)^{\lambda_3} \cdot p(t|s)^{\lambda_4} \cdot l(s|t)^{\lambda_5} \cdot l(t|s)^{\lambda_6} \cdot e^{\lambda_7}.$$

Here, s/t represent the source/target part of a rule in PTT, TRS, or PRS; $p(\cdot|\cdot)$ and $l(\cdot|\cdot)$ are translation probabilities and lexical weights of rules from PTT, TRS, and PRS. The derivation length penalty is controlled by λ_7.

In our string-to-tree model, for efficient decoding with integrated n-gram LM, we follow (Zhang et al., 2006) and inversely binarize all translation rules into Chomsky Normal Forms that contain at most two variables and can be incrementally scored by LM. In order to make use of the binarized rules in the CKY decoding, we add two kinds of glues rules:

$$\begin{aligned} S &\rightarrow {X_m}^{(1)}, {X_m}^{(1)}; \\ S &\rightarrow S^{(1)} {X_m}^{(2)}, S^{(1)} {X_m}^{(2)}. \end{aligned}$$

Here X_m ranges over the nonterminals appearing in a binarized rule set. These glue rules can be seen as an extension from X to $\{X_m\}$of the two glue rules described in (Chiang, 2007).

The string-to-tree decoder searches for the optimal derivation d^* that parses a Japanese string F into a packed forest of the set of all possible derivations D:

$$d^* = \arg\max_{d \in D} \{\lambda_1 \log p_{LM}(\tau(d)) + \lambda_2 |\tau(d)| + \lambda_3 g(d) + \log s(d|F)\}. \quad (3)$$

This formula differs from Equation 2 by replacing E_t with F in $s(d|\cdot)$ and adding $g(d)$, which is the number of glue rules used in d. Further definitions of $s(d|F)$ and $f(r)$ are identical with those used in Equation 2.

4.2 Decoding algorithms

In our translation models, we have made use of three kinds of translation rule sets which are trained separately. We perform *derivation-level combination* as described in (Liu et al., 2009b) for mixing different types of translation rules within one derivation.

For tree-to-string translation, we use a bottom-up beam search algorithm (Liu et al., 2006) for decoding an HPSG tree E_t. We keep at most 10 best derivations with distinct $\tau(d)$s at each node.

Recall the definition of minimum covering tree, which supports a faster way to retrieve available rules from PRS without generating all the subtrees. That is, when node n fortunately to be the root of some minimum covering tree(s), we use the tree(s) to seek available PAS-based rules in PRS. We keep a hash-table with the key to be the node identifier of n and the value to be a priority queue of available PAS-based rules. The hash-table is easy to be filled by one-time traversal of the terminal nodes in E_t. At each terminal node, we seek its minimum covering tree, retrieve PRS, and update the hash-table. For example, suppose we are decoding an HPSG tree (with gray nodes) shown in Figure 2. At t_1, we can extract its minimum covering tree with the root node to be c_0, then take this tree fragment as the key to retrieve PRS, and consequently put c_0 and the available rules in the hash-table. When decoding at c_0, we can directly access the hash-table looking for available PAS-based rules.

In contrast, we use a CKY-style algorithm with beam-pruning and cube-pruning (Chiang, 2007) to decode Japanese sentences. For each Japanese sentence F, the output of the chart-parsing algorithm is expressed as a hypergraph representing a set of derivations. Given such a hypergraph, we

	Train	Dev.	Test
# of sentences	994K	2K	2K
# of Jp words	28.2M	57.4K	57.1K
# of En words	24.7M	50.3K	49.9K

Table 3: Statistics of the JST corpus.

use the Algorithm 3 described in (Huang and Chiang, 2005) to extract its k-best ($k = 500$ in our experiments) derivations. Since different derivations may lead to the same target language string, we further adopt Algorithm 3's modification, i.e., keep a hash-table to maintain the unique target sentences (Huang et al., 2006), to efficiently generate the unique k-best translations.

4.3 Setups

The JST Japanese-English paper abstract corpus[4], which consists of one million parallel sentences, was used for training and testing. This corpus was constructed from a Japanese-English paper abstract corpus by using the method of Utiyama and Isahara (2007). Table 3 shows the statistics of this corpus. Making use of Enju 2.3.1, we successfully parsed 987,401 English sentences in the training set, with a parse rate of 99.3%. We modified this parser to output a packed forest for each English sentence.

We executed GIZA++ (Och and Ney, 2003) and *grow-diag-final-and* balancing strategy (Koehn et al., 2007) on the training set to obtain a phrase-aligned parallel corpus, from which bidirectional phrase translation tables were estimated. SRI Language Modeling Toolkit (Stolcke, 2002) was employed to train 5-gram English and Japanese LMs on the training set. We evaluated the translation quality using the case-insensitive BLEU-4 metric (Papineni et al., 2002). The MERT toolkit we used is Z-mert[5] (Zaidan, 2009).

The baseline system for comparison is Joshua (Li et al., 2009), a freely available decoder for hierarchical phrase-based SMT (Chiang, 2005). We respectively extracted 4.5M and 5.3M translation rules from the training set for the 4K English and Japanese sentences in the development and test sets. We used the default configuration of Joshua, expect setting the maximum number of items/rules and the k of k-best outputs to be the identical 200 for English-to-Japanese translation and 500 for Japanese-to-English translation.

We used four dual core Xeon machines (4×3.0GHz×2CPU, 4×64GB memory) to run all the experiments.

	PRS	C_3^S	C_3	F^S	F
tree nodes	TFS	POS	TFS	POS	TFS
# rules	0.9	62.1	83.9	92.5	103.7
# tree types	0.4	23.5	34.7	40.6	45.2
extract time	3.5	-	98.6	-	121.2

Table 4: Statistics of several kinds of tree-to-string rules. Here, the number is in million level and the time is in hour.

4.4 Results

Table 4 illustrates the statistics of several translation rule sets, which are classified by:

- using TFSs or simple POS/phrasal tags (annotated by a superscript S) to represent tree nodes;
- composed rules (PRS) extracted from the PAS of 1-best HPSG trees;
- composed rules (C_3), extracted from the tree structures of 1-best HPSG trees, and 3 is the maximum number of internal nodes in the tree fragments; and
- forest-based rules (F), where the packed forests are pre-pruned by the marginal probability-based inside-outside algorithm used in (Mi and Huang, 2008).

Table 5 reports the BLEU-4 scores achieved by decoding the test set making use of Joshua and our systems (t2s = tree-to-string and s2t = string-to-tree) under numerous rule sets. We analyze this table in terms of several aspects to prove the effectiveness of deep syntactic information for SMT.

Let's first look at the performance of TFSs. We take C_3^S and F^S as approximations of CFG-based translation rules. Comparing the BLEU-4 scores of PTT+C_3^S and PTT+C_3, we gained 0.56 (t2s) and 0.57 (s2t) BLEU-4 points which are significant improvements ($p < 0.05$). Furthermore, we gained 0.50 (t2s) and 0.62 (s2t) BLEU-4 points from PTT+F^S to PTT+F, which are also significant improvements ($p < 0.05$). The rich features included in TFSs contribute to these improvements.

Systems	BLEU-t2s	Decoding	BLEU-s2t
Joshua	21.79	0.486	19.73
PTT	18.40	0.013	17.21
PTT+PRS	22.12	0.031	19.33
PTT+C_3^S	23.56	2.686	20.59
PTT+C_3	24.12	2.753	21.16
PTT+C_3+PRS	24.13	2.930	21.20
PTT+F^S	24.25	3.241	22.05
PTT+F	**24.75**	3.470	**22.67**

Table 5: BLEU-4 scores (%) achieved by Joshua and our systems under numerous rule configurations. The decoding time (seconds per sentence) of tree-to-string translation is listed as well.

Also, BLEU-4 scores were inspiringly increased 3.72 (t2s) and 2.12 (s2t) points by appending PRS to PTT, comparing PTT with PTT+PRS. Furthermore, in Table 5, the decoding time (seconds per sentence) of tree-to-string translation by using PTT+PRS is more than 86 times faster than using the other tree-to-string rule sets. This suggests that the direct generation of minimum covering trees for rule matching is extremely faster than generating all subtrees of a tree node. Note that PTT performed extremely bad compared with all other systems or tree-based rule sets. The major reason is that we did not perform any reordering or distorting during decoding with PTT.

However, in both t2s and s2t systems, the BLEU-4 score benefits of PRS were covered by the composed rules: both PTT+C_3^S and PTT+C_3 performed significant better ($p < 0.01$) than PTT+PRS, and there are no significant differences when appending PRS to PTT+C_3. The reason is obvious: PRS is only a small subset of the composed rules, and the probabilities of rules in PRS were estimated by maximum likelihood, which is fast but biased compared with EM based estimation (Galley et al., 2006).

Finally, by using PTT+F, our systems achieved the best BLEU-4 scores of 24.75% (t2s) and 22.67% (s2t), both are significantly better ($p < 0.01$) than that achieved by Joshua.

5 Conclusion

We have proposed approaches of using deep syntactic information for extracting fine-grained tree-to-string translation rules from aligned HPSG forest-string pairs. The main contributions are the applications of GHKM-related algorithms (Galley et al., 2006; Mi and Huang, 2008) to HPSG forests and a linear-time algorithm for extracting composed rules from predicate-argument structures. We applied our fine-grained translation rules to a tree-to-string system and an Hiero-style string-to-tree system. Extensive experiments on large-scale bidirectional Japanese-English translations testified the significant improvements on BLEU score.

We argue the fine-grained translation rules are generic and applicable to many syntax-based SMT frameworks such as the forest-to-string model (Mi et al., 2008). Furthermore, it will be interesting to extract fine-grained tree-to-tree translation rules by integrating deep syntactic information in the source and/or target language side(s). These tree-to-tree rules are applicable for forest-to-tree translation models (Liu et al., 2009a).

Accurate Context-Free Parsing with Combinatory Categorial Grammar

Timothy A. D. Fowler and **Gerald Penn**
Department of Computer Science, University of Toronto
Toronto, ON, M5S 3G4, Canada
{tfowler, gpenn}@cs.toronto.edu

Abstract

The definition of combinatory categorial grammar (CCG) in the literature varies quite a bit from author to author. However, the differences between the definitions are important in terms of the language classes of each CCG. We prove that a wide range of CCGs are strongly context-free, including the CCG of CCGbank and of the parser of Clark and Curran (2007). In light of these new results, we train the PCFG parser of Petrov and Klein (2007) on CCGbank and achieve state of the art results in supertagging accuracy, PARSEVAL measures and dependency accuracy.

1 Introduction

Combinatory categorial grammar (CCG) is a variant of categorial grammar which has attracted interest for both theoretical and practical reasons. On the theoretical side, we know that it is mildly context-sensitive (Vijay-Shanker and Weir, 1994) and that it can elegantly analyze a wide range of linguistic phenomena (Steedman, 2000). On the practical side, we have corpora with CCG derivations for each sentence (Hockenmaier and Steedman, 2007), a wide-coverage parser trained on that corpus (Clark and Curran, 2007) and a system for converting CCG derivations into semantic representations (Bos et al., 2004).

However, despite being treated as a single unified grammar formalism, each of these authors use variations of CCG which differ primarily on which combinators are included in the grammar and the restrictions that are put on them. These differences are important because they affect whether the mild context-sensitivity proof of Vijay-Shanker and Weir (1994) applies. We will provide a generalized framework for CCG within which the full variation of CCG seen in the literature can be defined. Then, we prove that for a wide range of CCGs there is a context-free grammar (CFG) that has exactly the same derivations. Included in this class of strongly context-free CCGs are a grammar including all the derivations in CCGbank and the grammar used in the Clark and Curran parser.

Due to this insight, we investigate the potential of using tools from the probabilistic CFG community to improve CCG parsing results. The Petrov parser (Petrov and Klein, 2007) uses latent variables to refine the grammar extracted from a corpus to improve accuracy, originally used to improve parsing results on the Penn treebank (PTB). We train the Petrov parser on CCGbank and achieve the best results to date on sentences from section 23 in terms of supertagging accuracy, PARSEVAL measures and dependency accuracy.

These results should not be interpreted as proof that grammars extracted from the Penn treebank and from CCGbank are equivalent. Bos's system for building semantic representations from CCG derivations is only possible due to the categorial nature of CCG. Furthermore, the long distance dependencies involved in extraction and coordination phenomena have a more natural representation in CCG.

2 The Language Classes of Combinatory Categorial Grammars

A categorial grammar is a grammatical system consisting of a finite set of words, a set of categories, a finite set of sentential categories, a finite lexicon mapping words to categories and a rule system dictating how the categories can be combined. The set of categories are constructed from a finite set of atoms A (e.g. $A = \{S, NP, N, PP\}$) and a finite set of binary connectives B (e.g. $B = \{/, \backslash\}$) to build an infinite set of categories $\mathcal{C}(A, B)$ (e.g. $\mathcal{C}(A, B) = \{S, S\backslash NP, (S\backslash NP)/NP, \ldots\}$). For a category C, its size $|C|$ is the

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 335–344,
Uppsala, Sweden, 11-16 July 2010.

number of atom occurrences it contains. When not specified, connectives are left associative.

According to the literature, combinatory categorial grammar has been defined to have a variety of rule systems. These rule systems vary from a small rule set, motivated theoretically (Vijay-Shanker and Weir, 1994), to a larger rule set, motivated linguistically, (Steedman, 2000) to a very large rule set, motivated by practical coverage (Hockenmaier and Steedman, 2007; Clark and Curran, 2007). We provide a definition general enough to incorporate these four main variants of CCG, as well as others.

A combinatory categorial grammar (CCG) is a categorial grammar whose rule system consists of rule schemata where the left side is a sequence of categories and the right side is a single category where the categories may include variables over both categories and connectives. In addition, rule schemata may specify a sequence of categories and connectives using the ... convention[1]. When ... appears in a rule, it matches any sequence of categories and connectives according to the connectives adjacent to the .... For example, the rule schema for forward composition is:

$$X/Y, Y/Z \rightarrow X/Z$$

and the rule schema for generalized forward crossed composition is:

$$X/Y, Y|_1Z_1|_2 \ldots |_nZ_n \rightarrow X|_1Z_1|_2 \ldots |_nZ_n$$

where X, Y and Z_i for $1 \leq i \leq n$ are variables over categories and $|_i$ for $1 \leq i \leq n$ are variables over connectives. Figure 1 shows a CCG derivation from CCGbank.

A well-known categorial grammar which is not a CCG is Lambek categorial grammar (Lambek, 1958) whose introduction rules cannot be characterized as combinatory rules (Zielonka, 1981).

2.1 Classes for defining CCG

We define a number of *schema classes* general enough that the important variants of CCG can be defined by selecting some subset of the classes. In addition to the schema classes, we also define two *restriction classes* which define ways in which the rule schemata from the schema classes can be restricted. We define the following schema classes:

(1) Application

- $X/Y, Y \rightarrow X$
- $Y, X\backslash Y \rightarrow X$

(2) Composition

- $X/Y, Y/Z \rightarrow X/Z$
- $Y\backslash Z, X\backslash Y \rightarrow X\backslash Z$

(3) Crossed Composition

- $X/Y, Y\backslash Z \rightarrow X\backslash Z$
- $Y/Z, X\backslash Y \rightarrow X/Z$

(4) Generalized Composition

- $X/Y, Y/Z_1/\ldots/Z_n \rightarrow X/Z_1/\ldots/Z_n$
- $Y\backslash Z_1\backslash\ldots\backslash Z_n, X\backslash Y \rightarrow X\backslash Z_1\backslash\ldots\backslash Z_n$

(5) Generalized Crossed Composition

- $X/Y, Y|_1Z_1|_2\ldots|_nZ_n \rightarrow X|_1Z_1|_2\ldots|_nZ_n$
- $Y|_1Z_1|_2\ldots|_nZ_n, X\backslash Y \rightarrow X|_1Z_1|_2\ldots|_nZ_n$

(6) Reducing Generalized Crossed Composition

Generalized Composition or Generalized Crossed Composition where $|X| \leq |Y|$.

(7) Substitution

- $(X/Y)|_1Z, Y|_1Z \rightarrow X|_1Z$
- $Y|_1Z, (X\backslash Y)|_1Z \rightarrow X|_1Z$

(8) D Combinator[2]

- $X/(Y|_1Z), Y|_2W \rightarrow X|_2(W|_1Z)$
- $Y|_2W, X\backslash(Y|_1Z) \rightarrow X|_2(W|_1Z)$

(9) Type-Raising

- $X \rightarrow T/(T\backslash X)$
- $X \rightarrow T\backslash(T/X)$

(10) Finitely Restricted Type-Raising

- $X \rightarrow T/(T\backslash X)$ where $\langle X, T\rangle \in S$ for finite S
- $X \rightarrow T\backslash(T/X)$ where $\langle X, T\rangle \in S$ for finite S

(11) Finite Unrestricted Variable-Free Rules

- $\vec{X} \rightarrow Y$ where $\langle \vec{X}, Y\rangle \in S$ for finite S

[1]The ... convention (Vijay-Shanker and Weir, 1994) is essentially identical to the $ convention of Steedman (2000).

[2]Hoyt and Baldridge (2008) argue for the inclusion of the D Combinator in CCG.

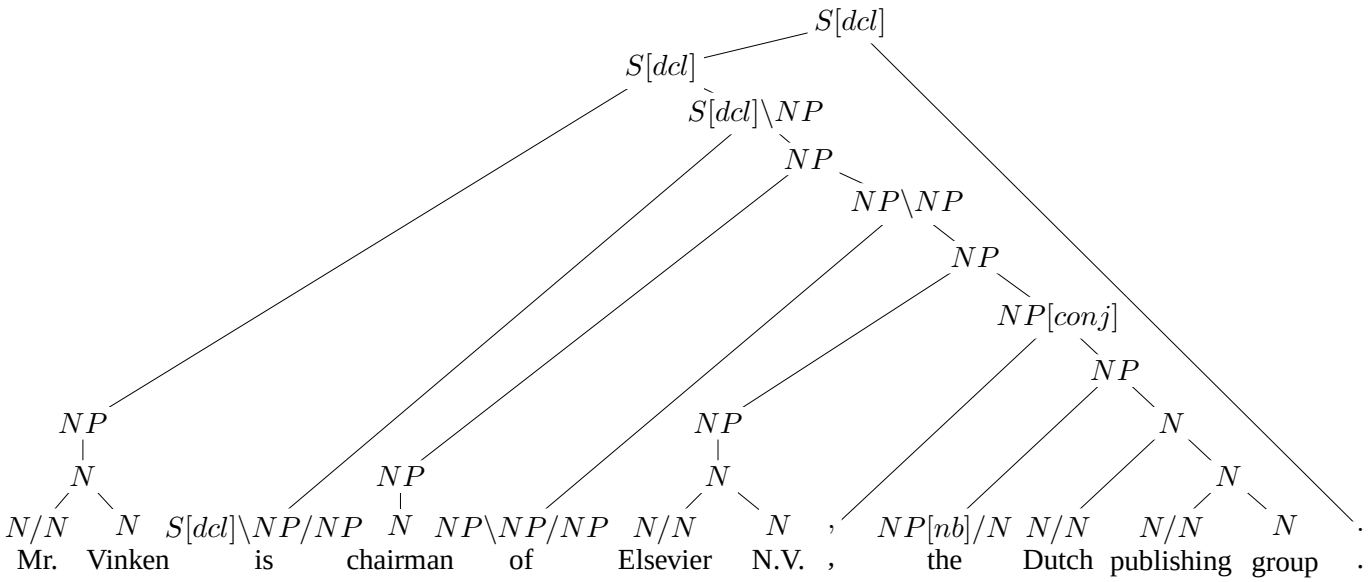

Figure 1: A CCG derivation from section 00 of CCGbank.

We define the following restriction classes:

(A) Rule Restriction to a Finite Set

The rule schemata in the schema classes of a CCG are limited to a finite number of instantiations.

(B) Rule Restrictions to Certain Categories [3]

The rule schemata in the schema classes of a CCG are limited to a finite number of instantiations although variables are allowed in the instantiations.

Vijay-Shanker and Weir (1994) define CCG to be schema class (4) with restriction class (B). Steedman (2000) defines CCG to be schema classes (1-5), (6), (10) with restriction class (B).

2.2 Strongly Context-Free CCGs

Proposition 1. *The set of atoms in any derivation of any CCG consisting of a subset of the schema classes (1-8) and (10-11) is finite.*

Proof. A finite lexicon can introduce only a finite number of atoms in lexical categories.

Any rule corresponding to a schema in the schema classes (1-8) has only those atoms on the right that occur somewhere on the left. Rules in classes (10-11) can each introduce a finite number of atoms, but there can be only a finite number of such rules, limiting the new atoms to a finite number. □

Definition 1. The *subcategories* for a category c are c_1 and c_2 if $c = c_1 \bullet c_2$ for $\bullet \in B$ and c if c is atomic. Its *second subcategories* are the subcategories of its subcategories.

Proposition 2. *Any CCG consisting of a subset of the rule schemata (1-3), (6-8) and (10-11) has derivations consisting of only a finite number of categories.*

Proof. We first prove the proposition excluding schema class (8). We will use structural induction on the derivations to prove that there is a bound on the size of the subcategories of any category in the derivation. The base case is the assignment of a lexical category to a word and the inductive step is the use of a rule from schema classes (1-4), (6-7) and (10-11).

Given that the lexicon is finite, there is a bound k on the size of the subcategories of lexical categories. Furthermore, there is a bound l on the size of the subcategories of categories on the right side of any rule in (10) and (11). Let $m = max(k, l)$.

For rules from schema class (1), the category on the right is a subcategory of the first category on the left, so the subcategories on the right are bound by m. For rules from schema classes (2-3), the category on the right has subcategories X and Z each of which is bound in size by m since they occur as subcategories of categories on the left.

For rules from schema class (6), since reducing generalized composition is a special case of re-

[3] Baldridge (2002) introduced a variant of CCG where modalities are added to the connectives / and \ along with variants of the combinatory rules based on these modalities. Our proofs about restriction class (B) are essentially identical to proofs regarding the multi-modal variant.

ducing generalized crossing composition, we need only consider the latter. The category on the right has subcategories $X|_1Z_1|_2 \ldots |_{n-1}|Z_{n-1}$ and Z_n. Z_n is bound in size by m because it occurs as a subcategory of the second category on the left. Then, the size of $Y|_1Z_1|_2 \ldots |_{n-1}|Z_{n-1}$ must be bound by m and since $|X| \leq |Y|$, the size of $X|_1Z_1|_2 \ldots |_{n-1}|Z_{n-1}$ must also be bound by m.

For rules from schema class (7), the category on the right has subcategories X and Z. The size of Z is bound by m because it is a subcategory of a category on the left. The size of X is bound by m because it is a second subcategory of a category on the left.

Finally, the use of rules in schema classes (10-11) have categories on the right that are bounded by l, which is, in turn, bounded by m. Then, by proposition 1, there must only be a finite number of categories in any derivation in a CCG consisting of a subset of rule schemata (1-3), (6-7) and (10-11).

The proof including schema class (8) is essentially identical except that k must be defined in terms of the size of the second subcategories. □

Definition 2. A grammar is *strongly context-free* if there exists a CFG such that the derivations of the two grammars are identical.

Proposition 3. *Any CCG consisting of a subset of the schema classes (1-3), (6-8) and (10-11) is strongly context-free.*

Proof. Since the CCG generates derivations whose categories are finite in number let C be that set of categories. Let $S(C, X)$ be the subset of C matching category X (which may have variables). Then, for each rule schema $C_1, C_2 \rightarrow C_3$ in (1-3) and (6-8), we construct a context-free rule $C'_3 \rightarrow C'_1, C'_2$ for each C'_i in $S(C, C_i)$ for $1 \leq i \leq 3$. Similarly, for each rule schema $C_1 \rightarrow C_2$ in (10), we construct a context-free rule $C'_2 \rightarrow C'_1$ which results in a finite number of such rules. Finally, for each rule schema $\vec{X} \rightarrow Z$ in (11) we construct a context-free rule $Z \rightarrow \vec{X}$. Then, for each entry in the lexicon $w \rightarrow C$, we construct a context-free rule $C \rightarrow w$.

The constructed CFG has precisely the same rules as the CCG restricted to the categories in C except that the left and right sides have been reversed. Thus, by proposition 2, the CFG has exactly the same derivations as the CCG. □

Proposition 4. *Any CCG consisting of a subset of the schema classes (1-3), (6-8) and (10-11) along with restriction class (B) is strongly context-free.*

Proof. If a CCG is allowed to restrict the use of its rules to certain categories as in schema class (B), then when we construct the context-free rules by enumerating only those categories in the set C allowed by the restriction. □

Proposition 5. *Any CCG that includes restriction class (A) is strongly context-free.*

Proof. We construct a context-free grammar with exactly those rules in the finite set of instantiations of the CCG rule schemata along with context-free rules corresponding to the lexicon. This CFG generates exactly the same derivations as the CCG. □

We have thus proved that of a wide range of the rule schemata used to define CCGs are context-free.

2.3 Combinatory Categorial Grammars in Practice

CCGbank (Hockenmaier and Steedman, 2007) is a corpus of CCG derivations that was semi-automatically converted from the Wall Street Journal section of the Penn treebank. Figure 2 shows a categorization of the rules used in CCGbank according to the schema classes defined in the preceding section where a rule is placed into the least general class to which it belongs. In addition to having no generalized composition other than the reducing variant, it should also be noted that in all generalized composition rules, $X = Y$ implying that the reducing class of generalized composition is a very natural schema class for CCGbank.

If we assume that type-raising is restricted to those instances occurring in CCGbank[4], then a CCG consisting of schema classes (1-3), (6-7) and (10-11) can generate all the derivations in CCGbank. By proposition 3, such a CCG is strongly context-free. One could also observe that since CCGbank is finite, its grammar is not only a context-free grammar but can produce only a finite number of derivations. However, our statement is much stronger because this CCG can generate all of the derivations in CCGbank given only the lexicon, the finite set of unrestricted rules and the finite number of type-raising rules.

[4]Without such an assumption, parsing is intractable.

Schema Class	*Rules*	*Instances*
Application	519	902176
Composition	102	7189
Crossed Composition	64	14114
Reducing Generalized Crossed Composition	50	612
Generalized Composition	0	0
Generalized Crossed Composition	0	0
Substitution	3	4
Type-Raising	27	3996
Unrestricted Rules	642	335011
Total	1407	1263102

Figure 2: The rules of CCGbank by schema class.

The Clark and Curran CCG Parser (Clark and Curran, 2007) is a CCG parser which uses CCGbank as a training corpus. Despite the fact that there is a strongly context-free CCG which generates all of the derivations in CCGbank, it is still possible that the grammar learned by the Clark and Curran parser is not a context-free grammar. However, in addition to rule schemata (1-6) and (10-11) they also include restriction class (A) by restricting rules to only those found in the training data[5]. Thus, by proposition 5, the Clark and Curran parser is a context-free parser.

3 A Latent Variable CCG Parser

The context-freeness of a number of CCGs should not be considered evidence that there is no advantage to CCG as a grammar formalism. Unlike the context-free grammars extracted from the Penn treebank, these allow for the categorial semantics that accompanies any categorial parse and for a more elegant analysis of linguistic structures such as extraction and coordination. However, because we now know that the CCG defined by CCGbank is strongly context-free, we can use tools from the CFG parsing community to improve CCG parsing.

To illustrate this point, we train the Petrov parser (Petrov and Klein, 2007) on CCGbank. The Petrov parser uses latent variables to refine a coarse-grained grammar extracted from a training corpus to a grammar which makes much more fine-grained syntactic distinctions. For example, in Petrov's experiments on the Penn treebank, the syntactic category NP was refined to the more fine-grained NP^1 and NP^2 roughly corresponding to NPs in subject and object positions. Rather than requiring such distinctions to be made in the corpus, the Petrov parser hypothesizes these splits automatically.

The Petrov parser operates by performing a fixed number of iterations of splitting, merging and smoothing. The splitting process is done by performing Expectation-Maximization to determine a likely potential split for each syntactic category. Then, during the merging process some of the splits are undone to reduce grammar size and avoid overfitting according to the likelihood of the split against the training data.

The Petrov parser was chosen for our experiments because it refines the grammar in a mathematically principled way without altering the nature of the derivations that are output. This is important because the input to the semantic backend and the system that converts CCG derivations to dependencies requires CCG derivations as they appear in CCGbank.

3.1 Experiments

Our experiments use CCGbank as the corpus and we use sections 02-21 for training (39603 sentences), 00 for development (1913 sentences) and 23 for testing (2407 sentences).

CCGbank, in addition to the basic atoms S, N, NP and PP, also differentiates both the S and NP atoms with *features* allowing more subtle distinctions. For example, declarative sentences are $S[dcl]$, wh-questions are $S[wq]$ and sentence fragments are $S[frg]$ (Hockenmaier and Steedman, 2007). These features allow finer control of the use of combinatory rules in the resulting grammars. However, this fine-grained control is exactly what the Petrov parser does automatically. Therefore, we trained the Petrov parser twice, once on the original version of CCGbank (denoted "Petrov") and once on a version of CCGbank without these features (denoted "Petrov no feats"). Furthermore, we will evaluate the parsers obtained after 0, 4, 5 and 6 training iterations (denoted I-0, I-4, I-5 and I-6). When we evaluate on sets of sentences for which not all parsers return an analysis, we report the coverage (denoted "Cover").

We use the `evalb` package for PARSEVAL evaluation and a modified version of Clark and

[5]The Clark and Curran parser has an option, which is disabled by default, for not restricting the rules to those that appear in the training data. However, they find that this restriction is "detrimental to neither parser accuracy or coverage" (Clark and Curran, 2007).

Figure 4: Supertagging accuracy on the sentences in section 23 that receive derivations from the three parsers shown.

Curran's `evaluate` script for dependency evaluation. To determine statistical significance, we obtain p-values from Bikel's randomized parsing evaluation comparator[6], modified for use with tagging accuracy, F-score and dependency accuracy.

3.2 Supertag Evaluation

Before evaluating the parse trees as a whole, we evaluate the categories assigned to words. In the supertagging literature, POS tagging and supertagging are distinguished – POS tags are the traditional Penn treebank tags (e.g. NN, VBZ and DT) and supertags are CCG categories. However, because the Petrov parser trained on CCGbank has no notion of Penn treebank POS tags, we can only evaluate the accuracy of the supertags.

The results are shown in figures 3 and 4 where the "Accuracy" column shows accuracy of the supertags against the CCGbank categories and the "No feats" column shows accuracy when features are ignored. Despite the lack of POS tags in the Petrov parser, we can see that it performs slightly better than the Clark and Curran parser. The difference in accuracy is only statistically significant between Clark and Curran's Normal Form model ignoring features and the Petrov parser trained on CCGbank without features (p-value = 0.013).

3.3 Constituent Evaluation

In this section we evaluate the parsers using the traditional PARSEVAL measures which measure recall, precision and F-score on constituents in both labeled and unlabeled versions. In addition, we report a variant of the labeled PARSEVAL measures where we ignore the features on the categories. For reasons of brevity, we report the PARSEVAL measures for all sentences in sections 00 and 23, rather than for sentences of length is less than 40 or less than 100. The results are essentially identical for those two sets of sentences.

Figure 5 gives the PARSEVAL measures on section 00 for Clark and Curran's two best models and the Petrov parser trained on the original CCGbank and the version without features after various numbers of training iterations. Figure 7 gives the accuracies on section 23.

In the case of Clark and Curran's hybrid model, the poor accuracy relative to the Petrov parsers can be attributed to the fact that this model chooses derivations based on the associated dependencies at the expense of constituent accuracy (see section 3.4). In the case of Clark and Curran's normal form model, the large difference between labeled and unlabeled accuracy is primarily due to the mislabeling of a small number of features (specifically, NP[nb] and NP[num]). The labeled accuracies without features gives the results when features are disregarded.

Due to the similarity of the accuracies and the difference in the coverage between I-5 of the Petrov parser on CCGbank and I-6 of the Petrov parser on CCGbank without features, we reevaluate their results on only those sentences for which they both return derivations in figures 6 and 8. These results show that the features in CCGbank actually inhibit accuracy (to a statistically significant degree in the case of unlabeled accuracy on section 00) when used as training data for the Petrov parser.

Figure 9 gives a comparison between the Petrov parser trained on the Penn treebank and on CCGbank. These numbers should not be directly compared, but the similarity of the unlabeled measures indicates that the difference between the structure of the Penn treebank and CCGbank is not large.[7]

3.4 Dependency Evaluation

The constituent-based PARSEVAL measures are simple to calculate from the output of the Petrov parser but the relationship of the PARSEVAL

[6] http://www.cis.upenn.edu/ dbikel/software.html

[7] Because punctuation in CCG can have grammatical function, we include it in our accuracy calculations resulting in lower scores for the Petrov parser trained on the Penn treebank than those reported in Petrov and Klein (2007).

scores to the quality of a parse is not entirely clear. For this reason, the word to word dependencies of categorial grammar parsers are often evaluated. This evaluation is aided by the fact that in addition to the CCG derivation for each sentence, CCGbank also includes a set of dependencies. Furthermore, extracting dependencies from a CCG derivation is well-established (Clark et al., 2002).

A CCG derivation can be converted into dependencies by, first, determining which arguments go with which functors as specified by the CCG derivation. This can be represented as in figure 10. Although this is not difficult, some care must be taken with respect to punctuation and the conjunction rules. Next, we reorient some of the edges according to information in the lexical categories. A language for specifying these instructions using variables and indices is given in Clark et al. (2002). This process is shown in figures 1, 10 and 11 with the directions of the dependencies reversed from Clark et al. (2002).

We used the CCG derivation to dependency converter `generate` included in the C&C tools package to convert the output of the Petrov parser to dependencies. Other than a CCG derivation, their system requires only the lexicon of edge reorientation instructions and methods for converting the unrestricted rules of CCGbank into the argument-functor relations. Important for the purpose of comparison, this system does not depend on their parser.

An unlabeled dependency is correct if the ordered pair of words is correct. A labeled dependency is correct if the ordered pair of words is correct, the head word has the correct category and the position of the category that is the source of that edge is correct. Figure 12 shows accuracies from the Petrov parser trained on CCGbank along with accuracies for the Clark and Curran parser. We only show accuracies for the Petrov parser trained on the original version of CCGbank because the dependency converter cannot currently generate dependencies for featureless derivations.

The relatively poor coverage of the Petrov parser is due to the failure of the dependency converter to output dependencies from valid CCG derivations. However, the coverage of the dependency converter is actually lower when run on the gold standard derivations indicating that this coverage problem is not indicative of inaccuracies in the Petrov parser. Due to the difference in coverage, we again evaluate the top two parsers on only those sentences that they both generate dependencies for and report those results in figures 13 and 14. The Petrov parser has better results by a statistically significant margin for both labeled and unlabeled recall and unlabeled F-score.

3.5 Time and Space Evaluation

As a final evaluation, we compare the resources that are required to both train and parse with the Petrov parser on the Penn Treebank, the Petrov parser on the original version of CCGbank, the Petrov parser on CCGbank without features and the Clark and Curran parser using the two models. All training and parsing was done on a 64-bit machine with 8 dual core 2.8 Ghz Opteron 8220 CPUs and 64GB of RAM. Our training times are much larger than those reported in Clark and Curran (2007) because we report the cumulative time spent on all CPUs rather than the maximum time spent on a CPU. Figure 15 shows the results.

As can be seen, the Clark and Curran parser has similar training times, although significantly greater RAM requirements than the Petrov parsers. In contrast, the Clark and Curran parser is significantly faster than the Petrov parsers, which we hypothesize to be attributed to the degree to which Clark and Curran have optimized their code, their use of `C++` as opposed to `Java` and their use of a supertagger to prune the lexicon.

4 Conclusion

We have provided a number of theoretical results proving that CCGbank contains no non-context-free structure and that the Clark and Curran parser is actually a context-free parser. Based on these results, we trained the Petrov parser on CCGbank and achieved state of the art results in terms of supertagging accuracy, PARSEVAL measures and dependency accuracy.

This demonstrates the following. First, the ability to extract semantic representations from CCG derivations is not dependent on the language class of a CCG. Second, using a dedicated supertagger, as opposed to simply using a general purpose tagger, is not necessary to accurately parse with CCG.

Acknowledgments

We would like to thank Stephen Clark, James Curran, Jackie C. K. Cheung and our three anonymous reviewers for their insightful comments.

Abstract

We propose a novel self-training method for a parser which uses a lexicalised grammar and supertagger, focusing on increasing the speed of the parser rather than its accuracy. The idea is to train the supertagger on large amounts of parser output, so that the supertagger can learn to supply the supertags that the parser will eventually choose as part of the highest-scoring derivation. Since the supertagger supplies fewer supertags overall, the parsing speed is increased. We demonstrate the effectiveness of the method using a CCG supertagger and parser, obtaining significant speed increases on newspaper text with no loss in accuracy. We also show that the method can be used to adapt the CCG parser to new domains, obtaining accuracy and speed improvements for Wikipedia and biomedical text.

1 Introduction

In many NLP tasks and applications, e.g. distributional similarity (Curran, 2004) and question answering (Dumais et al., 2002), large volumes of text and detailed syntactic information are both critical for high performance. To avoid a trade-off between these two, we need to increase parsing speed, but without losing accuracy.

Parsing with lexicalised grammar formalisms, such as Lexicalised Tree Adjoining Grammar and Combinatory Categorial Grammar (CCG; Steedman, 2000), can be made more efficient using a *supertagger*. Bangalore and Joshi (1999) call supertagging *almost parsing* because of the significant reduction in ambiguity which occurs once the supertags have been assigned.

In this paper, we focus on the CCG parser and supertagger described in Clark and Curran (2007). Since the CCG lexical category set used by the supertagger is much larger than the Penn Treebank POS tag set, the accuracy of supertagging is much lower than POS tagging; hence the CCG supertagger assigns multiple supertags[1] to a word, when the local context does not provide enough information to decide on the correct supertag.

The supertagger feeds lexical categories to the parser, and the two interact, sometimes using multiple passes over a sentence. If a spanning analysis cannot be found by the parser, the number of lexical categories supplied by the supertagger is increased. The supertagger-parser interaction influences speed in two ways: first, the larger the lexical ambiguity, the more derivations the parser must consider; second, each further pass is as costly as parsing a whole extra sentence.

Our goal is to increase parsing speed without loss of accuracy. The technique we use is a form of *self-training*, in which the output of the parser is used to train the supertagger component. The existing literature on self-training reports mixed results. Clark et al. (2003) were unable to improve the accuracy of POS tagging using self-training. In contrast, McClosky et al. (2006a) report improved accuracy through self-training for a two-stage parser and re-ranker.

Here our goal is not to improve accuracy, only to maintain it, which we achieve through an *adaptive* supertagger. The adaptive supertagger produces lexical categories that the parser would have used in the final derivation when using the baseline model. However, it does so with much lower ambiguity levels, and potentially during an earlier pass, which means sentences are parsed faster. By increasing the ambiguity level of the adaptive models to match the baseline system, we can also slightly increase supertagging accuracy, which can lead to higher parsing accuracy.

[1] We use *supertag* and *lexical category* interchangeably.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 345–355,
Uppsala, Sweden, 11-16 July 2010.

Using the parser to generate training data also has the advantage that it is not a domain specific process. Previous work has shown that parsers typically perform poorly outside of their training domain (Gildea, 2001). Using a newspaper-trained parser, we constructed new training sets for Wikipedia and biomedical text. These were used to create new supertagging models adapted to the different domains.

The self-training method of adapting the supertagger to suit the parser increased parsing speed by more than 50% across all three domains, without loss of accuracy. Using an adapted supertagger with ambiguity levels tuned to match the baseline system, we were also able to increase F-score on labelled grammatical relations by 0.75%.

2 Background

Many statistical parsers use two stages: a tagging stage that labels each word with its grammatical role, and a parsing stage that uses the tags to form a parse tree. Lexicalised grammars typically contain a much smaller set of rules than phrase-structure grammars, relying on tags (supertags) that contain a more detailed description of each word's role in the sentence. This leads to much larger tag sets, and shifts a large proportion of the search for an optimal derivation to the tagging component of the parser.

Figure 1 gives two sentences and their CCG derivations, showing how some of the syntactic ambiguity is transferred to the supertagging component in a lexicalised grammar. Note that the lexical category assigned to with is different in each case, reflecting the fact that the prepositional phrase attaches differently. Either we need a tagging model that can resolve this ambiguity, or both lexical categories must be supplied to the parser which can then attempt to resolve the ambiguity by eventually selecting between them.

2.1 Supertagging

Supertaggers typically use standard linear-time tagging algorithms, and only consider words in the local context when assigning a supertag. The C&C supertagger is similar to the Ratnaparkhi (1996) tagger, using features based on words and POS tags in a five-word window surrounding the target word, and defining a local probability distribution over supertags for each word in the sentence, given the previous two supertags. The Viterbi algorithm

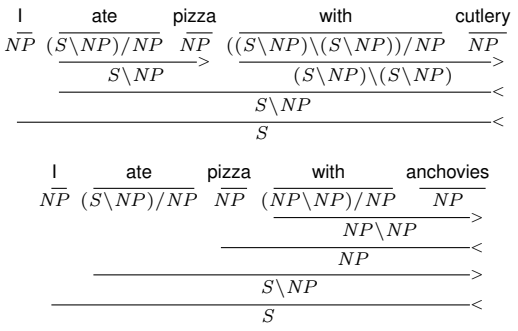

Figure 1: Two CCG derivations with PP ambiguity.

can be used to find the most probable supertag sequence. Alternatively the Forward-Backward algorithm can be used to efficiently sum over all sequences, giving a probability distribution over supertags for each word which is conditional only on the input sentence.

Supertaggers can be made accurate enough for wide coverage parsing using multi-tagging (Chen et al., 1999), in which more than one supertag can be assigned to a word; however, as more supertags are supplied by the supertagger, parsing efficiency decreases (Chen et al., 2002), demonstrating the influence of lexical ambiguity on parsing complexity (Sarkar et al., 2000).

Clark and Curran (2004) applied supertagging to CCG, using a flexible multi-tagging approach. The supertagger assigns to a word all lexical categories whose probabilities are within some factor, β, of the most probable category for that word. When the supertagger is integrated with the C&C parser, several progressively lower β values are considered. If a sentence is not parsed on one pass then the parser attempts to parse the sentence again with a lower β value, using a larger set of categories from the supertagger. Since most sentences are parsed at the first level (in which the average number of supertags assigned to each word is only slightly greater than one), this provides some of the speed benefit of single tagging, but without loss of coverage (Clark and Curran, 2004).

Supertagging has since been effectively applied to other formalisms, such as HPSG (Blunsom and Baldwin, 2006; Zhang et al., 2009), and as an information source for tasks such as Statistical Machine Translation (Hassan et al., 2007). The use of parser output for supertagger training has been explored for LTAG by Sarkar (2007). However, the focus of that work was on improving parser and supertagger accuracy rather than speed.

Previously	,	watch	imports	were	denied	such	duty-free	treatment

Figure 2: An example sentence and the sets of categories assigned by the supertagger. The first category in each column is correct and the categories used by the parser are marked in bold. The correct category for watch is included here, for expository purposes, but in fact was not provided by the supertagger.

2.2 Semi-supervised training

Previous exploration of semi-supervised training in NLP has focused on improving accuracy, often for the case where only small amounts of manually labelled training data are available. One approach is *co-training*, in which two models with independent views of the data iteratively inform each other by labelling extra training data. Sarkar (2001) applied co-training to LTAG parsing, in which the supertagger and parser provide the two views. Steedman et al. (2003) extended the method to a variety of parser pairs.

Another method is to use a re-ranker (Collins and Koo, 2002) on the output of a system to generate new training data. Like co-training, this takes advantage of a different view of the data, but the two views are not independent as the re-ranker is limited to the set of options produced by the system. This method has been used effectively to improve parsing performance on newspaper text (McClosky et al., 2006a), as well as adapting a Penn Treebank parser to a new domain (McClosky et al., 2006b).

As well as using independent views of data to generate extra training data, multiple views can be used to provide constraints at test time. Hollingshead and Roark (2007) improved the accuracy of a parsing pipeline by using the output of later stages to constrain earlier stages.

The only work we are aware of that uses self-training to improve the *efficiency* of parsers is van Noord (2009), who adopts a similar idea to the one in this paper for improving the efficiency of a Dutch parser based on a manually constructed HPSG grammar.

3 Adaptive Supertagging

The purpose of the supertagger is to cut down the search space for the parser by reducing the set of categories that must be considered for each word. A perfect supertagger would assign the correct category to every word. CCG supertaggers are about 92% accurate when assigning a single lexical category to each word (Clark and Curran, 2004). This is not accurate enough for wide coverage parsing and so a multi-tagging approach is used instead. In the final derivation, the parser uses one category from each set, and it is important to note that having the correct category in the set does not guarantee that the parser will use it.

Figure 2 gives an example sentence and the sets of lexical categories supplied by the supertagger, for a particular value of β.[2] The usual target of the supertagging task is to produce the top row of categories in Figure 2, the correct categories. We propose a new task that instead aims for the categories the parser will use, which are marked in bold for this case. The purpose of this new task is to improve speed.

The reason speed will be improved is that we can construct models that will constrain the set of possible derivations more than the baseline model. We can construct these models because we can obtain much more of our target output, parser-annotated sentences, than we could for the gold-standard supertagging task.

The new target data will contain tagging errors, and so supertagging accuracy measured against the correct categories may decrease. If we obtained perfect accuracy on our new task then we would be removing all of the categories not chosen by the parser. However, parsing accuracy will not decrease since the parser will still receive the categories it would have used, and will therefore be able to form the same highest-scoring derivation (and hence will choose it).

To test this idea we parsed millions of sentences

[2]Two of the categories for such have been left out for reasons of space, and the correct category for watch has been included for expository reasons. The fact that the supertagger does not supply this category is the reason that the parser does not analyse the sentence correctly.

in three domains, producing new data annotated with the categories that the parser used with the baseline model. We constructed new supertagging models that are adapted to suit the parser by training on the combination of these sets and the standard training corpora. We applied standard evaluation metrics for speed and accuracy, and explored the source of the changes in parsing performance.

4 Data

In this work, we consider three domains: newswire, Wikipedia text and biomedical text.

4.1 Training and accuracy evaluation

We have used Sections 02-21 of CCGbank (Hockenmaier and Steedman, 2007), the CCG version of the Penn Treebank (Marcus et al., 1993), as training data for the newspaper domain. Sections 00 and 23 were used for development and test evaluation. A further 113,346,430 tokens (4,566,241 sentences) of raw data from the Wall Street Journal section of the North American News Corpus (Graff, 1995) were parsed to produce the training data for adaptation. This text was tokenised using the C&C tools tokeniser and parsed using our baseline models. For the smaller training sets, sentences from 1988 were used as they would be most similar in style to the evaluation corpus. In all experiments the sentences from 1989 were excluded to ensure no overlap occurred with CCGbank.

As Wikipedia text we have used 794,024,397 tokens (51,673,069 sentences) from Wikipedia articles. This text was processed in the same way as the NANC data to produce parser-annotated training data. For supertagger evaluation, one thousand sentences were manually annotated with CCG lexical categories and POS tags. For parser evaluation, three hundred of these sentences were manually annotated with DepBank grammatical relations (King et al., 2003) in the style of Briscoe and Carroll (2006). Both sets of annotations were produced by manually correcting the output of the baseline system. The annotation was performed by Stephen Clark and Laura Rimell.

For the biomedical domain we have used several different resources. As gold standard data for supertagger evaluation we have used supertagged GENIA data (Kim et al., 2003), annotated by Rimell and Clark (2008). For parsing evaluation, grammatical relations from the BioInfer corpus were used (Pyysalo et al., 2007), with the same post-processing process as Rimell and Clark (2009) to convert the C&C parser output to Stanford format grammatical relations (de Marneffe et al., 2006). For adaptive training we have used 1,900,618,859 tokens (76,739,723 sentences) from the MEDLINE abstracts tokenised by McIntosh and Curran (2008). These sentences were POS-tagged and parsed twice, once as for the newswire and Wikipedia data, and then again, using the bio-specific models developed by Rimell and Clark (2009). Statistics for the sentences in the training sets are given in Table 1.

Source	Sentence Length			Corpus %
	Range	Average	Variance	
News	0-4	3.26	0.64	1.2
	5-20	14.04	17.41	39.2
	21-40	28.76	29.27	49.4
	41-250	49.73	86.73	10.2
	All	24.83	152.15	100.0
Wiki	0-4	2.81	0.60	22.4
	5-20	11.64	21.56	48.9
	21-40	28.02	28.48	24.3
	41-250	49.69	77.70	4.5
	All	15.33	154.57	100.0
Bio	0-4	2.98	0.75	0.9
	5-20	14.54	15.14	41.3
	21-40	28.49	29.34	48.0
	41-250	49.17	68.34	9.8
	All	24.53	139.35	100.0

Table 1: Statistics for sentences in the supertagger training data. Sentences containing more than 250 tokens were not included in our data sets.

4.2 Speed evaluation data

For speed evaluation we held out three sets of sentences from each domain-specific corpus. Specifically, we used 30,000, 4,000 and 2,000 unique sentences of length 5-20, 21-40 and 41-250 tokens respectively. Speeds on these length controlled sets were combined to calculate an overall parsing speed for the text in each domain. Note that more than 20% of the Wikipedia sentences were less than five words in length and the overall distribution is skewed towards shorter sentences compared to the other corpora.

5 Evaluation

We used the hybrid parsing model described in Clark and Curran (2007), and the Viterbi decoder to find the highest-scoring derivation. The multi-pass supertagger-parser interaction was also used.

The test data was excluded from training data for the supertagger for all of the newswire and Wikipedia models. For the biomedical models ten-

fold cross validation was used. The accuracy of supertagging is measured by multi-tagging at the first β level and considering a word correct if the correct tag is amongst any of the assigned tags.

For the biomedical parser evaluation we have used the parsing model and grammatical relation conversion script from Rimell and Clark (2009).

Our timing measurements are calculated in two ways. Overall times were measured using the C&C parser's timers. Individual sentence measurements were made using the Intel timing registers, since standard methods are not accurate enough for the short time it takes to parse a single sentence.

To check whether changes were statistically significant we applied the test described by Chinchor (1995). This measures the probability that two sets of responses are drawn from the same distribution, where a score below 0.05 is considered significant.

Models were trained on an Intel Core2Duo 3GHz with 4GB of RAM. The evaluation was performed on a dual quad-core Intel Xeon 2.27GHz with 16GB of RAM.

5.1 Tagging ambiguity optimisation

The number of lexical categories assigned to a word by the CCG supertagger depends on the probabilities calculated for each category and the β level being used. Each lexical category with a probability within a factor of β of the most probable category is included. This means that the choice of β level determines the tagging ambiguity, and so has great influence on parsing speed, accuracy and coverage. Also, the tagging ambiguity produced by a β level will vary between models. A more confident model will have a more peaked distribution of category probabilities for a word, and therefore need a smaller β value to assign the same number of categories.

Additionally, the C&C parser uses multiple β levels. The first pass over a sentence is at a high β level, resulting in a low tagging ambiguity. If the categories assigned are too restrictive to enable a spanning analysis, the system makes another pass with a lower β level, resulting in a higher tagging ambiguity. A maximum of five passes are made, with the β levels varying from 0.075 to 0.001.

We have taken two approaches to choosing β levels. When the aim of an experiment is to improve speed, we use the system's default β levels. While this choice means a more confident model will assign fewer tags, this simply reflects the fact that the model is more confident. It should produce similar accuracy results, but with lower ambiguity, which will lead to higher speed.

For accuracy optimisation experiments we tune the β levels to produce the same average tagging ambiguity as the baseline model on Section 00 of CCGbank. Accuracy depends heavily on the number of categories supplied, so the new models are at an accuracy disadvantage if they propose fewer categories. By matching the ambiguity of the default model, we can increase accuracy at the cost of some of the speed improvements the new models obtain.

6 Results

We have performed four primary sets of experiments to explore the ability of an adaptive supertagger to improve parsing speed or accuracy. In the first two experiments, we explore performance on the newswire domain, which is the source of training data for the parsing model and the baseline supertagging model. In the second set of experiments, we train on a mixture of gold standard newswire data and parser-annotated data from the target domain.

In both cases we perform two experiments. The first aimed to improve speed, keeping the β levels the same. This should lead to an increase in speed as the extra training data means the models are more confident and so have lower ambiguity than the baseline model for a given β value. The second experiment aimed to improve accuracy, tuning the β levels as described in the previous section.

6.1 Newswire speed improvement

In our first experiment, we trained supertagger models using Generalised Iterative Scaling (GIS) (Darroch and Ratcliff, 1972), the limited memory BFGS method (BFGS) (Nocedal and Wright, 1999), the averaged perceptron (Collins, 2002), and the margin infused relaxed algorithm (MIRA) (Crammer and Singer, 2003). Note that these are all alternative methods for estimating the *local* log-linear probability distributions used by the Ratnaparkhi-style tagger. We do not use global tagging models as in Lafferty et al. (2001) or Collins (2002). The training data consisted of Sections 02–21 of CCGbank and progressively larger quantities of parser-annotated NANC data – from zero to four million extra sentences. The results of these tests are presented in Table 2.

	Ambiguity (%)				Tagging Accuracy (%)				F-score				Speed (sents / sec)			
Data	0k	40k	400k	4m	0k	40k	400k	4m	0k	40k	400k	4m	0k	40k	400k	4m

	Higher tag amb.	2	1	1	-0.13	26.43	308.03	-3.4e-05	0.033	0.16

Table 3: Breakdown of the source of changes in speed. The test sentences are divided into nine sets based on the change in parsing behaviour between the baseline model and a model trained using MIRA, Sections 02-21 of CCGbank and 4,000,000 NANC sentences.

Using the default β levels we found that the perceptron-trained models lost accuracy, disqualifying them from this test. The BFGS, GIS and MIRA models produced mixed results, but no statistically significant decrease in accuracy, and as the amount of parser-annotated data was increased, parsing speed increased by up to 85%.

To determine the source of the speed improvement we considered the times recorded by the timing registers. In Table 3, we have aggregated these measurements based on the change in the pass at which the sentence is parsed, and how the tagging ambiguity changes on that pass. For sentences parsed on two different passes the ambiguity comparison is at the earlier pass. The "Total Time Change" section of the table is the change in parsing time for sentences of that type when parsing ten thousand sentences from the corpus. This takes into consideration the actual distribution of sentence lengths in the corpus.

Several effects can be observed in these results. 72% of sentences are parsed on the same pass, but with lower tag ambiguity (5th row in Table 3). This provides 44% of the speed improvement. Three to six times as many sentences are parsed on an earlier pass than are parsed on a later pass. This means the sentences parsed later have very little effect on the overall speed. At the same time, the average gain for sentences parsed earlier is almost always larger than the average cost for sentences parsed later. These effects combine to produce a particularly large improvement for the sentences parsed at an earlier pass. In fact, despite making up only 7% of sentences in the set, those parsed earlier with lower ambiguity provide 50% of the speed improvement.

It is also interesting to note the changes for sentences parsed on the same pass, with the same ambiguity. We may expect these sentences to be parsed in approximately the same amount of time, and this is the case for the short set, but not for the two larger sets, where we see an increase in parsing time. This suggests that the categories being supplied are more productive, leading to a larger set of possible derivations.

6.2 Newswire accuracy optimised

Any decrease in tagging ambiguity will generally lead to a decrease in accuracy. The parser uses a more sophisticated algorithm with global knowledge of the sentence and so we would expect it to be better at choosing categories than the supertagger. Unlike the supertagger it will exclude categories that cannot be used in a derivation. In the previous section, we saw that training the supertagger on parser output allowed us to develop models that produced the same categories, despite lower tagging ambiguity. Since they were trained on the categories the parser was able to use in derivations, these models should also now be providing categories that are more likely to be useful.

This leads us to our second experiment, opti-

	Tagging Accuracy (%)				F-score				Speed (sents / sec)

Table 5: Cross-corpus speed improvement, models trained with MIRA and 4,000,000 sentences. The highlighted values are the top speed for each evaluation set and results that are statistically indistinguishable from it.

mising accuracy on newswire. We used the same models as in the previous experiment, but tuned the β levels as described in Section 5.1.

Comparing Tables 2 and 4 we can see the influence of β level choice, and therefore tagging ambiguity. When the default β values were used ambiguity dropped consistently as more parser-annotated data was used, and category accuracy dropped in the same way. Tuning the β levels to match ambiguity produces the opposite trend.

Interestingly, while the decrease in supertag accuracy in the previous experiment did not translate into a decrease in F-score, the increase in tag accuracy here does translate into an increase in F-score. This indicates that the supertagger is adapting to suit the parser. In the previous experiment, the supertagger was still providing the categories the parser would have used with the baseline supertagging model, but it provided fewer other categories. Since the parser is not a perfect supertagger these other categories may in fact have been incorrect, and so supertagger accuracy goes down, without changing parsing results. Here we have allowed the supertagger to assign extra categories, which will only increase its accuracy.

The increase in F-score has two sources. First, our supertagger is more accurate, and so the parser is more likely to receive category sets that can be combined into the correct derivation. Also, the supertagger has been trained on categories that the parser is able to use in derivations, which means they are more productive.

As Table 6 shows, this change translates into an improvement of up to 0.75% in F-score on Section 23 of CCGbank. All of the new models in the table make a statistically significant improvement over the baseline.

Model	Tag. Acc. (%)	F-score (%)	Speed (sents/sec)
Baseline	96.51	85.20	39.6
GIS, 4,000k NANC	96.83	**85.95**	42.6
BFGS, 4,000k NANC	96.91	85.90	42.7
MIRA, 4,000k NANC	96.84	85.79	42.9

Table 6: Evaluation of top models on Section 23 of CCGbank. All changes in F-score are statistically significant.

It is also interesting to note that the results in Tables 2, 4 and 6, are similar for all of the training algorithms. However, the training times differ considerably. For all four algorithms the training time is proportional to the amount of data, but the GIS and BFGS models trained on only CCGbank took 4,500 and 4,200 seconds to train, while the equivalent perceptron and MIRA models took 90 and 95 seconds to train.

6.3 Annotation method comparison

To determine whether these improvements were dependent on the annotations being produced by the parser we performed a set of tests with supertagger, rather than parser, annotated data. Three extra training sets were created by annotating newswire sentences with supertags using the baseline supertagging model. One set used the one-best tagger, and two were produced using the most probable tag for each word out of the set supplied by the multi-tagger, with variations in the β value and dictionary cutoff for the two sets.

News	242	44.8	8.24
Wiki	224	42.0	6.10
Bio	268	41.5	6.48

Table 9: Cross-corpus speed for the baseline model on data sets balanced on sentence length.

As Table 8 shows, in all cases the use of supertagger-annotated data led to poorer performance than the baseline system, while the use of parser-annotated data led to an improvement in F-score. The parser has access to a range of information that the supertagger does not, producing a different view of the data that the supertagger can productively learn from.

6.4 Cross-domain speed improvement

When applying parsers out of domain they are typically slower and less accurate (Gildea, 2001). In this experiment, we attempt to increase speed on out-of-domain data. Note that for some of the results presented here it may appear that the C&C parser does not lose speed when out of domain, since the Wikipedia and biomedical corpora contain shorter sentences on average than the news corpus. However, by testing on balanced sets it is clear that speed does decrease, particularly for longer sentences, as shown in Table 9.

For our domain adaptation development experiments, we considered a collection of different models; here we only present results for the best set of models. For speed improvement these were MIRA models trained on 4,000,000 parser-annotated sentences from the target domain.

As Table 5 shows, this training method produces models adapted to the new domain. In particular, note that models trained on Wikipedia or the biomedical data produce lower F-scores[3] than the baseline on newswire. Meanwhile, on the target domain they are adapted to, these models achieve a higher F-score and parse sentences at least 45% faster than the baseline.

The changes in tagging ambiguity and accuracy also show that adaptation has occurred. In all cases, the new models have lower tagging ambiguity, and lower supertag accuracy. However, on the corpus of the extra data, the performance of the adapted models is comparable to the baseline model, which means the parser is probably still be receiving the same categories that it used from the sets provided by the baseline system.

6.5 Cross-domain accuracy optimised

The ambiguity tuning method used to improve accuracy on the newspaper domain can also be applied to the models trained on other domains. In Table 7, we have tested models trained using GIS and 400,000 sentences of parsed target-domain text, with β levels tuned to match ambiguity with the baseline.

As for the newspaper domain, we observe increased supertag accuracy and F-score. Also, in almost every case the new models perform worse than the baseline on domains other than the one they were trained on.

In some cases the models in Table 7 are less accurate than those in Table 5. This is because as well as optimising the β levels we have changed training methods. All of the training methods were tried, but only the method with the best results in newswire is included here, which for F-score when trained on 400,000 sentences was GIS.

The accuracy presented so far for the biomedi-

[3]Note that the F-scores for Wikipedia and biomedical text are reported to only three significant figures as only 300 and 500 sentences respectively were available for parser evaluation.

Table 10: Performance comparison for models using extra gold standard biomedical data. Models were trained with GIS and 4,000,000 extra sentences, and are tested using a POS-tagger trained on biomedical data.

cal model is considerably lower than that reported by Rimell and Clark (2009). This is because no gold standard biomedical training data was used in our experiments. Table 10 shows the results of adding Rimell and Clark's gold standard biomedical supertag data and using their biomedical POS-tagger. The table also shows how accuracy can be further improved by adding our parser-annotated data from the biomedical domain as well as the additional gold standard data.

7 Conclusion

This work has demonstrated that an adapted supertagger can improve parsing speed and accuracy. The purpose of the supertagger is to reduce the search space for the parser. By training the supertagger on parser output, we allow the parser to reach the derivation it would have found, sooner. This approach also enables domain adaptation, improving speed and accuracy outside the original domain of the parser.

The perceptron-based algorithms used in this work are also able to function online, modifying the model weights after each sentence is parsed. This could be used to construct a system that continuously adapts to the domain it is parsing.

By training on parser-annotated NANC data we constructed models that were adapted to the newspaper-trained parser. The fastest model parsed sentences 1.85 times as fast and was as accurate as the baseline system. Adaptive training is also an effective method of improving performance on other domains. Models trained on parser-annotated Wikipedia text and MEDLINE text had improved performance on these target domains, in terms of both speed and accuracy. Optimising for speed or accuracy can be achieved by modifying the β levels used by the supertagger, which controls the lexical category ambiguity at each level used by the parser.

The result is an accurate and efficient wide-coverage CCG parser that can be easily adapted for NLP applications in new domains without manually annotating data.

Abstract

We investigate active learning methods for Japanese dependency parsing. We propose active learning methods of using partial dependency relations in a given sentence for parsing and evaluate their effectiveness empirically. Furthermore, we utilize syntactic constraints of Japanese to obtain more labeled examples from precious labeled ones that annotators give. Experimental results show that our proposed methods improve considerably the learning curve of Japanese dependency parsing. In order to achieve an accuracy of over 88.3%, one of our methods requires only 34.4% of labeled examples as compared to passive learning.

1 Introduction

Reducing annotation cost is very important because supervised learning approaches, which have been successful in natural language processing, require typically a large number of labeled examples. Preparing many labeled examples is time consuming and labor intensive.

One of most promising approaches to this issue is active learning. Recently much attention has been paid to it in the field of natural language processing. Various tasks have been targeted in the research on active learning. They include word sense disambiguation, e.g., (Zhu and Hovy, 2007), POS tagging (Ringger et al., 2007), named entity recognition (Laws and Schütze, 2008), word segmentation, e.g., (Sassano, 2002), and parsing, e.g., (Tang et al., 2002; Hwa, 2004).

It is the main purpose of this study to propose methods of improving active learning for parsing by using a smaller constituent than a sentence as a unit that is selected at each iteration of active learning. Typically in active learning for parsing a sentence has been considered to be a basic unit for selection. Small constituents such as chunks have not been used in sample selection for parsing. We use Japanese dependency parsing as a target task in this study since a simple and efficient algorithm of parsing is proposed and, to our knowledge, active learning for Japanese dependency parsing has never been studied.

The remainder of the paper is organized as follows. Section 2 describes the basic framework of active learning which is employed in this research. Section 3 describes the syntactic characteristics of Japanese and the parsing algorithm that we use. Section 4 briefly reviews previous work on active learning for parsing and discusses several research challenges. In Section 5 we describe our proposed methods and others of active learning for Japanese dependency parsing. Section 6 describes experimental evaluation and discussion. Finally, in Section 7 we conclude this paper and point out some future directions.

2 Active Learning

2.1 Pool-based Active Learning

Our base framework of active learning is based on the algorithm of (Lewis and Gale, 1994), which is called *pool-based active learning*. Following their sequential sampling algorithm, we show in Figure 1 the basic flow of pool-based active learning. Various methods for selecting informative examples can be combined with this framework.

2.2 Selection Algorithm for Large Margin Classifiers

One of the most accurate approaches to classification tasks is an approach with large margin classifiers. Suppose that we are given data points $\{x_i\}$ such that the associated label y_i will be either -1 or 1, and we have a hyperplane of some large margin classifier defined by $\{x : f(x) = 0\}$ where the

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 356–365,
Uppsala, Sweden, 11-16 July 2010.

1. Build an initial classifier from an initial labeled training set.
2. While resources for labeling examples are available
   (a) Apply the current classifier to each unlabeled example
   (b) Find the m examples which are most *informative* for the classifier
   (c) Have annotators label the m examples
   (d) Train a new classifier on all labeled examples

	Lisa-ga	kare-ni	ano	pen-wo	age-ta.
	Lisa-subj	to him	that	pen-acc	give-past.
ID	0	1	2	3	4
Head	4	4	3	4	-

Figure 2: Sample sentence. An English translation is "Lisa gave that pen to him."

classification function is $G(x) = \text{sign}\{f(x)\}$. In pool-based active learning with large margin classifiers, selection of examples can be done as follows:

1. Compute $f(x_i)$ over all unlabeled examples x_i in the pool.
2. Sort x_i with $|f(x_i)|$ in ascending order.
3. Select top m examples.

This type of selection methods with SVMs is discussed in (Tong and Koller, 2000; Schohn and Cohn, 2000). They obtain excellent results on text classification. These selection methods are simple but very effective.

3 Japanese Parsing

3.1 Syntactic Units

A basic syntactic unit used in Japanese parsing is a *bunsetsu*, the concept of which was initially introduced by Hashimoto (1934). We assume that in Japanese we have a sequence of *bunsetsu*s before parsing a sentence. A *bunsetsu* contains one or more content words and zero or more function words.

A sample sentence in Japanese is shown in Figure 2. This sentence consists of five bunsetsus: *Lisa-ga, kare-ni, ano, pen-wo,* and *age-ta* where *ga, ni,* and *wo* are postpositions and *ta* is a verb ending for past tense.

3.2 Constraints of Japanese Dependency Analysis

Japanese is a head final language and in written Japanese we usually hypothesize the following:

- Each bunsetsu has only one head except the rightmost one.
- Dependency links between bunsetsus go from left to right.
- Dependencies do not cross one another.

We can see that these constraints are satisfied in the sample sentence in Figure 2. In this paper we also assume that the above constraints hold true when we discuss algorithms of Japanese parsing and active learning for it.

3.3 Algorithm of Japanese Dependency Parsing

We use Sassano's algorithm (Sassano, 2004) for Japanese dependency parsing. The reason for this is that it is very accurate and efficient[1]. Furthermore, it is easy to implement. His algorithm is one of the simplest form of shift-reduce parsers and runs in linear-time.[2] Since Japanese is a head final language and its dependencies are projective as described in Section 3.2, that simplification can be made.

The basic flow of Sassano's algorithm is shown in Figure 3, which is slightly simplified from the original by Sassano (2004). When we use this algorithm with a machine learning-based classifier, function Dep() in Figure 3 uses the classifier to decide whether two bunsetsus have a dependency relation. In order to prepare training examples for the trainable classifier used with his algorithm, we first have to convert a treebank to suitable labeled instances by using the algorithm in Figure 4. Note

[1] Iwatate et al. (2008) compare their proposed algorithm with various ones that include Sassano's, cascaded chunking (Kudo and Matsumoto, 2002), and one in (McDonald et al., 2005). Kudo and Matsumoto (2002) compare cascaded chunking with the CYK method (Kudo and Matsumoto, 2000). After considering these results, we have concluded so far that Sassano's is a reasonable choice for our purpose.

[2] Roughly speaking, Sassano's is considered to be a simplified version, which is modified for head final languages, of Nivre's (Nivre, 2003). Classifiers with Nivre's are required to handle multiclass prediction, while binary classifiers can work with Sassano's for Japanese.

Input: w_i: bunsetsus in a given sentence.
N: the number of bunsetsus.
Output: h_j: the head IDs of bunsetsus w_j.
Functions: Push(i, s): pushes i on the stack s.
Pop(s): pops a value off the stack s.
Dep(j, i, w): returns true when w_j should modify w_i. Otherwise returns false.

```
procedure Analyze(w, N, h)
var s: a stack for IDs of modifier bunsetsus
begin
  {−1 indicates no modifier candidate}
  Push(−1, s);
  Push(0, s);
  for i ← 1 to N − 1 do begin
    j ← Pop(s);
    while (j ≠ −1
        and ((i = N − 1) or Dep(j, i, w)) ) do
    begin
      h_j ← i;
      j ← Pop(s)
    end
    Push(j, s);
    Push(i, s)
  end
end
```

Figure 3: Algorithm of Japanese dependency parsing

that the algorithm in Figure 4 does not generate every pair of bunsetsus.[3]

4 Active Learning for Parsing

Most of the methods of active learning for parsing in previous work use selection of sentences that seem to contribute to the improvement of accuracy (Tang et al., 2002; Hwa, 2004; Baldridge and Osborne, 2004). Although Hwa suggests that sample selection for parsing would be improved by selecting finer grained constituents rather than sentences (Hwa, 2004), such methods have not been investigated so far.

Typical methods of selecting sentences are

[3]We show a sample set of generated examples for training the classifier of the parser in Figure 3. By using the algorithm in Figure 4, we can obtain labeled examples from the sample sentences in Figure 2: $\{0, 1,$ "O"$\}$, $\{1, 2,$ "O"$\}$, $\{2, 3,$ "D"$\}$, and $\{1, 3,$ "O"$\}$. Please see Section 5.2 for the notation used here. For example, an actual labeled instance generated from $\{2, 3,$ "D"$\}$ will be like "label=D, features={modifier-content-word=ano, ..., head-content-word=pen, ...}."

Input: h_i: the head IDs of bunsetsus w_i.
Function: Dep(j, i, w, h): returns true if $h_j = i$.
Otherwise returns false. Also prints a feature vector with a label according to h_j.

```
procedure Generate(w, N, h)
begin
  Push(−1, s);
  Push(0, s);
  for i ← 1 to N − 1 do begin
    j ← Pop(s);
    while (j ≠ −1
      and ((i = N − 1) or Dep(j, i, w, h)) ) do
    begin
      j ← Pop(s)
    end
    Push(j, s);
    Push(i, s)
  end
end
```

Figure 4: Algorithm of generating training examples

based on some entropy-based measure of a given sentence (e.g., (Tang et al., 2002)). We cannot use this kind of measures when we want to select other smaller constituents than sentences. Other bigger problem is an algorithm of parsing itself. If we sample smaller units rather than sentences, we have partially annotated sentences and have to use a parsing algorithm that can be trained from incompletely annotated sentences. Therefore, it is difficult to use some of probabilistic models for parsing. [4]

5 Active Learning for Japanese Dependency Parsing

In this section we describe sample selection methods which we investigated.

5.1 Sentence-wise Sample Selection

Passive Selection (Passive) This method is to select sequentially sentences that appear in the training corpus. Since it gets harder for the readers to reproduce the same experimental setting, we

[4]We did not employ *query-by-committee* (QBC) (Seung et al., 1992), which is another important general framework of active learning, since the selection strategy with large margin classifiers (Section 2.2) is much simpler and seems more practical for active learning in Japanese dependency parsing with smaller constituents.

avoid to use random sampling in this paper.

Minimum Margin Selection (Min) This method is to select sentences that contain bunsetsu pairs which have smaller margin values of outputs of the classifier used in parsing. The procedure of selection of MIN are summarized as follows. Assume that we have sentences s_i in the pool of unlabeled sentences.

1. Parse s_i in the pool with the current model.
2. Sort s_i with $\min |f(x_k)|$ where x_k are bunsetsu pairs in the sentence s_i. Note that x_k are not all possible bunsetsu pairs in s_i and they are limited to bunsetsu pairs checked in the process of parsing s_i.
3. Select top m sentences.

Averaged Margin Selection (Avg) This method is to select sentences that have smaller values of averaged margin values of outputs of the classifier in a give sentences over the number of decisions which are carried out in parsing. The difference between AVG and MIN is that for AVG we use $\sum |f(x_k)|/l$ where l is the number of calling Dep() in Figure 3 for the sentence s_i instead of $\min |f(x_k)|$ for MIN.

5.2 Chunk-wise Sample Selection

In chunk-wise sample selection, we select bunsetsu pairs rather than sentences. Bunsetsu pairs are selected from different sentences in a pool. This means that structures of sentences in the pool are partially annotated.

Note that we do not use every bunsetsu pair in a sentence. When we use Sassano's algorithm, we have to generate training examples for the classifier by using the algorithm in Figure 4. In other words, we should not sample bunsetsu pairs independently from a given sentence.

Therefore, we select bunsetsu pairs that have smaller margin values of outputs given by the classifier during the parsing process. All the sentences in the pool are processed by the current parser. We cannot simply split the sentences in the pool into labeled and unlabeled ones because we do not select every bunsetsu pair in a given sentence.

Naive Selection (Naive) This method is to select bunsetsu pairs that have smaller margin values of outputs of the classifier. Then it is assumed that annotators would label either "D" for the two bunsetsu having a dependency relation or "O", which represents the two does not.

Modified Simple Selection (ModSimple) Although NAIVE seems to work well, it did not (discussed later). MODSIMPLE is to select bunsetsu pairs that have smaller margin values of outputs of the classifier, which is the same as in NAIVE. The difference between MODSIMPLE and NAIVE is the way annotators label examples. Assume that we have an annotator and the learner selects some bunsetsu pair of the j-th bunsetsu and the i-th bunsetsu such that $j < i$. The annotator is then asked what the head of the j-th bunsetsu is. We define here the head bunsetsu is the k-th one.

We differently generate labeled examples from the information annotators give according to the relation among bunsetsus j, i, and k.

Below we use the notation $\{s, t, \text{"D"}\}$ to denote that the s-th bunsetsu modifies the t-th one. The use of "O" instead of "D" indicates that the s-th does not modify the t-th. That is generating $\{s, t, \text{"D"}\}$ means outputting an example with the label "D".

Case 1 if $j < i < k$, then generate $\{j, i, \text{"O"}\}$ and $\{j, k, \text{"D"}\}$.

Case 2 if $j < i = k$, then generate $\{j, k, \text{"D"}\}$.

Case 3 if $j < k < i$, then generate $\{j, k, \text{"D"}\}$. Note that we do not generate $\{j, i, \text{"O"}\}$ in this case because in Sassano's algorithm we do not need such labeled examples if j depends on k such that $k < i$.

Syntactically Extended Selection (Syn) This selection method is one based on MODSIMPLE and extended to generate more labeled examples for the classifier. You may notice that more labeled examples for the classifier can be generated from a single label which the annotator gives. Syntactic constraints of the Japanese language allow us to extend labeled examples.

For example, suppose that we have four bunsetsus A, B, C, and D in this order. If A depends on C, i.e., the head of A is C, then it is automatically derived that B also should depend on C because the Japanese language has the no-crossing constraint for dependencies (Section 3.2). By utilizing this property we can obtain more labeled examples from a single labeled one annotators give. In the example above, we obtain $\{A, B, \text{"O"}\}$ and $\{B, C, \text{"D"}\}$ from $\{A, C, \text{"D"}\}$.

Although we can employ various extensions to MODSIMPLE, we use a rather simple extension in this research.

Case 1 if $(j < i < k)$, then generate

- $\{j, i, \text{“O”}\}$,
- $\{k-1, k, \text{“D”}\}$ if $k-1 > j$,
- and $\{j, k, \text{“D”}\}$.

Case 2 if $(j < i = k)$, then generate

- $\{k-1, k, \text{“D”}\}$ if $k-1 > j$,
- and $\{j, k, \text{“D”}\}$.

Case 3 if $(j < k < i)$, then generate

- $\{k-1, k, \text{“D”}\}$ if $k-1 > j$,
- and $\{j, k, \text{“D”}\}$.

In SYN as well as MODSIMPLE, we generate examples with ”O” only for bunsetsu pairs that occur to the left of the correct head (i.e., case 1).

6 Experimental Evaluation and Discussion

6.1 Corpus

In our experiments we used the Kyoto University Corpus Version 2 (Kurohashi and Nagao, 1998). Initial seed sentences and a pool of unlabeled sentences for training are taken from the articles on January 1st through 8th (7,958 sentences) and the test data is a set of sentences in the articles on January 9th (1,246 sentences). The articles on January 10th were used for development. The split of these articles for training/test/development is the same as in (Uchimoto et al., 1999).

6.2 Averaged Perceptron

We used the averaged perceptron (AP) (Freund and Schapire, 1999) with polynomial kernels. We set the degree of the kernels to 3 since cubic kernels with SVM have proved effective for Japanese dependency parsing (Kudo and Matsumoto, 2000; Kudo and Matsumoto, 2002). We found the best value of the epoch T of the averaged perceptron by using the development set. We fixed $T = 12$ through all experiments for simplicity.

6.3 Features

There are features that have been commonly used for Japanese dependency parsing among related papers, e.g., (Kudo and Matsumoto, 2002; Sassano, 2004; Iwatate et al., 2008). We also used the same features here. They are divided into three groups: modifier *bunsetsu* features, head *bunsetsu* features, and gap features. A summary of the features is described in Table 1.

6.4 Implementation

We implemented a parser and a tool for the averaged perceptron in C++ and used them for experiments. We wrote the main program of active learning and some additional scripts in Perl and sh.

6.5 Settings of Active Learning

For initial seed sentences, first 500 sentences are taken from the articles on January 1st. In experiments about sentence wise selection, 500 sentences are selected at each iteration of active learning and labeled[5] and added into the training data. In experiments about chunk wise selection 4000 pairs of bunsetsus, which are roughly equal to the averaged number of bunsetsus in 500 sentences, are selected at each iteration of active learning.

6.6 Dependency Accuracy

We use dependency accuracy as a performance measure of a parser. The dependency accuracy is the percentage of correct dependencies. This measure is commonly used for the Kyoto University Corpus.

6.7 Results and Discussion

Learning Curves First we compare methods for sentence wise selection. Figure 5 shows that MIN is the best among them, while AVG is not good and similar to PASSIVE. It is observed that active learning with large margin classifiers also works well for Sassano’s algorithm of Japanese dependency parsing.

Next we compare chunk-wise selection with sentence-wise one. The comparison is shown in Figure 6. Note that we must carefully consider how to count labeled examples. In sentence wise selection we obviously count the number of sentences. However, it is impossible to count such number when we label bunsetsus pairs.

Therefore, we use the number of bunsetsus that have an annotated head. Although we know this may not be a completely fair comparison, we believe our choice in this experiment is reasonable

[5] In our experiments human annotators do not give labels. Instead, labels are given virtually from correct ones that the Kyoto University Corpus has.

Bunsetsu features for modifiers and heads	rightmost content word, rightmost function word, punctuation, parentheses, location (BOS or EOS)
Gap features	distance (1, 2–5, or 6 $\leq$), particles, parentheses, punctuation

for assessing the effect of reduction by chunk-wise selection.

In Figure 6 NAIVE has a better learning curve compared to MIN at the early stage of learning. However, the curve of NAIVE declines at the later stage and gets worse than PASSIVE and MIN.

Why does this phenomenon occur? It is because each bunsetsu pair is not independent and pairs in the same sentence are related to each other. They satisfy the constraints discussed in Section 3.2. Furthermore, the algorithm we use, i.e., Sassano's, assumes these constraints and has the specific order for processing bunsetsu pairs as we see in Figure 3. Let us consider the meaning of $\{j, i, \text{“O”}\}$ if the head of the j-th bunsetsu is the k-th one such that $j < k < i$. In the context of the algorithm in Figure 3, $\{j, i, \text{“O”}\}$ actually means that the j-th bunsetsu modifies th l-th one such that $i < l$. That is “O” does not simply mean that two bunsetsus does not have a dependency relation. Therefore, we should not generate $\{j, i, \text{“O”}\}$ in the case of $j < k < i$. Such labeled instances are not needed and the algorithm in Figure 4 does not generate them even if a fully annotated sentence is given. Based on the analysis above, we modified NAIVE and defined MODSIMPLE, where unnecessary labeled examples are not generated.

Now let us compare NAIVE with MODSIMPLE (Figure 7). MODSIMPLE is almost always better than PASSIVE and does not cause a significant deterioration of accuracy unlike NAIVE.[6]

Comparison of MODSIMPLE and SYN is shown in Figure 8. Both exhibit a similar curve. Figure 9 shows the same comparison in terms of required queries to human annotators. It shows that SYN is better than MODSIMPLE especially at the earlier stage of active learning.

Reduction of Annotations Next we examined the number of labeled bunsetsus to be required in

[6]We have to carefully see the curves of NAIVE and MODSIMPLE. In Figure 7 at the early stage NAIVE is slightly better than MODSIMPLE, while in Figure 9 NAIVE does not outperform MODSIMPLE. This is due to the difference of the way of accessing annotation efforts.

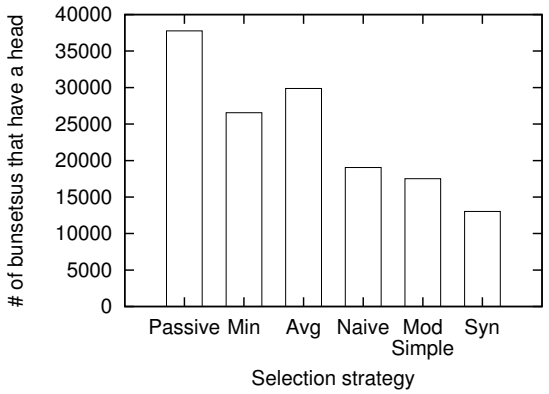

Figure 10: Number of labeled bunsetsus to be required to achieve an accuracy of over 88.3%.

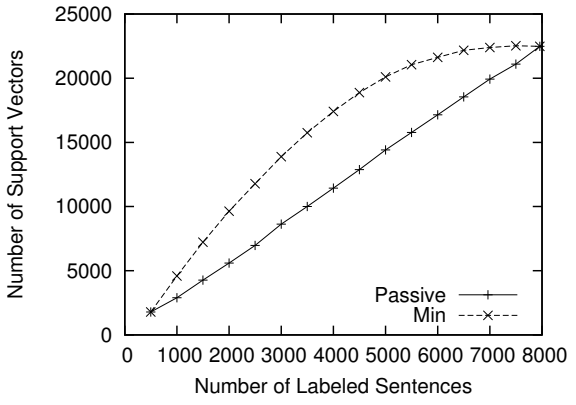

Figure 11: Changes of number of support vectors in sentence-wise active learning

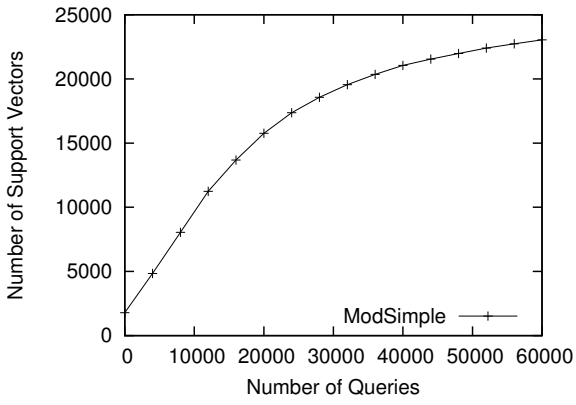

Figure 12: Changes of number of support vectors in chunk-wise active learning (MODSIMPLE)

order to achieve a certain level of accuracy. Figure 10 shows that the number of labeled bunsetsus to achieve an accuracy of over 88.3% depending on the active learning methods discussed in this research.

PASSIVE needs 37766 labeled bunsetsus which have a head to achieve an accuracy of 88.48%, while SYN needs 13021 labeled bunsetsus to achieve an accuracy of 88.56%. SYN requires only 34.4% of the labeled bunsetsu pairs that PASSIVE requires.

Stopping Criteria It is known that increment rate of the number of support vectors in SVM indicates saturation of accuracy improvement during iterations of active learning (Schohn and Cohn, 2000). It is interesting to examine whether the observation for SVM is also useful for support vectors[7] of the averaged perceptron. We plotted changes of the number of support vectors in the cases of both PASSIVE and MIN in Figure 11 and changes of the number of support vectors in the case of MODSIMPLE in Figure 12. We observed that the increment rate of support vectors mildly gets smaller. However, it is not so clear as in the case of text classification in (Schohn and Cohn, 2000).

Issues on Accessing the Total Cost of Annotation In this paper, we assume that each annotation cost for dependency relations is constant. It is however not true in an actual annotation work.[8] In addition, we have to note that it may be easier to annotate a whole sentence than some bunsetsu pairs in a sentence[9]. In a real annotation task, it will be better to show a whole sentence to annotators even when annotating some part of the sentence.

Nevertheless, it is noteworthy that our research shows the minimum number of annotations in preparing training examples for Japanese dependency parsing. The methods we have proposed must be helpful when checking repeatedly annotations that are important and might be wrong or difficult to label while building an annotated corpus. They also will be useful for domain adaptation of a dependency parser.[10]

Applicability to Other Languages and Other Parsing Algorithms We discuss here whether or not the proposed methods and the experiments are useful for other languages and other parsing algorithms. First we take languages similar to Japanese in terms of syntax, i.e., Korean and Mongolian. These two languages are basically head-final languages and have similar constraints in Section 3.2. Although no one has reported application of (Sassano, 2004) to the languages so far, we believe that similar parsing algorithms will be applicable to them and the discussion in this study would be useful.

On the other hand, the algorithm of (Sassano, 2004) cannot be applied to head-initial languages such as English. If target languages are assumed to be projective, the algorithm of (Nivre, 2003) can be used. It is highly likely that we will invent the effective use of finer-grained constituents, e.g., head-modifier pairs, rather than sentences in active learning for Nivre's algorithm with large margin classifiers since Sassano's seems to be a simplified version of Nivre's and they have several properties in common. However, syntactic constraints in European languages like English may be less helpful than those in Japanese because their dependency links do not have a single direction.

Even though the use of syntactic constraints is limited, smaller constituents will still be useful for other parsing algorithms that use some deterministic methods with machine learning-based classifiers. There are many algorithms that have such a framework, which include (Yamada and Matsumoto, 2003) for English and (Kudo and Matsumoto, 2002; Iwatate et al., 2008) for Japanese. Therefore, effective use of smaller constituents in active learning would not be limited to the specific algorithm.

7 Conclusion

We have investigated that active learning methods for Japanese dependency parsing. It is observed that active learning of parsing with the averaged perceptron, which is one of the large margin classifiers, works also well for Japanese dependency analysis.

[7] Following (Freund and Schapire, 1999), we use the term "support vectors" for AP as well as SVM. "Support vectors" of AP means vectors which are selected in the training phase and contribute to the prediction.

[8] Thus it is very important to construct models for estimating the actual annotation cost as Haertel et al. (2008) do.

[9] Hwa (2004) discusses similar aspects of researches on active learning.

[10] Ohtake (2006) examines heuristic methods of selecting sentences.

In addition, as far as we know, we are the first to propose the active learning methods of using partial dependency relations in a given sentence for parsing and we have evaluated the effectiveness of our methods. Furthermore, we have tried to obtain more labeled examples from precious labeled ones that annotators give by utilizing syntactic constraints of the Japanese language. It is noteworthy that linguistic constraints have been shown useful for reducing annotations in active learning for NLP.

Experimental results show that our proposed methods have improved considerably the learning curve of Japanese dependency parsing.

We are currently building a new annotated corpus with an annotation tool. We have a plan to incorporate our proposed methods to the annotation tool. We will use it to accelerate building of the large annotated corpus to improved our Japanese parser.

It would be interesting to explore the use of partially labeled constituents in a sentence in another language, e.g., English, for active learning.

Abstract

Finding allowable places in words to insert hyphens is an important practical problem. The algorithm that is used most often nowadays has remained essentially unchanged for 25 years. This method is the TEX hyphenation algorithm of Knuth and Liang. We present here a hyphenation method that is clearly more accurate. The new method is an application of conditional random fields. We create new training sets for English and Dutch from the CELEX European lexical resource, and achieve error rates for English of less than 0.1% for correctly allowed hyphens, and less than 0.01% for Dutch. Experiments show that both the Knuth/Liang method and a leading current commercial alternative have error rates several times higher for both languages.

1 Introduction

The task that we investigate is learning to split words into parts that are conventionally agreed to be individual written units. In many languages, it is acceptable to separate these units with hyphens, but it is not acceptable to split words arbitrarily. Another way of stating the task is that we want to learn to predict for each letter in a word whether or not it is permissible for the letter to be followed by a hyphen. This means that we tag each letter with either 1, for hyphen allowed following this letter, or 0, for hyphen not allowed after this letter.

The hyphenation task is also called orthographic syllabification (Bartlett et al., 2008). It is an important issue in real-world text processing, as described further in Section 2 below. It is also useful as a preprocessing step to improve letter-to-phoneme conversion, and more generally for text-to-speech conversion. In the well-known NETtalk system, for example, syllable boundaries are an input to the neural network in addition to letter identities (Sejnowski and Rosenberg, 1988). Of course, orthographic syllabification is not a fundamental scientific problem in linguistics. Nevertheless, it is a difficult engineering task that is worth studying for both practical and intellectual reasons.

The goal in performing hyphenation is to predict a sequence of 0/1 values as a function of a sequence of input characters. This sequential prediction task is significantly different from a standard (non-sequential) supervised learning task. There are at least three important differences that make sequence prediction difficult. First, the set of all possible sequences of labels is an exponentially large set of possible outputs. Second, different inputs have different lengths, so it is not obvious how to represent every input by a vector of the same fixed length, as is almost universal in supervised learning. Third and most important, too much information is lost if we learn a traditional classifier that makes a prediction for each letter separately. Even if the traditional classifier is a function of the whole input sequence, this remains true. In order to achieve high accuracy, correlations between neighboring predicted labels must be taken into account.

Learning to predict a sequence of output labels, given a sequence of input data items, is an instance of a structured learning problem. In general, structured learning means learning to predict outputs that have internal structure. This structure can be modeled; to achieve high predictive accuracy, when there are dependencies between parts of an output, it must be modeled. Research on structured learning has been highly successful, with sequence classification as its most important and successful subfield, and with conditional random fields (CRFs) as the most influential approach to learning sequence classifiers. In the present paper,

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 366–374,
Uppsala, Sweden, 11-16 July 2010.

we show that CRFs can achieve extremely good performance on the hyphenation task.

2 History of automated hyphenation

The earliest software for automatic hyphenation was implemented for RCA 301 computers, and used by the *Palm Beach Post-Tribune* and *Los Angeles Times* newspapers in 1962. These were two different systems. The Florida system had a dictionary of 30,000 words; words not in the dictionary were hyphenated after the third, fifth, or seventh letter, because the authors observed that this was correct for many words. The California system (Friedlander, 1968) used a collection of rules based on the rules stated in a version of Webster's dictionary. The earliest hyphenation software for a language other than English may have been a rule-based program for Finnish first used in 1964 (Jarvi, 2009).

The first formal description of an algorithm for hyphenation was in a patent application submitted in 1964 (Damerau, 1964). Other early publications include (Ocker, 1971; Huyser, 1976). The hyphenation algorithm that is by far the most widely used now is due to Liang (Liang, 1983). Although this method is well-known now as the one used in TEX and its derivatives, the first version of TEX used a different, simpler method. Liang's method was used also in `troff` and `groff`, which were the main original competitors of TEX, and is part of many contemporary software products, supposedly including Microsoft Word. Any major improvement over Liang's method is therefore of considerable practical and commercial importance.

Over the years, various machine learning methods have been applied to the hyphenation task. However, none have achieved high accuracy. One paper that presents three different learning methods is (van den Bosch et al., 1995). The lowest per-letter test error rate reported is about 2%. Neural networks have been used, but also without great success. For example, the authors of (Kristensen and Langmyhr, 2001) found that the TEX method is a better choice for hyphenating Norwegian.

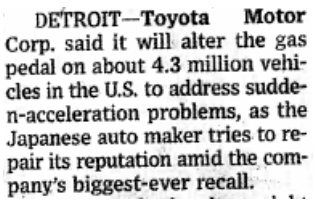
The highest accuracy achieved until now for the hyphenation task is by (Bartlett et al., 2008), who use a large-margin structured learning approach. Our work is similar, but was done fully independently. The accuracy we achieve is slightly higher: word-level accuracy of 96.33% compared to their 95.65% for English. Moreover, (Bartlett et al., 2008) do not address the issue that false positive hyphens are worse mistakes than false negative hyphens, which we address below. Also, they report that training on 14,000 examples requires about an hour, compared to 6.2 minutes for our method on 65,828 words. Perhaps more important for large-scale publishing applications, our system is about six times faster at syllabifying new text. The speed comparison is fair because the computer we use is slightly slower than the one they used.

Methods inspired by nonstatistical natural language processing research have also been proposed for the hyphenation task, in particular (Bouma, 2003; Tsalidis et al., 2004; Woestenburg, 2006; Haralambous, 2006). However, the methods for Dutch presented in (Bouma, 2003) were found to have worse performance than TEX. Moreover, our experimental results below show that the commercial software of (Woestenburg, 2006) allows hyphens incorrectly almost three times more often than TEX.

In general, a dictionary based approach has zero errors for words in the dictionary, but fails to work for words not included in it. A rule-based approach requires an expert to define manually the rules and exceptions for each language, which is laborious work. Furthermore, for languages such as English where hyphenation does not systematically follow general rules, such an approach does not have good results. A pattern-learning approach, like that of TEX, infers patterns from a training list of hyphenated words, and then uses these patterns to hyphenate text. Although useful patterns are learned automatically, both the TEX learning algorithm and the learned patterns must be hand-tuned to perform well (Liang, 1983).

Liang's method is implemented in a program named `PATGEN`, which takes as input a training set of hyphenated words, and outputs a collection of interacting hyphenation patterns. The standard pattern collections are named `hyphen.tex` for American English, `ukhyphen.tex` for British English, and `nehyph96.tex` for Dutch. The precise details of how different versions of TEX and LATEX use these pattern collections to do hyphenation in practice are unclear. At a minimum, current variants of TEX improve hyphenation accuracy by disallowing hyphens in the first and last two or three letters of every word, regardless of what the `PATGEN` patterns recommend.

Despite the success of Liang's method, incorrect hyphenations remain an issue with TEX and its current variants and competitors. For instance, incorrect hyphenations are common in the *Wall Street Journal*, which has the highest circulation of any newspaper in the U.S. An example is the hyphenation of the word "sudden" in this extract:



DETROIT—Toyota Motor Corp. said it will alter the gas pedal on about 4.3 million vehicles in the U.S. to address sudden-acceleration problems, as the Japanese auto maker tries to repair its reputation amid the company's biggest-ever recall.

It is the case that most hyphenation mistakes in the *Wall Street Journal* and other media are for proper nouns such as "Netflix" that do not appear in standard dictionaries, or in compound words such as "sudden-acceleration" above.

3 Conditional random fields

A linear-chain conditional random field (Lafferty et al., 2001) is a way to use a log-linear model for the sequence prediction task. We use the bar notation for sequences, so $\bar{x}$ means a sequence of variable length. Specifically, let $\bar{x}$ be a sequence of n letters and let $\bar{y}$ be a corresponding sequence of n tags. Define the log-linear model

$$p(\bar{y}|\bar{x};w) = \frac{1}{Z(\bar{x},w)} \exp \sum_j w_j F_j(\bar{x},\bar{y}).$$

The index j ranges over a large set of feature-functions. Each such function F_j is a sum along the output sequence for $i = 1$ to $i = n$:

$$F_j(\bar{x},\bar{y}) = \sum_{i=1}^{n} f_j(y_{i-1}, y_i, \bar{x}, i)$$

where each function f_j is a 0/1 indicator function that picks out specific values for neighboring tags y_{i-1} and y_i and a particular substring of $\bar{x}$. The denominator $Z(\bar{x},w)$ is a normalizing constant:

$$Z(\bar{x},w) = \sum_{\bar{y}} \exp \sum_j w_j F_j(\bar{x},\bar{y})$$

where the outer sum is over all possible labelings $\bar{y}$ of the input sequence $\bar{x}$. Training a CRF means finding a weight vector w that gives the best possible predictions

$$\bar{y}^* = \arg\max_{\bar{y}} p(\bar{y}|\bar{x};w)$$

for each training example $\bar{x}$.

The software we use as an implementation of conditional random fields is named CRF++ (Kudo, 2007). This implementation offers fast training since it uses L-BFGS (Nocedal and Wright, 1999), a state-of-the-art quasi-Newton method for large optimization problems. We adopt the default parameter settings of CRF++, so no development set or tuning set is needed in our work.

We define indicator functions f_j that depend on substrings of the input word, and on whether or not a hyphen is legal after the current and/or the previous letter. The substrings are of length 2 to 5, covering up to 4 letters to the left and right of the current letter. From all possible indicator functions we use only those that involve a substring that occurs at least once in the training data.

As an example, consider the word `hy-phen-ate`. For this word $\bar{x} = hyphenate$ and $\bar{y} = 010001000$. Suppose $i = 3$ so p is the current letter. Then exactly two functions f_j that depend on substrings of length 2 have value 1:

$$I(y_{i-1} = 1 \text{ and } y_i = 0 \text{ and } x_2x_3 = yp) = 1,$$
$$I(y_{i-1} = 1 \text{ and } y_i = 0 \text{ and } x_3x_4 = ph) = 1.$$

All other similar functions have value 0:

$$I(y_{i-1} = 1 \text{ and } y_i = 1 \text{ and } x_2x_3 = yp) = 0,$$
$$I(y_{i-1} = 1 \text{ and } y_i = 0 \text{ and } x_2x_3 = yq) = 0,$$

and so on. There are similar indicator functions for substrings up to length 5. In total, 2,916,942 different indicator functions involve a substring that appears at least once in the English dataset.

One finding of our work is that it is preferable to use a large number of low-level features, that is patterns of specific letters, rather than a smaller number of higher-level features such as consonant-vowel patterns. This finding is consistent with an emerging general lesson about many natural language processing tasks: the best performance is achieved with models that are discriminative, that are trained on as large a dataset as possible, and that have a very large number of parameters but are regularized (Halevy et al., 2009).

When evaluating the performance of a hyphenation algorithm, one should not just count how many words are hyphenated in exactly the same way as in a reference dictionary. One should also measure separately how many legal hyphens are actually predicted, versus how many predicted hyphens are in fact not legal. Errors of the second type are false positives. For any hyphenation

method, a false positive hyphen is a more serious mistake than a false negative hyphen, i.e. a hyphen allowed by the lexicon that the method fails to identify. The standard Viterbi algorithm for making predictions from a trained CRF is not tuned to minimize false positives. To address this difficulty, we use the forward-backward algorithm (Sha and Pereira, 2003; Culotta and McCallum, 2004) to estimate separately for each position the probability of a hyphen at that position. Then, we only allow a hyphen if this probability is over a high threshold such as 0.9.

Each hyphenation corresponds to one path through a graph that defines all 2^{k-1} hyphenations that are possible for a word of length k. The overall probability of a hyphen at any given location is the sum of the weights of all paths that do have a hyphen at this position, divided by the sum of the weights of all paths. The forward-backward algorithm uses the sum operator to compute the weight of a set of paths, instead of the max operator to compute the weight of a single highest-weight path. In order to compute the weight of all paths that contain a hyphen at a specific location, weight 0 is assigned to all paths that do not have a hyphen at this location.

4 Dataset creation

We start with the lexicon for English published by the Dutch Centre for Lexical Information at `http://www.mpi.nl/world/celex`. We download all English word forms with legal hyphenation points indicated by hyphens. These include plurals of nouns, conjugated forms of verbs, and compound words such as "off-line". We separate the components of compound words and phrases, leading to 204,466 words, of which 68,744 are unique. In order to eliminate abbreviations and proper names which may not be English, we remove all words that are not fully lower-case. In particular, we exclude words that contain capital letters, apostrophes, and/or periods. This leaves 66,001 words.

Among these words, 86 have two different hyphenations, and one has three hyphenations. For most of the 86 words with alternative hyphenations, these alternatives exist because different meanings of the words have different pronunciations, and the different pronunciations have different boundaries between syllables. This fact implies that no algorithm that operates on words in isolation can be a complete solution for the hyphenation task.[1]

We exclude the few words that have two or more different hyphenations from the dataset. Finally, we obtain 65,828 spellings. These have 550,290 letters and 111,228 hyphens, so the average is 8.36 letters and 1.69 hyphens per word. Informal inspection suggests that the 65,828 spellings contain no mistakes. However, about 1000 words follow British as opposed to American spelling.

The Dutch dataset of 293,681 words is created following the same procedure as for the English dataset, except that all entries from CELEX that are compound words containing dashes are discarded instead of being split into parts, since many of these are not in fact Dutch words.[2]

5 Experimental design

We use ten-fold cross validation for the experiments. In order to measure accuracy, we compute the confusion matrix for each method, and from this we compute error rates. We report both word-level and letter-level error rates. The word-level error rate is the fraction of words on which a method makes at least one mistake. The letter-level error rate is the fraction of letters for which the method predicts incorrectly whether or not a hyphen is legal after this letter. Table 1 explains the terminology that we use in presenting our results. Precision, recall, and F1 can be computed easily from the reported confusion matrices.

As an implementation of Liang's method we use TEX Hyphenator in Java software available at `http://texhyphj.sourceforge.net`. We evaluate this algorithm on our entire English and Dutch datasets using the appropriate language pattern files, and not allowing a hyphen to be placed between the first `lefthyphenmin` and last `righthyphenmin` letters of each word. For

[1] The single word with more than two alternative hyphenations is "invalid" whose three hyphenations are `in-va-lid in-val-id` and `in-valid`. Interestingly, the Merriam–Webster online dictionary also gives three hyphenations for this word, but not the same ones: `in-va-lid in-val-id invalid`. The American Heritage dictionary agrees with Merriam-Webster. The disagreement illustrates that there is a certain irreducible ambiguity or subjectivity concerning the correctness of hyphenations.

[2] Our English and Dutch datasets are available for other researchers and practitioners to use at `http://www.cs.ucsd.edu/users/elkan/hyphenation`. Previously a similar but smaller CELEX-based English dataset was created by (van den Bosch et al., 1995), but that dataset is not available online currently.

Abbr	Name	Description
TP	true positives	#hyphens predicted correctly
FP	false positives	#hyphens predicted incorrectly
TN	true negatives	#hyphens correctly not predicted
FN	false negatives	#hyphens failed to be predicted
owe	overall word-level errors	#words with at least one FP or FN
swe	serious word-level errors	#words with at least one FP
ower	overall word-level error rate	owe / (total #words)
swer	serious word-level error rate	swe / (total #words)
oler	overall letter-level error rate	(FP+FN) / (TP+TN+FP+FN)
sler	serious letter-level error rate	FP / (TP+TN+FP+FN)

Table 1: Alternative measures of accuracy. TP, TN, FP, and FN are computed by summing over the test sets of each fold of cross-validation.

English the default values are 2 and 3 respectively. For Dutch the default values are both 2.

The hyphenation patterns used by TeXHyphenator, which are those currently used by essentially all variants of TEX, may not be optimal for our new English and Dutch datasets. Therefore, we also do experiments with the PATGEN tool (Liang and Breitenlohner, 2008). These are learning experiments so we also use ten-fold cross validation in the same way as with CRF++. Specifically, we create a pattern file from 90% of the dataset using PATGEN, and then hyphenate the remaining 10% of the dataset using Liang's algorithm and the learned pattern file.

The PATGEN tool has many user-settable parameters. As is the case with many machine learning methods, no strong guidance is available for choosing values for these parameters. For English we use the parameters reported in (Liang, 1983). For Dutch we use the parameters reported in (Tutelaers, 1999). Preliminary informal experiments found that these parameters work better than alternatives. We also disallow hyphens in the first two letters of every word, and the last three letters for English, or last two for Dutch.

We also evaluate the TALO commercial software (Woestenburg, 2006). We know of one other commercial hyphenation application, which is named Dashes.[3] Unfortunately we do not have access to it for evaluation. We also cannot do a precise comparison with the method of (Bartlett et al., 2008). We do know that their training set was also derived from CELEX, and their maximum reported accuracy is slightly lower. Specifically, for English our word-level accuracy ("ower") is 96.33% while their best ("WA") is 95.65%.

6 Experimental results

In Table 2 and Table 3 we report the performance of the different methods on the English and Dutch datasets respectively. Figure 1 shows how the error rate is affected by increasing the CRF probability threshold for each language.

Figure 1 shows confidence intervals for the error rates. These are computed as follows. For a single Bernoulli trial the mean is p and the variance is $p(1-p)$. If N such trials are taken, then the observed success rate $f = S/N$ is a random variable with mean p and variance $p(1-p)/N$. For large N, the distribution of the random variable f approaches the normal distribution. Hence we can derive a confidence interval for p using the formula

$$Pr[-z \leq \frac{f-p}{\sqrt{p(1-p)/N}} \leq z] = c$$

where for a 95% confidence interval, i.e. for $c = 0.95$, we set $z = 1.96$. All differences between rows in Table 2 are significant, with one exception: the serious error rates for PATGEN and TALO are not statistically significantly different. A similar conclusion applies to Table 3.

For the English language, the CRF using the Viterbi path has overall error rate of 0.84%, compared to 6.81% for the TEX algorithm using American English patterns, which is eight times worse. However, the serious error rate for the CRF is less good: 0.41% compared to 0.24%. This weakness is remedied by predicting that a hyphen is allowable only if it has high probability. Figure 1 shows that the CRF can use a probability threshold up to 0.99, and still have lower overall error rate than the TEX algorithm. Fixing the probability threshold at 0.99, the CRF serious error rate is 0.04% (224 false positives) compared to 0.24% (1343 false positives) for the TEX algorithm.

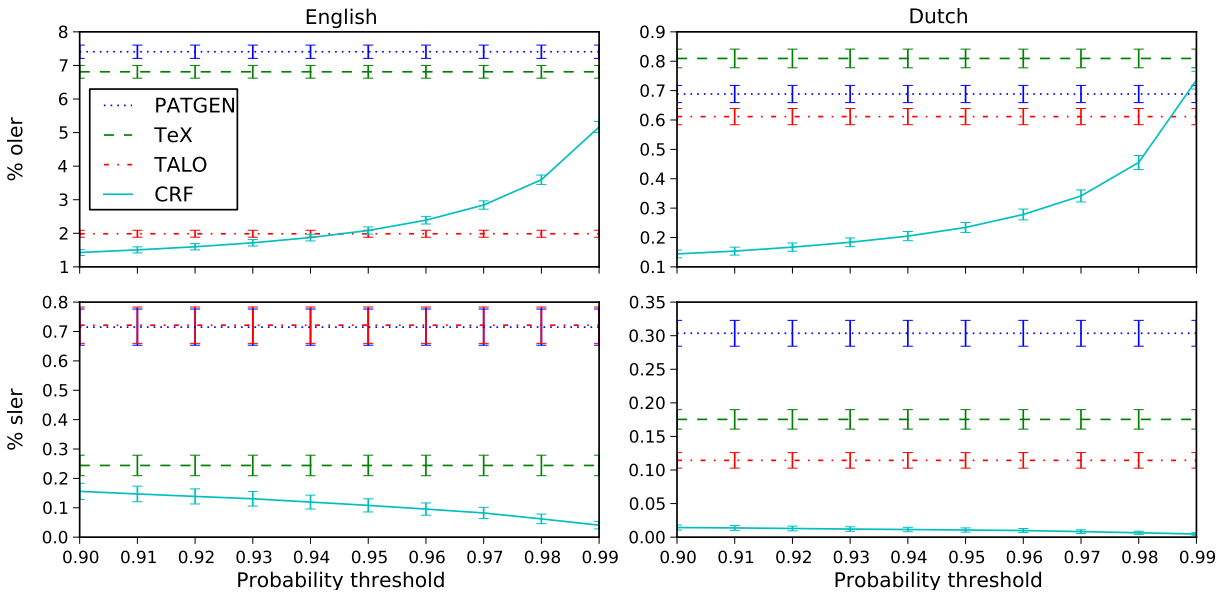

Figure 1: Total letter-level error rate and serious letter-level error rate for different values of threshold for the CRF. The left subfigures are for the English dataset, while the right ones are for the Dutch dataset. The TALO and PATGEN lines are almost identical in the bottom left subfigure.

Table 6: Performance on the 4000 most frequent English words.

For the English language, TALO yields overall error rate 1.99% with serious error rate 0.72%, so the standard CRF using the Viterbi path is better on both measures. The dominance of the CRF method can be increased further by using a probability threshold. Figure 1 shows that the CRF can use a probability threshold up to 0.94, and still have lower overall error rate than TALO. Using this threshold, the CRF serious error rate is 0.12% (657 false positives) compared to 0.72% (3970 false positives) for TALO.

For the Dutch language, the standard CRF using the Viterbi path has overall error rate 0.08%, compared to 0.81% for the TEX algorithm. The serious error rate for the CRF is 0.04% while for TEX it is 0.18%. Figure 1 shows that any probability threshold for the CRF of 0.99 or below yields lower error rates than the TEX algorithm. Using the threshold 0.99, the CRF has serious error rate only 0.005%.

For the Dutch language, the TALO method has overall error rate 0.61%. The serious error rate for TALO is 0.11%. The CRF dominance can again be increased via a high probability threshold. Figure 1 shows that this threshold can range up to 0.98, and still give lower overall error rate than TALO. Using the 0.98 threshold, the CRF has serious error rate 0.006% (206 false positives); in comparison the serious error rate of TALO is 0.11% (3638 false positives).

For both languages, PATGEN has higher serious letter-level and word-level error rates than TEX using the existing pattern files. This is expected since the pattern collections included in TEX distributions have been tuned over the years to minimize objectionable errors. The difference is especially pronounced for American English, for which the standard pattern collection has been manually improved over more than two decades by many people (Beeton, 2002). Initially, Liang optimized this pattern collection extensively by upweighting the most common words and by iteratively adding exception words found by testing the algorithm against a large dictionary from an unknown publisher (Liang, 1983).

One can tune PATGEN to yield either better overall error rate, or better serious error rate, but not both simultaneously, compared to the TEX algorithm using the existing pattern files for both languages. For the English dataset, if we use Liang's parameters for PATGEN as reported in (Sojka and Sevecek, 1995), we obtain overall error rate of 6.05% and serious error rate of 0.85%. It is possible that the specific patterns used in TEX implementations today have been tuned by hand to be better than anything the PATGEN software is capable of.

7 Additional experiments

This section presents empirical results following two experimental designs that are less standard, but that may be more appropriate for the hyphenation task.

First, the experimental design used above has an issue shared by many CELEX-based tagging or transduction evaluations: words are randomly divided into training and test sets without being grouped by stem. This means that a method can get credit for hyphenating "accents" correctly, when "accent" appears in the training data. Therefore, we do further experiments where the folds for evaluation are divided by stem, and not by word; that is, all versions of a base form of a word appear in the same fold. Stemming uses the English and Dutch versions of the Porter stemmer (Porter, 1980).[4] The 65,828 English words in our dictionary produce 27,100 unique stems, while the 293,681 Dutch words produce 169,693 unique stems. The results of these experiments are shown in Tables 4 and 5.

The main evaluation in the previous section is based on a list of unique words, which means that in the results each word is equally weighted. Because cross validation is applied, errors are always measured on testing subsets that are disjoint from the corresponding training subsets. Hence, the accuracy achieved can be interpreted as the performance expected when hyphenating unknown words, i.e. rare future words.

However, in real documents common words appear repeatedly. Therefore, the second less-standard experimental design for which we report results restricts attention to the most common English words. Specifically, we consider the top 4000 words that make up about three quarters of all word appearances in the American National Corpus, which consists of 18,300,430 words from written texts of all genres.[5] From the 4,471 most

[4] Available at http://snowball.tartarus.org/. A preferable alternative might be to use the information about the lemmas of words available directly in CELEX.

[5] Available at americannationalcorpus.org/SecondRelease/data/ANC-written-count.txt

frequent words in this list, if we omit the words not in our dataset of 89,019 hyphenated English words from CELEX, we get 4,000 words. The words that are omitted are proper names, contractions, incomplete words containing apostrophes, and abbreviations such as DNA. These 4,000 most frequent words make up 74.93% of the whole corpus.

We evaluate the following methods on the 4000 words: Liang's method using the American patterns file `hyphen.tex`, Liang's method using the patterns derived from `PATGEN` when trained on the whole English dataset, our CRF trained on the whole English dataset, and the same CRF with a probability threshold of 0.9. Results are shown in Table 6. In summary, TEX and `PATGEN` make serious errors on 43 and 113 of the 4000 words, respectively. With a threshold of 0.9, the CRF approach makes zero serious errors on these words.

8 Timings

Table 7 shows the speed of the alternative methods for the English dataset. The column "Features/Patterns" in the table reports the number of feature-functions used for the CRF, or the number of patterns used for the TEX algorithm. Overall, the CRF approach is about ten times slower than the TEX algorithm, but its performance is still acceptable on a standard personal computer. All experiments use a machine having a Pentium 4 CPU at 3.20GHz and 2GB memory. Moreover, informal experiments show that CRF training would be about eight times faster if we used CRFSGD rather than CRF++ (Bottou, 2008).

From a theoretical perspective, both methods have almost-constant time complexity per word if they are implemented using appropriate data structures. In TEX, hyphenation patterns are stored in a data structure that is a variant of a trie. The CRF software uses other data structures and optimizations that allow a word to be hyphenated in time that is almost independent of the number of feature-functions used.

9 Conclusions

Finding allowable places in words to insert hyphens is a real-world problem that is still not fully solved in practice. The main contribution of this paper is a hyphenation method that is clearly more accurate than the currently used Knuth/Liang method. The new method is an application of CRFs, which are a major advance of recent years in machine learning. We hope that the method proposed here is adopted in practice, since the number of serious errors that it makes is about a sixfold improvement over what is currently in use. A second contribution of this paper is to provide training sets for hyphenation in English and Dutch, so other researchers can, we hope, soon invent even more accurate methods. A third contribution of our work is a demonstration that current CRF methods can be used straightforwardly for an important application and outperform state-of-the-art commercial and open-source software; we hope that this demonstration accelerates the widespread use of CRFs.

Method	Features/ Patterns	Training time (s)	Testing time (s)	Speed (ms/word)
CRF	2916942	372.67	25.386	0.386
TEX (us)	4447	-	2.749	0.042
`PATGEN`	4488	33.402	2.889	0.044
TALO	-	-	8.400	0.128

Abstract

This paper demonstrates that the use of ensemble methods and carefully calibrating the decision threshold can significantly improve the performance of machine learning methods for morphological word decomposition. We employ two algorithms which come from a family of generative probabilistic models. The models consider segment boundaries as hidden variables and include probabilities for letter transitions within segments. The advantage of this model family is that it can learn from small datasets and easily generalises to larger datasets. The first algorithm PROMODES, which participated in the Morpho Challenge 2009 (an international competition for unsupervised morphological analysis) employs a lower order model whereas the second algorithm PROMODES-H is a novel development of the first using a higher order model. We present the mathematical description for both algorithms, conduct experiments on the morphologically rich language Zulu and compare characteristics of both algorithms based on the experimental results.

1 Introduction

Words are often considered as the smallest unit of a language when examining the grammatical structure or the meaning of sentences, referred to as syntax and semantics, however, words themselves possess an internal structure denominated by the term *word morphology*. It is worthwhile studying this internal structure since a language description using its morphological formation is more compact and complete than listing all possible words. This study is called *morphological analysis*. According to Goldsmith (2009) four tasks are assigned to morphological analysis: *word decomposition* into morphemes, building *morpheme dictionaries*, defining *morphosyntactical rules* which state how morphemes can be combined to valid words and defining *morphophonological rules* that specify phonological changes morphemes undergo when they are combined to words. Results of morphological analysis are applied in speech synthesis (Sproat, 1996) and recognition (Hirsimaki et al., 2006), machine translation (Amtrup, 2003) and information retrieval (Kettunen, 2009).

1.1 Background

In the past years, there has been a lot of interest and activity in the development of algorithms for morphological analysis. All these approaches have in common that they build a *morphological model* which is then applied to analyse words. Models are constructed using *rule-based methods* (Mooney and Califf, 1996; Muggleton and Bain, 1999), *connectionist methods* (Rumelhart and McClelland, 1986; Gasser, 1994) or *statistical* or *probabilistic* methods (Harris, 1955; Hafer and Weiss, 1974). Another way of classifying approaches is based on the *learning aspect* during the construction of the morphological model. If the data for training the model has the same structure as the desired output of the morphological analysis, in other words, if a morphological model is learnt from labelled data, the algorithm is classified under *supervised learning*. An example for a supervised algorithm is given by Oflazer et al. (2001). If the input data has no information towards the desired output of the analysis, the algorithm uses *unsupervised learning*. Unsupervised algorithms for morphological analysis are Linguistica (Goldsmith, 2001), Morfessor (Creutz, 2006) and Paramor (Monson, 2008). *Minimally or semi-supervised algorithms* are provided with partial information during the learning process. This

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 375–383,
Uppsala, Sweden, 11-16 July 2010.

has been done, for instance, by Shalonova et al. (2009) who provided stems in addition to a word list in order to find multiple pre- and suffixes. A comparison of different levels of supervision for morphology learning on Zulu has been carried out by Spiegler et al. (2008).

Our two algorithms, PROMODES and PROMODES-H, perform *word decomposition* and are based on *probabilistic methods* by incorporating a probabilistic generative model.[1] Their parameters can be estimated from either labelled data, using maximum likelihood estimates, or from unlabelled data by expectation maximization[2] which makes them either *supervised* or *unsupervised* algorithms.

The purpose of this paper is an analysis of the underlying probabilistic models and the types of errors committed by each one. Furthermore, it is investigated how the decision threshold can be calibrated and a model ensemble is tested.

The remainder is structured as follows. In Section 2 we introduce the probabilistic generative process and show in Sections 2.1 and 2.2 how we incorporate this process in PROMODES and PROMODES-H. We start our experiments with examining the learning behaviour of the algorithms in 3.1. Subsequently, we perform a position-wise comparison of predictions in 3.2, show how we find a better decision threshold for placing morpheme boundaries in 3.3 and combine both algorithms using a model ensemble to leverage individual strengths in 3.4. In 3.5 we examine how the single algorithms contribute to the result of the ensemble. In Section 4 we will compare our approaches to related work and in Section 5 we will draw our conclusions.

2 Probabilistic generative model

Intuitively, we could say that our models describe the process of word generation from the left to the right by alternately using two dice, the first for deciding whether to place a morpheme boundary in the current word position and the second to get a corresponding letter transition. We are trying to reverse this process in order to find the underlying sequence of tosses which determine the morpheme boundaries. We are applying the notion of a *probabilistic generative process* consisting of words as observed variables X and their hidden segmentation as latent variables Y. If a generative model is fully parameterised it can be reversed to find the underlying word decomposition by forming the conditional probability distribution $Pr(Y|X)$.

Let us first define the model-independent components. A given *word* $w_j \in W$ with $1 \leq j \leq |W|$ consists of n letters and has $m = n-1$ positions for inserting boundaries. A word's segmentation is depicted as a *boundary vector* $b_j = (b_{j1}, \ldots, b_{jm})$ consisting of *boundary values* $b_{ji} \in \{0,1\}$ with $1 \leq i \leq m$ which disclose whether or not a boundary is placed in position i. A *letter* $l_{j,i\text{-}1}$ precedes the position i in w_j and a letter l_{ji} follows it. Both letters $l_{j,i\text{-}1}$ and l_{ji} are part of an alphabet. Furthermore, we introduce a *letter transition* t_{ji} which goes from $l_{j,i\text{-}1}$ to l_{ji}.

2.1 PROMODES

PROMODES is based on a zero-order model for boundaries b_{ji} and on a first-order model for letter transitions t_{ji}. It describes a word's segmentation by its morpheme boundaries and resulting letter transitions within morphemes. A boundary vector b_j is found by evaluating each position i with

$$\begin{aligned} &\arg\max_{b_{ji}} Pr(b_{ji}|t_{ji}) = \\ &\arg\max_{b_{ji}} Pr(b_{ji})Pr(t_{ji}|b_{ji}) \quad . \end{aligned} \tag{1}$$

The first component of the equation above is the *probability distribution over non-/boundaries* $Pr(b_{ji})$. We assume that a boundary in i is inserted independently from other boundaries (zero-order) and the graphemic representation of the word, however, is conditioned on the length of the word m_j which means that the probability distribution is in fact $Pr(b_{ji}|m_j)$. We guarantee $\sum_{r=0}^{1} Pr(b_{ji}{=}r|m_j) = 1$. To simplify the notation in later explanations, we will refer to $Pr(b_{ji}|m_j)$ as $Pr(b_{ji})$.

The second component is the *letter transition probability distribution* $Pr(t_{ji}|b_{ji})$. We suppose a first-order Markov chain consisting of transitions t_{ji} from letter $l_{j,i\text{-}1} \in A_{\mathscr{B}}$ to letter $l_{ji} \in A$ where A is a regular letter alphabet and $A_{\mathscr{B}}{=}A \cup \{\mathscr{B}\}$ includes $\mathscr{B}$ as an abstract morpheme start symbol which can occur in $l_{j,i\text{-}1}$. For instance, the suffix '*s*' of the verb form *gets*, marking *3rd person singular*, would be modelled as $\mathscr{B} \rightarrow s$ whereas a morpheme internal transition could be $g \rightarrow e$. We

[1] PROMODES stands for PRObabilistic MOdel for different DEgrees of Supervision. The H of PROMODES-H refers to Higher order.

[2] In (Spiegler et al., 2009; Spiegler et al., 2010a) we have presented an unsupervised version of PROMODES.

guarantee $\sum_{l_{ji} \in A} Pr(t_{ji}|b_{ji})=1$ with t_{ji} being a transition from a certain $l_{j,i-1} \in A_{\mathscr{B}}$ to l_{ji}. The advantage of the model is that instead of evaluating an exponential number of possible segmentations (2^m), the best segmentation $b^*_j=(b^*_{j1},\ldots,b^*_{jm})$ is found with $2m$ position-wise evaluations using

$$b^*_{ji} = \arg\max_{b_{ji}} Pr(b_{ji}|t_{ji}) \quad (2)$$

$$= \begin{cases} 1, \text{ if } Pr(b_{ji}=1)Pr(t_{ji}|b_{ji}=1) \\ \quad > Pr(b_{ji}=0)Pr(t_{ji}|b_{ji}=0) \\ 0, \text{ otherwise } . \end{cases}$$

The simplifying assumptions made, however, reduce the expressive power of the model by not allowing any dependencies on preceding boundaries or letters. This can lead to over-segmentation and therefore influences the performance of PROMODES. For this reason, we have extended the model which led to PROMODES-H, a higher-order probabilistic model.

2.2 PROMODES-H

In contrast to the original PROMODES model, we also consider the boundary value $b_{j,i\text{-}1}$ and modify our transition assumptions for PROMODES-H in such a way that the new algorithm applies a first-order boundary model and a second-order transition model. A transition t_{ji} is now defined as a transition from an abstract symbol in $l_{j,i\text{-}1} \in \{\mathscr{N},\mathscr{B}\}$ to a letter in $l_{ji} \in A$. The abstract symbol is $\mathscr{N}$ or $\mathscr{B}$ depending on whether b_{ji} is 0 or 1. This holds equivalently for letter transitions $t_{j,i\text{-}1}$. The suffix of our previous example *gets* would be modelled $\mathscr{N} \rightarrow t \rightarrow \mathscr{B} \rightarrow s$.

Our boundary vector b_j is then constructed from

$$\arg\max_{b_{ji}} Pr(b_{ji}|t_{ji},t_{j,i\text{-}1},b_{j,i\text{-}1}) = \quad (3)$$
$$\arg\max_{b_{ji}} Pr(b_{ji}|b_{j,i\text{-}1})Pr(t_{ji}|b_{ji},t_{j,i\text{-}1},b_{j,i\text{-}1}) \ .$$

The first component, the *probability distribution over non-/boundaries* $Pr(b_{ji}|b_{j,i\text{-}1})$, satisfies $\sum_{r=0}^{1} Pr(b_{ji}=r|b_{j,i\text{-}1})=1$ with $b_{j,i\text{-}1}, b_{ji} \in \{0,1\}$. As for PROMODES, $Pr(b_{ji}|b_{j,i\text{-}1})$ is shorthand for $Pr(b_{ji}|b_{j,i\text{-}1},m_j)$. The second component, the *letter transition probability distribution* $Pr(t_{ji}|b_{ji},b_{j,i\text{-}1})$, fulfils $\sum_{l_{ji} \in A} Pr(t_{ji}|b_{ji},t_{j,i\text{-}1},b_{j,i\text{-}1})=1$ with t_{ji} being a transition from a certain $l_{j,i-1} \in A_{\mathscr{B}}$ to l_{ji}. Once again, we find the word's best segmentation b^*_j in $2m$ evaluations with

$$b^*_{ji} = \arg\max_{b_{ji}} Pr(b_{ji}|t_{ji},t_{j,i\text{-}1},b_{j,i\text{-}1}) = \quad (4)$$

$$\begin{cases} 1, \text{ if } Pr(b_{ji}=1|b_{j,i\text{-}1})Pr(t_{ji}|b_{ji}=1,t_{j,i\text{-}1},b_{j,i\text{-}1}) \\ \quad > Pr(b_{ji}=0|b_{j,i\text{-}1})Pr(t_{ji}|b_{ji}=0,t_{j,i\text{-}1},b_{j,i\text{-}1}) \\ 0, \text{ otherwise } . \end{cases}$$

We will show in the experimental results that increasing the memory of the algorithm by looking at $b_{j,i-1}$ leads to a better performance.

3 Experiments and Results

In the Morpho Challenge 2009, PROMODES achieved competitive results on Finnish, Turkish, English and German – and scored highest on non-vowelized and vowelized Arabic compared to 9 other algorithms (Kurimo et al., 2009). For the experiments described below, we chose the South African language *Zulu* since our research work mainly aims at creating morphological resources for under-resourced indigenous languages. Zulu is an *agglutinative language* with a complex morphology where multiple prefixes and suffixes contribute to a word's meaning. Nevertheless, it seems that segment boundaries are more likely in certain word positions. The PROMODES family harnesses this characteristic in combination with describing morphemes by letter transitions. From the *Ukwabelana corpus* (Spiegler et al., 2010b) we sampled 2500 Zulu words with a single segmentation each.

3.1 Learning with increasing experience

In our first experiment we applied 10-fold cross-validation on datasets ranging from 500 to 2500 words with the goal of measuring how the learning improves with increasing experience in terms of training set size. We want to remind the reader that our two algorithms are aimed at small datasets.

We randomly split each dataset into 10 subsets where each subset was a test set and the corresponding 9 remaining sets were merged to a training set. We kept the labels of the training set to determine model parameters through maximum likelihood estimates and applied each model to the test set from which we had removed the answer keys. We compared results on the test set against the ground truth by counting true positive (TP), false positive (FP), true negative (TN) and

false negative (FN) *morpheme boundary* predictions. Counts were summarised using precision[3], recall[4] and f-measure[5], as shown in Table 1.

Data	Precision	Recall	F-measure
500	0.7127±0.0418	0.3500±0.0272	0.4687±0.0284
1000	0.7435±0.0556	0.3350±0.0197	0.4614±0.0250
1500	0.7460±0.0529	0.3160±0.0150	0.4435±0.0206
2000	0.7504±0.0235	0.3068±0.0141	0.4354±0.0168
2500	0.7557±0.0356	0.3045±0.0138	0.4337±0.0163

(a) PROMODES

Data	Precision	Recall	F-measure
500	0.6983±0.0511	0.4938±0.0404	0.5776±0.0395
1000	0.6865±0.0298	0.5177±0.0177	0.5901±0.0205
1500	0.6952±0.0308	0.5376±0.0197	0.6058±0.0173
2000	0.7008±0.0140	0.5316±0.0146	0.6044±0.0110
2500	0.6941±0.0184	0.5396±0.0218	0.6068±0.0151

(b) PROMODES-H

Table 1: 10-fold cross-validation on Zulu.

For PROMODES we can see in Table 1a that the precision increases slightly from 0.7127 to 0.7557 whereas the recall decreases from 0.3500 to 0.3045 going from dataset size 500 to 2500. This suggests that to some extent fewer morpheme boundaries are discovered but the ones which are found are more likely to be correct. We believe that this effect is caused by the limited memory of the model which uses order zero for the occurrence of a boundary and order one for letter transitions. It seems that the model gets quickly saturated in terms of incorporating new information and therefore precision and recall do not drastically change for increasing dataset sizes. In Table 1b we show results for PROMODES-H. Across the datasets precision stays comparatively constant around a mean of 0.6949 whereas the recall increases from 0.4938 to 0.5396. Compared to PROMODES we observe an increase in recall between 0.1438 and 0.2351 at a cost of a decrease in precision between 0.0144 and 0.0616.

Since both algorithms show different behaviour with increasing experience and PROMODES-H yields a higher f-measure across all datasets, we will investigate in the next experiments how these differences manifest themselves at the boundary level.

[3] $precision = \frac{TP}{TP+FP}$.
[4] $recall = \frac{TP}{TP+FN}$.
[5] $f\text{-}measure = \frac{2 \cdot precision \cdot recall}{precision+recall}$.

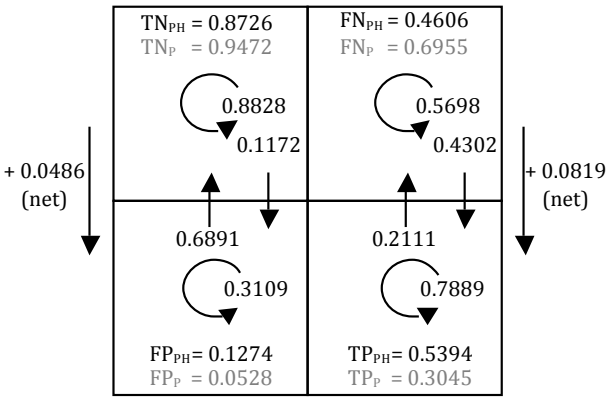

Figure 1: Contingency table for PROMODES [grey with subscript *P*] and PROMODES-H [black with subscript *PH*] results including gross and net changes of PROMODES-H.

3.2 Position-wise comparison of algorithmic predictions

In the second experiment, we investigated which aspects of PROMODES-H in comparison to PROMODES led to the above described differences in performance. For this reason we broke down the summary measures of precision and recall into their original components: true/false positive (TP/FP) and negative (TN/FN) counts presented in the 2×2 contingency table of Figure 1. For general evidence, we averaged across all experiments using relative frequencies. Note that the relative frequencies of positives (TP + FN) and negatives (TN + FP) each sum to one.

The goal was to find out how predictions in each word position changed when applying PROMODES-H instead of PROMODES. This would show where the algorithms agree and where they disagree. PROMODES classifies non-boundaries in 0.9472 of the times correctly as TN and in 0.0528 of the times falsely as boundaries (FP). The algorithm correctly labels 0.3045 of the positions as boundaries (TP) and 0.6955 falsely as non-boundaries (FN). We can see that PROMODES follows a rather conservative approach.

When applying PROMODES-H, the majority of the FP's are turned into non-boundaries, however, a slightly higher number of previously correctly labelled non-boundaries are turned into false boundaries. The net change is a 0.0486 increase in FP's which is the reason for the decrease in precision. On the other side, more false non-

boundaries (FN) are turned into boundaries than in the opposite direction with a net increase of 0.0819 of correct boundaries which led to the increased recall. Since the deduction of precision is less than the increase of recall, a better over-all performance of PROMODES-H is achieved.

In summary, PROMODES predicts more accurately non-boundaries whereas PROMODES-H is better at finding morpheme boundaries. So far we have based our decision for placing a boundary in a certain word position on Equation 2 and 4 assuming that $P(b_{ji}{=}1|\ldots) > P(b_{ji}{=}0|\ldots)$[6] gives the best result. However, if the underlying distribution for boundaries given the evidence is skewed, it might be possible to improve results by introducing a certain decision threshold for inserting morpheme boundaries. We will put this idea to the test in the following section.

3.3 Calibration of the decision threshold

For the third experiment we slightly changed our experimental setup. Instead of dividing datasets during 10-fold cross-validation into training and test subsets with the ratio of 9:1 we randomly split the data into training, validation and test sets with the ratio of 8:1:1. We then run our experiments and measured contingency table counts.

Rather than placing a boundary if $P(b_{ji}{=}1|\ldots) > P(b_{ji}{=}0|\ldots)$ which corresponds to $P(b_{ji}{=}1|\ldots) > 0.50$ we introduced a decision threshold $P(b_{ji}{=}1|\ldots) > h$ with $0 \leq h \leq 1$. This is based on the assumption that the underlying distribution $P(b_{ji}|\ldots)$ might be skewed and an optimal decision can be achieved at a different threshold. The optimal threshold was sought on the validation set and evaluated on the test set. An overview over the validation and test results is given in Table 2. We want to point out that the threshold which yields the best f-measure result on the validation set returns almost the same result on the separate test set for both algorithms which suggests the existence of a general optimal threshold.

Since this experiment provided us with a set of data points where the recall varied monotonically with the threshold and the precision changed accordingly, we reverted to *precision-recall curves* (PR curves) from machine learning. Following Davis and Goadrich (2006) the algorithmic performance can be analysed more informatively using these kinds of curves. The PR curve is plotted with recall on the x-axis and precision on the y-axis for increasing thresholds h. The PR curves for PROMODES and PROMODES-H are shown in Figure 2 on the validation set from which we learnt our optimal thresholds h^*. Points were connected for readability only – points on the PR curve cannot be interpolated linearly.

In addition to the PR curves, we plotted isometrics for corresponding f-measure values which are defined as $precision = \frac{f\text{-}measure \cdot recall}{2recall - f\text{-}measure}$ and are hyperboles. For increasing f-measure values the isometrics are moving further to the top-right corner of the plot. For a threshold of $h = 0.50$ (marked by '$\diamond$') PROMODES-H has a better performance than PROMODES. Nevertheless, across the entire PR curve none of the algorithms dominates. One curve would *dominate* another if all data points of the dominated curve were beneath or equal to the dominating one. PROMODES has its optimal threshold at $h^* = 0.36$ and PROMODES-H at $h^* = 0.37$ where PROMODES has a slightly higher f-measure than PROMODES-H. The points of optimal f-measure performance are marked with '$\triangle$' on the PR curve.

	Prec.	**Recall**	**F-meas.**
PROMODES validation (h=0.50)	0.7522	0.3087	0.4378
PROMODES test (h=0.50)	0.7540	0.3084	0.4378
PROMODES validation (h^*=0.36)	0.5857	0.7824	0.6699
PROMODES test (h^*=0.36)	0.5869	0.7803	0.6699
PROMODES-H validation (h=0.50)	0.6983	0.5333	0.6047
PROMODES-H test (h=0.50)	0.6960	0.5319	0.6030
PROMODES-H validation (h^*=0.37)	0.5848	0.7491	0.6568
PROMODES-H test (h^*=0.37)	0.5857	0.7491	0.6574

Table 2: PROMODES and PROMODES-H on validation and test set.

Summarizing, we have shown that both algorithms commit different errors at the word position level whereas PROMODES is better in predicting non-boundaries and PROMODES-H gives better results for morpheme boundaries at the default threshold of $h = 0.50$. In this section, we demonstrated that across different decision thresholds h for $P(b_{ji}{=}1|\ldots) > h$ none of algorithms dominates the other one, and at the optimal threshold PROMODES achieves a slightly higher performance than PROMODES-H. The question which arises is whether we can combine PROMODES and PROMODES-H in an *ensemble* that leverages individual strengths of both.

[6] Based on Equation 2 and 4 we use the notation $P(b_{ji}|\ldots)$ if we do not want to specify the algorithm.

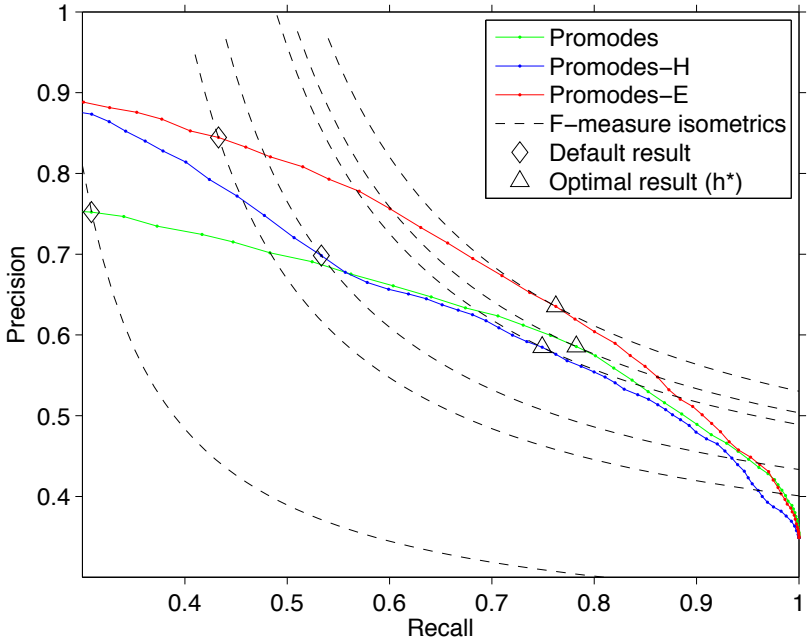

Figure 2: Precision-recall curves for algorithms on validation set.

3.4 A model ensemble to leverage individual strengths

A *model ensemble* is a set of individually trained classifiers whose predictions are combined when classifying new instances (Opitz and Maclin, 1999). The idea is that by combining PROMODES and PROMODES-H, we would be able to avoid certain errors each model commits by consulting the other model as well. We introduce PROMODES-E as the *ensemble* of PROMODES and PROMODES-H. PROMODES-E accesses the individual probabilities $Pr(b_{ji}{=}1|\dots)$ and simply averages them:

$$\frac{Pr(b_{ji}{=}1|t_{ji}) + Pr(b_{ji}{=}1|t_{ji}, b_{j,i\text{-}1}, t_{j,i\text{-}1})}{2} > h \quad .$$

As before, we used the default threshold $h = 0.50$ and found the calibrated threshold $h^* = 0.38$, marked with '◇' and '△' in Figure 2 and shown in Table 3. The calibrated threshold improves the f-measure over both PROMODES and PROMODES-H.

	Prec.	Recall	F-meas.
PROMODES-E validation (h=0.50)	0.8445	0.4328	0.5723
PROMODES-E test (h=0.50)	0.8438	0.4352	0.5742
PROMODES-E validation (h^*=0.38)	0.6354	0.7625	0.6931
PROMODES-E test (h^*=0.38)	0.6350	0.7620	0.6927

Table 3: PROMODES-E on validation and test set.

The optimal solution applying $h^* = 0.38$ is more balanced between precision and recall and boosted the original result by 0.1185 on the test set. Compared to its components PROMODES and PROMODES-H the f-measure increased by 0.0228 and 0.0353 on the test set.

In short, we have shown that by combining PROMODES and PROMODES-H and finding the optimal threshold, the ensemble PROMODES-E gives better results than the individual models themselves and therefore manages to leverage the individual strengths of both to a certain extend. However, can we pinpoint the exact contribution of each individual algorithm to the improved result? We try to find an answer to this question in the analysis of the subsequent section.

3.5 Analysis of calibrated algorithms and their model ensemble

For the entire dataset of 2500 words, we have examined boundary predictions dependent on the relative word position. In Figure 3 and 4 we have plotted the absolute counts of correct boundaries (TP) and non-boundaries (TN) which PROMODES predicted but not PROMODES-H, and vice versa, as continuous lines. We furthermore provided the number of individual predictions which were ultimately adopted by PROMODES-E in the ensemble as dashed lines.

In Figure 3a we can see for the default threshold that PROMODES performs better in predicting non-boundaries in the *middle* and the *end* of the word in comparison to PROMODES-H. Figure 3b

shows the statistics for correctly predicted boundaries. Here, PROMODES-H outperforms PROMODES in predicting correct boundaries across the *entire* word length. After the calibration, shown in Figure 4a, PROMODES-H improves the correct prediction of non-boundaries at the *beginning* of the word whereas PROMODES performs better at the *end*. For the boundary prediction in Figure 4b the signal disappears after calibration.

Concluding, it appears that our test language Zulu has certain features which are modelled best with either a lower or higher-order model. Therefore, the ensemble leveraged strengths of both algorithms which led to a better overall performance with a calibrated threshold.

4 Related work

We have presented two probabilistic generative models for word decomposition, PROMODES and PROMODES-H. Another generative model for morphological analysis has been described by Snover and Brent (2001) and Snover et al. (2002), however, they were interested in finding *paradigms* as sets of mutual exclusive operations on a word form whereas we are describing a generative process using morpheme boundaries and resulting letter transitions.

Moreover, our probabilistic models seem to resemble *Hidden Markov Models* (HMMs) by having certain states and transitions. The main difference is that we have dependencies between states as well as between emissions whereas in HMMs emissions only depend on the underlying state.

Combining different morphological analysers has been performed, for example, by Atwell and Roberts (2006) and Spiegler et al. (2009). Their approaches, though, used *majority vote* to decide whether a morpheme boundary is inserted in a certain word position or not. The algorithms themselves were treated as *black-boxes*.

Monson et al. (2009) described an indirect approach to probabilistically combine ParaMor (Monson, 2008) and Morfessor (Creutz, 2006). They used a natural language tagger which was trained on the output of ParaMor and Morfessor. The goal was to mimic each algorithm since ParaMor is rule-based and there is no access to Morfessor's internally used probabilities. The tagger would then return a probability for starting a new morpheme in a certain position based on the original algorithm. These probabilities in combination with a threshold, learnt on a different dataset, were used to merge word analyses. In contrast, our *ensemble* algorithm PROMODES-E directly accesses the probabilistic framework of each algorithm and combines them based on an optimal threshold learnt on a validation set.

5 Conclusions

We have presented a method to learn a *calibrated decision threshold* from a validation set and demonstrated that *ensemble methods* in connection with calibrated decision thresholds can give better results than the individual models themselves. We introduced two algorithms for word decomposition which are based on generative probabilistic models. The models consider segment boundaries as hidden variables and include probabilities for letter transitions within segments. PROMODES contains a lower order model whereas PROMODES-H is a novel development of PROMODES with a higher order model. For both algorithms, we defined the mathematical model and performed experiments on language data of the morphologically complex language *Zulu*. We compared the performance on increasing training set sizes and analysed for each word position whether their boundary prediction agreed or disagreed. We found out that PROMODES was better in predicting non-boundaries and PROMODES-H gave better results for morpheme boundaries at a default decision threshold. At an optimal decision threshold, however, both yielded a similar f-measure result. We then performed a further analysis based on relative word positions and found out that the calibrated PROMODES-H predicted non-boundaries better for initial word positions whereas the calibrated PROMODES for mid- and final word positions. For boundaries, the calibrated algorithms had a similar behaviour. Subsequently, we showed that a *model ensemble* of both algorithms in conjunction with finding an optimal threshold exceeded the performance of the single algorithms at their individually optimal threshold.

Abstract

If we take an existing supervised NLP system, a simple and general way to improve accuracy is to use unsupervised word representations as extra word features. We evaluate Brown clusters, Collobert and Weston (2008) embeddings, and HLBL (Mnih & Hinton, 2009) embeddings of words on both NER and chunking. We use near state-of-the-art supervised baselines, and find that each of the three word representations improves the accuracy of these baselines. We find further improvements by combining different word representations. You can download our word features, for off-the-shelf use in existing NLP systems, as well as our code, here: http://metaoptimize.com/projects/wordreprs/

1 Introduction

By using unlabelled data to reduce data sparsity in the labeled training data, semi-supervised approaches improve generalization accuracy. Semi-supervised models such as Ando and Zhang (2005), Suzuki and Isozaki (2008), and Suzuki et al. (2009) achieve state-of-the-art accuracy. However, these approaches dictate a particular choice of model and training regime. It can be tricky and time-consuming to adapt an existing supervised NLP system to use these semi-supervised techniques. It is preferable to use a simple and general method to adapt existing supervised NLP systems to be semi-supervised.

One approach that is becoming popular is to use unsupervised methods to induce word features—or to download word features that have already been induced—plug these word features into an existing system, and observe a significant increase in accuracy. But which word features are good for what tasks? Should we prefer certain word features? Can we combine them?

A *word representation* is a mathematical object associated with each word, often a vector. Each dimension's value corresponds to a feature and might even have a semantic or grammatical interpretation, so we call it a *word feature*. Conventionally, supervised lexicalized NLP approaches take a word and convert it to a symbolic ID, which is then transformed into a feature vector using a *one-hot* representation: The feature vector has the same length as the size of the vocabulary, and only one dimension is on. However, the one-hot representation of a word suffers from data sparsity: Namely, for words that are rare in the labeled training data, their corresponding model parameters will be poorly estimated. Moreover, at test time, the model cannot handle words that do not appear in the labeled training data. These limitations of one-hot word representations have prompted researchers to investigate unsupervised methods for inducing word representations over large unlabeled corpora. Word features can be hand-designed, but our goal is to learn them.

One common approach to inducing unsupervised word representation is to use clustering, perhaps hierarchical. This technique was used by a variety of researchers (Miller et al., 2004; Liang, 2005; Koo et al., 2008; Ratinov & Roth, 2009; Huang & Yates, 2009). This leads to a one-hot representation over a smaller vocabulary size. Neural language models (Bengio et al., 2001; Schwenk & Gauvain, 2002; Mnih & Hinton, 2007; Collobert & Weston, 2008), on the other hand, induce dense real-valued low-dimensional

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 384–394,
Uppsala, Sweden, 11-16 July 2010.

word embeddings using unsupervised approaches. (See Bengio (2008) for a more complete list of references on neural language models.)

Unsupervised word representations have been used in previous NLP work, and have demonstrated improvements in generalization accuracy on a variety of tasks. But different word representations have never been systematically compared in a controlled way. In this work, we compare different techniques for inducing word representations, evaluating them on the tasks of named entity recognition (NER) and chunking.

We retract former negative results published in Turian et al. (2009) about Collobert and Weston (2008) embeddings, given training improvements that we describe in Section 7.1.

2 Distributional representations

Distributional word representations are based upon a cooccurrence matrix F of size $W \times C$, where W is the vocabulary size, each row F_w is the initial representation of word w, and each column F_c is some context. Sahlgren (2006) and Turney and Pantel (2010) describe a handful of possible design decisions in contructing F, including choice of context types (left window? right window? size of window?) and type of frequency count (raw? binary? tf-idf?). F_w has dimensionality W, which can be too large to use F_w as features for word w in a supervised model. One can map F to matrix f of size $W \times d$, where $d \ll C$, using some function g, where $f = g(F)$. f_w represents word w as a vector with d dimensions. The choice of g is another design decision, although perhaps not as important as the statistics used to initially construct F.

The self-organizing semantic map (Ritter & Kohonen, 1989) is a distributional technique that maps words to two dimensions, such that syntactically and semantically related words are nearby (Honkela et al., 1995; Honkela, 1997).

LSA (Dumais et al., 1988; Landauer et al., 1998), LSI, and LDA (Blei et al., 2003) induce distributional representations over F in which each column is a *document* context. In most of the other approaches discussed, the columns represent word contexts. In LSA, g computes the SVD of F.

Hyperspace Analogue to Language (HAL) is another early distributional approach (Lund et al., 1995; Lund & Burgess, 1996) to inducing word representations. They compute F over a corpus of 160 million word tokens with a vocabulary size W of 70K word types. There are $2 \cdot W$ types of context (columns): The first or second W are counted if the word c occurs within a window of 10 to the left or right of the word w, respectively. f is chosen by taking the 200 columns (out of 140K in F) with the highest variances. ICA is another technique to transform F into f. (Väyrynen & Honkela, 2004; Väyrynen & Honkela, 2005; Väyrynen et al., 2007). ICA is expensive, and the largest vocabulary size used in these works was only 10K. As far as we know, ICA methods have not been used when the size of the vocab W is 100K or more.

Explicitly storing cooccurrence matrix F can be memory-intensive, and transforming F to f can be time-consuming. It is preferable that F never be computed explicitly, and that f be constructed *incrementally*. Řehůřek and Sojka (2010) describe an incremental approach to inducing LSA and LDA topic models over 270 millions word tokens with a vocabulary of 315K word types. This is similar in magnitude to our experiments.

Another incremental approach to constructing f is using a random projection: Linear mapping g is multiplying F by a random matrix chosen *a priori*. This *random indexing* method is motivated by the Johnson-Lindenstrauss lemma, which states that for certain choices of random matrix, if d is sufficiently large, then the original distances between words in F will be preserved in f (Sahlgren, 2005). Kaski (1998) uses this technique to produce 100-dimensional representations of documents. Sahlgren (2001) was the first author to use random indexing using narrow context. Sahlgren (2006) does a battery of experiments exploring different design decisions involved in constructing F, prior to using random indexing. However, like all the works cited above, Sahlgren (2006) only uses distributional representation to improve existing systems for one-shot classification tasks, such as IR, WSD, semantic knowledge tests, and text categorization. It is not well-understood what settings are appropriate to induce distributional word representations for structured prediction tasks (like parsing and MT) and sequence labeling tasks (like chunking and NER). Previous research has achieved repeated successes on these tasks using clustering representations (Section 3) and distributed representations (Section 4), so we focus on these representations in our work.

3 Clustering-based word representations

Another type of word representation is to induce a clustering over words. Clustering methods and

distributional methods can overlap. For example, Pereira et al. (1993) begin with a cooccurrence matrix and transform this matrix into a clustering.

3.1 Brown clustering

The Brown algorithm is a hierarchical clustering algorithm which clusters words to maximize the mutual information of bigrams (Brown et al., 1992). So it is a class-based bigram language model. It runs in time $O(V \cdot K^2)$, where V is the size of the vocabulary and K is the number of clusters.

The hierarchical nature of the clustering means that we can choose the word class at several levels in the hierarchy, which can compensate for poor clusters of a small number of words. One downside of Brown clustering is that it is based solely on bigram statistics, and does not consider word usage in a wider context.

Brown clusters have been used successfully in a variety of NLP applications: NER (Miller et al., 2004; Liang, 2005; Ratinov & Roth, 2009), PCFG parsing (Candito & Crabbé, 2009), dependency parsing (Koo et al., 2008; Suzuki et al., 2009), and semantic dependency parsing (Zhao et al., 2009).

Martin et al. (1998) presents algorithms for inducing hierarchical clusterings based upon word bigram *and trigram* statistics. Ushioda (1996) presents an extension to the Brown clustering algorithm, and learn hierarchical clusterings of words *as well as phrases*, which they apply to POS tagging.

3.2 Other work on cluster-based word representations

Lin and Wu (2009) present a K-means-like non-hierarchical clustering algorithm for phrases, which uses MapReduce.

HMMs can be used to induce a soft clustering, specifically a multinomial distribution over possible clusters (hidden states). Li and McCallum (2005) use an HMM-LDA model to improve POS tagging and Chinese Word Segmentation. Huang and Yates (2009) induce a fully-connected HMM, which emits a multinomial distribution over possible vocabulary words. They perform hard clustering using the Viterbi algorithm. (Alternately, they could keep the soft clustering, with the representation for a particular word token being the posterior probability distribution over the states.) However, the CRF chunker in Huang and Yates (2009), which uses their HMM word clusters as extra features, achieves F1 lower than a baseline CRF chunker (Sha & Pereira, 2003). Goldberg et al. (2009) use an HMM to assign POS tags to words, which in turns improves the accuracy of the PCFG-based Hebrew parser. Deschacht and Moens (2009) use a latent-variable language model to improve semantic role labeling.

4 Distributed representations

Another approach to word representation is to learn a distributed representation. (Not to be confused with *distributional* representations.) A distributed representation is dense, low-dimensional, and real-valued. Distributed word representations are called *word embeddings*. Each dimension of the embedding represents a latent feature of the word, hopefully capturing useful syntactic and semantic properties. A distributed representation is compact, in the sense that it can represent an exponential number of clusters in the number of dimensions.

Word embeddings are typically induced using *neural language models*, which use neural networks as the underlying predictive model (Bengio, 2008). Historically, training and testing of neural language models has been slow, scaling as the size of the vocabulary for each model computation (Bengio et al., 2001; Bengio et al., 2003). However, many approaches have been proposed in recent years to eliminate that linear dependency on vocabulary size (Morin & Bengio, 2005; Collobert & Weston, 2008; Mnih & Hinton, 2009) and allow scaling to very large training corpora.

4.1 Collobert and Weston (2008) embeddings

Collobert and Weston (2008) presented a neural language model that could be trained over billions of words, because the gradient of the loss was computed stochastically over a small sample of possible outputs, in a spirit similar to Bengio and Sénécal (2003). This neural model of Collobert and Weston (2008) was refined and presented in greater depth in Bengio et al. (2009).

The model is discriminative and non-probabilistic. For each training update, we read an n-gram $x = (w_1, \ldots, w_n)$ from the corpus. The model concatenates the learned embeddings of the n words, giving $e(w_1) \oplus \ldots \oplus e(w_n)$, where e is the lookup table and $\oplus$ is concatenation. We also create a *corrupted* or *noise* n-gram $\tilde{x} = (w_1, \ldots, w_{n-q}, \tilde{w_n})$, where $\tilde{w_n} \neq w_n$ is chosen uniformly from the vocabulary.[1] For convenience,

[1] In Collobert and Weston (2008), the middle word in the

we write $e(x)$ to mean $e(w_1) \oplus \ldots \oplus e(w_n)$. We predict a score $s(x)$ for x by passing $e(x)$ through a single hidden layer neural network. The training criterion is that n-grams that are present in the training corpus like x must have a score at least some margin higher than corrupted n-grams like $\tilde{x}$. Specifically: $L(x) = \max(0, 1 - s(x) + s(\tilde{x}))$. We minimize this loss stochastically over the n-grams in the corpus, doing gradient descent simultaneously over the neural network parameters *and* the embedding lookup table.

We implemented the approach of Collobert and Weston (2008), with the following differences:

- We did not achieve as low log-ranks on the English Wikipedia as the authors reported in Bengio et al. (2009), despite initially attempting to have identical experimental conditions.
- We corrupt the *last* word of each n-gram.
- We had a separate learning rate for the embeddings and for the neural network weights. We found that the embeddings should have a learning rate generally 1000–32000 times higher than the neural network weights. Otherwise, the unsupervised training criterion drops slowly.
- Although their sampling technique makes training fast, testing is still expensive when the size of the vocabulary is large. Instead of cross-validating using the log-rank over the validation data as they do, we instead used the moving average of the training loss on training examples before the weight update.

4.2 HLBL embeddings

The log-bilinear model (Mnih & Hinton, 2007) is a probabilistic and linear neural model. Given an n-gram, the model concatenates the embeddings of the $n - 1$ first words, and learns a linear model to predict the embedding of the last word. The similarity between the predicted embedding and the current actual embedding is transformed into a probability by exponentiating and then normalizing. Mnih and Hinton (2009) speed up model evaluation during training and testing by using a hierarchy to exponentially filter down the number of computations that are performed. This hierarchical evaluation technique was first proposed by Morin and Bengio (2005). The model, combined with this optimization, is called the *hierarchical log-bilinear (HLBL)* model.

n-gram is corrupted. In Bengio et al. (2009), the last word in the n-gram is corrupted.

5 Supervised evaluation tasks

We evaluate the hypothesis that one can take an existing, near state-of-the-art, supervised NLP system, and improve its accuracy by including word representations as word features. This technique for turning a supervised approach into a semi-supervised one is general and task-agnostic.

However, we wish to find out if certain word representations are preferable for certain tasks. Lin and Wu (2009) finds that the representations that are good for NER are poor for search query classification, and vice-versa. We apply clustering and distributed representations to NER and chunking, which allows us to compare our semi-supervised models to those of Ando and Zhang (2005) and Suzuki and Isozaki (2008).

5.1 Chunking

Chunking is a syntactic sequence labeling task. We follow the conditions in the CoNLL-2000 shared task (Sang & Buchholz, 2000).

The linear CRF chunker of Sha and Pereira (2003) is a standard near-state-of-the-art baseline chunker. In fact, many off-the-shelf CRF implementations now replicate Sha and Pereira (2003), including their choice of feature set:

- CRF++ by Taku Kudo (`http://crfpp.sourceforge.net/`)
- crfsgd by Léon Bottou (`http://leon.bottou.org/projects/sgd`)
- CRFsuite by by Naoaki Okazaki (`http://www.chokkan.org/software/crfsuite/`)

We use CRFsuite because it makes it simple to modify the feature generation code, so one can easily add new features. We use SGD optimization, and enable negative state features and negative transition features. ("`feature.possible_transitions=1, feature.possible_states=1`")

Table 1 shows the features in the baseline chunker. As you can see, the Brown and embedding features are unigram features, and do not participate in conjunctions like the word features and tag features do. Koo et al. (2008) sees further accuracy improvements on dependency parsing when using word representations in compound features.

The data comes from the Penn Treebank, and is newswire from the Wall Street Journal in 1989. Of the 8936 training sentences, we used 1000 randomly sampled sentences (23615 words) for development. We trained models on the 7936

- Word features: w_i for i in $\{-2,-1,0,+1,+2\}$, $w_i \wedge w_{i+1}$ for i in $\{-1,0\}$.
- Tag features: w_i for i in $\{-2,-1,0,+1,+2\}$, $t_i \wedge t_{i+1}$ for i in $\{-2,-1,0,+1\}$. $t_i \wedge t_{i+1} \wedge t_{i+2}$ for i in $\{-2,-1,0\}$.
- Embedding features [if applicable]: $e_i[d]$ for i in $\{-2,-1,0,+1,+2\}$, where d ranges over the dimensions of the embedding e_i.
- Brown features [if applicable]: $substr(b_i, 0, p)$ for i in $\{-2,-1,0,+1,+2\}$, where *substr* takes the p-length prefix of the Brown cluster b_i.

Table 1: Features templates used in the CRF chunker.

training partition sentences, and evaluated their F1 on the development set. After choosing hyperparameters to maximize the dev F1, we would retrain the model using these hyperparameters on the full 8936 sentence training set, and evaluate on test. One hyperparameter was l2-regularization sigma, which for most models was optimal at 2 or 3.2. The word embeddings also required a scaling hyperparameter, as described in Section 7.2.

5.2 Named entity recognition

NER is typically treated as a sequence prediction problem. Following Ratinov and Roth (2009), we use the regularized averaged perceptron model. Ratinov and Roth (2009) describe different sequence encoding like BILOU and BIO, and show that the BILOU encoding outperforms BIO, and the greedy inference performs competitively to Viterbi while being significantly faster. Accordingly, we use greedy inference and BILOU text chunk representation. We use the publicly available implementation from Ratinov and Roth (2009) (see the end of this paper for the URL). In our baseline experiments, we remove gazetteers and non-local features (Krishnan & Manning, 2006). However, we also run experiments that include these features, to understand if the information they provide mostly overlaps with that of the word representations.

After each epoch over the training set, we measured the accuracy of the model on the development set. Training was stopped after the accuracy on the development set did not improve for 10 epochs, generally about 50–80 epochs total. The epoch that performed best on the development set was chosen as the final model.

We use the following baseline set of features from Zhang and Johnson (2003):
- Previous two predictions y_{i-1} and y_{i-2}
- Current word x_i
- x_i word type information: all-capitalized, is-capitalized, all-digits, alphanumeric, etc.
- Prefixes and suffixes of x_i, if the word contains hyphens, then the tokens between the hyphens
- Tokens in the window $c = (x_{i-2}, x_{i-1}, x_i, x_{i+1}, x_{i+2})$
- Capitalization pattern in the window c
- Conjunction of c and y_{i-1}.

Word representation features, if present, are used the same way as in Table 1.

When using the lexical features, we normalize dates and numbers. For example, *1980* becomes **DDDD** and *212-325-4751* becomes **DDD*-*DDD*-*DDDD**. This allows a degree of abstraction to years, phone numbers, etc. This delexicalization is performed separately from using the word representation. That is, if we have induced an embedding for *12/3/2008* , we will use the embedding of *12/3/2008* , and **DD*/*D*/*DDDD** in the baseline features listed above.

Unlike in our chunking experiments, after we chose the best model on the development set, we used that model on the test set too. (In chunking, after finding the best hyperparameters on the development set, we would combine the dev and training set and training a model over this combined set, and then evaluate on test.)

The standard evaluation benchmark for NER is the CoNLL03 shared task dataset drawn from the Reuters newswire. The training set contains 204K words (14K sentences, 946 documents), the test set contains 46K words (3.5K sentences, 231 documents), and the development set contains 51K words (3.3K sentences, 216 documents).

We also evaluated on an out-of-domain (OOD) dataset, the MUC7 formal run (59K words). MUC7 has a different annotation standard than the CoNLL03 data. It has several NE types that don't appear in CoNLL03: money, dates, and numeric quantities. CoNLL03 has MISC, which is not present in MUC7. To evaluate on MUC7, we perform the following postprocessing steps prior to evaluation:

1. In the gold-standard MUC7 data, discard (label as 'O') all NEs with type NUMBER/MONEY/DATE.
2. In the predicted model output on MUC7 data, discard (label as 'O') all NEs with type MISC.

These postprocessing steps will adversely affect all NER models across-the-board, nonetheless allowing us to compare different models in a controlled manner.

6 Unlabled Data

Unlabeled data is used for inducing the word representations. We used the RCV1 corpus, which contains one year of Reuters English newswire, from August 1996 to August 1997, about 63 millions words in 3.3 million sentences. We left case intact in the corpus. By comparison, Collobert and Weston (2008) downcases words and delexicalizes numbers.

We use a preprocessing technique proposed by Liang, (2005, p. 51), which was later used by Koo et al. (2008): Remove all sentences that are less than 90% lowercase a–z. We assume that whitespace is not counted, although this is not specified in Liang's thesis. We call this preprocessing step *cleaning*.

In Turian et al. (2009), we found that all word representations performed better on the supervised task when they were induced on the clean unlabeled data, both embeddings and Brown clusters. This is the case even though the cleaning process was very aggressive, and discarded more than half of the sentences. According to the evidence and arguments presented in Bengio et al. (2009), the non-convex optimization process for Collobert and Weston (2008) embeddings might be adversely affected by noise and the statistical sparsity issues regarding rare words, especially at the beginning of training. For this reason, we hypothesize that learning representations over the most frequent words first and gradually increasing the vocabulary—a *curriculum* training strategy (Elman, 1993; Bengio et al., 2009; Spitkovsky et al., 2010)—would provide better results than cleaning.

After cleaning, there are 37 million words (58% of the original) in 1.3 million sentences (41% of the original). The cleaned RCV1 corpus has 269K word types. This is the vocabulary size, i.e. how many word representations were induced. Note that cleaning is applied only to the unlabeled data, not to the labeled data used in the supervised tasks.

RCV1 is a superset of the CoNLL03 corpus. For this reason, NER results that use RCV1 word representations are a form of transductive learning.

7 Experiments and Results

7.1 Details of inducing word representations

The Brown clusters took roughly 3 days to induce, when we induced 1000 clusters, the baseline in prior work (Koo et al., 2008; Ratinov & Roth, 2009). We also induced 100, 320, and 3200 Brown clusters, for comparison. (Because Brown clustering scales quadratically in the number of clusters, inducing 10000 clusters would have been prohibitive.) Because Brown clusters are hierarchical, we can use cluster supersets as features. We used clusters at path depth 4, 6, 10, and 20 (Ratinov & Roth, 2009). These are the prefixes used in Table 1.

The Collobert and Weston (2008) (C&W) embeddings were induced over the course of a few weeks, and trained for about 50 epochs. One of the difficulties in inducing these embeddings is that there is no stopping criterion defined, and that the quality of the embeddings can keep improving as training continues. Collobert (p.c.) simply leaves one computer training his embeddings indefinitely. We induced embeddings with 25, 50, 100, or 200 dimensions over 5-gram windows. In comparison to Turian et al. (2009), we use improved C&W embeddings in this work:

• They were trained for 50 epochs, not just 20 epochs.

• We initialized all embedding dimensions uniformly in the range [-0.01, +0.01], not [-1,+1]. For rare words, which are typically updated only 143 times per epoch[2], and given that our embedding learning rate was typically 1e-6 or 1e-7, this means that rare word embeddings will be concentrated around zero, instead of spread out randomly.

The HLBL embeddings were trained for 100 epochs (7 days).[3] Unlike our Collobert and Weston (2008) embeddings, we did not extensively tune the learning rates for HLBL. We used a learning rate of 1e-3 for both model parameters and embedding parameters. We induced embeddings with 100 dimensions over 5-gram windows, and embeddings with 50 dimensions over 5-gram windows. Embeddings were induced over one pass

[2] A rare word will appear 5 (window size) times per epoch as a positive example, and 37M (training examples per epoch) / 269K (vocabulary size) = 138 times per epoch as a corruption example.

[3] The HLBL model updates require fewer matrix multiplies than Collobert and Weston (2008) model updates. Additionally, HLBL models were trained on a GPGPU, which is faster than conventional CPU arithmetic.

approach using a random tree, not two passes with an updated tree and embeddings re-estimation.

7.2 Scaling of Word Embeddings

Like many NLP systems, the baseline system contains only binary features. The word embeddings, however, are real numbers that are not necessarily in a bounded range. If the range of the word embeddings is too large, they will exert more influence than the binary features.

We generally found that embeddings had zero mean. We can scale the embeddings by a hyperparameter, to control their standard deviation. Assume that the embeddings are represented by a matrix E:

$$E \leftarrow \sigma \cdot E / stddev(E) \quad (1)$$

σ is a scaling constant that sets the new standard deviation after scaling the embeddings.

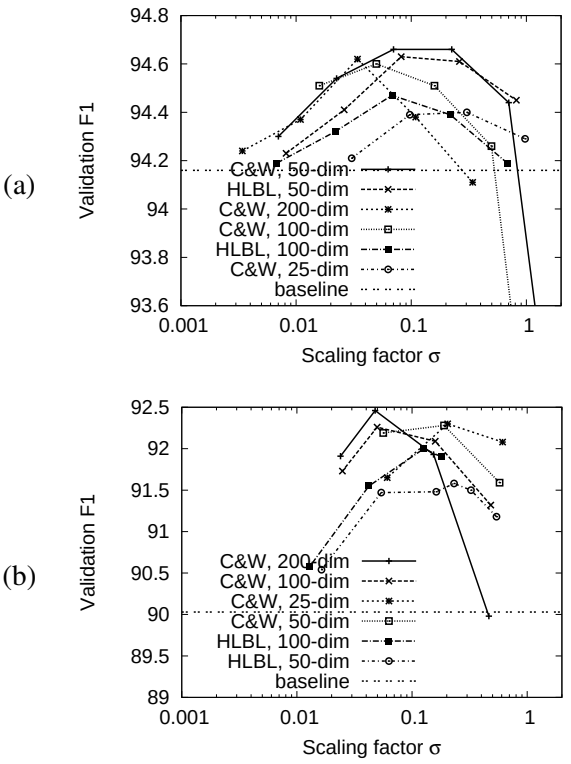

Figure 1: Effect as we vary the scaling factor σ (Equation 1) on the validation set F1. We experiment with Collobert and Weston (2008) and HLBL embeddings of various dimensionality. (a) Chunking results. (b) NER results.

Figure 1 shows the effect of scaling factor σ on both supervised tasks. We were surprised to find that on both tasks, across Collobert and Weston (2008) and HLBL embeddings of various dimensionality, that all curves had similar shapes and optima. This is one contributions of our work. In Turian et al. (2009), we were not able to prescribe a default value for scaling the embeddings. However, these curves demonstrate that a reasonable choice of scale factor is such that the embeddings have a standard deviation of 0.1.

7.3 Capacity of Word Representations

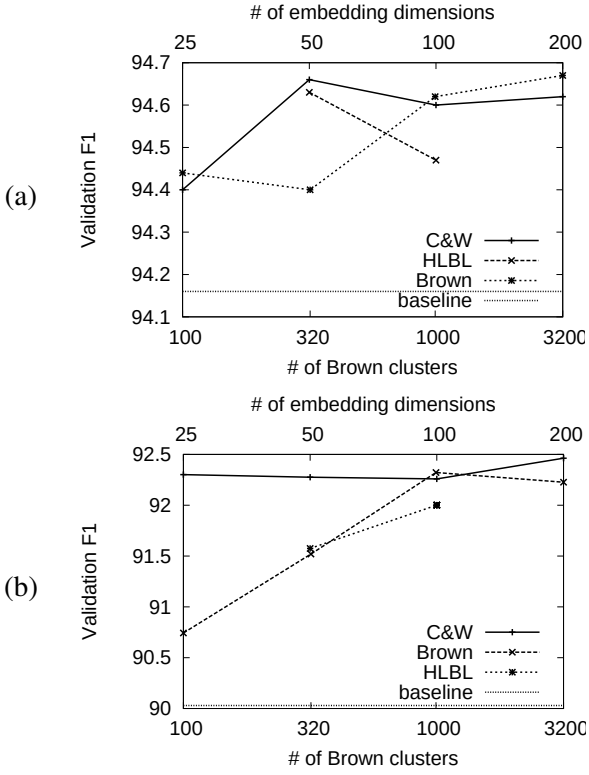

Figure 2: Effect as we vary the capacity of the word representations on the validation set F1. (a) Chunking results. (b) NER results.

There are capacity controls for the word representations: number of Brown clusters, and number of dimensions of the word embeddings. Figure 2 shows the effect on the validation F1 as we vary the capacity of the word representations.

In general, it appears that more Brown clusters are better. We would like to induce 10000 Brown clusters, however this would take several months.

In Turian et al. (2009), we hypothesized on the basis of solely the HLBL NER curve that higher-dimensional word embeddings would give higher accuracy. Figure 2 shows that this hypothesis is not true. For NER, the C&W curve is almost flat, and we were suprised to find the even 25-dimensional C&W word embeddings work so well. For chunking, 50-dimensional embeddings had the highest validation F1 for both C&W and HLBL. These curves indicates that the optimal capacity of the word embeddings is task-specific.

System	Dev	Test
Baseline	94.16	93.79
HLBL, 50-dim	94.63	94.00
C&W, 50-dim	94.66	94.10

Table 3: Final NER F1 results, showing the cumulative effect of adding word representations, non-local features, and gazetteers to the baseline. To speed up training, in combined experiments (C&W plus another word representation), we used the 50-dimensional C&W embeddings, not the 200-dimensional ones. In the last section, we show how many unlabeled words were used.

7.4 Final results

Table 2 shows the final chunking results and Table 3 shows the final NER F1 results. We compare to the state-of-the-art methods of Ando and Zhang (2005), Suzuki and Isozaki (2008), and—for NER—Lin and Wu (2009). Tables 2 and 3 show that accuracy can be increased further by combining the features from different types of word representations. But, if only one word representation is to be used, Brown clusters have the highest accuracy. Given the improvements to the C&W embeddings since Turian et al. (2009), C&W embeddings outperform the HLBL embeddings. On chunking, there is only a minute difference between Brown clusters and the embeddings. Combining representations leads to small increases in the test F1. In comparison to chunking, combining different word representations on NER seems gives larger improvements on the test F1.

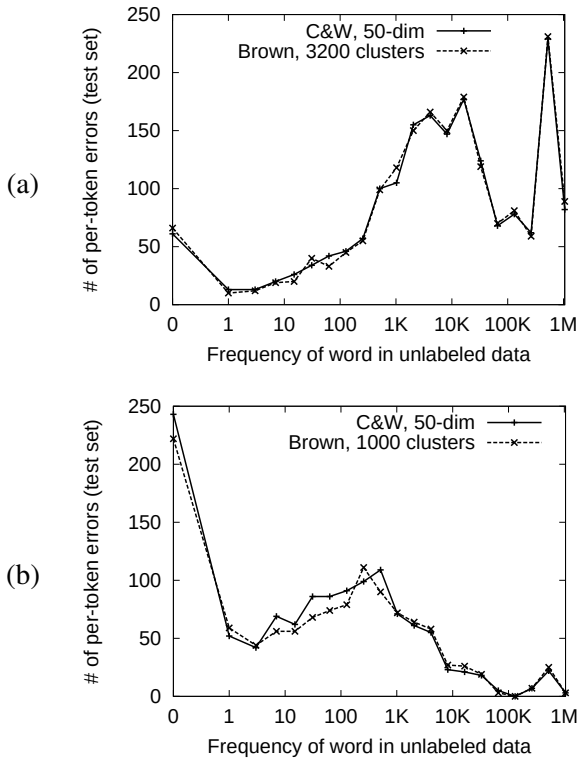

Figure 3: For word tokens that have different frequency in the unlabeled data, what is the total number of per-token errors incurred on the test set? (a) Chunking results. (b) NER results.

On NER, Brown clusters are superior to the word embeddings. Since much of the NER F1 is derived from decisions made over rare words, we suspected that Brown clustering has a superior representation for rare words. Brown makes a single hard clustering decision, whereas the embedding for a rare word is close to its initial value since it hasn't received many training updates (see Footnote 2). Figure 3 shows the total number of per-token errors incurred on the test set, depending upon the frequency of the word token in the unlabeled data. For NER, Figure 3 (b) shows that most errors occur on rare words, and that Brown clusters do indeed incur fewer errors for rare words. This supports our hypothesis that, for rare words, Brown clustering produces better representations than word embeddings that haven't received sufficient training updates. For chunking, Brown clusters and C&W embeddings incur almost identical numbers of errors, and errors are concentrated around the more common

words. We hypothesize that *non-rare* words have good representations, regardless of the choice of word representation technique. For tasks like chunking in which a syntactic decision relies upon looking at several token simultaneously, compound features that use the word representations might increase accuracy more (Koo et al., 2008).

Using word representations in NER brought larger gains on the out-of-domain data than on the in-domain data. We were surprised by this result, because the OOD data was not even used during the unsupervised word representation induction, as was the in-domain data. We are curious to investigate this phenomenon further.

Ando and Zhang (2005) present a semi-supervised learning algorithm called alternating structure optimization (ASO). They find a low-dimensional projection of the input features that gives good linear classifiers over auxiliary tasks. These auxiliary tasks are sometimes specific to the supervised task, and sometimes general language modeling tasks like "predict the missing word". Suzuki and Isozaki (2008) present a semi-supervised extension of CRFs. (In Suzuki et al. (2009), they extend their semi-supervised approach to more general conditional models.) One of the advantages of the semi-supervised learning approach that we use is that it is simpler and more general than that of Ando and Zhang (2005) and Suzuki and Isozaki (2008). Their methods dictate a particular choice of model and training regime and could not, for instance, be used with an NLP system based upon an SVM classifier.

Lin and Wu (2009) present a K-means-like non-hierarchical clustering algorithm for phrases, which uses MapReduce. Since they can scale to millions of phrases, and they train over 800B unlabeled words, they achieve state-of-the-art accuracy on NER using their phrase clusters. This suggests that extending word representations to phrase representations is worth further investigation.

8 Conclusions

Word features can be learned in advance in an unsupervised, task-inspecific, and model-agnostic manner. These word features, once learned, are easily disseminated with other researchers, and easily integrated into existing supervised NLP systems. The disadvantage, however, is that accuracy might not be as high as a semi-supervised method that includes task-specific information and that jointly learns the supervised and unsupervised tasks (Ando & Zhang, 2005; Suzuki & Isozaki, 2008; Suzuki et al., 2009).

Unsupervised word representations have been used in previous NLP work, and have demonstrated improvements in generalization accuracy on a variety of tasks. Ours is the first work to systematically compare different word representations in a controlled way. We found that Brown clusters and word embeddings both can improve the accuracy of a near-state-of-the-art supervised NLP system. We also found that combining different word representations can improve accuracy further. Error analysis indicates that Brown clustering induces better representations for rare words than C&W embeddings that have not received many training updates.

Another contribution of our work is a default method for setting the scaling parameter for word embeddings. With this contribution, word embeddings can now be used off-the-shelf as word features, with no tuning.

Future work should explore methods for inducing phrase representations, as well as techniques for increasing in accuracy by using word representations in *compound* features.

Replicating our experiments

You can visit `http://metaoptimize.com/projects/wordreprs/` to find: The word representations we induced, which you can download and use in your experiments; The code for inducing the word representations, which you can use to induce word representations on your own data; The NER and chunking system, with code for replicating our experiments.

Abstract

Automatically identifying the polarity of words is a very important task in Natural Language Processing. It has applications in text classification, text filtering, analysis of product review, analysis of responses to surveys, and mining online discussions. We propose a method for identifying the polarity of words. We apply a Markov random walk model to a large word relatedness graph, producing a polarity estimate for any given word. A key advantage of the model is its ability to accurately and quickly assign a polarity sign and magnitude to any word. The method could be used both in a semi-supervised setting where a training set of labeled words is used, and in an unsupervised setting where a handful of seeds is used to define the two polarity classes. The method is experimentally tested using a manually labeled set of positive and negative words. It outperforms the state of the art methods in the semi-supervised setting. The results in the unsupervised setting is comparable to the best reported values. However, the proposed method is faster and does not need a large corpus.

1 Introduction

Identifying emotions and attitudes from unstructured text is a very important task in Natural Language Processing. This problem has a variety of possible applications. For example, there has been a great body of work for mining product reputation on the Web (Morinaga et al., 2002; Turney, 2002). Knowing the reputation of a product is very important for marketing and customer relation management (Morinaga et al., 2002). Manually handling reviews to identify reputation is a very costly, and time consuming process given the overwhelming amount of reviews on the Web. A list of words with positive/negative polarity is a very valuable resource for such an application.

Another interesting application is mining online discussions. A threaded discussion is an electronic discussion in which software tools are used to help individuals post messages and respond to other messages. Threaded discussions include e-mails, e-mail lists, bulletin boards, newsgroups, or Internet forums. Threaded discussions act as a very important tool for communication and collaboration in the Web. An enormous number of discussion groups exists on the Web. Millions of users post content to these groups covering pretty much every possible topic. Tracking participant attitude towards different topics and towards other participants is a very interesting task. For example,Tong (2001) presented the concept of sentiment timelines. His system classifies discussion posts about movies as either positive or negative. This is used to produce a plot of the number of positive and negative sentiment messages over time. All those applications could benefit much from an automatic way of identifying semantic orientation of words.

In this paper, we study the problem of automatically identifying semantic orientation of any word by analyzing its relations to other words. Automatically classifying words as either positive or negative enables us to automatically identify the polarity of larger pieces of text. This could be a very useful building block for mining surveys, product reviews and online discussions. We apply a Markov random walk model to a large semantic word graph, producing a polarity estimate for any given word. Previous work on identifying the semantic orientation of words has addressed the problem as both a semi-supervised (Takamura et al., 2005) and an unsupervised (Turney and Littman, 2003) learning problem. In the semi-supervised setting, a training set of labeled words

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 395–403,
Uppsala, Sweden, 11-16 July 2010.

is used to train the model. In the unsupervised setting, only a handful of seeds is used to define the two polarity classes. The proposed method could be used both in a semi-supervised and in an unsupervised setting. Empirical experiments on a labeled set of words show that the proposed method outperforms the state of the art methods in the semi-supervised setting. The results in the unsupervised setting are comparable to the best reported values. The proposed method has the advantages that it is faster and it does not need a large training corpus.

The rest of the paper is structured as follows. In Section 2, we discuss related work. Section 3 presents our method for identifying word polarity. Section 4 describes our experimental setup. We conclude in Section 5.

2 Related Work

Hatzivassiloglou and McKeown (1997) proposed a method for identifying word polarity of adjectives. They extract all conjunctions of adjectives from a given corpus and then they classify each conjunctive expression as either the same orientation such as "simple and well-received" or different orientation such as "simplistic but well-received". The result is a graph that they cluster into two subsets of adjectives. They classify the cluster with the higher average frequency as positive. They created and labeled their own dataset for experiments. Their approach will probably works only with adjectives because there is nothing wrong with conjunctions of nouns or verbs with opposite polarities (e.g., "war and peace", "rise and fall", ..etc).

Turney and Littman (2003) identify word polarity by looking at its statistical association with a set of positive/negative seed words. They use two statistical measures for estimating association: Pointwise Mutual Information (PMI) and Latent Semantic Analysis (LSA). To get co-occurrence statistics, they submit several queries to a search engine. Each query consists of the given word and one of the seed words. They use the search engine near operator to look for instances where the given word is physically close to the seed word in the returned document. They present their method as an unsupervised method where a very small amount of seed words are used to define semantic orientation rather than train the model. One of the limitations of their method is that it requires a large corpus of text to achieve good performance. They use several corpora, the size of the best performing dataset is roughly one hundred billion words (Turney and Littman, 2003).

Takamura et al. (2005) proposed using spin models for extracting semantic orientation of words. They construct a network of words using gloss definitions, thesaurus, and co-occurrence statistics. They regard each word as an electron. Each electron has a spin and each spin has a direction taking one of two values: up or down. Two neighboring spins tend to have the same orientation from an energetic point of view. Their hypothesis is that as neighboring electrons tend to have the same spin direction, neighboring words tend to have similar polarity. They pose the problem as an optimization problem and use the mean field method to find the best solution. The analogy with electrons leads them to assume that each word should be either positive or negative. This assumption is not accurate because most of the words in the language do not have any semantic orientation. They report that their method could get misled by noise in the gloss definition and their computations sometimes get trapped in a local optimum because of its greedy optimization flavor.

Kamps et al. (2004) construct a network based on WordNet synonyms and then use the shortest paths between any given word and the words 'good' and 'bad' to determine word polarity. They report that using shortest paths could be very noisy. For example. 'good' and 'bad' themselves are closely related in WordNet with a 5-long sequence "good, sound, heavy, big, bad". A given word w may be more connected to one set of words (e.g., positive words), yet have a shorter path connecting it to one word in the other set. Restricting seed words to only two words affects their accuracy. Adding more seed words could help but it will make their method extremely costly from the computation point of view. They evaluate their method only using adjectives.

Hu and Liu (2004) use WordNet synonyms and antonyms to predict the polarity of words. For any word, whose polarity is unknown, they search WordNet and a list of seed labeled words to predict its polarity. They check if any of the synonyms of the given word has known polarity. If so, they label it with the label of its synonym. Otherwise, they check if any of the antonyms of the given word has known polarity. If so, they label it

with the opposite label of the antonym. They continue in a bootstrapping manner till they label all possible word. This method is quite similar to the shortest-path method proposed in (Kamps et al., 2004).

There are some other methods that try to build lexicons of polarized words. Esuli and Sebastiani (2005; 2006) use a textual representation of words by collating all the glosses of the word as found in some dictionary. Then, a binary text classifier is trained using the textual representation and applied to new words. Kim and Hovy (2004) start with two lists of positive and negative seed words. WordNet is used to expand these lists. Synonyms of positive words and antonyms of negative words are considered positive, while synonyms of negative words and antonyms of positive words are considered negative. A similar method is presented in (Andreevskaia and Bergler, 2006) where WordNet synonyms, antonyms, and glosses are used to iteratively expand a list of seeds. The sentiment classes are treated as fuzzy categories where some words are very central to one category, while others may be interpreted differently. Kanayama and Nasukawa (2006) use syntactic features and context coherency, the tendency for same polarities to appear successively , to acquire polar atoms.

Other related work is concerned with subjectivity analysis. Subjectivity analysis is the task of identifying text that present opinions as opposed to objective text that present factual information (Wiebe, 2000). Text could be either words, phrases, sentences, or any other chunks. There are two main categories of work on subjectivity analysis. In the first category, subjective words and phrases are identified without considering their context (Wiebe, 2000; Hatzivassiloglou and Wiebe, 2000; Banea et al., 2008). In the second category, the context of subjective text is used (Riloff and Wiebe, 2003; Yu and Hatzivassiloglou, 2003; Nasukawa and Yi, 2003; Popescu and Etzioni, 2005) Wiebe et al. (2001) lists a lot of applications of subjectivity analysis such as classifying emails and mining reviews. Subjectivity analysis is related to the proposed method because identifying the polarity of text is the natural next step that should follow identifying subjective text.

3 Word Polarity

We use a Markov random walk model to identify polarity of words. Assume that we have a network of words, some of which are labeled as either positive or negative. In this network, two words are connecting if they are related. Different sources of information could be used to decide whether two words are related or not. For example, the synonyms of any word are semantically related to it. The intuition behind that connecting semantically related words is that those words tend to have similar polarity. Now imagine a random surfer walking along the network starting from an unlabeled word w. The random walk continues until the surfer hits a labeled word. If the word w is positive then the probability that the random walk hits a positive word is higher and if w is negative then the probability that the random walk hits a negative word is higher. Similarly, if the word w is positive then the average time it takes a random walk starting at w to hit a positive node is less than the average time it takes a random walk starting at w to hit a negative node.

In the rest of this section, we will describe how we can construct a word relatedness graph in Section 3.1. The random walk model is described in Section 3.2. Hitting time is defined in Section‘3.3. Finally, an algorithm for computing a sign and magnitude for the polarity of any given word is described in Section 3.4.

3.1 Network Construction

We construct a network where two nodes are linked if they are semantically related. Several sources of information could be used as indicators of the relatedness of words. One such important source is WordNet (Miller, 1995). WordNet is a large lexical database of English. Nouns, verbs, adjectives and adverbs are grouped into sets of cognitive synonyms (synsets), each expressing a distinct concept (Miller, 1995). Synsets are interlinked by means of conceptual-semantic and lexical relations.

The simplest approach is to connect words that occur in the same WordNet synset. We can collect all words in WordNet, and add links between any two words that occurr in the same synset. The resulting graph is a graph $G(W, E)$ where W is a set of word / part-of-speech pairs for all the words in WordNet. E is the set of edges connecting each pair of synonymous words. Nodes represent word/pos pairs rather than words because the part of speech tags are helpful in disambiguating the different senses for a given word. For example,

the word "fine" has two different meanings when used as an adjective and as a noun.

Several other methods could be used to link words. For example, we can use other WordNet relations: hypernyms, similar to,...etc. Another source of links between words is co-occurrence statistics from corpus. Following the method presented in (Hatzivassiloglou and McKeown, 1997), we can connect words if they appear in a conjunctive form in the corpus. This method is only applicable to adjectives. If two adjectives are connected by "and" in conjunctive form, it is highly likely that they have the same semantic orientation. In all our experiments, we restricted the network to only WordNet relations. We study the effect of using co-occurrence statistics to connect words later at the end of our experiments. If more than one relation exists between any two words, the strength of the corresponding edge is adjusted accordingly.

3.2 Random Walk Model

Imagine a random surfer walking along the word relatedness graph G. Starting from a word with unknown polarity i , it moves to a node j with probability P_{ij} after the first step. The walk continues until the surfer hits a word with a known polarity. Seed words with known polarity act as an absorbing boundary for the random walk. If we repeat the number of random walks N times, the percentage of time at which the walk ends at a positive/negative word could be used as an indicator of its positive/negative polarity. The average time a random walk starting at w takes to hit the set of positive/negative nodes is also an indicator of its polarity. This view is closely related to the partially labeled classification with random walks approach in (Szummer and Jaakkola, 2002) and the semi-supervised learning using harmonic functions approach in (Zhu et al., 2003).

Let W be the set of words in our lexicon. We construct a graph whose nodes V are all words in W The edges E correspond to relatedness between words We define transition probabilities $P_{t+1|t}(j|i)$ from i to j by normalizing the weights of the edges out of node i, so:

$$P_{t+1|t}(j|i) = Wij / \sum_k W_{ik} \tag{1}$$

where k represents all nodes in the neighborhood of i. $P_{t2|t1}(j|i)$ denotes the transition probability from node i at step t_1 to node j at time step t_2. We note that the weights W_{ij} are symmetric and the transition probabilities $P_{t+1|t}(j|i)$ are not necessarily symmetric because of the node out degree normalization.

3.3 First-Passage Time

The mean first-passage (hitting) time $h(i|k)$ is defined as the average number of steps a random walker, starting in state $i \neq k$, will take to enter state k for the first time (Norris, 1997). Let $G = (V, E)$ be a graph with a set of vertices V, and a set of edges E. Consider a subset of vertices $S \subset V$, Consider a random walk on G starting at node $i \notin S$. Let N_t denote the position of the random surfer at time t. Let $h(i|S)$ be the the average number of steps a random walker, starting in state $i \notin S$, will take to enter a state $k \in S$ for the first time. Let T^S be the first-passage for any vertex in S.

$$P(T_S = t|N_0 = i) = \sum_{j \in V} p_{ij} \times P(T_S = t-1|N_0 = j) \tag{2}$$

$h(i|S)$ is the expectation of T_S. Hence:

$$\begin{aligned}
h(i|S) &= E(T_S|N_0 = i) \\
&= \sum_{t=1}^{\infty} t \times P(T_S = t|N_0 = i) \\
&= \sum_{t=1}^{\infty} t \sum_{j \in V} p_{ij} P(T_S = t-1|N_0 = j) \\
&= \sum_{j \in V} \sum_{t=1}^{\infty} (t-1) p_{ij} P(T_S = t-1|N_0 = j) \\
&+ \sum_{j \in V} \sum_{t=1}^{\infty} p_{ij} P(T_S = t-1|N_0 = j) \\
&= \sum_{j \in V} p_{ij} \sum_{t=1}^{\infty} t P(T_S = t|N_0 = j) + 1 \\
&= \sum_{j \in V} p_{ij} \times h(j|S) + 1
\end{aligned} \tag{3}$$

Hence the first-passage (hitting) time can be formally defined as:

$$h(i|S) = \begin{cases} 0 & i \in S \\ \sum_{j \in V} p_{ij} \times h(j|S) + 1 & \text{otherwise} \end{cases} \tag{4}$$

3.4 Word Polarity Calculation

Based on the description of the random walk model and the first-passage (hitting) time above,

we now propose our word polarity identification algorithm. We begin by constructing a word relatedness graph and defining a random walk on that graph as described above. Let S^+ and S^- be two sets of vertices representing seed words that are already labeled as either positive or negative respectively. For any given word w, we compute the hitting time $h(w|S^+)$, and $h(w|S^-)$ for the two sets iteratively as described earlier. if $h(w|S^+)$ is greater than $h(w|S^-)$, the word is classified as negative, otherwise it is classified as positive. The ratio between the two hitting times could be used as an indication of how positive/negative the given word is. This is useful in case we need to provide a confidence measure for the prediction. This could be used to allow the model to abstain from classifying words with when the confidence level is low.

Computing hitting time as described earlier may be time consuming especially if the graph is large. To overcome this problem, we propose a Monte Carlo based algorithm for estimating it. The algorithm is shown in Algorithm 1.

Algorithm 1 Word Polarity using Random Walks

Require: A word relatedness graph G

1: Given a word w in V
2: Define a random walk on the graph. the transition probability between any two nodes i, and j is defined as: $P_{t+1|t}(j|i) = Wij / \sum_k W_{ik}$
3: Start k independent random walks from w with a maximum number of steps m
4: Stop when a positive word is reached
5: Let $h^*(w|S^+)$ be the estimated value for $h(w|S^+)$
6: Repeat for negative words computing $h^*(w|S^-)$
7: **if** $h^*(w|S^+) \leq h^*(w|S^-)$ **then**
8: Classify w as positive
9: **else**
10: Classify w as negative
11: **end if**

4 Experiments

We performed experiments on the General Inquirer lexicon (Stone et al., 1966). We used it as a gold standard data set for positive/negative words. The dataset contains 4206 words, 1915 of which are positive and 2291 are negative. Some of the ambiguous words were removed like (Turney, 2002; Takamura et al., 2005).

We use WordNet (Miller, 1995) as a source of synonyms and hypernyms for the word relatedness graph. We used 10-fold cross validation for all tests. We evaluate our results in terms of accuracy. Statistical significance was tested using a 2-tailed paired t-test. All reported results are statistically significant at the 0.05 level. We perform experiments varying the parameters and the network. We also look at the performance of the proposed method for different parts of speech, and for different confidence levels We compare our method to the Semantic Orientation from PMI (SO-PMI) method described in (Turney, 2002), the Spin model (Spin) described in (Takamura et al., 2005), the shortest path (short-path) described in (Kamps et al., 2004), and the bootstrapping (bootstrap) method described in (Hu and Liu, 2004).

4.1 Comparisons with other methods

This method could be used in a semi-supervised setting where a set of labeled words are used and the system learns from these labeled nodes and from other unlabeled nodes. Under this setting, we compare our method to the spin model described in (Takamura et al., 2005). Table 2 compares the performance using 10-fold cross validation. The table shows that the proposed method outperforms the spin model. The spin model approach uses word glosses, WordNet synonym, hypernym, and antonym relations, in addition to co-occurrence statistics extracted from corpus. The proposed method achieves better performance by only using WordNet synonym, hypernym and similar to relations. Adding co-occurrence statistics slightly improved performance, while using glosses did not help at all.

We also compare our method to the SO-PMI method presented in (Turney, 2002). They describe this setting as unsupervised (Turney, 2002) because they only use 14 seeds as paradigm words that define the semantic orientation rather than train the model. After (Turney, 2002), we use our method to predict semantic orientation of words in the General Inquirer lexicon (Stone et al., 1966) using only 14 seed words. The network we used contains only WordNet relations. No glosses or co-occurrence statistics are used. The results comparing the SO-PMI method with different dataset sizes, the spin model, and the proposed method using only 14 seeds is shown in Table 2. We no-

Table 1: Accuracy for adjectives only for the spin model, the bootstrap method, and the random walk model.

spin-model	bootstrap	short-path	rand-walks
83.6	72.8	68.8	88.8

tice that the random walk method outperforms SO-PMI when SO-PMI uses datasets of sizes 1×10^7 and 2×10^9 words. The performance of SO-PMI and the random walk methods are comparable when SO-PMI uses a very large dataset (1×10^{11} words). The performance of the spin model approach is also comparable to the other 2 methods. The advantages of the random walk method over SO-PMI is that it is faster and it does not need a very large corpus like the one used by SO-PMI. Another advantage is that the random walk method can be used along with the labeled data from the General Inquirer lexicon (Stone et al., 1966) to get much better performance. This is costly for the SO-PMI method because that will require the submission of almost 4000 queries to a commercial search engine.

We also compare our method to the bootstrapping method described in (Hu and Liu, 2004), and the shortest path method described in (Kamps et al., 2004). We build a network using only WordNet synonyms and hypernyms. We restrict the test set to the set of adjectives in the General Inquirer lexicon (Stone et al., 1966) because this method is mainly interested in classifying adjectives. The performance of the spin model method, the bootstrapping method, the shortest path method, and the random walk method for only adjectives is shown in Table 1. We notice from the table that the random walk method outperforms both the spin model, the bootstrapping method, and the shortest path method for adjectives. The reported accuracy for the shortest path method only considers the words it could assign a non-zero orientation value. If we consider all words, the accuracy will drop to around 61%.

4.1.1 Varying Parameters

As we mentioned in Section 3.4, we use a parameter m to put an upper bound on the length of random walks. In this section, we explore the impact of this parameter on our method's performance.

Table 2: Accuracy for SO-PMI with different dataset sizes, the spin model, and the random walks model for 10-fold cross validation and 14 seeds.

-	CV	14 seeds
SO-PMI (1×10^7)	-	61.3
SO-PMI (2×10^9)	-	76.1
SO-PMI (1×10^{11})	-	**82.8**
Spin Model	91.5	81.9
Random Walks	**93.1**	82.1

Figure 1 shows the accuracy of the random walk method as a function of the maximum number of steps m. m varies from 5 to 50. We use a network built from WordNet synonyms and hypernyms only. The number of samples k was set to 1000. We perform 10-fold cross validation using the General Inquirer lexicon. We notice that the maximum number of steps m has very little impact on performance until it rises above 30. When it does, the performance drops by no more than 1%, and then it does not change anymore as m increases. An interesting observation is that the proposed method performs quite well with a very small number of steps (around 10). We looked at the dataset to understand why increasing the number of steps beyond 30 negatively affects performance. We found out that when the number of steps is very large, compared to the diameter of the graph, the random walk that starts at ambiguous words, that are hard to classify, have the chance of moving till it hits a node in the opposite class. That does not happen when the limit on the number of steps is smaller because those walks are then terminated without hitting any labeled nodes and hence ignored.

Next, we study the effect of the random of samples k on our method's performance. As explained in Section 3.4, k is the number of samples used by the Monte Carlo algorithm to find an estimate for the hitting time. Figure 2 shows the accuracy of the random walks method as a function of the number of samples k. We use the same settings as in the previous experiment. the only difference is that we fix m at 15 and vary k from 10 to 20000 (note the logarithmic scale). We notice that the performance is badly affected, when the value of k is very small (less than 100). We also notice that

after 1000, varying k has very little, if any, effect on performance. This shows that the Monte Carlo algorithm for computing the random walks hitting time performs quite well with values of the number of samples as small as 1000.

The preceding experiments suggest that the parameter have very little impact on performance. This suggests that the approach is fairly robust (i.e., it is quite insensitive to different parameter settings).

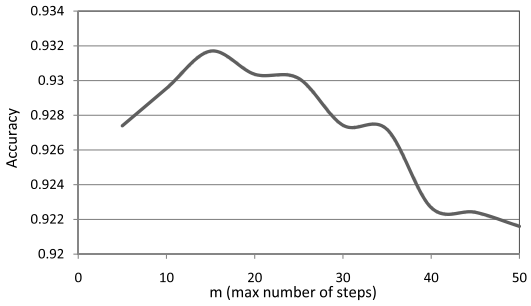

Figure 1: The effect of varying the maximum number of steps (m) on accuracy.

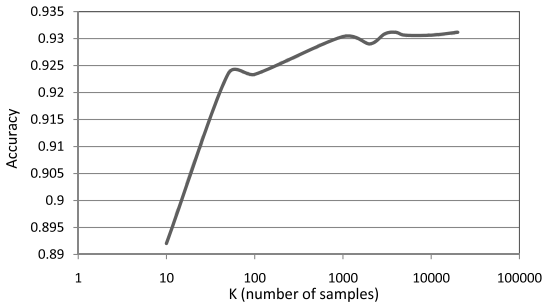

Figure 2: The effect of varying the number of samples (k) on accuracy.

4.1.2 Other Experiments

We now measure the performance of the proposed method when the system is allowed to abstain from classifying the words for which it have low confidence. We regard the ratio between the hitting time to positive words and hitting time to negative words as a confidence measure and evaluate the top words with the highest confidence level at different values of threshold. Figure 4 shows the accuracy for 10-fold cross validation and for using only 14 seeds at different thresholds. We notice that the accuracy improves by abstaining from classifying the difficult words. The figure shows that the top 60% words are classified with an accuracy greater than 99% for 10-fold cross validation and 92% with 14 seed words. This may be compared to the work descibed in (Takamura et al., 2005) where they achieve the 92% level when they only consider the top 1000 words (28%).

Figure 3 shows a learning curve displaying how the performance of the proposed method is affected with varying the labeled set size (i.e., the number of seeds). We notice that the accuracy exceeds 90% when the training set size rises above 20%. The accuracy steadily increases as the labeled data increases.

We also looked at the classification accuracy for different parts of speech in Figure 5. we notice that, in the case of 10-fold cross validation, the performance is consistent across parts of speech. However, when we only use 14 seeds all of which are adjectives, similar to (Turney and Littman, 2003), we notice that the performance on adjectives is much better than other parts of speech. When we use 14 seeds but replace some of the adjectives with verbs and nouns like (love, harm, friend, enemy), the performance for nouns and verbs improves considerably at the cost of losing a little bit of the performance on adjectives. We had a closer look at the results to find out what are the reasons behind incorrect predictions. We found two main reasons. First, some words are ambiguous and has more than one sense, possible with different orientations. Disambiguating the sense of words given their context before trying to predict their polarity should solve this problem. The second reason is that some words have very few connection in thesaurus. A possible solution to this might be identifying those words and adding more links to them from glosses of co-occurrence statistics in corpus.

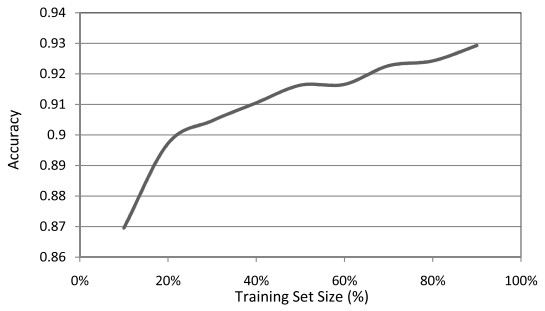

Figure 3: The effect of varying the number of seeds on accuracy.

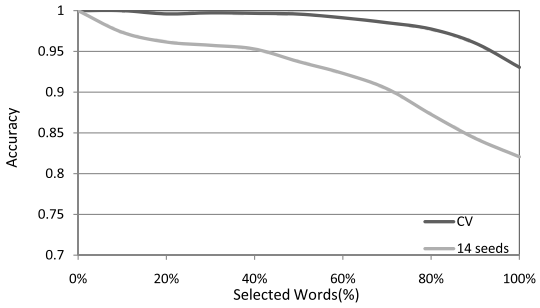

Figure 4: Accuracy for words with high confidence measure.

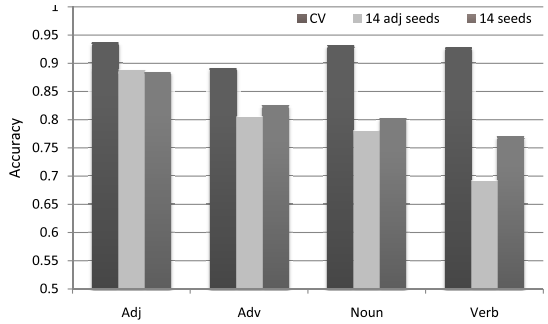

Figure 5: Accuracy for different parts of speech.

5 Conclusions

Predicting the semantic orientation of words is a very interesting task in Natural Language Processing and it has a wide variety of applications. We proposed a method for automatically predicting the semantic orientation of words using random walks and hitting time. The proposed method is based on the observation that a random walk starting at a given word is more likely to hit another word with the same semantic orientation before hitting a word with a different semantic orientation. The proposed method can be used in a semi-supervised setting where a training set of labeled words is used, and in an unsupervised setting where only a handful of seeds is used to define the two polarity classes. We predict semantic orientation with high accuracy. The proposed method is fast, simple to implement, and does not need any corpus.

Abstract

Existing works on sentiment analysis on product reviews suffer from the following limitations: (1) The knowledge of hierarchical relationships of products attributes is not fully utilized. (2) Reviews or sentences mentioning several attributes associated with complicated sentiments are not dealt with very well. In this paper, we propose a novel HL-SOT approach to labeling a product's attributes and their associated sentiments in product reviews by a Hierarchical Learning (HL) process with a defined Sentiment Ontology Tree (SOT). The empirical analysis against a human-labeled data set demonstrates promising and reasonable performance of the proposed HL-SOT approach. While this paper is mainly on sentiment analysis on reviews of one product, our proposed HL-SOT approach is easily generalized to labeling a mix of reviews of more than one products.

1 Introduction

As the internet reaches almost every corner of this world, more and more people write reviews and share opinions on the World Wide Web. The user-generated opinion-rich reviews will not only help other users make better judgements but they are also useful resources for manufacturers of products to keep track and manage customer opinions. However, as the number of product reviews grows, it becomes difficult for a user to manually learn the panorama of an interesting topic from existing online information. Faced with this problem, research works, e.g., (Hu and Liu, 2004; Liu et al., 2005; Lu et al., 2009), of sentiment analysis on product reviews were proposed and have become a popular research topic at the crossroads of information retrieval and computational linguistics.

Carrying out sentiment analysis on product reviews is not a trivial task. Although there have already been a lot of publications investigating on similar issues, among which the representatives are (Turney, 2002; Dave et al., 2003; Hu and Liu, 2004; Liu et al., 2005; Popescu and Etzioni, 2005; Zhuang et al., 2006; Lu and Zhai, 2008; Titov and McDonald, 2008; Zhou and Chaovalit, 2008; Lu et al., 2009), there is still room for improvement on tackling this problem. When we look into the details of each example of product reviews, we find that there are some intrinsic properties that existing previous works have not addressed in much detail.

First of all, product reviews constitute domain-specific knowledge. The product's attributes mentioned in reviews might have some relationships between each other. For example, for a digital camera, comments on image quality are usually mentioned. However, a sentence like "40D handles noise very well up to ISO 800", also refers to image quality of the camera 40D. Here we say "noise" is a sub-attribute factor of "image quality". We argue that the hierarchical relationship between a product's attributes can be useful knowledge if it can be formulated and utilized in product reviews analysis. Secondly, Vocabularies used in product reviews tend to be highly overlapping. Especially, for same attribute, usually same words or synonyms are involved to refer to them and to describe sentiment on them. We believe that labeling existing product reviews with attributes and corresponding sentiment forms an effective training resource to perform sentiment analysis. Thirdly, sentiments expressed in a review or even in a sentence might be opposite on different attributes and not every attributes mentioned are with sentiments. For example, it is common to find a fragment of a review as follows:
Example 1: *"...I am very impressed with this camera except for its a bit heavy weight especially with*

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 404–413,
Uppsala, Sweden, 11-16 July 2010.

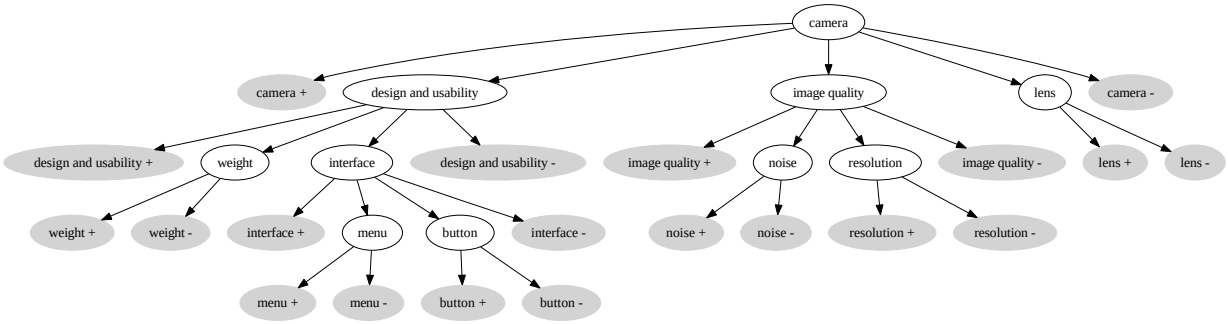

Figure 1: an example of part of a SOT for digital camera

extra lenses attached. It has many buttons and two main dials. The first dial is thumb dial, located near shutter button. The second one is the big round dial located at the back of the camera..."
In this example, the first sentence gives positive comment on the camera as well as a complaint on its heavy weight. Even if the words "lenses" appears in the review, it is not fair to say the customer expresses any sentiment on lens. The second sentence and the rest introduce the camera's buttons and dials. It's also not feasible to try to get any sentiment from these contents. We argue that when performing sentiment analysis on reviews, such as in the Example 1, more attention is needed to distinguish between attributes that are mentioned with and without sentiment.

In this paper, we study the problem of sentiment analysis on product reviews through a novel method, called the HL-SOT approach, namely Hierarchical Learning (HL) with Sentiment Ontology Tree (SOT). By sentiment analysis on product reviews we aim to fulfill two tasks, i.e., labeling a target text[1] with: 1) the product's attributes (attributes identification task), and 2) their corresponding sentiments mentioned therein (sentiment annotation task). The result of this kind of labeling process is quite useful because it makes it possible for a user to search reviews on particular attributes of a product. For example, when considering to buy a digital camera, a prospective user who cares more about image quality probably wants to find comments on the camera's image quality in other users' reviews. SOT is a tree-like ontology structure that formulates the relationships between a product's attributes. For example, Fig. 1 is a SOT for a digital camera[2]. The root node of the SOT is a camera itself. Each of the non-leaf nodes (white nodes) of the SOT represents an attribute of a camera[3]. All leaf nodes (gray nodes) of the SOT represent sentiment (positive/negative) nodes respectively associated with their parent nodes. A formal definition on SOT is presented in Section 3.1. With the proposed concept of SOT, we manage to formulate the two tasks of the sentiment analysis to be a hierarchical classification problem. We further propose a specific hierarchical learning algorithm, called HL-SOT algorithm, which is developed based on generalizing an online-learning algorithm H-RLS (Cesa-Bianchi et al., 2006). The HL-SOT algorithm has the same property as the H-RLS algorithm that allows multiple-path labeling (input target text can be labeled with nodes belonging to more than one path in the SOT) and partial-path labeling (the input target text can be labeled with nodes belonging to a path that does not end on a leaf). This property makes the approach well suited for the situation where complicated sentiments on different attributes are expressed in one target text. Unlike the H-RLS algorithm , the HL-SOT algorithm enables each classifier to separately learn its own specific threshold. The proposed HL-SOT approach is empirically analyzed against a human-labeled data set. The experimental results demonstrate promising and reasonable performance of our approach.

This paper makes the following contributions:

- To the best of our knowledge, with the proposed concept of SOT, the proposed HL-SOT approach is the first work to formulate the tasks of sentiment analysis to be a hierarchical classification problem.

- A specific hierarchical learning algorithm is

[1]Each product review to be analyzed is called target text in the following of this paper.

[2]Due to the space limitation, not all attributes of a digital camera are enumerated in this SOT; m+/m- means positive/negative sentiment associated with an attribute m.

[3]A product itself can be treated as an overall attribute of the product.

further proposed to achieve tasks of sentiment analysis in one hierarchical classification process.

- The proposed HL-SOT approach can be generalized to make it possible to perform sentiment analysis on target texts that are a mix of reviews of different products, whereas existing works mainly focus on analyzing reviews of only one type of product.

The remainder of the paper is organized as follows. In Section 2, we provide an overview of related work on sentiment analysis. Section 3 presents our work on sentiment analysis with HL-SOT approach. The empirical analysis and the results are presented in Section 4, followed by the conclusions, discussions, and future work in Section 5.

2 Related Work

The task of sentiment analysis on product reviews was originally performed to extract overall sentiment from the target texts. However, in (Turney, 2002), as the difficulty shown in the experiments, the whole sentiment of a document is not necessarily the sum of its parts. Then there came up with research works shifting focus from overall document sentiment to sentiment analysis based on product attributes (Hu and Liu, 2004; Popescu and Etzioni, 2005; Ding and Liu, 2007; Liu et al., 2005).

Document overall sentiment analysis is to summarize the overall sentiment in the document. Research works related to document overall sentiment analysis mainly rely on two finer levels sentiment annotation: *word-level sentiment annotation* and *phrase-level sentiment annotation*. The *word-level sentiment annotation* is to utilize the polarity annotation of words in each sentence and summarize the overall sentiment of each sentiment-bearing word to infer the overall sentiment within the text (Hatzivassiloglou and Wiebe, 2000; Andreevskaia and Bergler, 2006; Esuli and Sebastiani, 2005; Esuli and Sebastiani, 2006; Hatzivassiloglou and McKeown, 1997; Kamps et al., 2004; Devitt and Ahmad, 2007; Yu and Hatzivassiloglou, 2003). The *phrase-level sentiment annotation* focuses sentiment annotation on phrases not words with concerning that atomic units of expression is not individual words but rather appraisal groups (Whitelaw et al., 2005). In (Wilson et al., 2005), the concepts of *prior polarity* and *contextual polarity* were proposed. This paper presented a system that is able to automatically identify the *contextual polarity* for a large subset of sentiment expressions. In (Turney, 2002), an unsupervised learning algorithm was proposed to classify reviews as recommended or not recommended by averaging sentiment annotation of phrases in reviews that contain adjectives or adverbs. However, the performances of these works are not good enough for sentiment analysis on product reviews, where sentiment on each attribute of a product could be so complicated that it is unable to be expressed by overall document sentiment.

Attributes-based sentiment analysis is to analyze sentiment based on each attribute of a product. In (Hu and Liu, 2004), mining product features was proposed together with sentiment polarity annotation for each opinion sentence. In that work, sentiment analysis was performed on product attributes level. In (Liu et al., 2005), a system with framework for analyzing and comparing consumer opinions of competing products was proposed. The system made users be able to clearly see the strengths and weaknesses of each product in the minds of consumers in terms of various product features. In (Popescu and Etzioni, 2005), Popescu and Etzioni not only analyzed polarity of opinions regarding product features but also ranked opinions based on their strength. In (Liu et al., 2007), Liu et al. proposed Sentiment-PLSA that analyzed blog entries and viewed them as a document generated by a number of hidden sentiment factors. These sentiment factors may also be factors based on product attributes. In (Lu and Zhai, 2008), Lu et al. proposed a semi-supervised topic models to solve the problem of opinion integration based on the topic of a product's attributes. The work in (Titov and McDonald, 2008) presented a multi-grain topic model for extracting the ratable attributes from product reviews. In (Lu et al., 2009), the problem of rated attributes summary was studied with a goal of generating ratings for major aspects so that a user could gain different perspectives towards a target entity. All these research works concentrated on attribute-based sentiment analysis. However, the main difference with our work is that they did not sufficiently utilize the hierarchical relationships among a product attributes. Although a method of ontology-supported polarity mining, which also involved

ontology to tackle the sentiment analysis problem, was proposed in (Zhou and Chaovalit, 2008), that work studied polarity mining by machine learning techniques that still suffered from a problem of ignoring dependencies among attributes within an ontology's hierarchy. In the contrast, our work solves the sentiment analysis problem as a hierarchical classification problem that fully utilizes the hierarchy of the SOT during training and classification process.

3 The HL-SOT Approach

In this section, we first propose a formal definition on SOT. Then we formulate the HL-SOT approach. In this novel approach, tasks of sentiment analysis are to be achieved in a hierarchical classification process.

3.1 Sentiment Ontology Tree

As we discussed in Section 1, the hierarchial relationships among a product's attributes might help improve the performance of attribute-based sentiment analysis. We propose to use a tree-like ontology structure SOT, i.e., Sentiment Ontology Tree, to formulate relationships among a product's attributes. Here,we give a formal definition on what a SOT is.

Definition 1 *[SOT] SOT is an abbreviation for Sentiment Ontology Tree that is a tree-like ontology structure* $T(v, v^+, v^-, \mathbb{T})$. *$v$ is the root node of T which represents an attribute of a given product.* v^+ *is a positive sentiment leaf node associated with the attribute* v. v^- *is a negative sentiment leaf node associated with the attribute* v. $\mathbb{T}$ *is a set of subtrees. Each element of* $\mathbb{T}$ *is also a SOT* $T'(v', v'^+, v'^-, \mathbb{T}')$ *which represents a sub-attribute of its parent attribute node.*

By the Definition 1, we define a root of a SOT to represent an attribute of a product. The SOT's two leaf child nodes are sentiment (positive/negative) nodes associated with the root attribute. The SOT recursively contains a set of sub-SOTs where each root of a sub-SOT is a non-leaf child node of the root of the SOT and represent a sub-attribute belonging to its parent attribute. This definition successfully describes the hierarchical relationships among all the attributes of a product. For example, in Fig. 1 the root node of the SOT for a digital camera is its general overview attribute. Comments on a digital camera's general overview attribute appearing in a review might be like "this camera is great". The "camera" SOT has two sentiment leaf child nodes as well as three non-leaf child nodes which are respectively root nodes of sub-SOTs for sub-attributes "design and usability", "image quality", and "lens". These sub-attributes SOTs recursively repeat until each node in the SOT does not have any more non-leaf child node, which means the corresponding attributes do not have any sub-attributes, e.g., the attribute node "button" in Fig. 1.

3.2 Sentiment Analysis with SOT

In this subsection, we present the HL-SOT approach. With the defined SOT, the problem of sentiment analysis is able to be formulated to be a hierarchial classification problem. Then a specific hierarchical learning algorithm is further proposed to solve the formulated problem.

3.2.1 Problem Formulation

In the proposed HL-SOT approach, each target text is to be indexed by a unit-norm vector $x \in \mathcal{X}, \mathcal{X} = \mathbb{R}^d$. Let $\mathscr{Y} = \{1, ..., N\}$ denote the finite set of nodes in SOT. Let $y = \{y_1, ..., y_N\} \in \{0, 1\}^N$ be a label vector to a target text x, where $\forall i \in \mathscr{Y}$:

$$y_i = \begin{cases} 1, & \text{if } x \text{ is labeled by the classifier of node } i, \\ 0, & \text{if } x \text{ is not labeled by the classifier of node } i. \end{cases}$$

A label vector $y \in \{0, 1\}^N$ is said to respect SOT if and only if y satisfies $\forall i \in \mathscr{Y}, \forall j \in \mathcal{A}(i)$: if $y_i = 1$ then $y_j = 1$, where $\mathcal{A}(i)$ represents a set ancestor nodes of i, i.e.,$\mathcal{A}(i) = \{x | ancestor(i, x)\}$. Let $\mathcal{Y}$ denote a set of label vectors that respect SOT. Then the tasks of sentiment analysis can be formulated to be the goal of a hierarchical classification that is to learn a function $f : \mathcal{X} \rightarrow \mathcal{Y}$, that is able to label each target text $x \in \mathcal{X}$ with classifier of each node and generating with x a label vector $y \in \mathcal{Y}$ that respects SOT. The requirement of a generated label vector $y \in \mathcal{Y}$ ensures that a target text is to be labeled with a node only if its parent attribute node is labeled with the target text. For example, in Fig. 1 a review is to be labeled with "image quality +" requires that the review should be successively labeled as related to "camera" and "image quality". This is reasonable and consistent with intuition, because if a review cannot be identified to be related to a camera, it is not safe to infer that the review is commenting a camera's image quality with positive sentiment.

3.2.2 HL-SOT Algorithm

The algorithm H-RLS studied in (Cesa-Bianchi et al., 2006) solved a similar hierarchical classification problem as we formulated above. However, the H-RLS algorithm was designed as an online-learning algorithm which is not suitable to be applied directly in our problem setting. Moreover, the algorithm H-RLS defined the same value as the threshold of each node classifier. We argue that if the threshold values could be learned separately for each classifiers, the performance of classification process would be improved. Therefore we propose a specific hierarchical learning algorithm, named HL-SOT algorithm, that is able to train each node classifier in a batch-learning setting and allows separately learning for the threshold of each node classifier.

Defining the f function Let $w_1, ..., w_N$ be weight vectors that define linear-threshold classifiers of each node in SOT. Let $W = (w_1, ..., w_N)^\top$ be an $N \times d$ matrix called weight matrix. Here we generalize the work in (Cesa-Bianchi et al., 2006) and define the hierarchical classification function f as:

$$\hat{y} = f(x) = g(W \cdot x),$$

where $x \in \mathcal{X}, \hat{y} \in \mathcal{Y}$. Let $z = W \cdot x$. Then the function $\hat{y} = g(z)$ on an N-dimensional vector z defines:
$\forall i = 1, ..., N$:

$$\hat{y}_i = \begin{cases} \mathfrak{B}(z_i \geq \theta_i), & \text{if } i \text{ is a root node in SOT} \\ & \text{or } y_j = 1 \text{ for } j = \mathcal{P}(i), \\ 0, & \text{else} \end{cases}$$

where $\mathcal{P}(i)$ is the parent node of i in SOT and $\mathfrak{B}(S)$ is a boolean function which is 1 if and only if the statement S is true. Then the hierarchical classification function f is parameterized by the weight matrix $W = (w_1, ..., w_N)^\top$ and threshold vector $\theta = (\theta_1, ..., \theta_N)^\top$. The hierarchical learning algorithm HL-SOT is proposed for learning the parameters of W and θ.

Parameters Learning for f function Let D denote the training data set: $D = \{(r, l) | r \in \mathcal{X}, l \in \mathcal{Y}\}$. In the HL-SOT learning process, the weight matrix W is firstly initialized to be a 0 matrix, where each row vector w_i is a 0 vector. The threshold vector is initialized to be a 0 vector. Each instance in the training set D goes into the training process. When a new instance r_t is observed, each row vector $w_{i,t}$ of the weight matrix W_t is updated by a regularized least squares estimator given by:

$$w_{i,t} = (I + S_{i,Q(i,t-1)} S_{i,Q(i,t-1)}^\top + r_t r_t^\top)^{-1} \times S_{i,Q(i,t-1)} (l_{i,i_1}, l_{i,i_2}, ..., l_{i,i_{Q(i,t-1)}})^\top \quad (1)$$

where I is a $d \times d$ identity matrix, $Q(i, t-1)$ denotes the number of times the parent of node i observes a positive label before observing the instance r_t, $S_{i,Q(i,t-1)} = [r_{i_1}, ..., r_{i_{Q(i,t-1)}}]$ is a $d \times Q(i, t-1)$ matrix whose columns are the instances $r_{i_1}, ..., r_{i_{Q(i,t-1)}}$, and $(l_{i,i_1}, l_{i,i_2}, ..., l_{i,i_{Q(i,t-1)}})^\top$ is a $Q(i, t-1)$-dimensional vector of the corresponding labels observed by node i. The Formula 1 restricts that the weight vector $w_{i,t}$ of the classifier i is only updated on the examples that are positive for its parent node. Then the label vector $\hat{y}_{r_t}$ is computed for the instance r_t, before the real label vector l_{r_t} is observed. Then the current threshold vector θ_t is updated by:

$$\theta_{t+1} = \theta_t + \epsilon(\hat{y}_{r_t} - l_{r_t}), \quad (2)$$

where ϵ is a small positive real number that denotes a corrective step for correcting the current threshold vector θ_t. To illustrate the idea behind the Formula 2, let $y'_t = \hat{y}_{r_t} - l_{r_t}$. Let $y'_{i,t}$ denote an element of the vector y'_t. The Formula 2 correct the current threshold $\theta_{i,t}$ for the classifier i in the following way:

- If $y'_{i,t} = 0$, it means the classifier i made a proper classification for the current instance r_t. Then the current threshold θ_i does not need to be adjusted.

- If $y'_{i,t} = 1$, it means the classifier i made an improper classification by mistakenly identifying the attribute i of the training instance r_t that should have not been identified. This indicates the value of θ_i is not big enough to serve as a threshold so that the attribute i in this case can be filtered out by the classifier i. Therefore, the current threshold θ_i will be adjusted to be larger by ϵ.

- If $y'_{i,t} = -1$, it means the classifier i made an improper classification by failing to identify the attribute i of the training instance r_t that should have been identified. This indicates the value of θ_i is not small enough to serve as a threshold so that the attribute i in this case

  Compute $\hat{y}_{r_t} = f(r_t) = g(W_t \cdot r_t)$

  Observe label vector $l_{r_t} \in \mathcal{Y}$ of the instance r_t

  Update threshold vector θ_t by Formula 2

end for

END

can be recognized by the classifier i. Therefore, the current threshold θ_i will be adjusted to be smaller by ϵ.

The hierarchial learning algorithm HL-SOT is presented as in Algorithm 1. The HL-SOT algorithm enables each classifier to have its own specific threshold value and allows this threshold value can be separately learned and corrected through the training process. It is not only a batch-learning setting of the H-RLS algorithm but also a generalization to the latter. If we set the algorithm HL-SOT's parameter ϵ to be 0, the HL-SOT becomes the H-RLS algorithm in a batch-learning setting.

4 Empirical Analysis

In this section, we conduct systematic experiments to perform empirical analysis on our proposed HL-SOT approach against a human-labeled data set. In order to encode each text in the data set by a d-dimensional vector $x \in \mathbb{R}^d$, we first remove all the stop words and then select the top d frequency terms appearing in the data set to construct the index term space. Our experiments are intended to address the following questions:(1) whether utilizing the hierarchical relationships among labels help to improve the accuracy of the classification? (2) whether the introduction of separately learning threshold for each classifier help to improve the accuracy of the classification? (3) how does the corrective step ϵ impact the performance of the proposed approach?(4)how does the dimensionality d of index terms space impact the proposed approach's computing efficiency and accuracy?

4.1 Data Set Preparation

The data set contains 1446 snippets of customer reviews on digital cameras that are collected from a customer review website[4]. We manually construct a SOT for the product of digital cameras. The constructed SOT (e.g., Fig. 1) contains 105 nodes that include 35 non-leaf nodes representing attributes of the digital camera and 70 leaf nodes representing associated sentiments with attribute nodes. Then we label all the snippets with corresponding labels of nodes in the constructed SOT complying with the rule that a target text is to be labeled with a node only if its parent attribute node is labeled with the target text. We randomly divide the labeled data set into five folds so that each fold at least contains one example snippets labeled by each node in the SOT. For each experiment setting, we run 5 experiments to perform cross-fold evaluation by randomly picking three folds as the training set and the other two folds as the testing set. All the testing results are averages over 5 running of experiments.

4.2 Evaluation Metrics

Since the proposed HL-SOT approach is a hierarchical classification process, we use three classic loss functions for measuring classification performance. They are the One-error Loss (O-Loss) function, the Symmetric Loss (S-Loss) function, and the Hierarchical Loss (H-Loss) function:

- One-error loss (O-Loss) function is defined as:
$$L_O(\hat{y}, l) = \mathfrak{B}(\exists i : \hat{y}_i \neq l_i),$$
where $\hat{y}$ is the prediction label vector and l is the true label vector; $\mathfrak{B}$ is the boolean function as defined in Section 3.2.2.

- Symmetric loss (S-Loss) function is defined as:
$$L_S(\hat{y}, l) = \sum_{i=1}^{N} \mathfrak{B}(\hat{y}_i \neq l_i),$$

- Hierarchical loss (H-Loss) function is defined as:
$$L_H(\hat{y}, l) = \sum_{i=1}^{N} \mathfrak{B}(\hat{y}_i \neq l_i \wedge \forall j \in \mathcal{A}(i), \hat{y}_j = l_j),$$

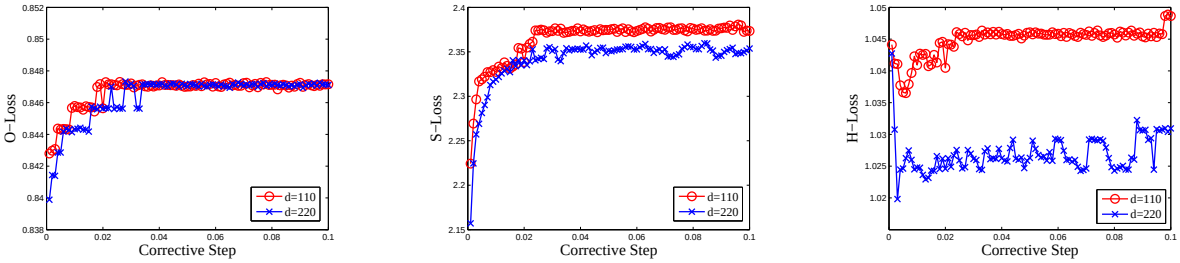
Table 1: Performance Comparisons (A Smaller Loss Value Means a Better Performance)

Metrics	Dimensinality=110			Dimensinality=220		
	H-RLS	HL-flat	HL-SOT	H-RLS	HL-flat	HL-SOT
O-Loss	0.9812	0.8772	**0.8443**	0.9783	0.8591	**0.8428**
S-Loss	8.5516	2.8921	**2.3190**	7.8623	2.8449	**2.2812**
H-Loss	3.2479	1.1383	**1.0366**	3.1029	1.1298	**1.0247**



(a) O-Loss (b) S-Loss (c) H-Loss

Figure 2: Impact of Corrective Step ϵ

where $\mathcal{A}$ denotes a set of nodes that are ancestors of node i in SOT.

Unlike the O-Loss function and the S-Loss function, the H-Loss function captures the intuition that loss should only be charged on a node whenever a classification mistake is made on a node of SOT but no more should be charged for any additional mistake occurring in the subtree of that node. It measures the discrepancy between the prediction labels and the true labels with consideration on the SOT structure defined over the labels. In our experiments, the recorded loss function values for each experiment running are computed by averaging the loss function values of each testing snippets in the testing set.

4.3 Performance Comparison

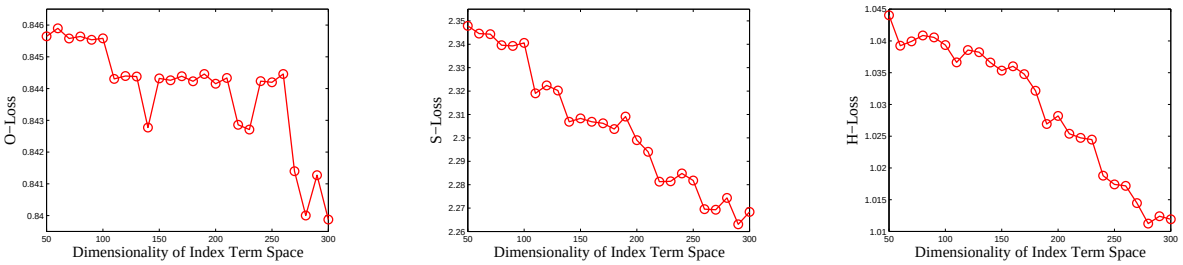
In order to answer the questions (1), (2) in the beginning of this section, we compare our HL-SOT approach with the following two baseline approaches:

- HL-flat: The HL-flat approach involves an algorithm that is a "flat" version of HL-SOT algorithm by ignoring the hierarchical relationships among labels when each classifier is trained. In the training process of HL-flat, the algorithm reflexes the restriction in the HL-SOT algorithm that requires the weight vector $w_{i,t}$ of the classifier i is only updated on the examples that are positive for its parent node.
- H-RLS: The H-RLS approach is implemented by applying the H-RLS algorithm studied in (Cesa-Bianchi et al., 2006). Unlike our proposed HL-SOT algorithm that enables the threshold values to be learned separately for each classifiers in the training process, the H-RLS algorithm only uses an identical threshold values for each classifiers in the classification process.

Experiments are conducted on the performance comparison between the proposed HL-SOT approach with HL-flat approach and the H-RLS approach. The dimensionality d of the index term space is set to be 110 and 220. The corrective step ϵ is set to be 0.005. The experimental results are summarized in Table 1. From Table 1, we can observe that the HL-SOT approach generally beats the H-RLS approach and HL-flat approach on O-Loss, S-Loss, and H-Loss respectively. The H-RLS performs worse than the HL-flat and the HL-SOT, which indicates that the introduction of separately learning threshold for each classifier did improve the accuracy of the classification. The HL-SOT approach performs better than the HL-flat, which demonstrates the effectiveness of utilizing the hierarchical relationships among labels.

4.4 Impact of Corrective Step ϵ

The parameter ϵ in the proposed HL-SOT approach controls the corrective step of the classifiers' thresholds when any mistake is observed in the training process. If the corrective step ϵ is set too large, it might cause the algorithm to be too



(a) O-Loss (b) S-Loss (c) H-Loss

Figure 3: Impact of Dimensionality d of Index Term Space ($\epsilon = 0.005$)

sensitive to each observed mistake. On the contrary, if the corrective step is set too small, it might cause the algorithm not sensitive enough to the observed mistakes. Hence, the corrective step ϵ is a factor that might impact the performance of the proposed approach. Fig. 2 demonstrates the impact of ϵ on O-Loss, S-Loss, and H-Loss. The dimensionality of index term space d is set to be 110 and 220. The value of ϵ is set to vary from 0.001 to 0.1 with each step of 0.001. Fig. 2 shows that the parameter ϵ impacts the classification performance significantly. As the value of ϵ increase, the O-Loss, S-Loss, and H-Loss generally increase (performance decrease). In Fig. 2c it is obviously detected that the H-Loss decreases a little (performance increase) at first before it increases (performance decrease) with further increase of the value of ϵ. This indicates that a finer-grained value of ϵ will not necessarily result in a better performance on the H-loss. However, a fine-grained corrective step generally makes a better performance than a coarse-grained corrective step.

4.5 Impact of Dimensionality d of Index Term Space

In the proposed HL-SOT approach, the dimensionality d of the index term space controls the number of terms to be indexed. If d is set too small, important useful terms will be missed that will limit the performance of the approach. However, if d is set too large, the computing efficiency will be decreased. Fig. 3 shows the impacts of the parameter d respectively on O-Loss, S-Loss, and H-Loss, where d varies from 50 to 300 with each step of 10 and the ϵ is set to be 0.005. From Fig. 3, we observe that as the d increases the O-Loss, S-Loss, and H-Loss generally decrease (performance increase). This means that when more terms are indexed better performance can be achieved by the HL-SOT approach. However,

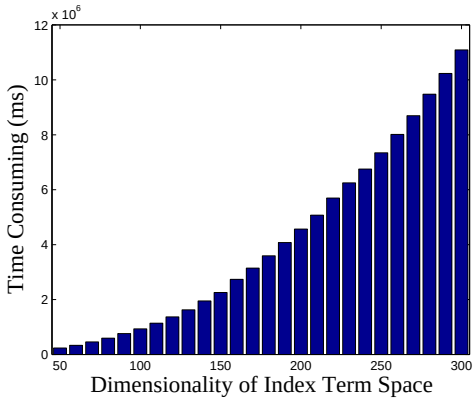


Figure 4: Time Consuming Impacted by d

considering the computing efficiency impacted by d, Fig. 4 shows that the computational complexity of our approach is non-linear increased with d's growing, which indicates that indexing more terms will improve the accuracy of our proposed approach although this is paid by decreasing the computing efficiency.

5 Conclusions, Discussions and Future Work

In this paper, we propose a novel and effective approach to sentiment analysis on product reviews. In our proposed HL-SOT approach, we define SOT to formulate the knowledge of hierarchical relationships among a product's attributes and tackle the problem of sentiment analysis in a hierarchical classification process with the proposed algorithm. The empirical analysis on a human-labeled data set demonstrates the promising results of our proposed approach. The performance comparison shows that the proposed HL-SOT approach outperforms two baselines: the HL-flat and the H-RLS approach. This confirms two intuitive motivations based on which our approach is proposed: 1) separately learning threshold values for

each classifier improve the classification accuracy; 2) knowledge of hierarchical relationships of labels improve the approach's performance. The experiments on analyzing the impact of parameter ϵ indicate that a fine-grained corrective step generally makes a better performance than a coarse-grained corrective step. The experiments on analyzing the impact of the dimensionality d show that indexing more terms will improve the accuracy of our proposed approach while the computing efficiency will be greatly decreased.

The focus of this paper is on analyzing review texts of one product. However, the framework of our proposed approach can be generalized to deal with a mix of review texts of more than one products. In this generalization for sentiment analysis on multiple products reviews, a "big" SOT is constructed and the SOT for each product reviews is a sub-tree of the "big" SOT. The sentiment analysis on multiple products reviews can be performed the same way the HL-SOT approach is applied on single product reviews and can be tackled in a hierarchical classification process with the "big" SOT.

This paper is motivated by the fact that the relationships among a product's attributes could be a useful knowledge for mining product review texts. The SOT is defined to formulate this knowledge in the proposed approach. However, what attributes to be included in a product's SOT and how to structure these attributes in the SOT is an effort of human beings. The sizes and structures of SOTs constructed by different individuals may vary. How the classification performance will be affected by variances of the generated SOTs is worthy of study. In addition, an automatic method to learn a product's attributes and the structure of SOT from existing product review texts will greatly benefit the efficiency of the proposed approach. We plan to investigate on these issues in our future work.

Abstract

In this paper, we adopt two views, personal and impersonal views, and systematically employ them in both supervised and semi-supervised sentiment classification. Here, personal views consist of those sentences which directly express speaker's feeling and preference towards a target object while impersonal views focus on statements towards a target object for evaluation. To obtain them, an unsupervised mining approach is proposed. On this basis, an ensemble method and a co-training algorithm are explored to employ the two views in supervised and semi-supervised sentiment classification respectively. Experimental results across eight domains demonstrate the effectiveness of our proposed approach.

1 Introduction

As a special task of text classification, sentiment classification aims to classify a text according to the expressed sentimental polarities of opinions such as '*thumb up*' or '*thumb down*' on the movies (Pang et al., 2002). This task has recently received considerable interests in the Natural Language Processing (NLP) community due to its wide applications.

In general, the objective of sentiment classification can be represented as a kind of binary relation *R*, defined as an ordered triple (*X*, *Y*, *G*), where *X* is an object set including different kinds of people (e.g. writers, reviewers, or users), *Y* is another object set including the target objects (e.g. products, events, or even some people), and *G* is a subset of the Cartesian product $X \times Y$. The concerned relation in sentiment classification is *X* 's evaluation on *Y*, such as '*thumb up*', '*thumb down*', '*favorable*', and '*unfavorable*'. Such relation is usually expressed in text by stating the information involving either a person (one element in *X*) or a target object itself (one element in *Y*). The first type of statement called personal view, e.g. '*I am so happy with this book*', contains *X* 's "subjective" feeling and preference towards a target object, which directly expresses sentimental evaluation. This kind of information is normally domain-independent and serves as highly relevant clues to sentiment classification. The latter type of statement called impersonal view, e.g. '*it is too small*', contains *Y* 's "objective" (i.e. or at least criteria-based) evaluation of the target object. This kind of information tends to contain much domain-specific classification knowledge. Although such information is sometimes not as explicit as personal views in classifying the sentiment of a text, speaker's sentiment is usually implied by the evaluation result.

It is well-known that sentiment classification is very domain-specific (Blitzer et al., 2007), so it is critical to eliminate its dependence on a large-scale labeled data for its wide applications. Since the unlabeled data is ample and easy to collect, a successful semi-supervised sentiment classification system would significantly minimize the involvement of labor and time. Therefore, given the two different views mentioned above, one promising application is to adopt them in co-training algorithms, which has been proven to be an effective semi-supervised learning strategy of incorporating unlabeled data to further improve the classification performance (Zhu, 2005). In addition, we would show that personal/impersonal views are linguistically marked and mining them in text can be easily performed without special annotation.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 414–423,
Uppsala, Sweden, 11-16 July 2010.

In this paper, we systematically employ personal/impersonal views in supervised and semi-supervised sentiment classification. First, an unsupervised bootstrapping method is adopted to automatically separate one document into personal and impersonal views. Then, both views are employed in supervised sentiment classification via an ensemble of individual classifiers generated by each view. Finally, a co-training algorithm is proposed to incorporate unlabeled data for semi-supervised sentiment classification.

The remainder of this paper is organized as follows. Section 2 introduces the related work of sentiment classification. Section 3 presents our unsupervised approach for mining personal and impersonal views. Section 4 and Section 5 propose our supervised and semi-supervised methods on sentiment classification respectively. Experimental results are presented and analyzed in Section 6. Section 7 discusses on the differences between personal/impersonal and subjective/objective. Finally, Section 8 draws our conclusions and outlines the future work.

2 Related Work

Recently, a variety of studies have been reported on sentiment classification at different levels: word level (Esuli and Sebastiani, 2005), phrase level (Wilson et al., 2009), sentence level (Kim and Hovy, 2004; Liu et al., 2005), and document level (Turney, 2002; Pang et al., 2002). This paper focuses on the document-level sentiment classification. Generally, document-level sentiment classification methods can be categorized into three types: unsupervised, supervised, and semi-supervised.

Unsupervised methods involve deriving a sentiment classifier without any labeled documents. Most of previous work use a set of labeled sentiment words called seed words to perform unsupervised classification. Turney (2002) determines the sentiment orientation of a document by calculating point-wise mutual information between the words in the document and the seed words of '*excellent*' and '*poor*'. Kennedy and Inkpen (2006) use a term-counting method with a set of seed words to determine the sentiment. Zagibalov and Carroll (2008) first propose a seed word selection approach and then apply the same term-counting method for Chinese sentiment classifications. These unsupervised approaches are believed to be domain-independent for sentiment classification.

Supervised methods consider sentiment classification as a standard classification problem in which labeled data in a domain are used to train a domain-specific classifier. Pang et al. (2002) are the first to apply supervised machine learning methods to sentiment classification. Subsequently, many other studies make efforts to improve the performance of machine learning-based classifiers by various means, such as using subjectivity summarization (Pang and Lee, 2004), seeking new superior textual features (Riloff et al., 2006), and employing document subcomponent information (McDonald et al., 2007). As far as the challenge of domain-dependency is concerned, Blitzer et al. (2007) present a domain adaptation approach for sentiment classification.

Semi-supervised methods combine unlabeled data with labeled training data (often small-scaled) to improve the models. Compared to the supervised and unsupervised methods, semi-supervised methods for sentiment classification are relatively new and have much less related studies. Dasgupta and Ng (2009) integrate various methods in semi-supervised sentiment classification including spectral clustering, active learning, transductive learning, and ensemble learning. They achieve a very impressive improvement across five domains. Wan (2009) applies a co-training method to semi-supervised learning with labeled English corpus and unlabeled Chinese corpus for Chinese sentiment classification.

3 Unsupervised Mining of Personal and Impersonal Views

As mentioned in Section 1, the objective of sentiment classification is to classify a specific binary relation: *X* 's evaluation on *Y*, where *X* is an object set including different kinds of persons and *Y* is another object set including the target objects to be evaluated. First of all, we focus on an analysis on sentences in product reviews regarding the two views: personal and impersonal views.

The personal view consists of personal sentences (i.e. *X* 's sentences) exemplified below:

I. Personal preference:
   E1: *I love this breadmaker!*
   E2: *I disliked it from the beginning.*
II. Personal emotion description:
   E3: *Very disappointed!*
   E4: *I am happy with the product.*
III. Personal actions:

E5: *Do not waste your money.*

E6: *I have recommended this machine to all my friends.*

The impersonal view consists of impersonal sentences (i.e. Y 's sentences) exemplified below:

I. Impersonal feature description:

E7: *They are too thin to start with.*

E8: *This product is extremely quiet.*

II. Impersonal evaluation:

E9: *It's great.*

E10: *The product is a waste of time and money.*

III. Impersonal actions:

E11: *This product not even worth a penny.*

E12: *It broke down again and again.*

We find that the subject of a sentence presents important cues for personal/impersonal views, even though a formal and computable definition of this contrast cannot be found. Here, subject refers to one of the two main constituents in the traditional English grammar (the other constituent being the predicate) (Crystal, 2003)[1]. For example, the subjects in the above examples of E1, E7 and E11 are '*I*', '*they*', and '*this product*' respectively. For automatic mining the two views, personal/impersonal sentences can be defined according to their subjects:

Personal sentence: the sentence whose subject is (or represents) a person.

Impersonal sentence: the sentence whose subject is not (does not represent) a person.

In this study, we mainly focus on product review classification where the target object in the set Y is not a person. The definitions need to be adjusted when the evaluation target itself is a person, e.g. the political sentiment classification by Durant and Smith (2007).

Our unsupervised mining approach for mining personal and impersonal sentences consists of two main steps. First, we extract an initial set of personal and impersonal sentences with some heuristic rules: If the first word of one sentence is (or implies) a personal pronoun including '*I*', '*we*', and '*do*', then the sentence is extracted as a personal sentence; If the first word of one sentence is an impersonal pronoun including '*it*', '*they*', '*this*', and '*these*', then the sentence is extracted as an impersonal sentence. Second, we apply the classifier which is trained with the initial set of personal and impersonal sentences to classify the remaining sentences. This step aims to classify the sentences without pronouns (e.g. E3). Figure 1 shows the unsupervised mining algorithm.

Input:

The training data D

Output:

All personal and impersonal sentences, i.e. sentence sets $S_{personal}$ and $S_{impersonal}$.

Procedure:

(1). Segment all documents in D to sentences S using punctuations (such as periods and interrogation marks)

(2). Apply the heuristic rules to classify the sentences S with proper pronouns into, S_{p1} and S_{i1}

(3). Train a binary classifier f_{p-i} with S_{p1} and S_{i1}

(4). Use f_{p-i} to classify the remaining sentences into S_{p2} and S_{i2}

(5). $S_{personal} = S_{p1} \bigcup S_{p2}$, $S_{impersonal} = S_{i1} \bigcup S_{i2}$

Figure 1: The algorithm for unsupervised mining personal and impersonal sentences from a training data

4 Employing Personal/Impersonal Views in Supervised Sentiment Classification

After unsupervised mining of personal and impersonal sentences, the training data is divided into two views: the personal view, which contains personal sentences, and the impersonal view, which contains impersonal sentences. Obviously, these two views can be used to train two different classifiers, f_1 and f_2, for sentiment classification respectively.

Since our mining approach is unsupervised, there inevitably exist some noises. In addition, the sentences of different views may share the same information for sentiment classification. For example, consider the following two sentences: '*It is a waste of money*.' and '*Do not waste your money*.' Apparently, the first one belongs to the impersonal view while the second one belongs to personal view, according to our heuristic rules. However, these two sentences share the same word, '*waste*', which conveys strong negative sentiment information. This suggests that training a single-view classifier f_3 with all sentences should help. Therefore, three base classifiers, f_1, f_2, and f_3, are eventually derived from the personal view, the impersonal

[1] The subject has the grammatical function in a sentence of relating its constituent (a noun phrase) by means of the verb to any other elements present in the sentence, i.e. objects, complements, and adverbials.

view and the single view, respectively. Each base classifier provides not only the class label outputs but also some kinds of confidence measurements, e.g. posterior probabilities of the testing sample belonging to each class.

Formally, each base classifier f_l $(l = 1,2,3)$ assigns a test sample (denoted as x_l) a posterior probability vector $\vec{P}(x_l)$:

$$\vec{P}(x_l) = < p(c_1 \mid x_l), p(c_2 \mid x_l) >^t$$

where $p(c_1 \mid x_l)$ denotes the probability that the l-th base classifier considers the sample belonging to c_1.

In the ensemble learning literature, various methods have been presented for combining base classifiers. The combining methods are categorized into two groups (Duin, 2002): fixed rules such as voting rule, product rule, and sum rule (Kittler et al., 1998), and trained rules such as weighted sum rule (Fumera and Roli, 2005) and meta-learning approaches (Vilalta and Drissi, 2002). In this study, we choose a fixed rule and a trained rule to combine the three base classifiers f_1, f_2, and f_3.

The chosen fixed rule is product rule which combine base classifiers by multiplying the posterior possibilities and using the multiplied possibility for decision, i.e.

$$assign \quad y \to c_j$$

$$where \ \ j = \arg\max_i \prod_{l=1}^{3} p(c_i \mid x_l)$$

The chosen trained rule is stacking (Vilalta and Drissi, 2002; Džeroski and Ženko, 2004) where a meta-classifier is trained with the output of the base classifiers as the input. Formally, let x' denote a feature vector of a sample from the development data. The output of the l-th base classifier f_l on this sample is the probability distribution over the category set $\{c_1, c_2\}$, i.e.

$$\vec{P}(x'_l) = < p(c_1 \mid x'_l), p_l(c_2 \mid x'_l) >$$

Then, a meta-classifier is trained using the development data with the meta-level feature vector $x^{meta} \in R^{2\times 3}$

$$x^{meta} = < \vec{P}(x'_{l=1}), \vec{P}(x'_{l=2}), \vec{P}(x'_{l=3}) >$$

In our experiments, we perform stacking with 4-fold cross validation to generate meta-training data where each fold is used as the development data and the other three folds are used to train the base classifiers in the training phase.

5 Employing Personal/Impersonal Views in Semi-Supervised Sentiment Classification

Semi-supervised learning is a strategy which combines unlabeled data with labeled training data to improve the models. Given the two-view classifiers f_1 and f_2 along with the single-view classifier f_3, we perform a co-training algorithm for semi-supervised sentiment classification. The co-training algorithm is a specific semi-supervised learning approach which starts with a set of labeled data and increases the amount of labeled data using the unlabeled data by bootstrapping (Blum and Mitchell, 1998). Figure 2 shows the co-training algorithm in our semi-supervised sentiment classification.

Input:

The labeled data L containing personal sentence set $S_{L-personal}$ and impersonal sentence set $S_{L-impersonal}$

The unlabeled data U containing personal sentence set $S_{U-personal}$ and impersonal sentence set $S_{U-impersonal}$

Output:

New labeled data L

Procedure:

Loop for N iterations until $U = \phi$

(1). Learn the first classifier f_1 *with* $S_{L-personal}$

(2). Use f_1 *to label samples from U with* $S_{U-personal}$

(3). Choose n_1 *positive and* n_1 *negative most confidently predicted samples* A_1

(4). Learn the second classifier f_2 *with* $S_{L-impersonal}$

(5). Use f_2 *to label samples from U with* $S_{U-impersonal}$

(6). Choose n_2 *positive and* n_2 *negative most confidently predicted samples* A_2

(7). Learn the third classifier f_3 *with* L

(8). Use f_3 *to label samples from U*

(9). Choose n_3 *positive and* n_3 *negative most confidently predicted samples* A_3

(10). Add samples $A_1 \cup A_2 \cup A_3$ *with the corresponding labels into* L

(11). Update $S_{L-personal}$ *and* $S_{L-impersonal}$

Figure 2: Our co-training algorithm for semi-supervised sentiment classification

After obtaining the new labeled data, we can either adopt one classifier (i.e. f_3) or a combined classifier (i.e. $f_1 + f_2 + f_3$) in further training and testing. In our experimentation, we explore both of them with the former referred to as **co-training and single classifier** and the latter referred to as **co-training and combined classifier**.

6 Experimental Studies

We have systematically explored our method on product reviews from eight domains: book, DVD, electronic appliances, kitchen appliances, health, network, pet and software.

6.1 Experimental Setting

The product reviews on the first four domains (book, DVD, electronic, and kitchen appliances) come from the multi-domain sentiment classification corpus, collected from http://www.amazon.com/ by Blitzer et al. (2007)[2]. Besides, we also collect the product views from http://www.amazon.com/ on other four domains (health, network, pet and software)[3]. Each of the eight domains contains 1000 positive and 1000 negative reviews. Figure 3 gives the distribution of personal and impersonal sentences in the training data (75% labeled data of all data). It shows that there are more impersonal sentences than personal ones in each domain, in particular in the DVD domain, where the number of impersonal sentences is at least twice as many as that of personal sentences. This unusual phenomenon is mainly attributed to the fact that many objective descriptions, e.g. the movie plot introductions, are expressed in the DVD domain which makes the extracted personal and impersonal sentences rather unbalanced.

We apply both support vector machine (SVM) and Maximum Entropy (ME) algorithms with the help of the SVM-light[4] and Mallet[5] tools. All parameters are set to their default values. We find that ME performs slightly better than SVM on the average. Furthermore, ME offers posterior probability information which is required for combination methods. Thus we apply the ME classification algorithm for further combination and co-training. In particular, we only employ Boolean features, representing the presence or absence of a word in a document. Finally, we perform *t*-test to evaluate the significance of the performance difference between two systems with different methods (Yang and Liu, 1999).

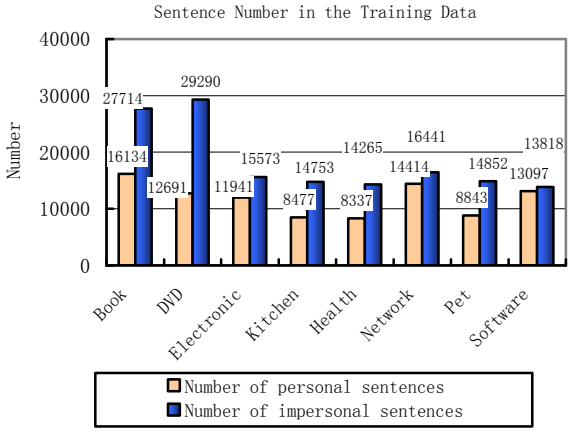

Figure 3: Distribution of personal and impersonal sentences in the training data of each domain

6.2 Experimental Results on Supervised Sentiment Classification

4-fold cross validation is performed for supervised sentiment classification. For comparison, we generate two random views by randomly splitting the whole feature space into two parts. Each part is seen as a view and used to train a classifier. The combination (two random view classifiers along with the single-view classifier f_3) results are shown in the last column of Table 1. The comparison between random two views and our proposed two views will clarify whether the performance gain comes truly from our proposed two-view mining, or simply from using the classifier combination strategy.

Table 1 shows the performances of different classifiers, where the single-view classifier f_3 which uses all sentences for training and testing, is considered as our baseline. Note that the baseline performances of the first four domains are worse than the ones reported in Blitzer et al. (2007). But their experiment is performed with only one split on the data with 80% as the training data and 20% as the testing data, which means the size of their training data is larger than ours. Also, we find that our performances are similar to the ones (described as fully supervised results) reported in Dasgupta and Ng (2009) where the same data in the four domains are used and 10-fold cross validation is performed.

[2] http://www.seas.upenn.edu/~mdredze/datasets/sentiment/

[3] Note that the second version of multi-domain sentiment classification corpus does contain data from many other domains. However, we find that the reviews in the other domains contain many duplicated samples. Therefore, we re-collect the reviews from http://www.amazon.com/ and filter those duplicated ones. The new collection is here: http://llt.cbs.polyu.edu.hk/~lss/ACL2010_Data_SSLi.zip

[5] http://mallet.cs.umass.edu/

Domain	Personal View Classifier f_1	Impersonal View Classifier f_2	Single View Classifier (**baseline**) f_3	Combination (Stacking) $f_1 + f_2 + f_3$	Combination (Product rule) $f_1 + f_2 + f_3$	Combination with two random views (Product rule)
Book	0.7004	0.7474	0.7654	0.7919	**0.7949**	0.7546
DVD	0.6931	0.7663	0.7884	0.8079	**0.8165**	0.8054
Electronic	0.7414	0.7844	0.8074	0.8304	**0.8364**	0.8210
Kitchen	0.7430	0.8030	0.8290	0.8555	**0.8565**	0.8152
Health	0.7000	0.7370	0.7559	0.7780	**0.7815**	0.7548
Network	0.7655	0.7710	0.8265	0.8360	**0.8435**	0.8312
Pet	0.6940	0.7145	0.7390	0.7565	**0.7665**	0.7423
Software	0.7035	0.7205	0.7470	**0.7730**	0.7715	0.7615
AVERAGE	*0.7176*	*0.7555*	*0.7823*	*0.8037*	***0.8084***	*0.7858*

Table 1: Performance of supervised sentiment classification

From Table 1, we can see that impersonal view classifier f_1 consistently performs better than personal view classifier f_2. Similar to the sentence distributions, the difference in the classification performances between these two views in the DVD domain is the largest (0.6931 vs. 0.7663).

Both the combination methods (stacking and product rule) significantly outperform the baseline in each domain (p-value<0.01) with a decent average performance improvement of 2.61%. Although the performance difference between the product rule and stacking is not significant, the product rule is obviously a better choice as it involves much easier implementation. Therefore, in the semi-supervised learning process, we only use the product rule to combine the individual classifiers. Finally, it shows that random generation of two views with the combination method of the product rule only slightly outperforms the baseline on the average (*0.7858* vs. *0.7823*) but performs much worse than our unsupervised mining of personal and impersonal views.

6.3 Experimental Results on Semi-supervised Sentiment Classification

We systematically evaluate and compare our two-view learning method with various semi-supervised ones as follows:

Self-training, which uses the unlabeled data in a bootstrapping way like co-training yet limits the number of classifiers and the number of views to one. Only the baseline classifier f_3 is used to select most confident unlabeled samples in each iteration.

Transductive SVM, which seeks the largest separation between labeled and unlabeled data through regularization (Joachims, 1999). We implement it with the help of the SVM-light tool.

Co-training with random two-view generation (briefly called **co-training with random views**), where two views are generated by randomly splitting the whole feature space into two parts.

In semi-supervised sentiment classification, the data are randomly partitioned into labeled training data, unlabeled data, and testing data with the proportion of 10%, 70% and 20% respectively. Figure 4 reports the classification accuracies in all iterations, where **baseline** indicates the supervised classifier f_3 trained on the 10% data; both **co-training and single classifier** and **co-training and combined classifier** refer to co-training using our proposed personal and impersonal views. But the former merely applies the baseline classifier f_3 trained the new labeled data to test on the testing data while the latter applies the combined classifier $f_1 + f_2 + f_3$. In each iteration, two top-confident samples in each category are chosen, i.e. $n_1 = n_2 = n_3 = 2$. For clarity, results of other methods (e.g. **self-training**, **transductive SVM**) are not shown in Figure 4 but will be reported in Figure 5 later.

Figure 4 shows that **co-training and combined classifier** always outperforms **co-training and single classifier**. This again justifies the effectiveness of our two-view learning on supervised sentiment classification.

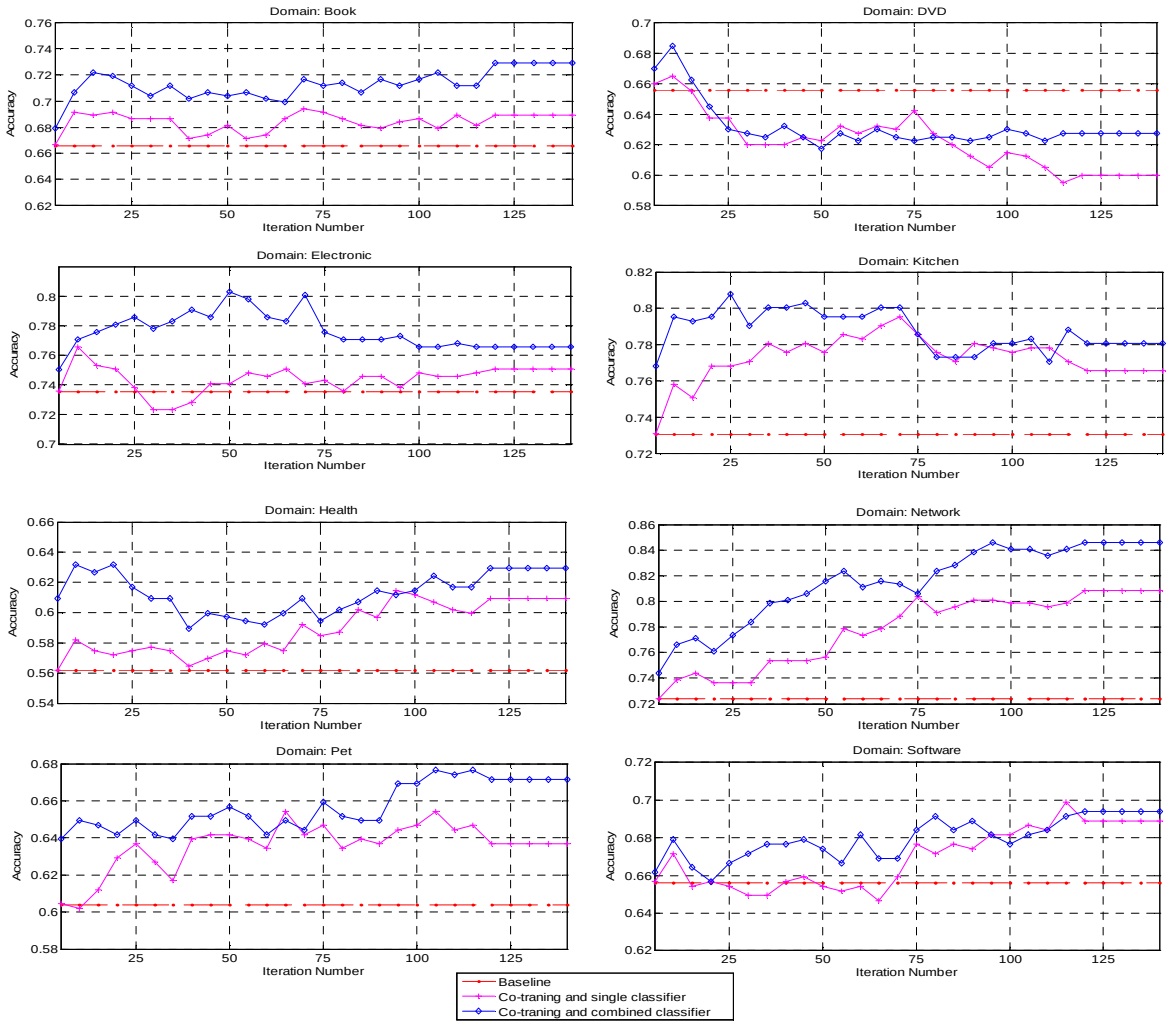

Figure 4: Classification performance vs. iteration numbers (using 10% labeled data as training data)

One open question is whether the unlabeled data improve the performance. Let us set aside the influence of the combination strategy and focus on the effectiveness of semi-supervised learning by comparing the baseline and **co-training and single classifier**. Figure 4 shows different results on different domains. Semi-supervised learning fails on the DVD domain while on the three domains of book, electronic, and software, semi-supervised learning benefits slightly (p-value>0.05). In contrast, semi-supervised learning benefits much on the other four domains (health, kitchen, network, and pet) from using unlabeled data and the performance improvements are statistically significant (p-value<0.01). Overall speaking, we think that the unlabeled data are very helpful as they lead to about 4% accuracy improvement on the average except for the DVD domain. Along with the supervised combination strategy, our approach can significantly improve the performance more than 7% on the average compared to the baseline.

Figure 5 shows the classification results of different methods with different sizes of the labeled data: 5%, 10%, and 15% of all data, where the testing data are kept the same (20% of all data). Specifically, the results of other methods including **self-training**, **transductive SVM**, and **random views** are presented when 10% labeled data are used in training. It shows that **self-training** performs much worse than our approach and fails to improve the performance of five of the eight domains. **Transductive SVM** performs even worse and can only improve the performance of the "software" domain. Although c**o-training with random views** outperforms the baseline on four of the eight domains, it performs worse than **co-training and single classifier.** This suggests that the impressive improvements are mainly due to our unsupervised two-view mining rather than the combination strategy.

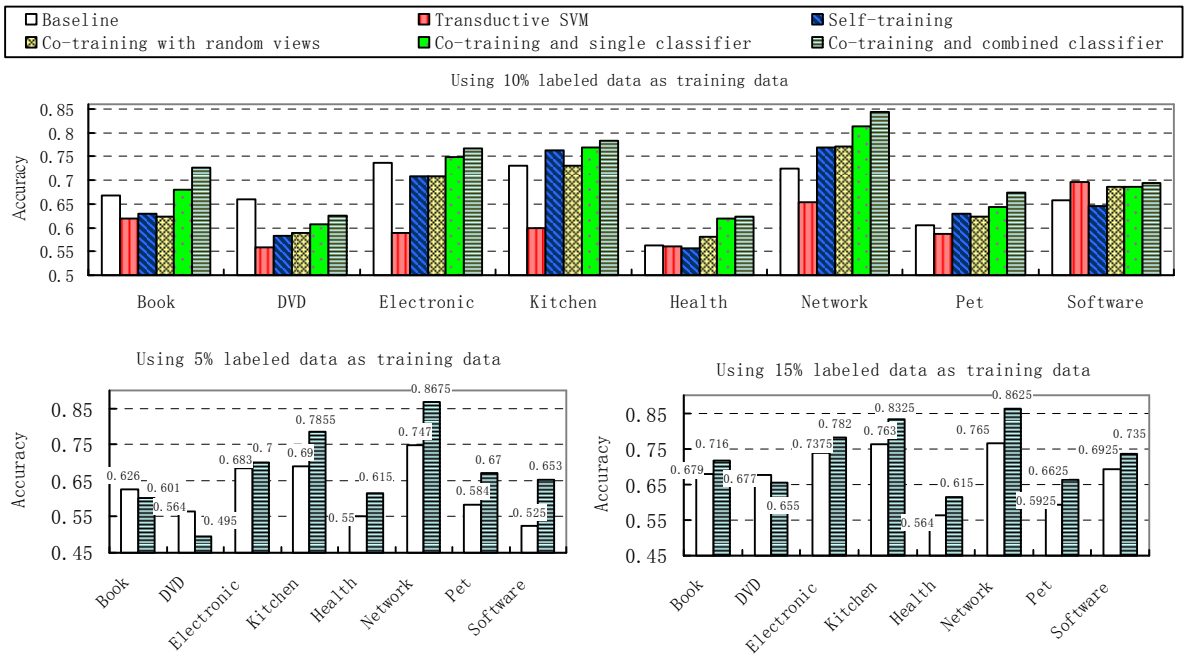

Figure 5: Performance of semi-supervised sentiment classification when 5%, 10%, and 15% labeled data are used

Figure 5 also shows that our approach is rather robust and achieves excellent performances in different training data sizes, although our approach fails on two domains, i.e. book and DVD, when only 5% of the labeled data are used. This failure may be due to that some of the samples in these two domains are too ambiguous and hard to classify. Manual checking shows that quite a lot of samples on these two domains are even too difficult for professionals to give a high-confident label. Another possible reason is that there exist too many objective descriptions in these two domains, thus introducing too much noisy information for semi-supervised learning.

The effectiveness of different sizes of chosen samples in each iteration is also evaluated like $n_1 = n_2 = n_3 = 6$ and $n_1 = 3, n_2 = n_3 = 6$ (This assignment is considered because the personal view classifier performs worse than the other two classifiers). Our experimental results are still unsuccessful in the DVD domain and do not show much difference on other domains. We also test the co-training approach without the single-view classifier f_3. Experimental results show that the inclusion of the single-view classifier f_3 slightly helps the co-training approach. The detailed discussion of the results is omitted due to space limit.

6.4 Why our approach is effective?

One main reason for the effectiveness of our approach on supervised learning is the way how personal and impersonal views are dealt with. As personal and impersonal views have different ways of expressing opinions, splitting them into two separations can filter some classification noises. For example, in the sentence of "*I have seen amazing dancing, and good dancing. This was TERRIBLE dancing!*". The first sentence is classified as a personal sentence and the second one is an impersonal sentence. Although the words '*amazing*' and '*good*' convey strong positive sentiment information, the whole text is negative. If we get the bag-of-words from the whole text, the classification result will be wrong. Rather, splitting the text into two parts based on different views allows correct classification as the personal view rarely contains impersonal words such as '*amazing*' and '*good*'. The classification result will thus be influenced by the impersonal view.

In addition, a document may contain both personal and impersonal sentences, and each of them, to a certain extent, , provides classification evidence. In fact, we randomly select 50 documents in the domain of kitchen appliances and find that 80% of the documents take both personal and impersonal sentences in which both of them express explicit opinions. That is to say, the two views provide different, complementary information for classification. This qualifies the success requirement of co-training algorithm to some extend. This might be the reason for the effectiveness of our approach on semi-supervised learning.

7 Discussion on Personal/Impersonal vs. Subjective/Objective

As mentioned in Section 1, personal view contains *X* 's "subjective" feeling, and impersonal view contains *Y* 's "objective" (i.e. or at least criteria-based) evaluation of the target object. However, our technically-defined concepts of personal/impersonal are definitely different from subjective/objective: Personal view can certainly contain many objective expressions, e.g. '*I bought this electric kettle*' and impersonal view can contain many subjective expressions, e.g. '*It is disappointing*'.

Our technically-defined personal/impersonal views are two different ways to describe opinions. Personal sentences are often used to express opinions in a direct way and their target object should be one of *X*. Impersonal ones are often used to express opinions in an indirect way and their target object should be one of *Y*. The ideal definition of personal (or impersonal) view given in Section 1 is believed to be a subset of our technical definition of personal (or impersonal) view. Thus impersonal view may contain both *Y* 's objective evaluation (more likely to be domain independent) and subjective *Y*'s description.

In addition, simply splitting text into subjective/objective views is not particularly helpful. Since a piece of objective text provides rather limited implicit classification information, the classification abilities of the two views are very unbalanced. This makes the co-training process unfeasible. Therefore, we believe that our technically-defined personal/impersonal views are more suitable for two-view learning compared to subjective/objective views.

8 Conclusion and Future Work

In this paper, we propose a robust and effective two-view model for sentiment classification based on personal/impersonal views. Here, the personal view consists of subjective sentences whose subject is a person, whereas the impersonal view consists of objective sentences whose subject is not a person. Such views are lexically cued and can be obtained without pre-labeled data and thus we explore an unsupervised learning approach to mine them. Combination methods and a co-training algorithm are proposed to deal with supervised and semi-supervised sentiment classification respectively. Evaluation on product reviews from eight domains shows that our approach significantly improves the performance across all eight domains on supervised sentiment classification and greatly outperforms the baseline with more than 7% accuracy improvement on the average across seven of eight domains (except the DVD domain) on semi-supervised sentiment classification.

In the future work, we will integrate the subjectivity summarization strategy (Pang and Lee, 2004) to help discard noisy objective sentences. Moreover, we need to consider the cases when both *X* and *Y* appear in a sentence. For example, the sentence "*I think they're poor*" should be an impersonal view but wrongly classified as a personal one according to our technical rules. We believe that these will help improve our approach and hopefully are applicable to the DVD domain. Another interesting and practical idea is to integrate active learning (Settles, 2009), another popular but principally different kind of semi-supervised learning approach, with our two-view learning approach to build high-performance systems with the least labeled data.

A Latent Dirichlet Allocation method for Selectional Preferences

Abstract

The computation of *selectional preferences*, the admissible argument values for a relation, is a well-known NLP task with broad applicability. We present LDA-SP, which utilizes LinkLDA (Erosheva et al., 2004) to model selectional preferences. By simultaneously inferring latent topics and topic distributions over relations, LDA-SP combines the benefits of previous approaches: like traditional class-based approaches, it produces human-interpretable classes describing each relation's preferences, but it is competitive with non-class-based methods in predictive power.

We compare LDA-SP to several state-of-the-art methods achieving an 85% increase in recall at 0.9 precision over mutual information (Erk, 2007). We also evaluate LDA-SP's effectiveness at filtering improper applications of inference rules, where we show substantial improvement over Pantel *et al.*'s system (Pantel et al., 2007).

1 Introduction

Selectional Preferences encode the set of admissible argument values for a relation. For example, locations are likely to appear in the second argument of the relation *X is headquartered in Y* and companies or organizations in the first. A large, high-quality database of preferences has the potential to improve the performance of a wide range of NLP tasks including semantic role labeling (Gildea and Jurafsky, 2002), pronoun resolution (Bergsma et al., 2008), textual inference (Pantel et al., 2007), word-sense disambiguation (Resnik, 1997), and many more. Therefore, much attention has been focused on automatically computing them based on a corpus of relation instances.

Resnik (1996) presented the earliest work in this area, describing an information-theoretic approach that inferred selectional preferences based on the WordNet hypernym hierarchy. Recent work (Erk, 2007; Bergsma et al., 2008) has moved away from generalization to known classes, instead utilizing distributional similarity between nouns to generalize beyond observed relation-argument pairs. This avoids problems like WordNet's poor coverage of proper nouns and is shown to improve performance. These methods, however, no longer produce the generalized class for an argument.

In this paper we describe a novel approach to computing selectional preferences by making use of unsupervised topic models. Our approach is able to combine benefits of both kinds of methods: it retains the generalization and human-interpretability of class-based approaches and is also competitive with the direct methods on predictive tasks.

Unsupervised topic models, such as latent Dirichlet allocation (LDA) (Blei et al., 2003) and its variants are characterized by a set of hidden topics, which represent the underlying semantic structure of a document collection. For our problem these topics offer an intuitive interpretation – they represent the (latent) set of classes that store the preferences for the different relations. Thus, topic models are a natural fit for modeling our relation data.

In particular, our system, called LDA-SP, uses LinkLDA (Erosheva et al., 2004), an extension of LDA that simultaneously models *two* sets of distributions for each topic. These two sets represent the two arguments for the relations. Thus, LDA-SP is able to capture information about the pairs of topics that commonly co-occur. This information is very helpful in guiding inference.

We run LDA-SP to compute preferences on a massive dataset of binary relations $r(a_1, a_2)$ ex-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 424–434,
Uppsala, Sweden, 11-16 July 2010.

tracted from the Web by TEXTRUNNER (Banko and Etzioni, 2008). Our experiments demonstrate that LDA-SP significantly outperforms state of the art approaches obtaining an 85% increase in recall at precision 0.9 on the standard pseudo-disambiguation task.

Additionally, because LDA-SP is based on a formal probabilistic model, it has the advantage that it can naturally be applied in many scenarios. For example, we can obtain a better understanding of similar relations (Table 1), filter out incorrect inferences based on querying our model (Section 4.3), as well as produce a repository of class-based preferences with a little manual effort as demonstrated in Section 4.4. In all these cases we obtain high quality results, for example, massively outperforming Pantel et al.'s approach in the textual inference task.[1]

2 Previous Work

Previous work on selectional preferences can be broken into four categories: class-based approaches (Resnik, 1996; Li and Abe, 1998; Clark and Weir, 2002; Pantel et al., 2007), similarity based approaches (Dagan et al., 1999; Erk, 2007), discriminative (Bergsma et al., 2008), and generative probabilistic models (Rooth et al., 1999).

Class-based approaches, first proposed by Resnik (1996), are the most studied of the four. They make use of a pre-defined set of classes, either manually produced (e.g. WordNet), or automatically generated (Pantel, 2003). For each relation, some measure of the overlap between the classes and observed arguments is used to identify those that best describe the arguments. These techniques produce a human-interpretable output, but often suffer in quality due to an incoherent taxonomy, inability to map arguments to a class (poor lexical coverage), and word sense ambiguity.

Because of these limitations researchers have investigated non-class based approaches, which attempt to directly classify a given noun-phrase as plausible/implausible for a relation. Of these, the *similarity based approaches* make use of a distributional similarity measure between arguments and evaluate a heuristic scoring function:

$$S_{\text{rel}}(\text{arg}) = \sum_{\text{arg}' \in \text{Seen}(\text{rel})} \text{sim}(\text{arg}, \text{arg}') \cdot \text{wt}_{\text{rel}}(\text{arg})$$

[1] Our repository of selectional preferences is available at `http://www.cs.washington.edu/research/ldasp`.

Erk (2007) showed the advantages of this approach over Resnik's information-theoretic class-based method on a pseudo-disambiguation evaluation. These methods obtain better lexical coverage, but are unable to obtain any abstract representation of selectional preferences.

Our solution fits into the general category of *generative probabilistic models*, which model each relation/argument combination as being generated by a latent class variable. These classes are automatically learned from the data. This retains the class-based flavor of the problem, without the knowledge limitations of the explicit class-based approaches. Probably the closest to our work is a model proposed by Rooth et al. (1999), in which each class corresponds to a multinomial over relations and arguments and EM is used to learn the parameters of the model. In contrast, we use a LinkLDA framework in which each relation is associated with a corresponding multinomial distribution over classes, and each argument is drawn from a class-specific distribution over words; LinkLDA captures co-occurrence of classes in the two arguments. Additionally we perform full Bayesian inference using collapsed Gibbs sampling, in which parameters are integrated out (Griffiths and Steyvers, 2004).

Recently, Bergsma *et. al.* (2008) proposed the first *discriminative approach* to selectional preferences. Their insight that pseudo-negative examples could be used as training data allows the application of an SVM classifier, which makes use of many features in addition to the relation-argument co-occurrence frequencies used by other methods. They automatically generated positive and negative examples by selecting arguments having high and low mutual information with the relation. Since it is a discriminative approach it is amenable to feature engineering, but needs to be retrained and tuned for each task. On the other hand, generative models produce complete probability distributions of the data, and hence can be integrated with other systems and tasks in a more principled manner (see Sections 4.2.2 and 4.3.1). Additionally, unlike LDA-SP Bergsma et al.'s system doesn't produce human-interpretable topics. Finally, we note that LDA-SP and Bergsma's system are potentially complimentary – the output of LDA-SP could be used to generate higher-quality training data for Bergsma, potentially improving their results.

Topic models such as LDA (Blei et al., 2003) and its variants have recently begun to see use in many NLP applications such as summarization (Daumé III and Marcu, 2006), document alignment and segmentation (Chen et al., 2009), and inferring class-attribute hierarchies (Reisinger and Pasca, 2009). Our particular model, LinkLDA, has been applied to a few NLP tasks such as simultaneously modeling the words appearing in blog posts and users who will likely respond to them (Yano et al., 2009), modeling topic-aligned articles in different languages (Mimno et al., 2009), and word sense induction (Brody and Lapata, 2009).

Finally, we highlight two systems, developed independently of our own, which apply LDA-style models to similar tasks. Ó Séaghdha (2010) proposes a series of LDA-style models for the task of computing selectional preferences. This work learns selectional preferences between the following grammatical relations: verb-object, noun-noun, and adjective-noun. It also focuses on jointly modeling the generation of both predicate and argument, and evaluation is performed on a set of human-plausibility judgments obtaining impressive results against Keller and Lapata's (2003) Web hit-count based system. Van Durme and Gildea (2009) proposed applying LDA to general knowledge templates extracted using the KNEXT system (Schubert and Tong, 2003). In contrast, our work uses LinkLDA and focuses on modeling multiple arguments of a relation (*e.g.*, the subject and direct object of a verb).

3 Topic Models for Selectional Prefs.

We present a series of topic models for the task of computing selectional preferences. These models vary in the amount of independence they assume between a_1 and a_2. At one extreme is IndependentLDA, a model which assumes that both a_1 and a_2 are generated completely independently. On the other hand, JointLDA, the model at the other extreme (Figure 1) assumes both arguments of a specific extraction are generated based on a single hidden variable z. LinkLDA (Figure 2) lies between these two extremes, and as demonstrated in Section 4, it is the best model for our relation data.

We are given a set R of binary relations and a corpus $\mathcal{D} = \{r(a_1, a_2)\}$ of extracted instances for these relations. [2] Our task is to compute, for each argument a_i of each relation r, a set of usual argument values (noun phrases) that it takes. For example, for the relation *is headquartered in* the first argument set will include companies like *Microsoft, Intel, General Motors* and second argument will favor locations like *New York, California, Seattle*.

3.1 IndependentLDA

We first describe the straightforward application of LDA to modeling our corpus of extracted relations. In this case two separate LDA models are used to model a_1 and a_2 independently.

In the generative model for our data, each relation r has a corresponding multinomial over topics θ_r, drawn from a Dirichlet. For each extraction, a hidden topic z is first picked according to θ_r, and then the observed argument a is chosen according to the multinomial β_z.

Readers familiar with topic modeling terminology can understand our approach as follows: we treat each relation as a document whose contents consist of a bags of words corresponding to all the noun phrases observed as arguments of the relation in our corpus. Formally, LDA generates each argument in the corpus of relations as follows:

for each topic $t = 1 \ldots T$ **do**
  Generate β_t according to symmetric Dirichlet distribution Dir(η).
end for
for each relation $r = 1 \ldots |R|$ **do**
  Generate θ_r according to Dirichlet distribution Dir(α).
  for each tuple $i = 1 \ldots N_r$ **do**
    Generate $z_{r,i}$ from Multinomial(θ_r).
    Generate the argument $a_{r,i}$ from multinomial $\beta_{z_{r,i}}$.
  end for
end for

One weakness of IndependentLDA is that it doesn't jointly model a_1 and a_2 together. Clearly this is undesirable, as information about which topics one of the arguments favors can help inform the topics chosen for the other. For example, class pairs such as (*team*, *game*), (*politician*, *political issue*) form much more plausible selectional preferences than, say, (*team*, *political issue*), (*politician*, *game*).

[2] We focus on binary relations, though the techniques presented in the paper are easily extensible to n-ary relations.

3.2 JointLDA

As a more tightly coupled alternative, we first propose JointLDA, whose graphical model is depicted in Figure 1. The key difference in JointLDA (versus LDA) is that instead of one, it maintains *two* sets of topics (latent distributions over words) denoted by β and γ, one for classes of each argument. A topic id k represents a pair of topics, β_k and γ_k, that co-occur in the arguments of extracted relations. Common examples include *(Person, Location), (Politician, Political issue), etc.* The hidden variable $z = k$ indicates that the noun phrase for the first argument was drawn from the multinomial β_k, and that the second argument was drawn from γ_k. The per-relation distribution θ_r is a multinomial over the topic ids and represents the selectional preferences, both for arg1s and arg2s of a relation r.

Although JointLDA has many desirable properties, it has some drawbacks as well. Most notably, in JointLDA topics correspond to pairs of multinomials (β_k, γ_k); this leads to a situation in which multiple redundant distributions are needed to represent the same underlying semantic class. For example consider the case where we we need to represent the following selectional preferences for our corpus of relations: (*person*, *location*), (*person*, *organization*), and (*person*, *crime*). Because JointLDA requires a separate pair of multinomials for each topic, it is forced to use 3 separate multinomials to represent the class *person*, rather than learning a single distribution representing *person* and choosing 3 different topics for a_2. This results in poor generalization because the data for a single class is divided into multiple topics.

In order to address this problem while maintaining the sharing of influence between a_1 and a_2, we next present LinkLDA, which represents a compromise between IndependentLDA and JointLDA. LinkLDA is more flexible than JointLDA, allowing different topics to be chosen for a_1, and a_2, however still models the generation of topics from the same distribution for a given relation.

3.3 LinkLDA

Figure 2 illustrates the LinkLDA model in the plate notation, which is analogous to the model in (Erosheva et al., 2004). In particular note that each a_i is drawn from a different hidden topic z_i, however the z_i's are drawn from the same distribution θ_r for a given relation r. To facilitate learning related topic pairs between arguments we employ a sparse prior over the per-relation topic distributions. Because a few topics are likely to be assigned most of the probability mass for a given relation it is more likely (although not necessary) that the same topic number k will be drawn for both arguments.

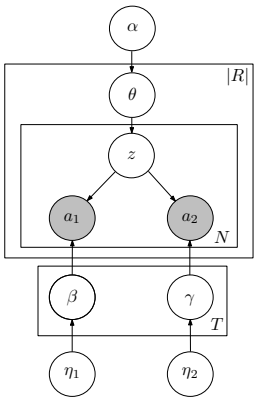

Figure 1: JointLDA

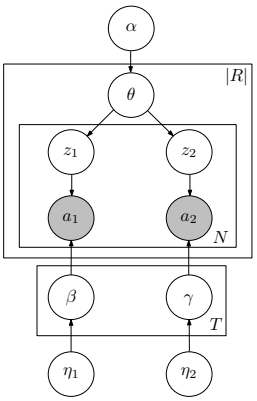

Figure 2: LinkLDA

When comparing LinkLDA with JointLDA the better model may not seem immediately clear. On the one hand, JointLDA jointly models the generation of both arguments in an extracted tuple. This allows one argument to help disambiguate the other in the case of ambiguous relation strings. LinkLDA, however, is more flexible; rather than requiring both arguments to be generated from one of $|Z|$ possible pairs of multinomials (β_z, γ_z), LinkLDA allows the arguments of a given extraction to be generated from $|Z|^2$ possible pairs. Thus, instead of imposing a hard constraint that $z_1 = z_2$ (as in JointLDA), LinkLDA simply assigns a higher probability to states in which $z_1 = z_2$, because both hidden variables are drawn from the same (sparse) distribution θ_r. LinkLDA can thus re-use argument classes, choosing different combinations of topics for the arguments if it fits the data better. In Section 4 we show experimentally that LinkLDA outperforms JointLDA (and IndependentLDA) by wide margins. We use LDA-SP to refer to LinkLDA in all the experiments below.

3.4 Inference

For all the models we use collapsed Gibbs sampling for inference in which each of the hidden variables (*e.g.*, $z_{r,i,1}$ and $z_{r,i,2}$ in LinkLDA) are sampled sequentially conditioned on a full-assignment to all others, integrating out the parameters (Griffiths and Steyvers, 2004). This produces robust parameter estimates, as it allows computation of expectations over the posterior distribution

as opposed to estimating maximum likelihood parameters. In addition, the integration allows the use of sparse priors, which are typically more appropriate for natural language data. In all experiments we use hyperparameters $\alpha = \eta_1 = \eta_2 = 0.1$. We generated initial code for our samplers using the Hierarchical Bayes Compiler (Daume III, 2007).

3.5 Advantages of Topic Models

There are several advantages to using topic models for our task. First, they naturally model the class-based nature of selectional preferences, but don't take a pre-defined set of classes as input. Instead, they compute the classes automatically. This leads to better lexical coverage since the issue of matching a new argument to a known class is side-stepped. Second, the models naturally handle ambiguous arguments, as they are able to assign different topics to the same phrase in different contexts. Inference in these models is also scalable – linear in both the size of the corpus as well as the number of topics. In addition, there are several scalability enhancements such as SparseLDA (Yao et al., 2009), and an approximation of the Gibbs Sampling procedure can be efficiently parallelized (Newman et al., 2009). Finally we note that, once a topic distribution has been learned over a set of training relations, one can efficiently apply inference to unseen relations (Yao et al., 2009).

4 Experiments

We perform three main experiments to assess the quality of the preferences obtained using topic models. The first is a task-independent evaluation using a pseudo-disambiguation experiment (Section 4.2), which is a standard way to evaluate the quality of selectional preferences (Rooth et al., 1999; Erk, 2007; Bergsma et al., 2008). We use this experiment to compare the various topic models as well as the best model with the known state of the art approaches to selectional preferences. Secondly, we show significant improvements to performance at an end-task of textual inference in Section 4.3. Finally, we report on the quality of a large database of Wordnet-based preferences obtained after manually associating our topics with Wordnet classes (Section 4.4).

4.1 Generalization Corpus

For all experiments we make use of a corpus of $r(a_1, a_2)$ tuples, which was automatically extracted by TEXTRUNNER (Banko and Etzioni, 2008) from 500 million Web pages.

To create a *generalization corpus* from this large dataset. We first selected 3,000 relations from the middle of the tail (we used the 2,000-5,000 most frequent ones)[3] and collected all instances. To reduce sparsity, we discarded all tuples containing an NP that occurred fewer than 50 times in the data. This resulted in a vocabulary of about 32,000 noun phrases, and a set of about 2.4 million tuples in our generalization corpus.

We inferred topic-argument and relation-topic multinomials (β, γ, and θ) on the generalization corpus by taking 5 samples at a lag of 50 after a burn in of 750 iterations. Using multiple samples introduces the risk of *topic drift* due to lack of identifiability, however we found this to not be a problem in practice. During development we found that the topics tend to remain stable across multiple samples after sufficient burn in, and multiple samples improved performance. Table 1 lists sample topics and high ranked words for each (for both arguments) as well as relations favoring those topics.

4.2 Task Independent Evaluation

We first compare the three LDA-based approaches to each other and two state of the art similarity based systems (Erk, 2007) (using mutual information and Jaccard similarity respectively). These similarity measures were shown to outperform the generative model of Rooth et al. (1999), as well as class-based methods such as Resnik's. In this pseudo-disambiguation experiment an observed tuple is paired with a pseudo-negative, which has both arguments randomly generated from the whole vocabulary (according to the corpus-wide distribution over arguments). The task is, for each relation-argument pair, to determine whether it is observed, or a random distractor.

4.2.1 Test Set

For this experiment we gathered a primary corpus by first randomly selecting 100 high-frequency relations *not* in the generalization corpus. For each relation we collected all tuples containing arguments in the vocabulary. We held out 500 randomly selected tuples as the test set. For each tu-

[3] Many of the most frequent relations have very weak selectional preferences, and thus provide little signal for inferring meaningful topics. For example, the relations *has* and *is* can take just about any arguments.

Table 1: Example argument lists from the inferred topics. For each topic number t we list the most probable values according to the multinomial distributions for each argument (β_t and γ_t). The middle column reports a few relations whose inferred topic distributions θ_r assign highest probability to t.

ple $r(a_1, a_2)$ in the held-out set, we removed all tuples in the training set containing either of the *rel-arg* pairs, *i.e.*, any tuple matching $r(a_1, *)$ or $r(*, a_2)$. Next we used collapsed Gibbs sampling to infer a distribution over topics, θ_r, for each of the relations in the primary corpus (based solely on tuples in the training set) using the topics from the generalization corpus.

For each of the 500 observed tuples in the test-set we generated a pseudo-negative tuple by randomly sampling two noun phrases from the distribution of NPs in both corpora.

4.2.2 Prediction

Our prediction system needs to determine whether a specific relation-argument pair is admissible according to the selectional preferences or is a random distractor (D). Following previous work, we perform this experiment independently for the two relation-argument pairs (r, a_1) and (r, a_2).

We first compute the probability of observing a_1 for first argument of relation r given that it is not a distractor, $P(a_1|r, \neg D)$, which we approximate by its probability given an estimate of the parameters inferred by our model, marginalizing over hidden topics t. The analysis for the second argument is similar.

$$\begin{aligned} P(a_1|r, \neg D) \approx P_{LDA}(a_1|r) &= \sum_{t=0}^{T} P(a_1|t)P(t|r) \\ &= \sum_{t=0}^{T} \beta_t(a_1)\theta_r(t) \end{aligned}$$

A simple application of Bayes Rule gives the probability that a particular argument is not a distractor. Here the distractor-related probabilities are independent of r, *i.e.*, $P(D|r) = P(D)$, $P(a_1|D, r) = P(a_1|D)$, *etc.* We estimate $P(a_1|D)$ according to their frequency in the generalization corpus.

$$\begin{aligned} P(\neg D|r, a_1) &= \frac{P(\neg D|r)P(a_1|r, \neg D)}{P(a_1|r)} \\ &\approx \frac{P(\neg D)P_{LDA}(a_1|r)}{P(D)P(a_1|D) + P(\neg D)P_{LDA}(a_1|r)} \end{aligned}$$

4.2.3 Results

Figure 3 plots the precision-recall curve for the pseudo-disambiguation experiment comparing the three different topic models. LDA-SP, which uses LinkLDA, substantially outperforms both IndependentLDA and JointLDA.

Next, in figure 4, we compare LDA-SP with mutual information and Jaccard similarities using both the generalization and primary corpus for

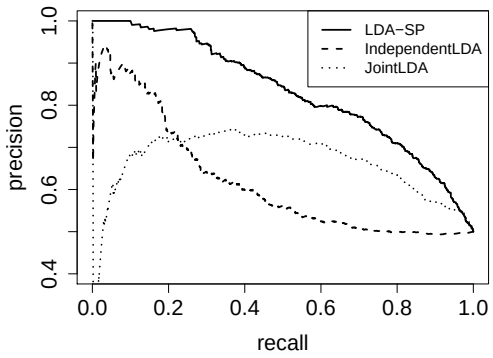

Figure 3: Comparison of LDA-based approaches on the pseudo-disambiguation task. LDA-SP (LinkLDA) substantially outperforms the other models.

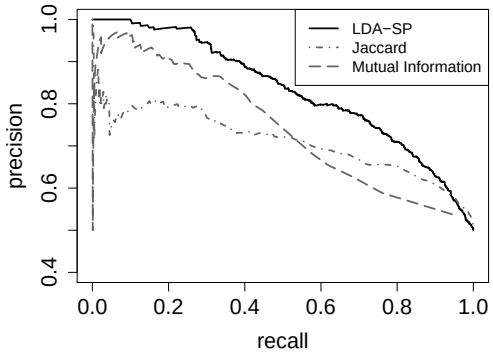

Figure 4: Comparison to similarity-based selectional preference systems. LDA-SP obtains 85% higher recall at precision 0.9.

computation of similarities. We find LDA-SP significantly outperforms these methods. Its edge is most noticed at high precisions; it obtains 85% more recall at 0.9 precision compared to mutual information. Overall LDA-SP obtains an 15% increase in the area under precision-recall curve over mutual information. All three systems' AUCs are shown in Table 2; LDA-SP's improvements over both Jaccard and mutual information are highly significant with a significance level less than 0.01 using a paired t-test.

In addition to a superior performance in selectional preference evaluation LDA-SP also produces a set of coherent topics, which can be useful in their own right. For instance, one could use them for tasks such as set-expansion (Carlson et al., 2010) or automatic thesaurus induction (Etzioni et al., 2005; Kozareva et al., 2008).

	LDA-SP	MI-Sim	Jaccard-Sim
AUC	0.833	0.727	0.711

Table 2: Area under the precision recall curve. LDA-SP's AUC is significantly higher than both similarity-based methods according to a paired t-test with a significance level below 0.01.

4.3 End Task Evaluation

We now evaluate LDA-SP's ability to improve performance at an end-task. We choose the task of improving textual entailment by learning selectional preferences for inference rules and filtering inferences that do not respect these. This application of selectional preferences was introduced by Pantel *et. al.* (2007). For now we stick to inference rules of the form $r_1(a_1, a_2) \Rightarrow r_2(a_1, a_2)$, though our ideas are more generally applicable to more complex rules. As an example, the rule (X *defeats* Y) $\Rightarrow$ (X *plays* Y) holds when X and Y are both sports teams, however fails to produce a reasonable inference if X and Y are *Britain* and *Nazi Germany* respectively.

4.3.1 Filtering Inferences

In order for an inference to be plausible, both relations must have similar selectional preferences, and further, the arguments must obey the selectional preferences of both the antecedent r_1 and the consequent r_2.[4] Pantel et al. (2007) made use of these intuitions by producing a set of class-based selectional preferences for each relation, then filtering out any inferences where the arguments were incompatible with the intersection of these preferences. In contrast, we take a probabilistic approach, evaluating the quality of a specific inference by measuring the probability that the arguments in both the antecedent and the consequent were drawn from the same hidden topic in our model. Note that this probability captures both the requirement that the antecedent and consequent have similar selectional preferences, and that the arguments from a particular instance of the rule's application match their overlap.

We use $z_{r_i,j}$ to denote the topic that generates the j^{th} argument of relation r_i. The probability that the two arguments a_1, a_2 were drawn from the same hidden topic factorizes as follows due to the conditional independences in our model:[5]

$$P(z_{r_1,1} = z_{r_2,1}, z_{r_1,2} = z_{r_2,2}|a_1, a_2) = P(z_{r_1,1} = z_{r_2,1}|a_1)P(z_{r_1,2} = z_{r_2,2}|a_2)$$

[4] Similarity-based and discriminative methods are not applicable to this task as they offer no straightforward way to compare the similarity between selectional preferences of two relations.

[5] Note that all probabilities are conditioned on an estimate of the parameters θ, β, γ from our model, which are omitted for compactness.

To compute each of these factors we simply marginalize over the hidden topics:

$$P(z_{r_1,j} = z_{r_2,j}|a_j) = \sum_{t=1}^{T} P(z_{r_1,j} = t|a_j)P(z_{r_2,j} = t|a_j)$$

where $P(z = t|a)$ can be computed using Bayes rule. For example,

$$\begin{aligned} P(z_{r_1,1} = t|a_1) &= \frac{P(a_1|z_{r_1,1} = t)P(z_{r_1,1} = t)}{P(a_1)} \\ &= \frac{\beta_t(a_1)\theta_{r_1}(t)}{P(a_1)} \end{aligned}$$

4.3.2 Experimental Conditions

In order to evaluate LDA-SP's ability to filter inferences based on selectional preferences we need a set of inference rules between the relations in our corpus. We therefore mapped the DIRT Inference rules (Lin and Pantel, 2001), (which consist of pairs of dependency paths) to TEXTRUNNER relations as follows. We first gathered all instances in the generalization corpus, and for each $r(a_1, a_2)$ created a corresponding simple sentence by concatenating the arguments with the relation string between them. Each such simple sentence was parsed using Minipar (Lin, 1998). From the parses we extracted all dependency paths between nouns that contain only words present in the TEXTRUNNER relation string. These dependency paths were then matched against each pair in the DIRT database, and all pairs of associated relations were collected producing about 26,000 inference rules.

Following Pantel et al. (2007) we randomly sampled 100 inference rules. We then automatically filtered out any rules which contained a negation, or for which the antecedent and consequent contained a pair of antonyms found in WordNet (this left us with 85 rules). For each rule we collected 10 random instances of the antecedent, and generated the consequent. We randomly sampled 300 of these inferences to hand-label.

4.3.3 Results

In figure 5 we compare the precision and recall of LDA-SP against the top two performing systems described by Pantel et al. (ISP.IIM-$\vee$ and ISP.JIM, both using the CBC clusters (Pantel, 2003)). We find that LDA-SP achieves both higher precision and recall than ISP.IIM-$\vee$. It is also able to achieve the high-precision point of ISP.JIM and can trade precision to get a much larger recall.

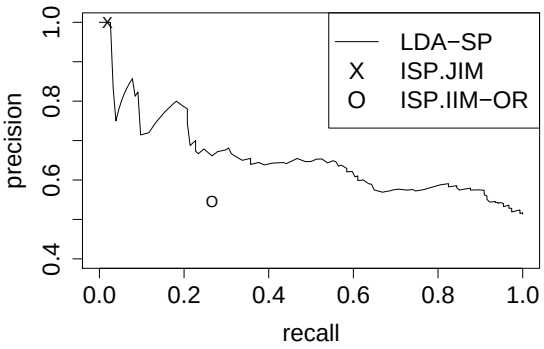

Figure 5: Precision and recall on the inference filtering task.

Table 3: Top 10 and Bottom 10 ranked inference rules ranked by LDA-SPafter automatically filtering out negations and antonyms (using WordNet).

In addition we demonstrate LDA-SP's ability to rank inference rules by measuring the Kullback Leibler Divergence[6] between the topic-distributions of the antecedent and consequent, θ_{r_1} and θ_{r_2} respectively. Table 3 shows the top 10 and bottom 10 rules out of the 26,000 ranked by KL Divergence after automatically filtering antonyms (using WordNet) and negations. For slight variations in rules (*e.g.*, symmetric pairs) we mention only one example to show more variety.

[6]KL-Divergence is an information-theoretic measure of the similarity between two probability distributions, and defined as follows: $KL(P||Q) = \sum_x P(x) \log \frac{P(x)}{Q(x)}$.

4.4 A Repository of Class-Based Preferences

Finally we explore LDA-SP's ability to produce a repository of human interpretable class-based selectional preferences. As an example, for the relation *was born in*, we would like to infer that the plausible arguments include (*person*, *location*) and (*person*, *date*).

Since we already have a set of topics, our task reduces to mapping the inferred topics to an equivalent class in a taxonomy (*e.g.*, WordNet). We experimented with automatic methods such as Resnik's, but found them to have all the same problems as directly applying these approaches to the SP task.[7] Guided by the fact that we have a relatively small number of topics (600 total, 300 for each argument) we simply chose to label them manually. By labeling this small number of topics we can infer class-based preferences for an arbitrary number of relations.

In particular, we applied a semi-automatic scheme to map topics to WordNet. We first applied Resnik's approach to automatically shortlist a few candidate WordNet classes for each topic. We then manually picked the best class from the shortlist that best represented the 20 top arguments for a topic (similar to Table 1). We marked all incoherent topics with a special symbol $\emptyset$. This process took one of the authors about 4 hours to complete.

To evaluate how well our topic-class associations carry over to unseen relations we used the same random sample of 100 relations from the pseudo-disambiguation experiment.[8] For each argument of each relation we picked the top two topics according to frequency in the 5 Gibbs samples. We then discarded any topics which were labeled with $\emptyset$; this resulted in a set of 236 predictions. A few examples are displayed in table 4.

We evaluated these classes and found the accuracy to be around 0.88. We contrast this with Pantel's repository,[9] the only other released database of selectional preferences to our knowledge. We evaluated the same 100 relations from his website and tagged the top 2 classes for each argument and evaluated the accuracy to be roughly 0.55.

[7] Perhaps recent work on automatic coherence ranking (Newman et al., 2010) and labeling (Mei et al., 2007) could produce better results.

[8] Recall that these 100 were not part of the original 3,000 in the generalization corpus, and are, therefore, representative of new "unseen" relations.

people#1	will love	show#3
organization#1	has responded to	accusation#2
administrative_unit#1	has appointed	administrator#3

Table 4: Class-based Selectional Preferences.

We emphasize that tagging a pair of class-based preferences is a highly subjective task, so these results should be treated as preliminary. Still, these early results are promising. We wish to undertake a larger scale study soon.

5 Conclusions and Future Work

We have presented an application of topic modeling to the problem of automatically computing selectional preferences. Our method, LDA-SP, learns a distribution over topics for each relation while simultaneously grouping related words into these topics. This approach is capable of producing human interpretable classes, however, avoids the drawbacks of traditional class-based approaches (poor lexical coverage and ambiguity). LDA-SP achieves state-of-the-art performance on predictive tasks such as pseudo-disambiguation, and filtering incorrect inferences.

Because LDA-SP generates a complete probabilistic model for our relation data, its results are easily applicable to many other tasks such as identifying similar relations, ranking inference rules, *etc.* In the future, we wish to apply our model to automatically discover new inference rules and paraphrases.

Finally, our repository of selectional preferences for 10,000 relations is available at http://www.cs.washington.edu/research/ldasp.

Latent variable models of selectional preference

Abstract

This paper describes the application of so-called *topic models* to selectional preference induction. Three models related to Latent Dirichlet Allocation, a proven method for modelling document-word co-occurrences, are presented and evaluated on datasets of human plausibility judgements. Compared to previously proposed techniques, these models perform very competitively, especially for infrequent predicate-argument combinations where they exceed the quality of Web-scale predictions while using relatively little data.

1 Introduction

Language researchers have long been aware that many words place semantic restrictions on the words with which they can co-occur in a syntactic relationship. Violations of these restrictions make the sense of a sentence odd or implausible:

(1) Colourless green ideas sleep furiously.

(2) The deer shot the hunter.

Recognising whether or not a selectional restriction is satisfied can be an important trigger for metaphorical interpretations (Wilks, 1978) and also plays a role in the time course of human sentence processing (Rayner et al., 2004). A more relaxed notion of *selectional preference* captures the idea that certain classes of entities are more likely than others to fill a given argument slot of a predicate. In Natural Language Processing, knowledge about probable, less probable and wholly infelicitous predicate-argument pairs is of value for numerous applications, for example semantic role labelling (Gildea and Jurafsky, 2002; Zapirain et al., 2009). The notion of selectional preference is not restricted to surface-level predicates such as verbs and modifiers, but also extends to semantic frames (Erk, 2007) and inference rules (Pantel et al., 2007).

The fundamental problem that selectional preference models must address is data sparsity: in many cases insufficient corpus data is available to reliably measure the plausibility of a predicate-argument pair by counting its observed frequency. A rarely seen pair may be fundamentally implausible (*a carrot laughed*) or plausible but rarely expressed (*a manservant laughed*).[1] In general, it is beneficial to smooth plausibility estimates by integrating knowledge about the frequency of other, similar predicate-argument pairs. The task thus share some of the nature of language modelling; however, it is a task less amenable to approaches that require very large training corpora and one where the semantic quality of a model is of greater importance.

This paper takes up tools ("topic models") that have been proven successful in modelling document-word co-occurrences and adapts them to the task of selectional preference learning. Advantages of these models include a well-defined generative model that handles sparse data well, the ability to jointly induce semantic classes and predicate-specific distributions over those classes, and the enhanced statistical strength achieved by sharing knowledge across predicates. Section 2 surveys prior work on selectional preference modelling and on semantic applications of topic models. Section 3 describes the models used in our experiments. Section 4 provides details of the experimental design. Section 5 presents results for our models on the task of predicting human plausibility judgements for predicate-argument combinations; we show that performance is generally competi-

[1] At time of writing, Google estimates 855 hits for "*a|the carrot|carrots laugh|laughs|laughed*" and 0 hits for "*a|the manservant|manservants|menservants laugh|laughs|laughed*"; many of the *carrot* hits are false positives but a significant number are true subject-verb observations.

tive with or superior to a number of other models, including models using Web-scale resources, especially for low-frequency examples. In Section 6 we wrap up by summarising the paper's conclusions and sketching directions for future research.

2 Related work

2.1 Selectional preference learning

The representation (and latterly, learning) of selectional preferences for verbs and other predicates has long been considered a fundamental problem in computational semantics (Resnik, 1993). Many approaches to the problem use lexical taxonomies such as WordNet to identify the semantic classes that typically fill a particular argument slot for a predicate (Resnik, 1993; Clark and Weir, 2002; Schulte im Walde et al., 2008). In this paper, however, we focus on methods that do not assume the availability of a comprehensive taxonomy but rather induce semantic classes automatically from a corpus of text. Such methods are more generally applicable, for example in domains or languages where handbuilt semantic lexicons have insufficient coverage or are non-existent.

Rooth et al. (1999) introduced a model of selectional preference induction that casts the problem in a probabilistic latent-variable framework. In Rooth et al.'s model each observed predicate-argument pair is probabilistically generated from a latent variable, which is itself generated from an underlying distribution on variables. The use of latent variables, which correspond to coherent clusters of predicate-argument interactions, allow probabilities to be assigned to predicate-argument pairs which have not previously been observed by the model. The discovery of these predicate-argument clusters and the estimation of distributions on latent and observed variables are performed simultaneously via an Expectation Maximisation procedure. The work presented in this paper is inspired by Rooth et al.'s latent variable approach, most directly in the model described in Section 3.3. Erk (2007) and Padó et al. (2007) describe a corpus-driven smoothing model which is not probabilistic in nature but relies on similarity estimates from a "semantic space" model that identifies semantic similarity with closeness in a vector space of co-occurrences. Bergsma et al. (2008) suggest learning selectional preferences in a discriminative way, by training a collection of SVM classifiers to recognise likely and unlikely arguments for predicates of interest.

Keller and Lapata (2003) suggest a simple alternative to smoothing-based approaches. They demonstrate that noisy counts from a Web search engine can yield estimates of plausibility for predicate-argument pairs that are superior to models learned from a smaller parsed corpus. The assumption inherent in this approach is that given sufficient text, all plausible predicate-argument pairs will be observed with frequency roughly correlated with their degree of plausibility. While the model is undeniably straightforward and powerful, it has a number of drawbacks: it presupposes an extremely large corpus, the like of which will only be available for a small number of domains and languages, and it is only suitable for relations that are identifiable by searching raw text for specific lexical patterns.

2.2 Topic modelling

The task of inducing coherent semantic clusters is common to many research areas. In the field of document modelling, a class of methods known as "topic models" have become a de facto standard for identifying semantic structure in documents. These include the Latent Dirichlet Allocation (LDA) model of Blei et al. (2003) and the Hierarchical Dirichlet Process model of Teh et al. (2006). Formally seen, these are hierarchical Bayesian models which induce a set of latent variables or topics that are shared across documents. The combination of a well-defined probabilistic model and Gibbs sampling procedure for estimation guarantee (eventual) convergence and the avoidance of degenerate solutions. As a result of intensive research in recent years, the behaviour of topic models is well-understood and computationally efficient implementations have been developed. The tools provided by this research are used in this paper as the building blocks of our selectional preference models.

Hierarchical Bayesian modelling has recently gained notable popularity in many core areas of natural language processing, from morphological segmentation (Goldwater et al., 2009) to opinion modelling (Lin et al., 2006). Yet so far there have been relatively few applications to traditional lexical semantic tasks. Boyd-Graber et al. (2007) integrate a model of random walks on the WordNet graph into an LDA topic model to build an unsupervised word sense disambiguation system. Brody

and Lapata (2009) adapt the basic LDA model for application to unsupervised word sense induction; in this context, the topics learned by the model are assumed to correspond to distinct senses of a particular lemma. Zhang et al. (2009) are also concerned with inducing multiple senses for a particular term; here the goal is to identify distinct entity types in the output of a pattern-based entity set discovery system. Reisinger and Paşca (2009) use LDA-like models to map automatically acquired attribute sets onto the WordNet hierarchy. Griffiths et al. (2007) demonstrate that topic models learned from document-word co-occurrences are good predictors of semantic association judgements by humans.

Simultaneously to this work, Ritter et al. (2010) have also investigated the use of topic models for selectional preference learning. Their goal is slightly different to ours in that they wish to model the probability of a binary predicate taking two specified arguments, i.e., $P(n_1, n_2|v)$, whereas we model the joint and conditional probabilities of a predicate taking a single specified argument. The model architecture they propose, LinkLDA, falls somewhere between our LDA and DUAL-LDA models. Hence LinkLDA could be adapted to estimate $P(n, v|r)$ as DUAL-LDA does, but a preliminary investigation indicates that it does not perform well in this context. The most likely explanation is that LinkLDA generates its two arguments independently, which may be suitable for distinct argument positions of a given predicate but is unsuitable when one of those "arguments" is in fact the predicate.

The models developed in this paper, though intended for semantic modelling, also bear some similarity to the internals of generative syntax models such as the "infinite tree" (Finkel et al., 2007). In some ways, our models are less ambitious than comparable syntactic models as they focus on specific fragments of grammatical structure rather than learning a more general representation of sentence syntax. It would be interesting to evaluate whether this restricted focus improves the quality of the learned model or whether general syntax models can also capture fine-grained knowledge about combinatorial semantics.

3 Three selectional preference models

3.1 Notation

In the model descriptions below we assume a predicate vocabulary of V types, an argument vocabulary of N types and a relation vocabulary of R types. Each predicate type is associated with a singe relation; for example the predicate type *eat:V:dobj* (the direct object of the verb *eat*) is treated as distinct from *eat:V:subj* (the subject of the verb *eat*). The training corpus consists of W observations of argument-predicate pairs. Each model has at least one vocabulary of Z arbitrarily labelled latent variables. f_{zn} is the number of observations where the latent variable z has been associated with the argument type n, f_{zv} is the number of observations where z has been associated with the predicate type v and f_{zr} is the number of observations where z has been associated with the relation r. Finally, $f_{z\cdot}$ is the total number of observations associated with z and $f_{\cdot v}$ is the total number of observations containing the predicate v.

3.2 Latent Dirichlet Allocation

As noted above, LDA was originally introduced to model sets of documents in terms of topics, or clusters of terms, that they share in varying proportions. For example, a research paper on bioinformatics may use some vocabulary that is shared with general computer science papers and some vocabulary that is shared with biomedical papers. The analogical move from modelling document-term cooccurrences to modelling predicate-argument cooccurrences is intuitive: we assume that each predicate is associated with a distribution over semantic classes ("topics") and that these classes are shared across predicates. The high-level "generative story" for the LDA selectional preference model is as follows:

(1) For each predicate v, draw a multinomial distribution Θ_v over argument classes from a Dirichlet distribution with parameters α.

(2) For each argument class z, draw a multinomial distribution Φ_z over argument types from a Dirichlet with parameters β.

(3) To generate an argument for v, draw an argument class z from Θ_v and then draw an argument type n from Φ_z

The resulting model can be written as:

$$P(n|v, r) = \sum_z P(n|z)P(z|v, r) \quad (1)$$

$$\propto \sum_z \frac{f_{zn} + \beta}{f_{z\cdot} + N\beta} \frac{f_{zv} + \alpha_z}{f_{\cdot v} + \sum_{z'} \alpha_{z'}} \quad (2)$$

Due to multinomial-Dirichlet conjugacy, the distributions Θ_v and Φ_z can be integrated out and do not appear explicitly in the above formula. The first term in (2) can be seen as a smoothed estimate of the probability that class z produces the argument n; the second is a smoothed estimate of the probability that predicate v takes an argument belonging to class z. One important point is that the smoothing effects of the Dirichlet priors on Θ_v and Φ_z are greatest for predicates and arguments that are rarely seen, reflecting an intuitive lack of certainty. We assume an asymmetric Dirichlet prior on Θ_v (the α parameters can differ for each class) and a symmetric prior on Φ_z (all β parameters are equal); this follows the recommendations of Wallach et al. (2009) for LDA. This model estimates predicate-argument probabilities conditional on a given predicate v; it cannot by itself provide joint probabilities $P(n, v|r)$, which are needed for our plausibility evaluation.

Given a dataset of predicate-argument combinations and values for the hyperparameters α and β, the probability model is determined by the class assignment counts f_{zn} and f_{zv}. Following Griffiths and Steyvers (2004), we estimate the model by Gibbs sampling. This involves resampling the topic assignment for each observation in turn using probabilities estimated from all other observations. One efficiency bottleneck in the basic sampler described by Griffiths and Steyvers is that the entire set of topics must be iterated over for each observation. Yao et al. (2009) propose a reformulation that removes this bottleneck by separating the probability mass $p(z|n, v)$ into a number of buckets, some of which only require iterating over the topics currently assigned to instances of type n, typically far fewer than the total number of topics. It is possible to apply similar reformulations to the models presented in Sections 3.3 and 3.4 below; depending on the model and parameterisation this can reduce the running time dramatically.

Unlike some topic models such as HDP (Teh et al., 2006), LDA is *parametric*: the number of topics Z must be set by the user in advance. However, Wallach et al. (2009) demonstrate that LDA is relatively insensitive to larger-than-necessary choices of Z when the Dirichlet parameters α are optimised as part of model estimation. In our implementation we use the optimisation routines provided as part of the Mallet library, which use an iterative procedure to compute a maximum likelihood estimate of these hyperparameters.[2]

3.3 A Rooth et al.-inspired model

In Rooth et al.'s (1999) selectional preference model, a latent variable is responsible for generating both the predicate and argument types of an observation. The basic LDA model can be extended to capture this kind of predicate-argument interaction; the generative story for the resulting ROOTH-LDA model is as follows:

(1) For each relation r, draw a multinomial distribution Θ_r over interaction classes from a Dirichlet distribution with parameters α.

(2) For each class z, draw a multinomial Φ_z over argument types from a Dirichlet distribution with parameters β and a multinomial Ψ_z over predicate types from a Dirichlet distribution with parameters γ.

(3) To generate an observation for r, draw a class z from Θ_r, then draw an argument type n from Φ_z and a predicate type v from Ψ_z.

The resulting model can be written as:

$$P(n, v|r) = \sum_z P(n|z)P(v|z)P(z|r) \quad (3)$$

$$\propto \sum_z \frac{f_{zn} + \beta}{f_{z\cdot} + N\beta} \frac{f_{zv} + \gamma}{f_{z\cdot} + V\gamma} \frac{f_{zr} + \alpha_z}{f_{\cdot r} + \sum_{z'} \alpha_{z'}} \quad (4)$$

As suggested by the similarity between (4) and (2), the ROOTH-LDA model can be estimated by an LDA-like Gibbs sampling procedure.

Unlike LDA, ROOTH-LDA does model the joint probability $P(n, v|r)$ of a predicate and argument co-occurring. Further differences are that information about predicate-argument co-occurrence is only shared within a given interaction class rather than across the whole dataset and that the distribution Φ_z is not specific to the predicate v but rather to the relation r. This could potentially lead to a loss of model quality, but in practice the ability to induce "tighter" clusters seems to counteract any deterioration this causes.

3.4 A "dual-topic" model

In our third model, we attempt to combine the advantages of LDA and ROOTH-LDA by clustering arguments and predicates according to separate

[2] http://mallet.cs.umass.edu/

class vocabularies. Each observation is generated by two latent variables rather than one, which potentially allows the model to learn more flexible interactions between arguments and predicates.:

(1) For each relation r, draw a multinomial distribution Ξ_r over predicate classes from a Dirichlet with parameters κ.

(2) For each predicate class c, draw a multinomial Ψ_c over predicate types and a multinomial Θ_c over argument classes from Dirichlets with parameters γ and α respectively.

(3) For each argument class z, draw a multinomial distribution Φ_z over argument types from a Dirichlet with parameters β.

(4) To generate an observation for r, draw a predicate class c from Ξ_r, a predicate type from Ψ_c, an argument class z from Θ_c and an argument type from Φ_z.

The resulting model can be written as:

$$P(n,v|r) = \sum_c \sum_z P(n|z)P(z|c)P(v|c)P(c|r) \quad (5)$$

$$\propto \sum_c \sum_z \frac{f_{zn}+\beta}{f_{z\cdot}+N\beta} \frac{f_{zc}+\alpha_z}{f_{\cdot c}+\sum_{z'}\alpha_{z'}} \times \frac{f_{cv}+\gamma}{f_{c\cdot}+V\gamma} \frac{f_{cr}+\kappa_c}{f_{\cdot r}+\sum_{c'}\kappa_{c'}} \quad (6)$$

To estimate this model, we first resample the class assignments for all arguments in the data and then resample class assignments for all predicates. Other approaches are possible – resampling argument and then predicate class assignments for each observation in turn, or sampling argument and predicate assignments together by blocked sampling – though from our experiments it does not seem that the choice of scheme makes a significant difference.

4 Experimental setup

In the document modelling literature, probabilistic topic models are often evaluated on the likelihood they assign to unseen documents; however, it has been shown that higher log likelihood scores do not necessarily correlate with more semantically coherent induced topics (Chang et al., 2009). One popular method for evaluating selectional preference models is by testing the correlation between their predictions and human judgements of plausibility on a dataset of predicate-argument pairs. This can be viewed as a more semantically relevant measurement of model quality than likelihood-based methods, and also permits comparison with non-probabilistic models. In Section 5, we use two plausibility datasets to evaluate our models and compare to other previously published results.

We trained our models on the 90-million word written component of the British National Corpus (Burnard, 1995), parsed with the RASP toolkit (Briscoe et al., 2006). Predicates occurring with just one argument type were removed, as were all tokens containing non-alphabetic characters; no other filtering was done. The resulting datasets consisted of 3,587,172 verb-object observations with 7,954 predicate types and 80,107 argument types, 3,732,470 noun-noun observations with 68,303 predicate types and 105,425 argument types, and 3,843,346 adjective-noun observations with 29,975 predicate types and 62,595 argument types.

During development we used the verb-noun plausibility dataset from Padó et al. (2007) to direct the design of the system. Unless stated otherwise, all results are based on runs of 1,000 iterations with 100 classes, with a 200-iteration burnin period after which hyperparameters were reestimated every 50 iterations.[3] The probabilities estimated by the models ($P(n|v,r)$ for LDA and $P(n,v|r)$ for ROOTH- and DUAL-LDA) were sampled every 50 iterations post-burnin and averaged over three runs to smooth out variance. To compare plausibility scores for different predicates, we require the joint probability $P(n,v|r)$; as LDA does not provide this, we approximate $P_{LDA}(n,v|r) = P_{BNC}(v|r)P_{LDA}(n|v,r)$, where $P_{BNC}(v|r)$ is proportional to the frequency with which predicate v is observed as an instance of relation r in the BNC.

For comparison, we reimplemented the methods of Rooth et al. (1999) and Padó et al. (2007). As mentioned above, Rooth et al. use a latent-variable model similar to (4) but without priors, trained via EM. Our implementation (henceforth ROOTH-EM) chooses the number of classes from the range $(20, 25, \ldots, 50)$ through 5-fold cross-validation on a held-out log-likelihood measure. Settings outside this range did not give good results. Again, we run for 1,000 iterations and average predictions over

[3] These settings were based on the MALLET defaults; we have not yet investigated whether modifying the simulation length or burnin period is beneficial.

three runs. Padó et al. (2007), a refinement of Erk (2007), is a non-probabilistic method that smooths predicate-argument counts with counts for other observed arguments of the same predicate, weighted by the similarity between arguments. Following their description, we use a 2,000-dimensional space of syntactic co-occurrence features appropriate to the relation being predicted, weight features with the G^2 transformation and compute similarity with the cosine measure.

5 Results

5.1 Induced semantic classes

Table 1 shows sample semantic classes induced by models trained on the corpus of BNC verb-object co-occurrences. LDA clusters nouns only, while ROOTH-LDA and ROOTH-EM learn classes that generate both nouns and verbs and DUAL-LDA clusters nouns and verbs separately. The LDA clusters are generally sensible: class 0 is exemplified by *agreement* and *contract* and class 1 by *information* and *datum*. There are some unintuitive blips, for example *country* appears between *knowledge* and *understanding* in class 2. The ROOTH-LDA classes also feel right: class 0 deals with nouns such as *force*, *team* and *army* which one might *join*, *arm* or *lead* and class 1 corresponds to "things that can be opened or closed" such as a *door*, an *eye* or a *mouth* (though the model also makes the questionable prediction that all these items can plausibly be locked or slammed). The DUAL-LDA classes are notably less coherent, especially when it comes to clustering verbs: DUAL-LDA's class 0V, like ROOTH-LDA's class 0, has verbs that take groups as objects but its class 1V mixes sensible conflations (*turn*, *round*) with very common verbs such as *see* and *have* and the unrelated *break*. The general impression given by inspection of the DUAL-LDA model is that it has problems with mixing and does not manage to learn a good model; we have tried a number of solutions (e.g., blocked sampling of argument and predicate classes), without overcoming this brittleness. Unsurprisingly, ROOTH-EM's classes have a similar feel to ROOTH-LDA; our general impression is that some of ROOTH-EM's classes look even more coherent than the LDA-based models, presumably because it does not use priors to smooth its per-class distributions.

5.2 Comparison with Keller and Lapata (2003)

Keller and Lapata (2003) collected a dataset of human plausibility judgements for three classes of grammatical relation: verb-object, noun-noun modification and adjective-noun modification. The items in this dataset were not chosen to balance plausibility and implausibility (as in prior psycholinguistic experiments) but according to their corpus frequency, leading to a more realistic task. 30 predicates were selected for each relation; each predicate was matched with three arguments from different co-occurrence bands in the BNC, e.g., *naughty-girl* (high frequency), *naughty-dog* (medium) and *naughty-lunch* (low). Each predicate was also matched with three random arguments

Table 2: Results (Pearson r and Spearman ρ correlations) on Keller and Lapata's (2003) plausibility data

with which it does not co-occur in the BNC (e.g., *naughty-regime, naughty-rival, naughty-protocol*). In this way two datasets (*Seen* and *Unseen*) of 90 items each were assembled for each predicate.

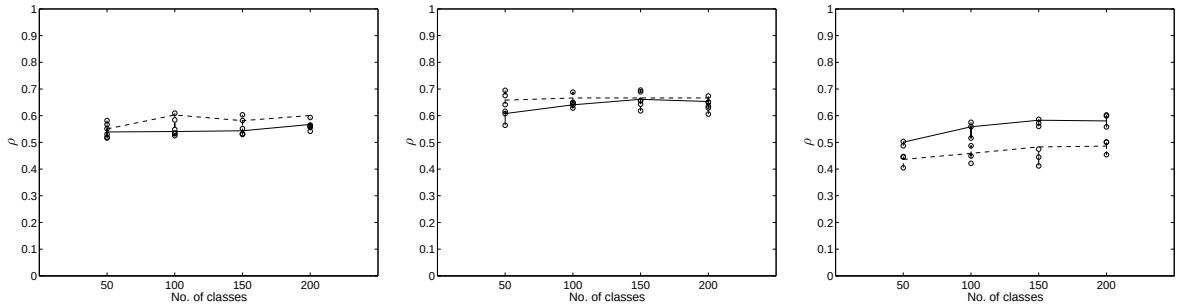
Table 2 presents results for a variety of predictive models – the Web frequencies reported by Keller and Lapata (2003) for two search engines, frequencies from the RASP-parsed BNC,[4] the reimplemented methods of Rooth et al. (1999) and Padó et al. (2007), and the LDA, ROOTH-LDA and DUAL-LDA topic models. Following Keller and Lapata, we report Pearson correlation coefficients between log-transformed predicted frequencies and the gold-standard plausibility scores (which are already log-transformed). We also report Spearman rank correlations except where we do not have the original predictions (the Web count models), for completeness and because the predictions of preference models are may not be log-normally distributed as corpus counts are. Zero values (found only in the BNC frequency predictions) were smoothed by 0.1 to facilitate the log transformation; it seems natural to take a zero prediction as a non-specific prediction of very low plausibility rather than a "missing value" as is done in other work (e.g., Padó et al., 2007).

Despite their structural differences, LDA and ROOTH-LDA perform similarly - indeed, their predictions are highly correlated. ROOTH-LDA scores best overall, outperforming Padó et al.'s (2007) method and ROOTH-EM on every dataset and evaluation measure, and outperforming Keller and Lapata's (2003) Web predictions on every Unseen dataset. LDA also performs consistently well, surpassing ROOTH-EM and Padó et al. on all but one occasion. For frequent predicate-argument pairs (Seen datasets), Web counts are clearly better; however, the BNC counts are unambiguously superior to LDA and ROOTH-LDA (whose predictions are based entirely on the generative model even for observed items) for the Seen verb-object data only. As might be suspected from the mixing problems observed with DUAL-LDA, this model does not perform as well as LDA and ROOTH-LDA, though it does hold its own against the other selectional preference methods.

To identify significant differences between models, we use the statistical test for correlated correlation coefficients proposed by Meng et al. (1992), which is appropriate for correlations that share the same gold standard.[5] For the seen data there are few significant differences: ROOTH-LDA and LDA are significantly better ($p < 0.01$) than Padó et al.'s model for Pearson's r on seen noun-noun data, and ROOTH-LDA is also significantly better ($p < 0.01$) using Spearman's ρ. For the unseen datasets, the BNC frequency predictions are unsurprisingly significantly worse at the $p < 0.01$ level than all smoothing models. LDA and ROOTH-LDA are significantly better ($p < 0.01$) than Padó et al. on every unseen dataset; ROOTH-EM is significantly better ($p < 0.01$) than Padó et al. on Unseen adjectives for both correlations. Meng et al.'s test does not find significant differences between ROOTH-EM and the LDA models despite the latter's clear advantages (a number of conditions do come close). This is because their predictions are highly correlated, which is perhaps

[4]The correlations presented here for BNC counts are notably better than those reported by Keller and Lapata (2003), presumably reflecting our use of full parsing rather than shallow parsing.

[5]We cannot compare our data to Keller and Lapata's Web counts as we do not possess their per-item scores.



(a) Verb-object (b) Noun-noun (c) Adjective-noun

Figure 1: Effect of number of argument classes on Spearman rank correlation with LDA: the solid and dotted lines show the Seen and Unseen datasets respectively; bars show locations of individual samples

unsurprising given that they are structurally similar models trained on the same data. We hypothesise that the main reason for the superior numerical performance of the LDA models over EM is the principled smoothing provided by the use of Dirichlet priors, which has a small but discriminative effect on model predictions. Collating the significance scores, we find that ROOTH-LDA achieves the most positive outcomes, followed by LDA and then by ROOTH-EM. DUAL-LDA is found significantly better than Padó et al.'s model on unseen adjective-noun combinations, and significantly worse than the same model on seen adjective-noun data.

Latent variable models that use EM for inference can be very sensitive to the number of latent variables chosen. For example, the performance of ROOTH-EM worsens quickly if the number of clusters is overestimated; for the Keller and Lapata datasets, settings above 50 classes lead to clear overfitting and a precipitous drop in Pearson correlation scores. On the other hand, Wallach et al. (2009) demonstrate that LDA is relatively insensitive to the choice of topic vocabulary size Z when the α and β hyperparameters are optimised appropriately during estimation. Figure 1 plots the effect of Z on Spearman correlation for the LDA model. In general, Wallach et al.'s finding for document modelling transfers to selectional preference models; within the range $Z = 50$–200 performance remains at a roughly similar level. In fact, we do not find that performance becomes significantly less robust when hyperparameter reestimation is deactiviated; correlation scores simply drop by a small amount (1–2 points), irrespective of the Z chosen. ROOTH-LDA (not graphed) seems slightly more sensitive to Z; this may be because the α parameters in this model operate on the relation level rather than the document level and thus fewer "observations" of class distributions are available when reestimating them.

5.3 Comparison with Bergsma et al. (2008)

As mentioned in Section 2.1, Bergsma et al. (2008) propose a discriminative approach to preference learning. As part of their evaluation, they compare their approach to a number of others, including that of Erk (2007), on a plausibility dataset collected by Holmes et al. (1989). This dataset consists of 16 verbs, each paired with one plausible object (e.g., *write-letter*) and one implausible object (*write-market*). Bergsma et al.'s model, trained on the 3GB AQUAINT corpus, is the only model reported to achieve perfect accuracy on distinguishing plausible from implausible arguments. It would be interesting to do a full comparison that controls for size and type of corpus data; in the meantime, we can report that the LDA and ROOTH-LDA models trained on verb-object observations in the BNC (about 4 times smaller than AQUAINT) also achieve a perfect score on the Holmes et al. data.[6]

6 Conclusions and future work

This paper has demonstrated how Bayesian techniques originally developed for modelling the topical structure of documents can be adapted to learn probabilistic models of selectional preference. These models are especially effective for estimating plausibility of low-frequency items, thus distinguishing rarity from clear implausibility.

The models presented here derive their predictions by modelling predicate-argument plausibility through the intermediary of latent variables. As observed in Section 5.2 this may be a suboptimal

[6] Bergsma et al. report that all plausible pairs were seen in their corpus; three were unseen in ours, as well as 12 of the implausible pairs.

strategy for frequent combinations, where corpus counts are probably reliable and plausibility judgements may be affected by lexical collocation effects. One principled method for folding corpus counts into LDA-like models would be to use hierarchical priors, as in the n-gram topic model of Wallach (2006). Another potential direction for system improvement would be an integration of our generative model with Bergsma et al.'s (2008) discriminative model – this could be done in a number of ways, including using the induced classes of a topic model as features for a discriminative classifier or using the discriminative classifier to produce additional high-quality training data from noisy unparsed text.

Comparison to plausibility judgements gives an intrinsic measure of model quality. As mentioned in the Introduction, selectional preferences have many uses in NLP applications, and it will be interesting to evaluate the utility of Bayesian preference models in contexts such as semantic role labelling or human sentence processing modelling. The probabilistic nature of topic models, coupled with an appropriate probabilistic task model, may facilitate the integration of class induction and task learning in a tight and principled way. We also anticipate that latent variable models will prove effective for learning selectional preferences of semantic predicates (e.g., FrameNet roles) where direct estimation from a large corpus is not a viable option.

Improving the Use of Pseudo-Words for Evaluating Selectional Preferences

Nathanael Chambers and Dan Jurafsky

Stanford University
{natec,jurafsky}@stanford.edu

Abstract

This paper improves the use of pseudo-words as an evaluation framework for selectional preferences. While pseudo-words originally evaluated word sense disambiguation, they are now commonly used to evaluate selectional preferences. A selectional preference model ranks a set of possible arguments for a verb by their semantic fit to the verb. Pseudo-words serve as a proxy evaluation for these decisions. The evaluation takes an argument of a verb like *drive* (e.g. *car*), pairs it with an alternative word (e.g. *car/rock*), and asks a model to identify the original. This paper studies two main aspects of pseudo-word creation that affect performance results. (1) Pseudo-word evaluations often evaluate only a subset of the words. We show that selectional preferences should instead be evaluated on the data in its entirety. (2) Different approaches to selecting partner words can produce overly optimistic evaluations. We offer suggestions to address these factors and present a simple baseline that outperforms the state-of-the-art by 13% absolute on a newspaper domain.

1 Introduction

For many natural language processing (NLP) tasks, particularly those involving meaning, creating labeled test data is difficult or expensive. One way to mitigate this problem is with pseudo-words, a method for automatically creating test corpora without human labeling, originally proposed for word sense disambiguation (Gale et al., 1992; Schutze, 1992). While pseudo-words are now less often used for word sense disambigation, they are a common way to evaluate *selectional preferences*, models that measure the strength of association between a predicate and its argument filler, e.g., that the noun *lunch* is a likely object of *eat*. Selectional preferences are useful for NLP tasks such as parsing and semantic role labeling (Zapirain et al., 2009). Since evaluating them in isolation is difficult without labeled data, pseudo-word evaluations can be an attractive evaluation framework.

Pseudo-word evaluations are currently used to evaluate a variety of language modeling tasks (Erk, 2007; Bergsma et al., 2008). However, *evaluation design varies across research groups*. This paper studies the evaluation itself, showing how choices can lead to overly optimistic results if the evaluation is not designed carefully. We show in this paper that current methods of applying pseudo-words to selectional preferences vary greatly, and suggest improvements.

A pseudo-word is the concatenation of two words (e.g. *house/car*). One word is the original in a document, and the second is the *confounder*. Consider the following example of applying pseudo-words to the selectional restrictions of the verb *focus*:

***Original**: This story focuses on the campaign.*
***Test**: This story/part focuses on the campaign/meeting.*

In the original sentence, *focus* has two arguments: a subject *story* and an object *campaign*. In the test sentence, each argument of the verb is replaced by pseudo-words. A model is evaluated by its success at determining which of the two arguments is the original word.

Two problems exist in the current use of

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 445–453,
Uppsala, Sweden, 11-16 July 2010.

pseudo-words to evaluate selectional preferences. First, selectional preferences historically focus on subsets of data such as *unseen* words or words in certain frequency ranges. While work on unseen data is important, evaluating on the entire dataset provides an accurate picture of a model's overall performance. Most other NLP tasks today evaluate *all* test examples in a corpus. We will show that *seen* arguments actually dominate newspaper articles, and thus propose creating test sets that include all verb-argument examples to avoid artificial evaluations.

Second, pseudo-word evaluations vary in how they choose confounders. Previous work has attempted to maintain a similar corpus frequency to the original, but it is not clear how best to do this, nor how it affects the task's difficulty. We argue in favor of using nearest-neighbor frequencies and show how using random confounders produces overly optimistic results.

Finally, we present a surprisingly simple baseline that outperforms the state-of-the-art and is far less memory and computationally intensive. It outperforms current similarity-based approaches by over 13% when the test set includes all of the data. We conclude with a suggested backoff model based on this baseline.

2 History of Pseudo-Word Disambiguation

Pseudo-words were introduced simultaneously by two papers studying statistical approaches to word sense disambiguation (WSD). Schütze (1992) simply called the words, 'artificial ambiguous words', but Gale et al. (1992) proposed the succinct name, *pseudo-word*. Both papers cited the sparsity and difficulty of creating large labeled datasets as the motivation behind pseudo-words. Gale et al. selected unambiguous words from the corpus and paired them with random words from different thesaurus categories. Schütze paired his words with confounders that were 'comparable in frequency' and 'distinct semantically'. Gale et al.'s pseudo-word term continues today, as does Schütze's frequency approach to selecting the confounder.

Pereira et al. (1993) soon followed with a selectional preference proposal that focused on a language model's effectiveness on *unseen* data. The work studied clustering approaches to assist in similarity decisions, predicting which of two verbs was the correct predicate for a given noun object. One verb v was the original from the source document, and the other v' was randomly generated. This was the first use of such verb-noun pairs, as well as the first to test only on *unseen* pairs.

Several papers followed with differing methods of choosing a test pair (v, n) and its confounder v'. Dagan et al. (1999) tested all *unseen* (v, n) occurrences of the most frequent 1000 verbs in his corpus. They then sorted verbs by corpus frequency and chose the neighboring verb v' of v as the confounder to ensure the closest frequency match possible. Rooth et al. (1999) tested 3000 random (v, n) pairs, but required the verbs and nouns to appear between 30 and 3000 times in training. They also chose confounders randomly so that the new pair was *unseen*.

Keller and Lapata (2003) specifically addressed the impact of *unseen* data by using the web to first 'see' the data. They evaluated unseen pseudo-words by attempting to first observe them in a larger corpus (the Web). One modeling difference was to disambiguate the nouns as selectional preferences instead of the verbs. Given a test pair (v, n) and its confounder (v, n'), they used web searches such as "v Det n" to make the decision. Results beat or matched current results at the time. We present a similarly motivated, but new web-based approach later.

Very recent work with pseudo-words (Erk, 2007; Bergsma et al., 2008) further blurs the lines between what is included in training and test data, using frequency-based and semantic-based reasons for deciding what is included. We discuss this further in section 5.

As can be seen, there are two main factors when devising a pseudo-word evaluation for selectional preferences: (1) choosing (v, n) pairs from the test set, and (2) choosing the confounding n' (or v'). The confounder has not been looked at in detail and as best we can tell, these factors have varied significantly. Many times the choices are well motivated based on the paper's goals, but in other cases the motivation is unclear.

3 How Frequent is Unseen Data?

Most NLP tasks evaluate their entire datasets, but as described above, most selectional preference evaluations have focused only on unseen data. This section investigates the extent of unseen examples in a typical training/testing environment

of newspaper articles. The results show that even with a small training size, seen examples dominate the data. We argue that, absent a system's need for specialized performance on unseen data, a representative test set should include the dataset in its entirety.

3.1 Unseen Data Experiment

We use the New York Times (NYT) and Associated Press (APW) sections of the Gigaword Corpus (Graff, 2002), as well as the British National Corpus (BNC) (Burnard, 1995) for our analysis. Parsing and SRL evaluations often focus on newspaper articles and Gigaword is large enough to facilitate analysis over varying amounts of training data. We parsed the data with the Stanford Parser[1] into dependency graphs. Let (v_d, n) be a verb v with grammatical dependency $d \in \{subject, object, prep\}$ filled by noun n. Pairs (v_d, n) are chosen by extracting every such dependency in the graphs, setting the head predicate as v and the head word of the dependent d as n. All prepositions are condensed into *prep*.

We randomly selected documents from the year 2001 in the NYT portion of the corpus as development and test sets. Training data for APW and NYT include all years 1994-2006 (minus NYT development and test documents). We also identified and removed duplicate documents[2]. The BNC in its entirety is also used for training as a single data point. We then record every seen (v_d, n) pair during training that is seen two or more times[3] and then count the number of unseen pairs in the NYT development set (1455 tests).

Figure 1 plots the percentage of unseen arguments against training size when trained on either NYT or APW (the APW portion is smaller in total size, and the smaller BNC is provided for comparison). The first point on each line (the highest points) contains approximately the same number of words as the BNC (100 million). Initially, about one third of the arguments are unseen, but that percentage quickly falls close to 10% as additional training is included. This suggests that an evaluation focusing only on unseen data is not representative, potentially missing up to 90% of the data.

[1] http://nlp.stanford.edu/software/lex-parser.shtml

[2] Any two documents whose first two paragraphs in the corpus files are identical.

[3] Our results are thus conservative, as including all single occurrences would achieve even smaller unseen percentages.

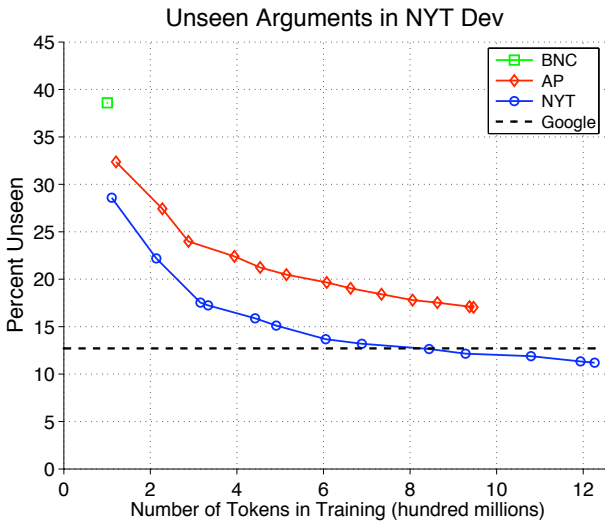

Figure 1: Percentage of NYT development set that is unseen when trained on varying amounts of data. The two lines represent training with NYT or APW data. The APW set is smaller in size from the NYT. The dotted line uses Google n-grams as training. The x-axis represents tokens $\times 10^8$.

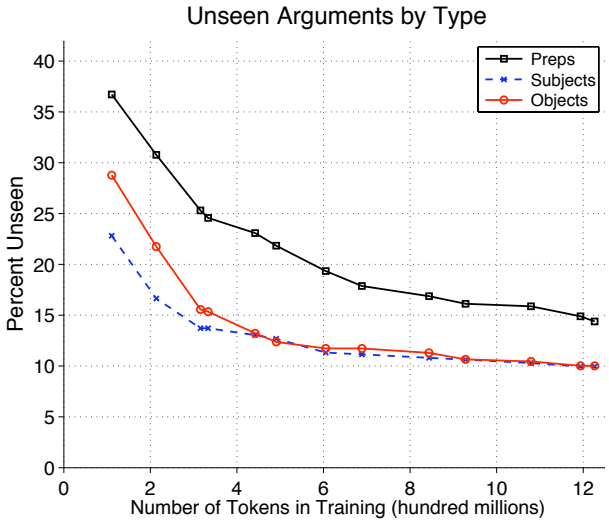

Figure 2: Percentage of subject/object/preposition arguments in the NYT development set that is unseen when trained on varying amounts of NYT data. The x-axis represents tokens $\times 10^8$.

The third line across the bottom of the figure is the number of unseen pairs using Google n-gram data as proxy argument counts. Creating argument counts from n-gram counts is described in detail below in section 5.2. We include these Web counts to illustrate how an openly available source of counts affects unseen arguments. Finally, figure 2 compares which dependency types are seen the least in training. Prepositions have the largest unseen percentage, but not surprisingly, also make up less of the training examples overall.

In order to analyze why pairs are unseen, we analyzed the distribution of *rare* words across unseen and seen examples. To define rare nouns, we order head words by their individual corpus frequencies. A noun is *rare* if it occurs in the lowest 10% of the list. We similarly define *rare verbs* over their ordered frequencies (we count verb lemmas, and do not include the syntactic relations). Corpus counts covered 2 years of the AP section, and we used the development set of the NYT section to extract the seen and unseen pairs. Figure 3 shows the percentage of rare nouns and verbs that occur in unseen and seen pairs. 24.6% of the verbs in unseen pairs are rare, compared to only 4.5% in seen pairs. The distribution of rare nouns is less contrastive: 13.3% vs 8.9%. This suggests that many unseen pairs are unseen mainly because they contain low-frequency verbs, rather than because of containing low-frequency argument heads.

Given the large amount of seen data, we believe evaluations should include all data examples to best represent the corpus. We describe our full evaluation results and include a comparison of different training sizes below.

4 How to Select a Confounder

Given a test set S of pairs $(v_d, n) \in S$, we now address how best to select a confounder n'. Work in WSD has shown that confounder choice can make the pseudo-disambiguation task significantly easier. Gaustad (2001) showed that human-generated pseudo-words are more difficult to classify than random choices. Nakov and Hearst (2003) further illustrated how random confounders are easier to identify than those selected from semantically ambiguous, yet related concepts. Our approach evaluates selectional preferences, not WSD, but our results complement these findings.

We identified three methods of confounder selection based on varying levels of corpus frequency: (1) choose a *random* noun, (2) choose a random noun from a *frequency bucket* similar to the original noun's frequency, and (3) select the *nearest neighbor*, the noun with frequency closest to the original. These methods evaluate the range of choices used in previous work. Our experiments compare the three.

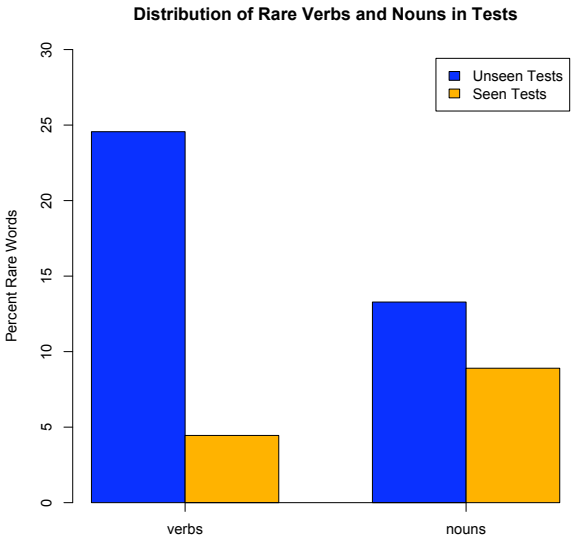

Figure 3: Comparison between seen and unseen tests (verb,relation,noun). 24.6% of unseen tests have rare verbs, compared to just 4.5% in seen tests. The rare nouns are more evenly distributed across the tests.

5 Models

5.1 A New Baseline

The analysis of unseen slots suggests a baseline that is surprisingly obvious, yet to our knowledge, has not yet been evaluated. Part of the reason is that early work in pseudo-word disambiguation explicitly tested only unseen pairs[4]. Our evaluation will include seen data, and since our analysis suggests that up to 90% is seen, a strong baseline should address this seen portion.

[4]Recent work does include some seen data. Bergsma et al. (2008) test pairs that fall below a mutual information threshold (might include some seen pairs), and Erk (2007) selects a subset of roles in FrameNet (Baker et al., 1998) to test and uses all labeled instances within this subset (unclear what portion of subset of data is seen). Neither evaluates all of the seen data, however.

We propose a conditional probability baseline:

$$P(n|v_d) = \begin{cases} \frac{C(v_d,n)}{C(v_d,*)} & \text{if } C(v_d,n) > 0 \\ 0 & \text{otherwise} \end{cases}$$

where $C(v_d, n)$ is the number of times the head word n was seen as an argument to the predicate v, and $C(v_d, *)$ is the number of times v_d was seen with any argument. Given a test (v_d, n) and its confounder (v_d, n'), choose n if $P(n|v_d) > P(n'|v_d)$, and n' otherwise. If $P(n|v_d) = P(n'|v_d)$, randomly choose one.

Lapata et al. (1999) showed that corpus frequency and conditional probability correlate with human decisions of adjective-noun plausibility, and Dagan et al. (1999) appear to propose a very similar baseline for verb-noun selectional preferences, but the paper evaluates *unseen* data, and so the conditional probability model is not studied.

We later analyze this baseline against a more complicated smoothing approach.

5.2 A Web Baseline

If conditional probability is a reasonable baseline, better performance may just require more data. Keller and Lapata (2003) proposed using the web for this task, querying for specific phrases like 'Verb Det N' to find syntactic objects. Such a web corpus would be attractive, but we'd like to find subjects and prepositional objects as well as objects, and also ideally we don't want to limit ourselves to patterns. Since parsing the web is unrealistic, a reasonable compromise is to make rough counts when pairs of words occur in close proximity to each other.

Using the Google n-gram corpus, we recorded all verb-noun co-occurrences, defined by appearing in any order in the same n-gram, up to and including 5-grams. For instance, the test pair $(throw_{subject}, ball)$ is considered *seen* if there exists an n-gram such that *throw* and *ball* are both included. We count all such occurrences for all verb-noun pairs. We also avoided over-counting co-occurrences in lower order n-grams that appear again in 4 or 5-grams. This crude method of counting has obvious drawbacks. Subjects are not distinguished from objects and nouns may not be actual arguments of the verb. However, it is a simple baseline to implement with these freely available counts.

Thus, we use conditional probability as defined in the previous section, but define the count $C(v_d, n)$ as the number of times v and n (ignoring d) appear in the same n-gram.

5.3 Smoothing Model

We implemented the current state-of-the-art smoothing model of Erk (2007). The model is based on the idea that the arguments of a particular verb slot tend to be similar to each other. Given two potential arguments for a verb, the correct one should correlate higher with the arguments observed with the verb during training.

Formally, given a verb v and a grammatical dependency d, the score for a noun n is defined:

$$S_{v_d}(n) = \sum_{w \in Seen(v_d)} sim(n,w) * C(v_d, w) \quad (1)$$

where $sim(n, w)$ is a noun-noun similarity score, $Seen(v_d)$ is the set of seen head words filling the slot v_d during training, and $C(v_d, n)$ is the number of times the noun n was seen filling the slot v_d The similarity score $sim(n, w)$ can thus be one of many vector-based similarity metrics[5]. We evaluate both Jaccard and Cosine similarity scores in this paper, but the difference between the two is small.

6 Experiments

Our training data is the NYT section of the Gigaword Corpus, parsed into dependency graphs. We extract all (v_d, n) pairs from the graph, as described in section 3. We randomly chose 9 documents from the year 2001 for a development set, and 41 documents for testing. The test set consisted of 6767 (v_d, n) pairs. All verbs and nouns are stemmed, and the development and test documents were isolated from training.

6.1 Varying Training Size

We repeated the experiments with three different training sizes to analyze the effect data size has on performance:

- **Train x1**: Year 2001 of the NYT portion of the Gigaword Corpus. After removing duplicate documents, it contains approximately 110 million tokens, comparable to the 100 million tokens in the BNC corpus.

[5] A similar type of smoothing was proposed in earlier work by Dagan et al. (1999). A noun is represented by a vector of verb slots and the number of times it is observed filling each slot.

- **Train x2**: Years 2001 and 2002 of the NYT portion of the Gigaword Corpus, containing approximately 225 million tokens.
- **Train x10**: The entire NYT portion of Gigaword (approximately 1.2 billion tokens). It is an order of magnitude larger than *Train x1*.

6.2 Varying the Confounder

We generated three different confounder sets based on word corpus frequency from the 41 test documents. Frequency was determined by counting all tokens with noun POS tags. As motivated in section 4, we use the following approaches:

- **Random**: choose a random confounder from the set of nouns that fall within some broad corpus frequency range. We set our range to eliminate (approximately) the top 100 most frequent nouns, but otherwise arbitrarily set the lower range as previous work seems to do. The final range was $[30, 400000]$.
- **Buckets**: all nouns are bucketed based on their corpus frequencies[6]. Given a test pair (v_d, n), choose the bucket in which n belongs and randomly select a confounder n' from that bucket.
- **Neighbor**: sort all seen nouns by frequency and choose the confounder n' that is the nearest neighbor of n with greater frequency.

6.3 Model Implementation

None of the models can make a decision if they identically score both potential arguments (most often true when both arguments were not seen with the verb in training). As a result, we extend all models to randomly guess (50% performance) on pairs they cannot answer.

The conditional probability is reported as **Baseline**. For the web baseline (reported as **Google**), we stemmed all words in the Google n-grams and counted every verb v and noun n that appear in Gigaword. Given two nouns, the noun with the higher co-occurrence count with the verb is chosen. As with the other models, if the two nouns have the same counts, it randomly guesses.

The smoothing model is named **Erk** in the results with both Jaccard and Cosine as the similarity metric. Due to the large vector representations of the nouns, it is computationally wise to trim their vectors, but also important to do so for best performance. A noun's representative vector consists of verb slots and the number of times the noun was seen in each slot. We removed any verb slot not seen more than x times, where x varied based on all three factors: the dataset, confounder choice, and similarity metric. We optimized x on the development data with a linear search, and used that cutoff on each test. Finally, we trimmed any vectors over 2000 in size to reduce the computational complexity. Removing this strict cutoff appears to have little effect on the results.

Finally, we report backoff scores for Google and Erk. These consist of always choosing the Baseline if it returns an answer (not a guessed unseen answer), and then backing off to the Google/Erk result for Baseline unknowns. These are labeled **Backoff Google** and **Backoff Erk**.

7 Results

Results are given for the two dimensions: *confounder choice* and *training size*. Statistical significance tests were calculated using the approximate randomization test (Yeh, 2000) with 1000 iterations.

Figure 4 shows the performance change over the different confounder methods. *Train x2* was used for training. Each model follows the same progression: it performs extremely well on the random test set, worse on buckets, and the lowest on the nearest neighbor. The conditional probability **Baseline** falls from 91.5 to 79.5, a 12% absolute drop from completely random to neighboring frequency. The **Erk** smoothing model falls 27% from 93.9 to 68.1. The **Google** model generally performs the worst on all sets, but its 74.3% performance with random confounders is significantly better than a 50-50 random choice. This is notable since the Google model only requires n-gram counts to implement. The **Backoff Erk** model is the best, using the **Baseline** for the majority of decisions and backing off to the Erk smoothing model when the Baseline cannot answer.

Figure 5 (shown on the next page) varies the training size. We show results for both Bucket Frequencies and Neighbor Frequencies. The only difference between columns is the amount of training data. As expected, the Baseline improves as the training size is increased. The Erk model, somewhat surprisingly, shows no continual gain with more training data. The Jaccard and Cosine simi-

[6] We used frequency buckets of 4, 10, 25, 200, 1000, >1000. Adding more buckets moves the evaluation closer to *Neighbor*, less is closer to *Random*.

Varying the Confounder Frequency

	Random	Buckets	Neighbor
Baseline	**91.5**	89.1	79.5
Erk-Jaccard	**93.9***	82.7*	68.1*
Erk-Cosine	**91.2**	81.8*	65.3*
Google	**74.3***	70.4*	59.4*
Backoff Erk	**96.6***	91.8*	80.8*
Backoff Goog	**92.7†**	89.7	79.8

Figure 4: Trained on two years of NYT data (Train x2). Accuracy of the models on the same NYT test documents, but with three different ways of choosing the confounders. * indicates statistical significance with the column's Baseline at the $p < 0.01$ level, † at $p < 0.05$. Random is overly optimistic, reporting performance far above more conservative (selective) confounder choices.

Baseline Details

	Train	Train x2	Train x10
Precision	96.1	95.5*	95.0†
Accuracy	78.2	82.0*	88.1*
Accuracy +50%	87.5	89.1*	91.7*

Figure 6: Results from the *buckets* confounder test set. Baseline precision, accuracy (the same as recall), and accuracy when you randomly guess the tests that Baseline does not answer. All numbers are statistically significant * with p-value < 0.01 from the number to their left.

larity scores perform similarly in their model. The Baseline achieves the highest accuracies (91.7% and 81.2%) with *Train x10*, outperforming the best Erk model by 5.2% and 13.1% absolute on buckets and nearest neighbor respectively. The backoff models improve the baseline by just under 1%. The Google n-gram backoff model is almost as good as backing off to the Erk smoothing model.

Finally, figure 6 shows the Baseline's precision and overall accuracy. Accuracy is the same as recall when the model does not guess between pseudo words that have the same conditional probabilities. *Accuracy +50%* (the full Baseline in all other figures) shows the gain from randomly choosing one of the two words when uncertain. Precision is extremely high.

8 Discussion

Confounder Choice: Performance is strongly influenced by the method used when choosing confounders. This is consistent with findings for WSD that corpus frequency choices alter the task (Gaustad, 2001; Nakov and Hearst, 2003). Our results show the gradation of performance as one moves across the spectrum from completely random to closest in frequency. The Erk model dropped 27%, Google 15%, and our baseline 12%. The overly optimistic performance on random data suggests using the nearest neighbor approach for experiments. Nearest neighbor avoids evaluating on 'easy' datasets, and our baseline (at 79.5%) still provides room for improvement. But perhaps just as important, the nearest neighbor approach facilitates the most reproducibile results in experiments since there is little ambiguity in how the confounder is selected.

Realistic Confounders: Despite its overoptimism, the random approach to confounder selection may be the correct approach in some circumstances. For some tasks that need selectional preferences, random confounders may be more realistic. It's possible, for example, that the options in a PP-attachment task might be distributed more like the random rather than nearest neighbor models. In any case, this is difficult to decide without a specific application in mind. Absent such specific motiviation, a nearest neighbor approach is the most conservative, and has the advantage of creating a reproducible experiment, whereas random choice can vary across design.

Training Size: Training data improves the conditional probability baseline, but does not help the smoothing model. Figure 5 shows a lack of improvement across training sizes for both jaccard and cosine implementations of the Erk model. The *Train x1* size is approximately the same size used in Erk (2007), although on a different corpus. We optimized argument cutoffs for each training size, but the model still appears to suffer from additional noise that the conditional probability baseline does not. This may suggest that observing a test argument with a verb in training is more reliable than a smoothing model that compares all training arguments against that test example.

High Precision Baseline: Our conditional probability baseline is very precise. It outperforms the smoothed similarity based **Erk** model and gives high results across tests. The only combination when Erk is better is when the training data includes just one year (one twelfth of the NYT section) and the confounder is chosen com-

Varying the Training Size

	Bucket Frequency			Neighbor Frequency		
	Train x1	Train x2	Train x10	Train x1	Train x2	Train x10
Baseline	87.5	89.1	**91.7**	78.4	79.5	**81.2**
Erk-Jaccard	86.5*	82.7*	83.1*	66.8*	68.1*	65.5*
Erk-Cosine	82.1*	81.8*	81.1*	66.1*	65.3*	65.7*
Google	-	-	70.4*	-	-	59.4*
Backoff Erk	92.6*	91.8*	92.6*	79.4*	80.8*	**81.7***
Backoff Google	88.6	89.7	91.9†	78.7	79.8	81.2

Figure 5: Accuracy of varying NYT training sizes. The left and right tables represent two confounder choices: choose the confounder with frequency buckets, and choose by nearest frequency neighbor. Trainx1 starts with year 2001 of NYT data, Trainx2 doubles the size, and Trainx10 is 10 times larger. * indicates statistical significance with the column's Baseline at the $p < 0.01$ level, † at $p < 0.05$.

pletely randomly. These results appear consistent with Erk (2007) because that work used the BNC corpus (the same size as one year of our data) and Erk chose confounders randomly within a broad frequency range. Our reported results include every (v_d, n) in the data, not a subset of particular semantic roles. Our reported 93.9% for Erk-Jaccard is also significantly higher than their reported 81.4%, but this could be due to the random choices we made for confounders, or most likely corpus differences between Gigaword and the subset of FrameNet they evaluated.

Ultimately we have found that complex models for selectional preferences may not be necessary, depending on the task. The higher computational needs of smoothing approaches are best for backing off when unseen data is encountered. Conditional probability is the best choice for seen examples. Further, analysis of the data shows that as more training data is made available, the seen examples make up a much larger portion of the test data. Conditional probability is thus a very strong starting point if selectional preferences are an internal piece to a larger application, such as semantic role labeling or parsing.

Perhaps most important, these results illustrate the disparity in performance that can come about when designing a pseudo-word disambiguation evaluation. It is crucially important to be clear during evaluations about how the confounder was generated. We suggest the approach of sorting nouns by frequency and using a neighbor as the confounder. This will also help avoid evaluations that produce overly optimistic results.

9 Conclusion

Current performance on various natural language tasks is being judged and published based on pseudo-word evaluations. It is thus important to have a clear understanding of the evaluation's characteristics. We have shown that the evaluation is strongly affected by confounder choice, suggesting a nearest frequency neighbor approach to provide the most reproducible performance and avoid overly optimistic results. We have shown that evaluating entire documents instead of subsets of the data produces vastly different results. We presented a conditional probability baseline that is both novel to the pseudo-word disambiguation task and strongly outperforms state-of-the-art models on entire documents. We hope this provides a new reference point to the pseudo-word disambiguation task, and enables selectional preference models whose performance on the task similarly transfers to larger NLP applications.

Abstract

We present a novel scheme to apply factored phrase-based SMT to a language pair with very disparate morphological structures. Our approach relies on syntactic analysis on the source side (English) and then encodes a wide variety of local and non-local syntactic structures as *complex structural tags* which appear as additional factors in the training data. On the target side (Turkish), we only perform morphological analysis and disambiguation but treat the complete complex morphological tag as a factor, instead of separating morphemes. We incrementally explore capturing various syntactic substructures as complex tags on the English side, and evaluate how our translations improve in BLEU scores. Our maximal set of source and target side transformations, coupled with some additional techniques, provide an 39% relative improvement from a baseline 17.08 to 23.78 BLEU, all averaged over 10 training and test sets. Now that the syntactic analysis on the English side is available, we also experiment with more long distance constituent reordering to bring the English constituent order close to Turkish, but find that these transformations do not provide any additional consistent tangible gains when averaged over the 10 sets.

1 Introduction

Statistical machine translation into a morphologically complex language such as Turkish, Finnish or Arabic, involves the generation of target words with the proper morphology, in addition to properly ordering the target words. Earlier work on translation from English to Turkish (Oflazer and Durgar-El-Kahlout, 2007; Oflazer, 2008; Durgar-El-Kahlout and Oflazer, 2010) has used an approach which relied on identifying the contextually correct parts-of-speech, roots and any morphemes on the English side, and the complete sequence of roots and overt derivational and inflectional morphemes for each word on the Turkish side. Once these were identified as separate tokens, they were then used as "words" in a standard phrase-based framework (Koehn et al., 2003). They have reported that, given the typical complexity of Turkish words, there was a substantial percentage of words whose morphological structure was incorrect: either the morphemes were not applicable for the part-of-speech category of the root word selected, or the morphemes were in the wrong order. The main reason given for these problems was that the same statistical translation, reordering and language modeling mechanisms were being employed to *both* determine the morphological structure of the words *and*, at the same time, get the global order of the words correct. Even though a significant improvement of a standard word-based baseline was achieved, further analysis hinted at a direction where morphology and syntax on the Turkish side had to be dealt with using separate mechanisms.

Motivated by the observation that many local and some nonlocal syntactic structures in English essentially map to morphologically complex words in Turkish, we present a radically different approach which does not segment Turkish words into morphemes, but uses a representation equivalent to the full word form. On the English side, we rely on a full syntactic analysis using a dependency parser. This analysis then lets us abstract and encode many local and some nonlocal syntactic structures as complex tags (dynamically, as opposed to the static complex tags as proposed by Birch et *al.* (2007) and Hassan et *al.* (2007)). Thus

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 454–464,
Uppsala, Sweden, 11-16 July 2010.

we can bring the representation of English syntax closer to the Turkish morphosyntax.

Such an approach enables the following: (i) Driven by the pattern of morphological structures of full word forms on the Turkish side represented as root words and complex tags, we can identify and reorganize phrases on the English side, to "align" English syntax to Turkish morphology wherever possible. (ii) Continuous and discontinuous variants of certain (syntactic) phrases can be conflated during the SMT phrase extraction process. (iii) The length of the English sentences can be dramatically reduced, as most function words encoding syntax are now abstracted into complex tags. (iv) The representation of both the source and the target sides of the parallel corpus can now be mostly normalized. *This facilitates the use of factored phrase-based translation that was not previously applicable due to the morphological complexity on the target side and mismatch between source and target morphologies.*

We find that with the full set of syntax-to-morphology transformations and some additional techniques we can get about 39% relative improvement in BLEU scores over a word-based baseline and about 28% improvement of a factored baseline, all experiments being done over 10 training and test sets. We also find that further constituent reordering taking advantage of the syntactic analysis of the source side, does not provide tangible improvements when averaged over the 10 data sets.

This paper is organized as follows: Section 2 presents the basic idea behind syntax-to-morphology alignment. Section 3 describes our experimental set-up and presents results from a sequence of incremental syntax-to-morphology transformations, and additional techniques. Section 4 summarizes our constituent reordering experiments and their results. Section 5 presents a review of related work and situates our approach.

We assume that the reader is familiar with the basics of phrase-based statistical machine translation (Koehn et al., 2003) and factored statistical machine translation (Koehn and Hoang, 2007).

2 Syntax-to-Morphology Mapping

In this section, we describe how we map between certain source language syntactic structures and target words with complex morphological structures. At the top of Figure 1, we see a pair of (syntactic) phrases, where we have (positionally) aligned the words that should be translated to each other. We can note that the function words *on* and

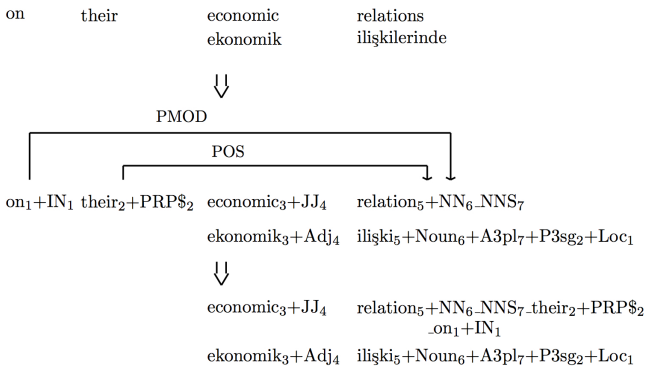

Figure 1: Transformation of an English prepositional phrase

their are not really aligned to any of the Turkish words as they really correspond to two of the morphemes of the last Turkish word.

When we tag and syntactically analyze the English side into dependency relations, and morphologically analyze and disambiguate the Turkish phrase, we get the representation in the middle of Figure 1, where we have co-indexed components that should map to each other, and some of the syntactic relations that the function words are involved in are marked with dependency links.[1]

The basic idea in our approach is to take various function words on the English side, whose syntactic relationships are identified by the parser, and then package them as complex tags on the related content words. So, in this example, if we move the first two function words from the English side and attach as *syntactic tags* to the word they are in dependency relation with, we get the aligned representation at the bottom of Figure 1.[2,3] Here we can note that all root words and tags that correspond to each other are nicely structured and are in the same relative order. In fact, we can treat each token as being composed of two factors: the roots and the accompanying tags. The tags on the Turkish side encode morphosyntactic information encoded in the morphology of the words, *while the*

[1]The meanings of various tags are as follows: Dependency Labels: **PMOD** - Preposition Modifier; **POS** - Possessive. Part-of-Speech Tags for the English words: **+IN** - Preposition; **+PRP$** - Possessive Pronoun; **+JJ** - Adjective; **+NN** - Noun; **+NNS** - Plural Noun. Morphological Feature Tags in the Turkish Sentence: **+A3pl** - 3rd person plural; **+P3sg** - 3rd person singular possessive; **+Loc** - Locative case. Note that we mark an English plural noun as **+NN_NNS** to indicate that the root is a noun and there is a plural morpheme on it. Note also that *economic* is also related to *relations* but we are not interested in such content words and their relations.

[2]We use _ to prefix such syntactic tags on the English side.

[3]The order is important in that we would like to attach the same sequence of function words in the same order so that the resulting tags on the English side are the same.

(complex) tags on the English side encode local (and sometimes, non-local) syntactic information. Furthermore, we can see that before the transformations, the English side has 4 words, while afterwards it has only 2 words. We find (and elaborate later) that this reduction in the English side of the training corpus, in general, is about 30%, and is correlated with improved BLEU scores. We believe the removal of many function words and their folding into complex tags (which do not get involved in GIZA++ alignment – we only align the root words) seems to improve alignment as there are less number of "words" to worry about during that process.[4]

Another interesting side effect of this representation is the following. As the complex syntactic tags on the English side are based on syntactic relations and not necessarily positional proximity, the tag for *relations* in a phrase like *in their cultural, historical and economic relations* would be exactly the same as above. Thus phrase extraction algorithms can conflate all constructs like *in their ... economic relations* as one phrase, regardless of the intervening modifiers, assuming that parser does its job properly.

Not all cases can be captured as cleanly as the example above, but most transformations capture local and nonlocal syntax involving many function words and then encode syntax with complex tags resembling full morphological tags on the Turkish side. *These transformations, however, are not meant to perform sentence level constituent reordering on the English side.* We explore these later.

We developed set of about 20 linguistically-motivated syntax-to-morphology transformations which had variants parameterized depending on what, for instance, the preposition or the adverbial was, and how they map to morphological structure on the Turkish side. For instance, one general rule handles cases like *while ... verb* and *if ... verb* etc., mapping these to appropriate complex tags. It is also possible that multiple transformations can apply to generate a single English complex tag: a portion of the tag can come from a verb complex transformation, and another from an adverbial phrase transformation involving a marked such as *while*. Our transformations handle the following cases:

- Prepositions attach to the head-word of their complement noun phrase as a component in its complex tag.
- Possessive pronouns attach to the head-word they specify.
- The possessive markers following a noun (separated by the tokenizer) attached to the noun.
- Auxiliary verbs and negation markers attach to the lexical verb that they form a verb complex with.
- Modals attach to the lexical verb they modify.
- Forms of *be* used as predicates with adjectival or nominal dependents attach to the dependent.
- Forms of *be* or *have* used to form passive voice with past participle verbs, and forms of *be* used with *-ing* verbs to form present continuous verbs, attach to the verb.
- Various adverbial clauses formed with *if*, *while*, *when*, etc., are reorganized so that these markers attach to the head verb of the clause.

As stated earlier, these rules are linguistically motivated and are based on the morphological structure of the *target* language words. Hence for different target languages these rules will be different. The rules recognize various local and nonlocal syntactic structures in the source side parse tree that correspond to complex morphological of target words and then remove source function words folding them into complex tags. For instance, the transformations in Figure 1 are handled by scripts that process Malt Parser's dependency structure output and that essentially implement the following sequence of rules expressed as pseudo code:

```
1) if  (<Y>+PRP$ POS <Z>+NN<TAG>)
   then {
        APPEND <Y>+PRP$ TO <Z>+NN<TAG>
        REMOVE <Y>+PRP$
     }

2) if (<X>+IN  PMOD <Z>+NN<TAG>)
   then {
        APPEND <X>+IN TO <Z>+NN<TAG>
        REMOVE <X>+IN
     }
```

Here <X>, <Y> and <Z> can be considered as Prolog like-variables that bind to patterns (mostly root words), and the conditions check for specified dependency relations (e.g., PMOD) between the left and the right sides. When the condition is satisfied, then the part matching the function word is removed and its syntactic information is appended to form the complex tag on the noun (<TAG> would either match null string or any previously appended function word markers.)[5]

[4] Fraser (2009) uses the first four letters of German words after morphological stripping and compound decomposition to help with alignment in German to English and reverse translation.

[5] We outline two additional rules later when we see a more complex example in Figure 2.

There are several other rules that handle more mundane cases of date and time constructions (for which, the part of the date construct which the parser attaches a preposition, is usually different than the part on the Turkish side that gets inflected with case markers, and these have to be reconciled by overriding the parser output.)

The next section presents an example of a sentence with multiple transformations applied, after discussing the preprocessing steps.

3 Experimental Setup and Results

3.1 Data Preparation

We worked on an English-Turkish parallel corpus which consists of approximately 50K sentences with an average of 23 words in English sentences and 18 words in Turkish sentences. This is the same parallel data that has been used in earlier SMT work on Turkish (Durgar-El-Kahlout and Oflazer, 2010). Let's assume we have the following pair of parallel sentences:

E: if a request is made orally the authority must make a record of it
T: istek sözlü olarak yapılmışsa yetkili makam bunu kaydetmelidir

On the English side of the data, we use the Stanford Log-Linear Tagger (Toutanova et al., 2003), to tag the text with Penn Treebank Tagset. On the Turkish side, we perform a full morphological analysis, (Oflazer, 1994), and morphological disambiguation (Yuret and Türe, 2006) to select the contextually salient interpretation of words. We then remove any morphological features that are not explicitly marked by an *overt morpheme*.[6] So for both sides we get,

E: if+IN a+DT request+NN is+VBZ made+VBN orally+RB the+DT authority+NN must+MD make+VB a+DT record+NN of+IN it+PRP
T: istek+Noun sözlü+Adj olarak+Verb+ByDoingSo yap+Verb+Pass+Narr+Cond yetkili+Adj makam+Noun bu+Pron+Acc kaydet+Verb+Neces+Cop

Finally we parse the English sentences using MaltParser (Nivre et al., 2007), which gives us labeled dependency parses. On the output of the parser, we make one more transformation. We replace each word with its root, and possibly add an additional tag for any inflectional information conveyed by overt morphemes or exceptional forms. This is done by running the TreeTagger (Schmid, 1994) on the English side which provides the roots in addition to the tags, and then carrying over this information to the parser output. For example, `is` is tagged as `be+VB_VBZ`, `made` is tagged as `make+VB_VBN`, and a word like `books` is tagged as `book+NN_NNS` (and not as `books+NNS`). On the Turkish side, each marker with a preceding + is a morphological feature. The first marker is the part-of-speech tag of the root and the remainder are the overt inflectional and derivational markers of the word. For example, the analysis `kitap+Noun+P2pl+A3pl+Gen` for a word like `kitap-lar-ınız-ın`[7] (*of your books*) represents the root `kitap` (*book*), a `Noun`, with third person plural agreement `A3pl`, second person plural possessive agreement, `P2pl` and genitive case `Gen`.

The sentence representations in the middle part of Figure 2 show these sentences with some of the dependency relations (relevant to our transformations) extracted by the parser, explicitly marked as labeled links. The representation at the bottom of this figure (except for the co-indexation markers) corresponds to the final transformed form of the parallel training and test data. The co-indexation is meant to show which root words on one side map to which on the other side. Ultimately we would want the alignment process to uncover the *root word alignments* indicated here. *We can also note that the initial form of the English sentence has 14 words and the final form after transformations, has 7 words (with complex tags).*[8]

3.2 Experiments

We evaluated the impact of the transformations in factored phrase-based SMT with an English-Turkish data set which consists of 52712 parallel sentences. In order to have more confidence in the impact of our transformations, we randomly generated 10 training, test and tune set combinations. For each combination, the latter two were 1000 sentences each and the remaining 50712 sentences were used as training sets.[9,10]

We performed our experiments with the Moses toolkit (Koehn et al., 2007). In order to encourage long distance reordering in the decoder, we used a distortion limit of -1 and a distortion weight of

[6] For example, the morphological analyzer outputs `+A3sg` to mark a singular noun, if there is no explicit plural morpheme. Such markers are removed.

[7] – shows surface morpheme boundaries.

[8] We could give two more examples of rules to process the if-clause in the example in Figure 2. These rules would be applied sequentially: The first rule recognizes the passive construction mediated by `be+VB<AGR>` forming a verb complex (`VC`) with `<Y>+VB_VBN` and appends the former to the complex tag on the latter and then deletes the former token. The second rule then recognizes `<X>+IN` relating to `<Y>+VB<TAGS>`with `VMOD` and appends the former to the complex tag on the latter and then deletes the former token.

[9] The tune set was not used in this work but reserved for future work so that meaningful comparisons could be made.

[10] It is possible that the 10 test sets are not mutually exclusive.

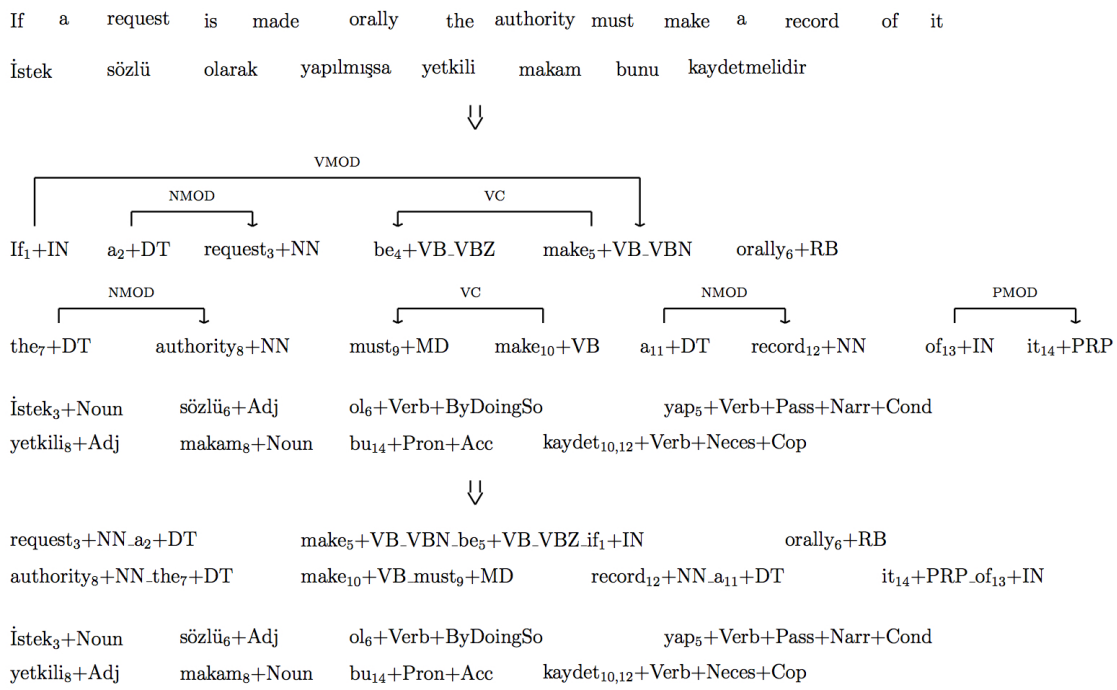

Figure 2: An English-Turkish sentence pair with multiple transformations applied

0.1.[11] We did not use MERT to further optimize our model.[12]

For evaluation, we used the BLEU metric (Papineni et al., 2001). Each experiment was repeated over the 10 data sets. Wherever meaningful, we report the average BLEU scores over 10 data sets along with the maximum and minimum values and the standard deviation.

[11]These allow and do not penalize unlimited distortions.

[12]The experience with MERT for this language pair has not been very positive. Earlier work on Turkish indicates that starting with default Moses parameters and applying MERT to the resulting model does not even come close to the performance of the model with those two specific parameters set as such (*distortion limit -1* and *distortion weight 0.1*), most likely because the default parameters do not encourage the range of distortions that are needed to deal with the constituent order differences. Earlier work on Turkish also shows that even when the *weight-d* parameter is initialized with this specific value, the space explored for distortion weight and other parameters do not produce any improvements on the test set, even though MERT claims there are improvements on the tune set.

The other practical reasons for not using MERT were the following: at the time we performed this work, the discussion thread at `http://www.mail-archive.com/moses-support@mit.edu/msg01012.html` indicated that MERT was not tested on multiple factors. The discussion thread at `http://www.mail-archive.com/moses-support@mit.edu/msg00262.html` claimed that MERT does not help very much with factored models. With these observations, we opted not to experiment with MERT with the multiple factor approach we employed, given that it would be risky and time consuming to run MERT needed for 10 different models and then not necessarily see any (consistent) improvements. MERT however is orthogonal to the improvements we achieve here and can always be applied on top of the best model we get.

3.2.1 The Baseline Systems

As a baseline system, we built a standard phrase-based system, using the surface forms of the words without any transformations, and with a 3-gram LM in the decoder. We also built a second baseline system with a factored model. Instead of using just the surface form of the word, we included the root, part-of-speech and morphological tag information into the corpus as additional factors alongside the surface form.[13] Thus, a token is represented with three factors as `Surface|Root|Tags` where `Tags` are complex tags on the English side, and morphological tags on the Turkish side.[14]

Moses lets word alignment to align over any of the factors. We aligned our training sets using only the root factor to conflate statistics from different forms of the same root. The rest of the factors are then automatically assumed to be aligned, based on the root alignment. Furthermore, in factored models, we can employ different language models for different factors. For the initial set of experiments we used 3-gram LMs for all the factors.

For factored decoding, we employed a model whereby we let the decoder translate a surface form directly, but if/when that fails, the decoder can back-off with a generation model that builds a target word from independent translations of the root and tags.

[13]In Moses, factors are separated by a '|' symbol.

[14]Concatenating `Root` and `Tags` gives the `Surface` form, in that the surface is unique given this concatenation.

The results of our baseline models are given in top two rows of Table 1. As expected, the word-based baseline performs worse than the factored baseline. We believe that the use of multiple language models (some much less sparse than the surface LM) in the factored baseline is the main reason for the improvement.

3.2.2 Applying Syntax-to-Morphology Mapping Transformations

To gauge the effects of transformations separately, we first performed them in batches on the English side. These batches were (i) transformations involving nouns and adjectives (*Noun+Adj*), (ii) transformations involving verbs (*Verb*), (iii) transformations involving adverbs (*Adv*), and (iv) transformations involving verbs and adverbs (*Verb+Adv*).

We also performed one set of transformations on the Turkish side. In general, English prepositions translate as case markers on Turkish nouns. However, there are quite a number of lexical *postpositions* in Turkish which also correspond to English prepositions. To normalize these with the handling of case-markers, we treated these postpositions as if they were case-markers and attached them to the immediately preceding noun, and then aligned the resulting training data (*PostP*).[15]

The results of these experiments are presented in Table 1. We can observe that the combined syntax-to-morphology transformations on the source side provide a substantial improvement by themselves and a simple target side transformation on top of those provides a further boost to 21.96 BLEU which represents a 28.57% relative improvement over the word-based baseline and a 18.00% relative improvement over the factored baseline.

Experiment	Ave.	STD	Max.	Min.
Baseline	17.08	0.60	17.99	15.97
Factored Baseline	**18.61**	**0.76**	**19.41**	**16.80**
Noun+Adj	21.33	0.62	22.27	20.05
Verb	19.41	0.62	20.19	17.99
Adv	18.62	0.58	19.24	17.30
Verb+Adv	19.42	0.59	20.17	18.13
Noun+Adj +Verb+Adv	**21.67**	**0.72**	**22.66**	**20.38**
Noun+Adj+Verb +Adv+PostP	**21.96**	**0.72**	**22.91**	**20.67**

Table 1: BLEU scores for a variety of transformation combinations

We can see that every transformation improves the baseline system and the highest performance is attained when all transformations are performed. However when we take a closer look at the individual transformations performed on English side, we observe that not all of them have the same effect. While *Noun+Adj* transformations give us an increase of 2.73 BLEU points, *Verbs* improve the result by only 0.8 points and improvement with *Adverbs* is even lower. To understand why we get such a difference, we investigated the correlation of the decrease in the number of tokens on both sides of the parallel data, with the change in BLEU scores. The graph in Figure 3 plots the BLEU scores and the number of tokens in the two sides of the training data as the data is modified with transformations. We can see that as the number of tokens in English decrease, the BLEU score increases. In order to measure the relationship between these two variables statistically, we performed a correlation analysis and found that there is a strong negative correlation of -0.99 between the BLEU score and the number of English tokens. We can also note that the largest reduction in the number of tokens comes with the application of the *Noun+Adj* transformations, which correlates with the largest increase in BLEU score.

It is also interesting to look at the n-gram precision components of the BLEU scores (again averaged). In Table 2, we list these for words (actual BLEU), roots (BLEU-R) to see how effective we are in getting the root words right, and morphological tags, (BLEU-M), to see how effective we are in getting just the morphosyntax right. It

		1-gr.	2-gr.	3-gr.	4-gr.
BLEU	21.96	55.73	27.86	16.61	10.68
BLEU-R	27.63	68.60	35.49	21.08	13.47
BLEU-M	27.93	67.41	37.27	21.40	13.41

Table 2: Details of Word, Root and Morphology BLEU Scores

seems we are getting almost 69% of the root words and 68% of the morphological tags correct, but not necessarily getting the combination equally as good, since only about 56% of the full word forms are correct. One possible way to address is to use longer distance constraints on the morphological tag factors, to see if we can select them better.

3.2.3 Experiments with higher-order language models

Factored phrase-based SMT allows the use of multiple language models for the target side, for different factors during decoding. Since the number of possible distinct morphological tags (the morphological tag vocabulary size) in our training data

[15]Note than in this case, the translations would be generated in the same format, but we then split such postpositions from the words they are attached to, during decoding, and *then* evaluate the BLEU score.

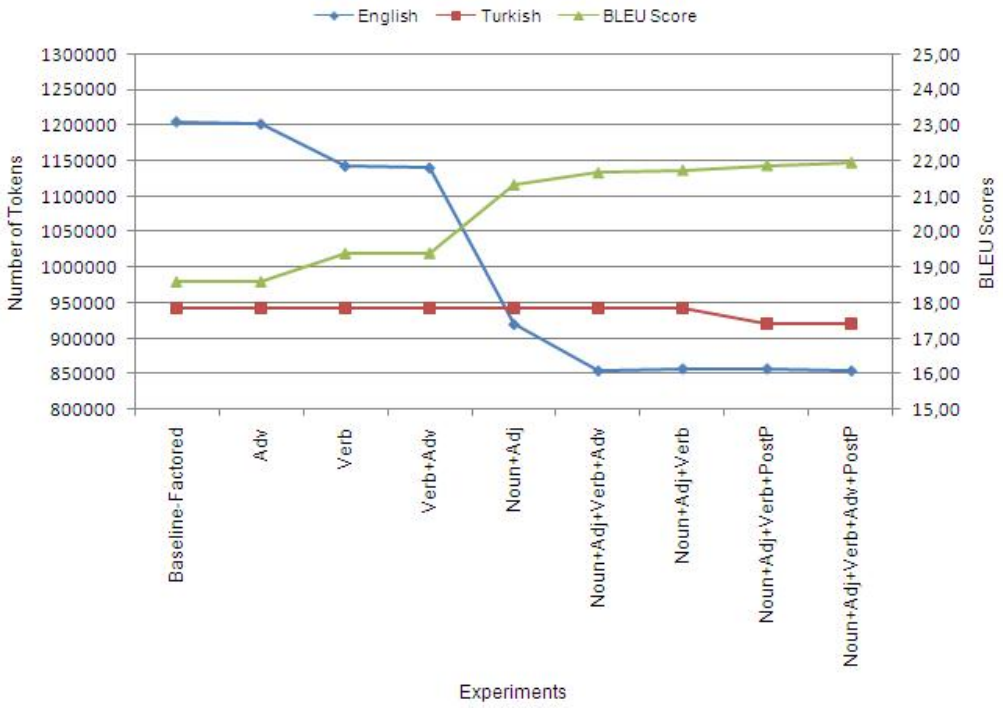

Figure 3: BLEU scores vs number of tokens in the training sets

(about 3700) is small compared to distinct number of surface forms (about 52K) and distinct roots (about 15K including numbers), it makes sense to investigate the contribution of higher order n-gram language models for the morphological tag factor on the target side, to see if we can address the observation in the previous section.

Using the data transformed with *Noun+Adj+Verb+Adv+PostP* transformations which previously gave us the best results overall, we experimented with using higher order models (4-grams to 9-grams) during decoding, for the morphological tag factor models, keeping the surface and root models at 3-gram. We observed that for all the 10 data sets, the improvements were consistent for up to 8-gram. The BLEU with the 8-gram *for only the morphological tag factor* averaged over the 10 data sets was **22.61** (max: 23.66, min: 21.37, std: 0.72) compared to the 21.96 in Table 1. Using a 4-gram *root* LM, considerably less sparse than word forms but more sparse that tags, we get a BLEU score of **22.80** (max: 24.07, min: 21.57, std: 0.85). The details of the various BLEU scores are shown in the two halves of Table 3. It seems that larger n-gram LMs contribute to the larger n-gram precisions contributing to the BLEU but not to the unigram precision.

3-gram root LM		**1-gr.**	**2-gr.**	**3-gr.**	**4-gr.**
BLEU	22.61	55.85	28.21	17.16	11.36
BLEU-R	28.21	68.67	35.80	21.55	14.07
BLEU-M	28.68	67.50	37.59	22.02	14.22
4-gram root LM		**1-gr.**	**2-gr.**	**3-gr.**	**4-gr.**
BLEU	22.80	55.85	28.39	17.34	11.54
BLEU-R	28.48	68.68	35.97	21.79	14.35
BLEU-M	28.82	67.49	37.63	22.17	14.40

Table 3: Details of Word, Root and Morphology BLEU Scores, with 8-gram tag LM and 3/4-gram root LMs

3.2.4 Augmenting the Training Data

In order to alleviate the lack of large scale parallel corpora for the English–Turkish language pair, we experimented with augmenting the training data with reliable phrase pairs obtained from a previous alignment. Phrase table entries for the surface factors produced by Moses after it does an alignment on the roots, contain the English (e) and Turkish (t) parts of a pair of aligned phrases, and the probabilities, $p(e|t)$, the conditional probability that the English phrase is e given that the Turkish phrase is t, and $p(t|e)$, the conditional probability that the Turkish phrase is t given the English phrase is e. Among these phrase table entries, those with $p(e|t) \approx p(t|e)$ and $p(t|e) + p(e|t)$ larger than some threshold, can be considered as reliable mutual translations, in that they mostly translate to each other and not much to others. We extracted

from the phrase table those phrases with $0.9 \leq p(e|t)/p(t|e) \leq 1.1$ and $p(t|e) + p(e|t) \geq 1.5$ and added them to the training data to further bias the alignment process. The resulting BLEU score was **23.78** averaged over 10 data sets (max: 24.52, min: 22.25, std: 0.71).[16]

4 Experiments with Constituent Reordering

The transformations in the previous section *do not perform any constituent level reordering*, but rather *eliminate* certain English function words as tokens in the text and fold them into complex syntactic tags. That is, no transformations reorder the English SVO order to Turkish SOV,[17] for instance, or move postnominal prepositional phrase modifiers in English, to prenominal phrasal modifiers in Turkish. Now that we have the parses of the English side, we have also investigated a more comprehensive set of reordering transformations which perform the following constituent reorderings to bring English constituent order more in line with the Turkish constitent order at the top and embedded phrase levels:

- Object reordering (*ObjR*), in which the objects and their dependents are moved in front of the verb.
- Adverbial phrase reordering (*AdvR*), which involve moving post-verbal adverbial phrases in front of the verb.
- Passive sentence agent reordering (*PassAgR*), in which any post-verbal agents marked by *by*, are moved in front of the verb.
- Subordinate clause reordering (*SubCR*) which involve moving postnominal relative clauses or prepositional phrase modifers in front of any modifiers of the head noun. Similarly any prepositional phrases attached to verbs are moved to in front of the verb.

We performed these reorderings on top of the data obtained with the *Noun+Adj+Verb+Adv+PostP* transformations earlier in Section 3.2.2 and used the same decoder parameters. Table 4 shows the performance obtained after various combination of reordering operations over the 10 data sets. Although there were some improvements for certain cases, none of reordering gave consistent improvements for all the data sets. A cursory examinations of the alignments produced after these reordering transformations indicated that the resulting root alignments were not necessarily that close to being monotonic as we would have expected.

Experiment	Ave.	STD	Max.	Min.
Baseline	**21.96**	**0.72**	**22.91**	**20.67**
ObjR	21.94	0.71	23.12	20.56
ObjR+AdvR	21.73	0.50	22.44	20.69
ObjR+PassAgR	21.88	0.73	23.03	20.51
ObjR+SubCR	21.88	0.61	22.77	20.92

5 Related Work

Statistical Machine Translation into a morphologically rich language is a challenging problem in that, on the target side, the decoder needs to generate both the right sequence of constituents and the right sequence of morphemes for each word. Furthermore, since for such languages one can generate tens of hundreds of inflected variants, standard word-based alignment approaches suffer from sparseness issues. Koehn (2005) applied standard phrase-based SMT to Finnish using the Europarl corpus and reported that translation to Finnish had the worst BLEU scores.

Using morphology in statistical machine translation has been addressed by many researchers for translation from or into morphologically rich(er) languages. Niessen and Ney (2004) used morphological decomposition to get better alignments. Yang and Kirchhoff (2006) have used phrase-based backoff models to translate unknown words by morphologically decomposing the unknown source words. Lee (2004) and Zolmann et *al.* (2006) have exploited morphology in Arabic-English SMT. Popovic and Ney (2004) investigated improving translation quality from inflected languages by using stems, suffixes and part-of-speech tags. Goldwater and McClosky (2005) use morphological analysis on the Czech side to get improvements in Czech-to-English statistical machine translation. Minkov et *al.* (2007) have used morphological postprocessing on the target side, to improve translation quality. Avramidis and Koehn (2008) have annotated English with additional morphological information extracted from a syntactic tree, and have used this in translation to Greek and Czech. Recently, Bisazza and Federico (2009) have applied morphological segmentation in *Turkish-to-English* statistical machine translation and found that it provides nontrivial BLEU

[16] These experiments were done on top of the model in 3.2.3 with a 3-gram word and root LMs and 8-gram tag LM.

[17] Although Turkish is a free-constituent order language, SOV is the dominant order in text.

score improvements.

In the context of translation from English to Turkish, Durgar-El Kahlout and Oflazer (2010) have explored different representational units of the lexical morphemes and found that selectively splitting morphemes on the target side provided nontrivial improvement in the BLEU score. Their approach was based on splitting the target Turkish side, into constituent morphemes while our approach in this paper is the polar opposite: we do not segment morphemes on the Turkish side but rather join function words on the English side to the related content words. Our approach is somewhat similar to recent approaches that use complex syntactically-motivated complex tags. Birch et *al.* (2007) have integrated more syntax in a factored translation approach by using CCG supertags as a separate factor and have reported a 0.46 BLEU point improvement in Dutch-to-English translations. Although they used supertags, these were obtained not via syntactic analysis but by supertagging, while we determine, on the fly, the appropriate syntactic tags based on syntactic structure. A similar approach based on supertagging was proposed by Hassan et *al.* (2007). They used both CCG supertags and LTAG supertags in Arabic-to-English phrase-based translation and have reported about 6% relative improvement in BLEU scores. In the context of reordering, one recent work (Xu et al., 2009), was able to get an improvement of 0.6 BLEU points by using source syntactic analysis and a constituent reordering scheme like ours for English-to-Turkish translation, but without using any morphology.

6 Conclusions

We have presented a novel way to incorporate source syntactic structure in English-to-Turkish phrase-based machine translation by parsing the source sentences and then encoding many local and nonlocal source syntactic structures as additional complex tag factors. Our goal was to obtain representations of source syntactic structures that parallel target morphological structures, and enable us to extend factored translation, in applicability, to languages with very disparate morphological structures.

In our experiments over a limited amount training data, but repeated with 10 different training and test sets, we found that syntax-to-morphology mapping transformations on the source side sentences, along with a very small set of transformations on the target side, coupled with some additional techniques provided about 39% relative improvement in BLEU scores over a word-based baseline and about 28% improvement of a factored baseline. We also experimented with numerous additional syntactic reordering transformation on the source to further bring the constituent order in line with the target order but found that these did not provide any tangible improvements when averaged over the 10 different data sets.

It is possible that the techniques presented in this paper may be less effective if the available data is much larger, but we have reasons to believe that they will still be effective then also. The reduction in size of the source language side of the training corpus seems to be definitely effective and there no reason why such a reduction (if not more) will not be observed in larger data. Also, the preprocessing of English prepositional phrases and many adverbial phrases usually involve rather long distance relations in the source side syntactic structure[18] and when such structures are coded as complex tags on the nominal or verbal heads, such long distance syntax is effectively "localized" and thus can be better captured with the limited window size used for phrase extraction.

One limitation of the approach presented here is that it is not directly applicable in the reverse direction. The data encoding and set-up can directly be employed to generate English "translation" expressed as a sequence of root and complex tag combinations, but then some of the complex tags could encode various syntactic constructs. To finalize the translation after the decoding step, the function words/tags in the complex tag would then have to be unattached and their proper positions in the sentence would have to be located. The problem is essentially one of generating multiple candidate sentences with the unattached function words ambiguously positioned (say in a lattice) and then use a second language model to rerank these sentences to select the target sentence. This is an avenue of research that we intend to look at in the very near future.

Abstract

We present a novel approach to integrate transliteration into Hindi-to-Urdu statistical machine translation. We propose two probabilistic models, based on conditional and joint probability formulations, that are novel solutions to the problem. Our models consider both transliteration and translation when translating a particular Hindi word given the context whereas in previous work transliteration is only used for translating OOV (out-of-vocabulary) words. We use transliteration as a tool for disambiguation of Hindi homonyms which can be both translated or transliterated or transliterated differently based on different contexts. We obtain final BLEU scores of 19.35 (conditional probability model) and 19.00 (joint probability model) as compared to 14.30 for a baseline phrase-based system and 16.25 for a system which transliterates OOV words in the baseline system. This indicates that transliteration is useful for more than only translating OOV words for language pairs like Hindi-Urdu.

1 Introduction

Hindi is an official language of India and is written in Devanagari script. Urdu is the national language of Pakistan, and also one of the state languages in India, and is written in Perso-Arabic script. Hindi inherits its vocabulary from Sanskrit while Urdu descends from several languages including Arabic, Farsi (Persian), Turkish and Sanskrit. Hindi and Urdu share grammatical structure and a large proportion of vocabulary that they both inherited from Sanskrit. Most of the verbs and closed-class words (pronouns, auxiliaries, case-markers, etc) are the same. Because both languages have lived together for centuries, some Urdu words which originally came from Arabic and Farsi have also mixed into Hindi and are now part of the Hindi vocabulary. The spoken form of the two languages is very similar.

The extent of overlap between Hindi and Urdu vocabulary depends upon the domain of the text. Text coming from the literary domain like novels or history tend to have more Sanskrit (for Hindi) and Persian/Arabic (for Urdu) vocabulary. However, news wire that contains text related to media, sports and politics, etc., is more likely to have common vocabulary.

In an initial study on a small news corpus of 5000 words, randomly selected from BBC[1] News, we found that approximately 62% of the Hindi types are also part of Urdu vocabulary and thus can be transliterated while only 38% have to be translated. This provides a strong motivation to implement an end-to-end translation system which strongly relies on high quality transliteration from Hindi to Urdu.

Hindi and Urdu have similar sound systems but transliteration from Hindi to Urdu is still very hard because some phonemes in Hindi have several orthographic equivalents in Urdu. For example the "z" sound[2] can only be written as ज़ whenever it occurs in a Hindi word but can be written as ذ, ز, ض and ظ in an Urdu word. Transliteration becomes non-trivial in cases where the multiple orthographic equivalents for a Hindi word are all valid Urdu words. Context is required to resolve ambiguity in such cases. Our transliterator (described in sections 3.1.2 and 4.1.3) gives an accuracy of 81.6% and a 25-best accuracy of 92.3%.

Transliteration has been previously used only as a back-off measure to translate NEs (Name Entities) and OOV words in a pre- or post-processing step. The problem we are solving is more difficult than techniques aimed at handling OOV words,

अंबर	امبر/آسمان	Amb@r	Sky/Ambar
विजय	وِجے/جیت	vId_Ze	Victory/Vijay

Table 2: Hindi Words That Can Be Translated or Transliterated in Different Contexts

which focus primarily on name transliteration, because we need different transliterations in different contexts; in their case context is irrelevant. For example: consider the problem of transliterating the English word "read" to a phoneme representation in the context "I will read" versus the context "I have read". An example of this for Hindi to Urdu transliteration: the two Urdu words صورت (face/condition) and سورت (chapter of the Koran) are both written as सूरत (sur@t_d) in Hindi. The two are pronounced identically in Urdu but written differently. In such cases we hope to choose the correct transliteration by using context. Some other examples are shown in Table 1.

Sometimes there is also an ambiguity of whether to translate or transliterate a particular word. The Hindi word शान्ती, for example, will be translated to سکون (peace, s@kun) when it is a common noun but transliterated to شانتی (Shanti, SAnt_di) when it is a proper name. We try to model whether to translate or transliterate in a given situation. Some other examples are shown in Table 2.

The remainder of this paper is organized as follows. Section 2 provides a review of previous work. Section 3 introduces two probabilistic models for integrating translations and transliterations into a translation model which are based on conditional and joint probability distributions. Section 4 discusses the training data, parameter optimization and the initial set of experiments that compare our two models with a baseline Hindi-Urdu phrase-based system and with two transliteration-aided phrase-based systems in terms of BLEU scores (Papineni et al., 2001). Section 5 performs an error analysis showing interesting weaknesses in the initial formulations. We remedy the problems by adding some heuristics and modifications to our models which show improvements in the results as discussed in section 6. Section 7 gives two examples illustrating how our model decides whether to translate or transliterate and how it is able to choose among different valid transliterations given the context. Section 8 concludes the paper.

2 Previous Work

There has been a significant amount of work on transliteration. We can break down previous work into three groups. The first group is generic transliteration work, which is evaluated outside of the context of translation. This work uses either grapheme or phoneme based models to transliterate words lists (Knight and Graehl, 1998; Li et al., 2004; Ekbal et al., 2006; Malik et al., 2008). The work by Malik et al. addresses Hindi to Urdu transliteration using hand-crafted rules and a phonemic representation; it ignores translation context.

A second group deals with out-of-vocabulary words for SMT systems built on large parallel corpora, and therefore focuses on name transliteration, which is largely independent of context. Al-Onaizan and Knight (2002) transliterate Arabic NEs into English and score them against their respective translations using a modified IBM Model 1. The options are further re-ranked based on different measures such as web counts and using co-reference to resolve ambiguity. These re-ranking methodologies can not be performed in SMT at the decoding time. An efficient way to compute and re-rank the transliterations of NEs and integrate them on the fly might be possible. However, this is not practical in our case as our model considers transliterations of all input words and not just NEs. A log-linear block transliteration model is applied to OOV NEs in Arabic to English SMT by Zhao et al. (2007). This work is also transliterating only NEs and not doing any disambiguation. The best method proposed by Kashani et al. (2007) integrates translations provided by external sources such as transliteration or rule-base translation of numbers and dates, for an arbitrary number of entries within the input text. Our work is different from Kashani et al. (2007) in that our model compares transliterations with translations

on the fly whereas transliterations in Kashani et al. do not compete with internal phrase tables. They only compete amongst themselves during a second pass of decoding. Hermjakob et al. (2008) use a tagger to identify good candidates for transliteration (which are mostly NEs) in input text and add transliterations to the SMT phrase table dynamically such that they can directly compete with translations during decoding. This is closer to our approach except that we use transliteration as an alternative to translation for all Hindi words. Our focus is disambiguation of Hindi homonyms whereas they are concentrating only on transliterating NE's. Moreover, they are working with a large bitext so they can rely on their translation model and only need to transliterate NEs and OOVs. Our translation model is based on data which is both sparse and noisy. Therefore we pit transliterations against translations for every input word. Sinha (2009) presents a rule-based MT system that uses Hindi as a pivot to translate from English to Urdu. This work also uses transliteration only for the translation of unknown words. Their work can not be used for direct translation from Hindi to Urdu (independently of English) "due to various ambiguous mappings that have to be resolved".

The third group uses transliteration models inside of a cross-lingual IR system (AbdulJaleel and Larkey, 2003; Virga and Khudanpur, 2003; Pirkola et al., 2003). Picking a single best transliteration or translation in context is not important in an IR system. Instead, all the options are used by giving them weights and context is typically not taken into account.

3 Our Approach

Both of our models combine a character-based transliteration model with a word-based translation model. Our models look for the most probable Urdu token sequence u_1^n for a given Hindi token sequence h_1^n. We assume that each Hindi token is mapped to exactly one Urdu token and that there is no reordering. The assumption of no reordering is reasonable given the fact that Hindi and Urdu have identical grammar structure and the same word order. An Urdu token might consist of more than one Urdu word[3]. The following sections give a mathematical formulation of our two models, Model-1 and Model-2.

3.1 Model-1 : Conditional Probability Model

Applying a noisy channel model to compute the most probable translation $\hat{u}_1^n$, we get:

$$\arg\max_{u_1^n} p(u_1^n|h_1^n) = \arg\max_{u_1^n} p(u_1^n)p(h_1^n|u_1^n) \quad (1)$$

3.1.1 Language Model

The **language model (LM)** $p(u_1^n)$ is implemented as an n-gram model using the SRILM-Toolkit (Stolcke, 2002) with Kneser-Ney smoothing. The parameters of the language model are learned from a monolingual Urdu corpus. The language model is defined as:

$$p(u_1^n) = \prod_{i=1}^{n} p_{LM}(u_i|u_{i-k}^{i-1}) \quad (2)$$

where k is a parameter indicating the amount of context used (e.g., $k = 4$ means 5-gram model). u_i can be a single or a multi-word token. A multi-word token consists of two or more Urdu words. For a multi-word u_i we do multiple language model look-ups, one for each u_{i_x} in $u_i = u_{i_1}, \ldots, u_{i_m}$ and take their product to obtain the value $p_{LM}(u_i|u_{i-k}^{i-1})$.

Language Model for Unknown Words: Our model generates transliterations that can be known or unknown to the language model and the translation model. We refer to the words known to the language model and to the translation model as LM-known and TM-known words respectively and to words that are unknown as LM-unknown and TM-unknown respectively.

We assign a special value ψ to the LM-unknown words. If one or more u_{i_x} in a multi-word u_i are LM-unknown we assign a language model score $p_{LM}(u_i|u_{i-k}^{i-1}) = \psi$ for the entire u_i, meaning that we consider partially known transliterations to be as bad as fully unknown transliterations. The parameter ψ controls the trade-off between LM-known and LM-unknown transliterations. It does not influence translation options because they are always LM-known in our case. This is because our monolingual corpus also contains the Urdu part of translation corpus. The optimization of ψ is described in section 4.2.1.

[3]This occurs frequently in case markers with nouns, derivational affixes and compounds etc. These are written as single words in Hindi as opposed to Urdu where they are written as two words. For example खूबसूरत (beautiful ; xubsur@t_d) and आपका (your's ; ApkA) are written as خوب صورت and آپ کا respectively in Urdu.

3.1.2 Translation Model

The **translation model (TM)** $p(h_1^n|u_1^n)$ is approximated with a context-independent model:

$$p(h_1^n|u_1^n) = \prod_{i=1}^{n} p(h_i|u_i) \quad (3)$$

where h_i and u_i are Hindi and Urdu tokens respectively. Our model estimates the conditional probability $p(h_i|u_i)$ by interpolating a word-based model and a character-based (transliteration) model.

$$p(h_i|u_i) = \lambda p_w(h_i|u_i) + (1-\lambda)p_c(h_i|u_i) \quad (4)$$

The parameters of the **word-based translation model** $p_w(h|u)$ are estimated from the word alignments of a small parallel corpus. We only retain 1-1/1-N (1 Hindi word, 1 or more Urdu words) alignments and throw away N-1 and M-N alignments for our models. This is further discussed in section 4.1.1.

The **character-based transliteration model** $p_c(h|u)$ is computed in terms of $p_c(h,u)$, a joint character model, which is also used for Chinese-English back-transliteration (Li et al., 2004) and Bengali-English name transliteration (Ekbal et al., 2006). The character-based transliteration probability is defined as follows:

$$\begin{aligned} p_c(h,u) &= \sum_{a_1^n \in align(h,u)} p(a_1^n) \\ &= \sum_{a_1^n \in align(h,u)} \prod_{i=1}^{n} p(a_i|a_{i-k}^{i-1}) \end{aligned} \quad (5)$$

where a_i is a pair consisting of the i-th Hindi character h_i and the sequence of 0 or more Urdu characters that it is aligned with. A sample alignment is shown in Table 3(b) in section 4.1.3. Our best results are obtained with a 5-gram model. The parameters $p(a_i|a_{i-k}^{i-1})$ are estimated from a small transliteration corpus which we automatically extracted from the translation corpus. The extraction details are also discussed in section 4.1.3. Because our overall model is a conditional probability model, joint-probabilities are marginalized using character-based prior probabilities:

$$p_c(h|u) = \frac{p_c(h,u)}{p_c(u)} \quad (6)$$

The **prior probability** $p_c(u)$ of the character sequence $u = c_1^m$ is defined with a character-based language model:

$$p_c(u) = \prod_{i=1}^{m} p(c_i|c_{i-k}^{i-1}) \quad (7)$$

The parameters $p(c_i|c_{i-k}^{i-1})$ are estimated from the Urdu part of the character-aligned transliteration corpus. Replacing (6) in (4) we get:

$$p(h_i|u_i) = \lambda p_w(h_i|u_i) + (1-\lambda)\frac{p_c(h_i,u_i)}{p_c(u_i)} \quad (8)$$

Having all the components of our model defined we insert (8) and (2) in (1) to obtain the final equation:

$$\begin{aligned} \hat{u}_1^n = \arg\max_{u_1^n} \prod_{i=1}^{n} p_{LM}(u_i|u_{i-k}^{i-1})[\lambda p_w(h_i|u_i) \\ + (1-\lambda)\frac{p_c(h_i,u_i)}{p_c(u_i)}] \end{aligned} \quad (9)$$

The optimization of the interpolating factor λ is discussed in section 4.2.1.

3.2 Model-2 : Joint Probability Model

This section briefly defines a variant of our model where we interpolate joint probabilities instead of conditional probabilities. Again, the **translation model** $p(h_1^n|u_1^n)$ is approximated with a context-independent model:

$$p(h_1^n|u_1^n) = \prod_{i=1}^{n} p(h_i|u_i) = \prod_{i=1}^{n} \frac{p(h_i,u_i)}{p(u_i)} \quad (10)$$

The joint probability $p(h_i,u_i)$ of a Hindi and an Urdu word is estimated by interpolating a word-based model and a character-based model.

$$p(h_i,u_i) = \lambda p_w(h_i,u_i) + (1-\lambda)p_c(h_i,u_i) \quad (11)$$

and the prior probability $p(u_i)$ is estimated as:

$$p(u_i) = \lambda p_w(u_i) + (1-\lambda)p_c(u_i) \quad (12)$$

The parameters of the translation model $p_w(h_i,u_i)$ and the word-based prior probabilities $p_w(u_i)$ are estimated from the 1-1/1-N word-aligned corpus (the one that we also used to estimate translation probabilities $p_w(h_i|u_i)$ previously).

The character-based transliteration probability $p_c(h_i,u_i)$ and the character-based prior probability $p_c(u_i)$ are defined by (5) and (7) respectively in

the previous section. Putting (11) and (12) in (10) we get

$$p(h_1^n|u_1^n) = \prod_{i=1}^{n} \frac{\lambda p_w(h_i, u_i) + (1-\lambda) p_c(h_i, u_i)}{\lambda p_w(u_i) + (1-\lambda) p_c(u_i)} \quad (13)$$

The idea is to interpolate joint probabilities and divide them by the interpolated marginals. The final equation for Model-2 is given as:

$$\hat{u}_1^n = \arg\max_{u_1^n} \prod_{i=1}^{n} p_{LM}(u_i|u_{i-k}^{i-1}) \times \frac{\lambda p_w(h_i, u_i) + (1-\lambda) p_c(h_i, u_i)}{\lambda p_w(u_i) + (1-\lambda) p_c(u_i)} \quad (14)$$

3.3 Search

The decoder performs a stack-based search using a beam-search algorithm similar to the one used in Pharoah (Koehn, 2004a). It searches for an Urdu string that maximizes the product of translation probability and the language model probability (equation 1) by translating one Hindi word at a time. It is implemented as a two-level process. At the lower level, it computes n-best transliterations for each Hindi word h_i according to $p_c(h, u)$. The joint probabilities given by $p_c(h, u)$ are marginalized for each Urdu transliteration to give $p_c(h|u)$. At the higher level, transliteration probabilities are interpolated with $p_w(h|u)$ and then multiplied with language model probabilities to give the probability of a hypothesis. We use 20-best translations and 25-best transliterations for $p_w(h|u)$ and $p_c(h|u)$ respectively and a 5-gram language model.

To keep the search space manageable and time complexity polynomial we apply pruning and recombination. Since our model uses monotonic decoding we only need to recombine hypotheses that have the same context (last n-1 words). Next we do histogram-based pruning, maintaining the 100-best hypotheses for each stack.

4 Evaluation

4.1 Training

This section discusses the training of the different model components.

4.1.1 Translation Corpus

We used the freely available EMILLE Corpus as our bilingual resource which contains roughly 13,000 Urdu and 12,300 Hindi sentences. From these we were able to sentence-align 7000 sentence pairs using the sentence alignment algorithm given by Moore (2002).

The word alignments for this task were extracted by using GIZA++ (Och and Ney, 2003) in both directions. We extracted a total of 107323 alignment pairs (5743 N-1 alignments, 8404 M-N alignments and 93176 1-1/1-N alignments). Of these alignments M-N and N-1 alignment pairs were ignored. We manually inspected a sample of 1000 instances of M-N/N-1 alignments and found that more than 70% of these were (totally or partially) wrong. Of the 30% correct alignments, roughly one-third constitute N-1 alignments. Most of these are cases where the Urdu part of the alignment actually consists of two (or three) words but was written without space because of lack of standard writing convention in Urdu. For example جا سکتے (can go ; d_ZA s@kt_de) is alternatively written as جاسکتے (can go ; d_ZAs@kt_de) i.e. without space. We learned that these N-1 translations could be safely dropped because we can generate a separate Urdu word for each Hindi word. For valid M-N alignments we observed that these could be broken into 1-1/1-N alignments in most of the cases. We also observed that we usually have coverage of the resulting 1-1 and 1-N alignments in our translation corpus. Looking at the noise in the incorrect alignments we decided to drop N-1 and M-N cases. We do not model deletions and insertions so we ignored null alignments. Also 1-N alignments with gaps were ignored. Only the alignments with contiguous words were kept.

4.1.2 Monolingual Corpus

Our monolingual Urdu corpus consists of roughly 114K sentences. This comprises 108K sentences from the data made available by the University of Leipzig[4] + 5600 sentences from the training data of each fold during cross validation.

4.1.3 Transliteration Corpus

The training corpus for transliteration is extracted from the 1-1/1-N word-alignments of the EMILLE corpus discussed in section 4.1.1. We use an edit distance algorithm to align this training corpus at the character level and we eliminate translation pairs with high edit distance which are unlikely to be transliterations.

[4] http://corpora.informatik.uni-leipzig.de/

We used our knowledge of the Hindi and Urdu scripts to define the initial character mapping. The mapping was further extended by looking into available Hindi-Urdu transliteration systems[5,6] and other resources (Gupta, 2004; Malik et al., 2008; Jawaid and Ahmed, 2009). Each pair in the character map is assigned a cost. A Hindi character that always map to only one Urdu character is assigned a cost of 0 whereas the Hindi characters that map to different Urdu characters are assigned a cost of 0.2. The edit distance metric allows insert, delete and replace operations. The handcrafted pairs define the cost of replace operations. We set a cost of 0.6 for deletions and insertions. These costs were optimized on held out data. The details of optimization are not mentioned due to limited space. Using this metric we filter out the word pairs with high edit-distance to extract our transliteration corpus. We were able to extract roughly 2100 unique pairs along with their alignments. The resulting alignments are modified by merging unaligned $\emptyset \rightarrow 1$ (no character on source side, 1 character on target side) or $\emptyset \rightarrow N$ alignments with the preceding alignment pair. If there is no preceding alignment pair then it is merged with the following pair. Table 3 gives an example showing initial alignment (a) and the final alignment (b) after applying the merge operation. Our model retains $1 \rightarrow \emptyset$ and $N \rightarrow \emptyset$ alignments as deletion operations.

a)	Hindi	$\emptyset$	b	c	$\emptyset$	e	f
	Urdu	A	XY	C	D	$\emptyset$	F
b)	Hindi		b	c		e	f
	Urdu		AXY	CD		$\emptyset$	F

Table 3: Alignment (a) Before (b) After Merge

The parameters $p_c(h, u)$ and $p_c(u)$ are trained on the aligned corpus using the SRILM toolkit. We use Add-1 smoothing for unigrams and Kneser-Ney smoothing for higher n-grams.

4.1.4 Diacritic Removal and Normalization

In Urdu, short vowels are represented with diacritics but these are rarely written in practice. In order to keep the data consistent, all diacritics are removed. This loss of information is not harmful when transliterating/translating from Hindi to Urdu because undiacritized text is equally readable to native speakers as its diacritized counter part. However leaving occasional diacritics in the corpus can worsen the problem of data sparsity by creating spurious ambiguity[7].

There are a few Urdu characters that have multiple equivalent Unicodes. All such forms are normalized to have only one representation[8].

4.2 Experimental Setup

We perform a 5-fold cross validation taking 4/5 of the data as training and 1/5 as test data. Each fold comprises roughly 1400 test sentences and 5600 training sentences.

4.2.1 Parameter Optimization

Our model contains two parameters λ (the interpolating factor between translation and transliteration modules) and ψ (the factor that controls the trade-off between LM-known and LM-unknown transliterations). The interpolating factor λ is initialized, inspired by Written-Bell smoothing, with a value of $\frac{N}{N+B}$[9]. We chose a very low value $1e^{-40}$ for the factor ψ initially, favoring LM-known transliterations very strongly. Both of these parameters are optimized as described below.

Because our training data is very sparse we do not use held-out data for parameter optimization. Instead we optimize these parameters by performing a 2-fold optimization for each of the 5 folds. Each fold is divided into two halves. The parameters λ and ψ are optimized on the first half and the other half is used for testing, then optimization is done on the second half and the first half is used for testing. The optimal value for parameter λ occurs between 0.7-0.84 and for the parameter ψ between $1e^{-5}$ and $1e^{-10}$.

4.2.2 Results

Baseline Pb_0: We ran Moses (Koehn et al., 2007) using Koehn's training scripts[10], doing a 5-fold cross validation with no reordering[11]. For the other parameters we use the default values i.e. 5-gram language model and maximum phrase-length= 6. Again, the language model is imple-

[6]Malerkotla.org: http://translate.malerkotla.co.in

[7]It should be noted though that diacritics play a very important role when transliterating in the reverse direction because these are virtually always written in Hindi as dependent vowels.

[11]Results are worse with reordering enabled.

M	Pb_0	Pb_1	Pb_2	M_1	M_2
BLEU	14.3	16.25	16.13	18.6	17.05

Table 4: Comparing Model-1 and Model-2 with Phrase-based Systems

mented as an n-gram model using the SRILM-Toolkit with Kneser-Ney smoothing. Each fold comprises roughly 1400 test sentences, 5000 in training and 600 in dev[12]. We also used two methods to incorporate transliterations in the phrase-based system:

Post-process Pb_1: All the OOV words in the phrase-based output are replaced with their top-candidate transliteration as given by our transliteration system.

Pre-process Pb_2: Instead of adding transliterations as a post process we do a second pass by adding the unknown words with their top-candidate transliteration to the training corpus and rerun Koehn's training script with the new training corpus. Table 4 shows results (taking arithmetic average over 5 folds) from Model-1 and Model-2 in comparison with three baselines discussed above.

Both our systems (Model-1 and Model-2) beat the baseline phrase-based system with a BLEU point difference of 4.30 and 2.75 respectively. The transliteration aided phrase-based systems Pb_1 and Pb_2 are closer to our Model-2 results but are way below Model-1 results. The difference of 2.35 BLEU points between M_1 and Pb_1 indicates that transliteration is useful for more than only translating OOV words for language pairs like Hindi-Urdu. Our models choose between translations and transliterations based on context unlike the phrase-based systems Pb_1 and Pb_2 which use transliteration only as a tool to translate OOV words.

5 Error Analysis

Based on preliminary experiments we found three major flaws in our initial formulations. This section discusses each one of them and provides some heuristics and modifications that we employ to try to correct deficiencies we found in the two models described in section 3.1 and 3.2.

[12]After having the MERT parameters, we add the 600 dev sentences back into the training corpus, retrain GIZA, and then estimate a new phrase table on all 5600 sentences. We then use the MERT parameters obtained before together with the newer (larger) phrase-table set.

5.1 Heuristic-1

A lot of errors occur because our translation model is built on very sparse and noisy data. The motivation for this heuristic is to counter wrong alignments at least in the case of verbs and functional words (which are often transliterations). This heuristic favors translations that also appear in the n-best transliteration list over only-translation and only-transliteration options. We modify the translation model for both the conditional and the joint model by adding another factor which strongly weighs translation+transliteration options by taking the square-root of the product of the translation and transliteration probabilities. Thus modifying equations (8) and (11) in Model-1 and Model-2 we obtain equations (15) and (16) respectively:

$$p(h_i|u_i) = \lambda_1 p_w(h_i|u_i) + \lambda_2 \frac{p_c(h_i,u_i)}{p_c(u_i)} + \lambda_3 \sqrt{p_w(h_i|u_i)\frac{p_c(h_i,u_i)}{p_c(u_i)}} \quad (15)$$

$$p(h_i,u_i) = \lambda_1 p_w(h_i,u_i) + \lambda_2 p_c(h_i,u_i) + \lambda_3 \sqrt{p_w(h_i,u_i)p_c(h_i,u_i)} \quad (16)$$

For the optimization of lambda parameters we hold the value of the translation coefficient λ_1[13] and the transliteration coefficient λ_2 constant (using the optimized values as discussed in section 4.2.1) and optimize λ_3 again using 2-fold optimization on all the folds as described above[14].

5.2 Heuristic-2
