dependency parsing.

3. A CNN-based architecture for classifying sentences to 12 information units followed by rules to generate triples (semantic statements that pair scientific terms with a relation, modeled toward subject-predicate-object RDF statements for KG building).

The rest of this paper is organized as follows: Section 2 briefly summarizes some related works similar to this task followed by the problem statement of this task. Section 4 describes the details of the data provided by the organizers. Section 5 and 6 presents the details of our model for all three phases of the task, including the structure and its implementations, along with results and experimental details. The conclusions and the directions for the future research are provided in Section 8.

## 2 Related Work

Although this is a relatively new challenge, we found some related investigations in the literature. [Vogt et al. \(2020\)](#) proposed a novel semantic data model for modeling the contribution of scientific investigations of three domains, viz. Medicine, Computer Science, and Agriculture. The model includes a schema of relevant concepts highlighting six core information units, viz. Objective, Method, Activity, Agent, Material, and Result. They introduced the idea of building blocks called Knowledge Graph Cells for its knowledge graph application.

[Gupta and Manning \(2011\)](#) introduced a new categorization of key aspects of scientific articles, which is (1) FOCUS: main contribution, (2) TECHNIQUE: method or tool used, and (3) DOMAIN: application domain. They extracted the aspects by matching semantic patterns to dependency trees and learn the patterns using bootstrapping. They also present a case study on the computational linguistics community using the three aspects extracted from its articles, verifying our system’s results and showing novel results for the dynamics and the overall influence of computational linguistics subfields.

[Hayashi et al. \(2020\)](#) introduced a new task of disentangled paper summarization to generate summaries for the paper contributions and the work context to help identify the key findings shared in articles.

[Rusu et al. \(2007\)](#) presented an approach to extracting subject-predicate-object triplets from En-

glish sentences. They used four different well-known syntactic parsers for English to generate parse trees from the sentences, followed by extraction of triplets from the parse trees using parser-dependent techniques. A machine learning approach has been used by [Dali and Fortuna \(2008\)](#) to extract subject-predicate-object triplets from English sentences. Support Vector Machine (SVM) is used to train a model on human annotated triplets, and the features are computed from three parser.

## 3 Problem Definition

The problems are defined by the shared task organizers.

1. For Phase-1 (End-to-end Pipeline), given a scientific paper we have to output contributing sentence  $S_1, S_2, S_3 \dots S_{|n|}$  (where  $n$  is the number of contributing sentences present in the document), scientific term and predicate phrases from the contributing sentences and finally triples information for particular information units.
2. For Phase-2, Part 1 (Phrases and Triples), we are provided with gold annotated contributing sentences and we have to output scientific terms and predicate phrases from the contributing sentences.
3. Lastly, for Phase 2, Part 2 (Triples Extraction), along with the gold annotated contributing terms, the gold-labeled scientific term and predicate phrases are also provided. We have to output the triplets information for particular information units.

Table 2 shows the three sub-tasks with an example.

## 4 Dataset Description

[D’Souza et al. \(2021\)](#) released the data for this task. We are provided with a training set of 55084 sentences, taken from 236 annotated papers from across 24 various fields in the NLP domain (such as natural language inference, question answering, sarcasm detection, etc.). Out of these, 5084 comes under the category of contributing sentences, and the remaining are non-contributing sentences. Triples are organized into three (minimum) up to 12 information units (Research Problem, Approach, Model, Code, Dataset, Experimental Setup, Hyperparameters, Baselines, Results, Tasks, Experiments, and Ablation Analysis). The detailed description of

Information unit	Description	Example
Research Problem	It determines the research challenge addressed by a contribution using the predicate has ResearchProblem. By definition, it is the focus of the research investigation, in other words, the issue for which the solution must be obtained.	A Question - Focused Multi- Factor Attention Network for Question Answering
Approach or Model	Essentially, this is the contribution of the paper as the solution proposed for the research problem.	"More specifically , unlike existing models where the query attention is applied either token - wise or sentence - wise to allow weighted aggregation , the Gated - Attention ( GA ) module proposed in this work allows the query to directly interact with each dimension of the token embeddings at the semantic - level , and is applied layer - wise as information filters during the multi-hop representation learning process ." & First , it is embedding - agnostic , meaning that one of the main ( and perhaps most important ) hyperparameters in NLP pipelines is made obsolete .
Code	It is the link to the software on an opensource hosting platform such as Gitlab or Github or on the author's website.	We compute a vector gate as a linear projection of the token features followed l Code is available at <a href="https://github.com/kimiyoung/fg-gating">https://github.com/kimiyoung/fg-gating</a> l ar Xiv: 1611.01724v2 [ cs.CL ] 11 Sep 2017
Dataset	This is another aspect of the contribution solution in the form of a dataset.	To address this , this paper introduces the Stanford Natural Language Inference ( SNLI ) corpus , a collection of sentence pairs labeled for entailment , contradiction , and semantic independence .
Experimental Setup or Hyperparameters	Includes details about the platform including both hardware (e.g., GPU) and software (e.g., Tensorflow library) for implementing the machine learning solution; and of variables, that determine the network structure (e.g., number of hidden units) and how the network is trained (e.g., learning rate), for tuning the software to the task objective. It is called Experimental Setup when hardware details are provided, otherwise Hyperparameters.	We used pre-trained 300D Glove 840B vectors to initialize the word embeddings . & This takes two days using Tensorflow and a single NVIDIA K80 GPU . provide an official evaluation script that allows us to measure F 1 score and EM score by comparing the prediction and ground truth answers .
Baselines	They are the listed systems that a proposed Approach or Model is compared against.	( 5 ) BM25 : BM25 is a bag - of - words retrieval function that ranks a set of reviews based on the question terms appearing in each review .
Results	The main findings or outcomes reported in the article text for the ResearchProblem.	Overall , we observe a significant improvement with all three configurations , effectively showing the benefit of training a QA model in a semisupervised fashion with a large language model .
Tasks	The Approach or Model, particularly in multi-task settings, are tested on more than one task, in which case, we list all the experimental tasks. The experimental tasks are often synonymous with the experimental datasets since it is common in NLP for tasks to be defined over datasets. And where lists of Tasks are concerned, the Tasks can include the ExperimentalSetup as a sub information unit.	All the above subtasks have been modeled as binary classification problems : kernel - based classifiers are trained and the classification score is used to sort the instances and produce the final ranking .
Experiments	It is a container information unit that includes one or more of the previous discussed units as sub information units. Can be combination of lists of Tasks, ExperimentalSetup and Results, or a combination of Approach, ExperimentalSetup and Results.	The temperature parameter ? of Gumbel - Softmax is set to 1.0 , and we did not find that temperature annealing improves performance .
Ablation Analysis	It is a form of Results that describes the performance of components in an Approach or Model.	In , we removed dense connections over both co-attentive and recurrent features , and the performance degraded to 88.5.

(ES, used, BERTBASE model)
(BERTBASE model, pre-trained on, English Wikipedia)
(BERTBASE model, pre-trained on, BooksCorpus)
(BERTBASE model, for, 1M steps)

Table 2: Example of a Contributing Sentence, corresponding Scientific Term and Predicate Phrase, and extracted Triples

these information units is shown in Table 1. Overall, the annotated corpus contains 2631 triples (avg. of 52 triples per article). Its data elements comprise 1033 unique subjects, 843 unique predicates, and 2182 unique objects. Of all tasks, relation classification has the highest number of unique triples (544) and named entity recognition the least (473).

## 5 Proposed Approach

We describe our approach for all three phases of the competition as follows:-

### 5.1 Phase-I: Identifying Contributing Sentences

#### 5.1.1 Sentence Filtering

Initially, we use the Scholarcy API<sup>2</sup> to do some preliminary data analysis to understand some essential information (key concepts, highlighted sentences) in the challenge corpus.

To reduce the data-imbalance ratio of contributing and non-contributing sentences, we filter out most non-contributing sentences. We employ a simple bi-gram filtering to achieve this. We extract all the bi-gram pairs from the entire training corpus and assign each bi-gram pair a score (number of times the bi-gram pairs occurs in the corpus divided by 1000), based on which we set a threshold<sup>3</sup> and filter out the sentences. After filtering, 37.4% non contributing sentences are removed while only 7.07% of contributing sentences are filtered. The example in Figure 1 explains our approach.

*We have a state of the art model with an initial learning rate of 0.05,*

<sup>2</sup><https://www.scholarcy.com/>

<sup>3</sup>see our Github link mentioned in the abstract for details

Bigram tuples	Score
('<s>', 'We')	0.361
('<s>', 'The')	0.267
('of', 'the')	0.262
('on', 'the')	0.174
('in', 'the')	0.148
('<s>', 'In')	0.147
('to', 'the')	0.11
('with', 'the')	0.101
('and', 'the')	0.098
('state', 'of')	0.088
('the', 'art')	0.088
('with', 'a')	0.081
('the', 'model')	0.08
('our', 'model')	0.079
('learning', 'rate')	0.073
('<s>', 'Our')	0.071
('for', 'the')	0.068
('We', 'use')	0.068
('set', 'to')	0.064
('<s>', 'For')	0.063
('In', 'this')	0.058
('that', 'the')	0.058
('of', '%')	0.053
('word', 'embeddings')	0.053
('rate', 'of')	0.051
('natural', 'language')	0.05
('we', 'propose')	0.05
('is', 'a')	0.049
('from', 'the')	0.048
('this', 'paper')	0.047
('the', 'performance')	0.047
('based', 'on')	0.046
('<s>', 'To')	0.046
('is', 'set')	0.046
('question', 'answering')	0.044
('which', 'is')	0.044
('number', 'of')	0.044
('and', 'a')	0.042
('use', 'the')	0.042
('<s>', 'This')	0.04
('of', '< e >')	0.04
('batch', 'size')	0.04
('the', 'best')	0.039

Table 3: The topmost Bigram scores in non-increasing order; here(<s> denotes start token <e> denotes end token

From our generated list of bi-gram scores:

(< s >, 'We'), has a score of 0.308, ('state', 'of') has a score of 0.088 and so on. The total score is then calculated by summing the score of individual bi-grams.

#### 5.1.2 Classification Model

Input is the sequence of filtered sentences  $S = S_1, \dots, S_n$ , where  $n \leq 10$ . We set a threshold of 10 sentences on the number of sentences per sequence as released BERT pretrained weights support sequences of up to 512 word-pieces (Wu et al., 2016). The standard [CLS] is inserted as the first token of the sequence, and another delimiter token [SEP] is used for separating the segments.

After processing each sentence, we feed it into a SciBERT model (Beltagy et al., 2019) which is a variant of BERT, trained on scientific papers, as shown in Figure 2. The pre-training task of BERT (Devlin et al., 2019a) depends on two unsupervised sub-tasks: masked language modeling

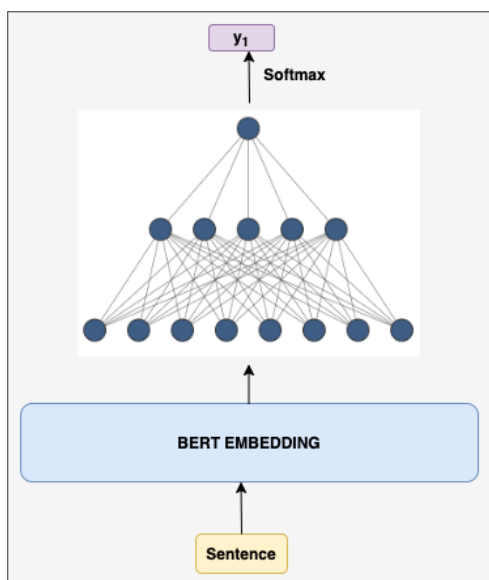

Figure 2: Classification of Contributing and Non-Contributing using a pre-trained SciBERT model

(MLM) and next sentence prediction(NSP). These two sub-tasks use the same model architecture but with different input patterns and different output layer. In MLM, a fixed amount of tokens of the input sequences is masked, and the model is trained for predicting the original tokens of the masked tokens. In NSP, the model has to predict whether two sequences of text are naturally following each other or not. 50% data is generated automatically by taking sentence pairs next to each other, and the other 50% is generated by taking sentence pairs randomly from the unlabeled corpus. The initial input embedding( $E_{Tok}$ ) is calculated by summing up the token, sentence and positional embedding. In the case of MLM, the final hidden vector of each of the masked tokens is passed to a softmax classifier(output layer) to predict the original token. On the other hand, during NSP, the final hidden vector( $C$ ) of the [CLS] token is fed to a binary classifier(output layer) to predict whether the input pair is following each other or not.

In the fine-tuning part for downstream tasks, we use the encoding of the [SEP] tokens to classify each sentence. The transformer layers (Devlin et al., 2019a) allows the model to fine-tune the weights of these special tokens according to the task-specific training data. We use a multi-layer feed forward network on top of the [SEP] representations of each sentence to classify them to the categories(is contributing or not?). During fine-tuning, the model learns appropriate weights for

Model	F1 (with filtering)	F1 (w/o filtering)
CNN+Glove	0.3123	0.1347
$Bert_{base}$	0.3578	0.1681
Our model	0.3987	0.1872

Table 4: Result of classification to contributing sentences, all are F1 scores

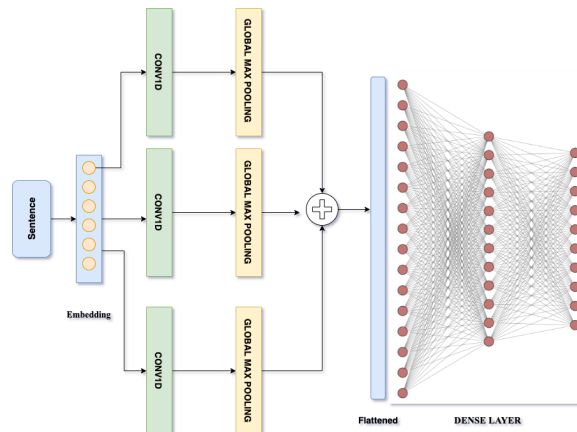

Figure 3: Architecture of classification of sentence into corresponding information units

the [SEP] token to capture contextual information and learn sentence structure and relations between continuous sentences (through the next sentence objective). Further, we use a softmax classifier on top of the MLP to predict the label’s probability.

### 5.1.3 Experimental Setup

We perform all our experiments on a GPU (GeForce RTX 2070) with 8 GB of memory. In phase-1, for contribution and non-contributing sentence classification task, we use the AllenNLP (Gardner et al., 2018) toolkit for the model implementation. As in prior work (Devlin et al., 2019b), for training we use the dropout of 0.1, the Adam optimizer for 2-5 epochs, and learning rates of  $5e-6$ ,  $1e-5$ ,  $2e-5$ , or  $5e-5$ .

## 5.2 Phase-II, Part 1: Phrase and Triples Extraction

Our system used an unsupervised rule-based system for extracting scientific entities and their predicates from the contributing sentences. As part of our initial experiments, we tried existing keyword extraction models such as RAKE, but they did not produce good results (e.g. F1 of 0.1062), as they are not tuned to this dataset. Given the paucity of training data for this task, we built a rule-based model for phrase extraction. We used the spacy

Phase	Avg F1	Sentences	Phrases span only	Information units	Triples + all units
Phase-1	0.3205	0.3987	0.1563	0.7172	0.0097
Phase-2, Part-1	0.5252	1.00	0.3740	0.7172	0.0097
Phase-2, Part-2	0.5971	1.00	1.00	0.3472	0.0413
<b>Top-performing System</b>					
Phase-1	0.4703	0.5941	0.4522	0.7293	0.1379
Phase-2, Part-1	0.7612	1.00	0.7857	0.8249	0.4344
Phase-2, Part-2	0.8594	1.00	1.00	0.8249	0.6129

Table 5: Our results for the three phases. Note: All scores in the table are F1 scores

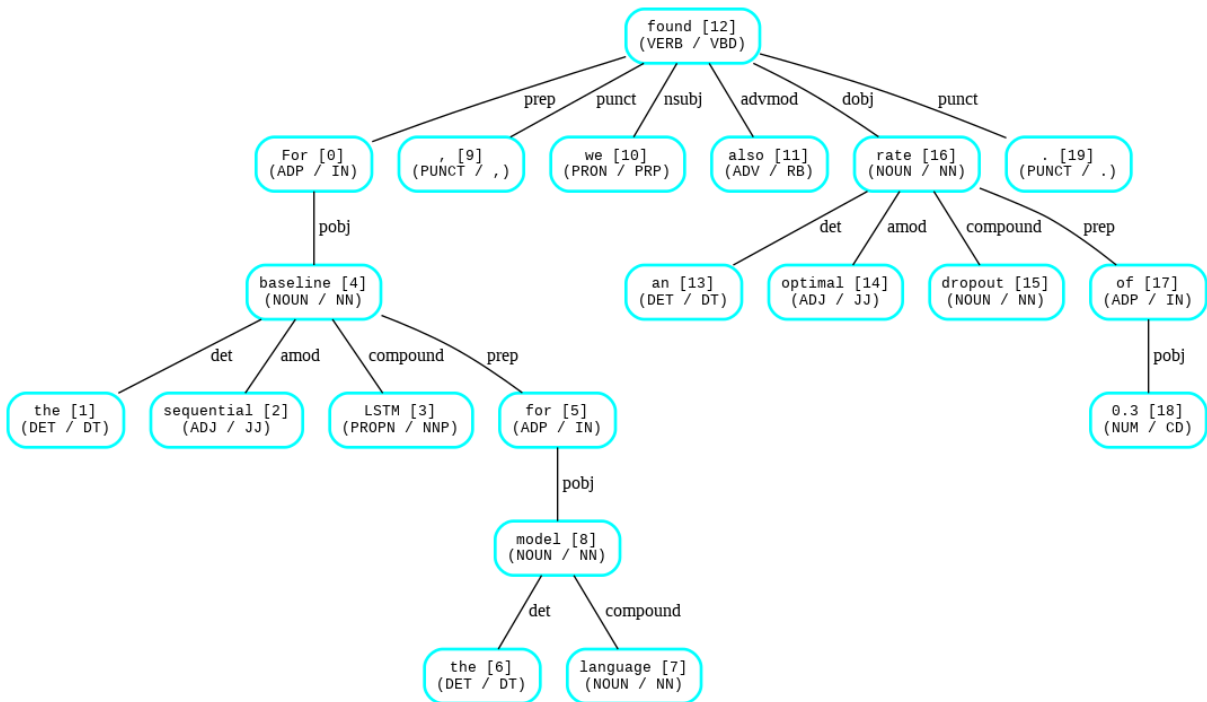

Figure 4: Example showing dependency parsing tree of a sentence

Non-contributing sentences misclassified as contributing sentences.	Reason
A model only achieved an F1 score of 86.5 on our development set, that is over 2 points lower than the 88.7 of a LSTM + A+D model.	Our model fails to differentiate between a general sentence that gives essential information but has no relation to the paper's model
As a by-product of our investigation, a variant of the RNNG without ensembling achieved the best reported supervised phrase - structure parsing ( 93.6 F1 ; English PTB ) and , through conversion , dependency parsing ( 95.8 UAS , 94.6 LAS ; PTB SD ).	Our model misclassified those sentences as contributing sentence which contains a large number of scientific terms
The elements of the stack that comprise the current constituent ( going back to the last 2 <a href="https://github.com/clab/rnng/tree/">https://github.com/clab/rnng/tree/</a>	It misclassified those sentences as contributing, which contains links that are not explicitly related to the paper

Table 6: Error analysis of Phase-1 (contributing sentence)

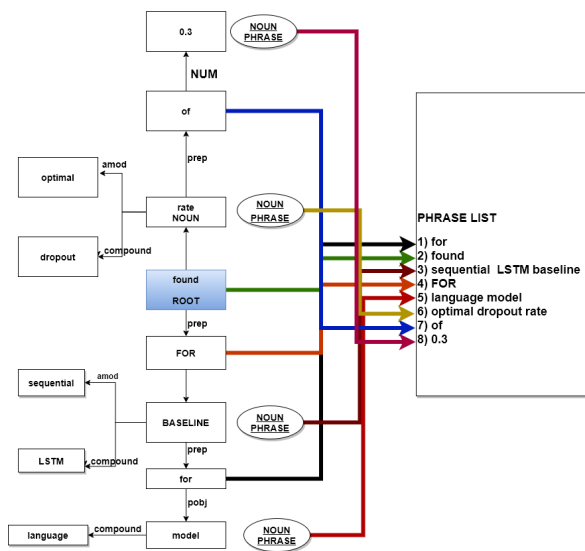

Figure 5: Illustration of addition of phrases to phrase list following rules for the sentence in Figure 4

True phrases	Predicted phrases
both models	models
tuned	tuned
dropout rate	dropout rate
to maximize	maximize
validation set likelihood	validation set likelihood
obtaining	
optimal rates	optimal rates
of	For
0.2 ( discriminative )	
0.3 ( generative )	

Table 7: Error analysis of Phase-2 (Phrase Extraction)

dependency parser<sup>4</sup> to generate a dependency tree for each contributing sentence. An example tree for the sentence, "For the sequential LSTM baseline for the language model, we also found an optimal dropout rate of 0.3," is shown in Figure 4. The rules specified are in such a format that considers some of the minute details, like if a word with "nsubj" dependency tag is a pronoun occurring at the start of the sentence, then the word should not be included in the phrase. We observed that the "ROOT" of the parsing tree (here: found) is primarily a constituent of the phrase list for that sentence, so we appended it. Next, we started exploring some particular child nodes of the "ROOT" node (mainly with dependency tags "dobj," prep," "advmod") as we tried to extract and form a proper noun, verb phrases, as shown in Figure 4. As soon as a child node with "NOUN" tag is found, complete noun phrase, is appended to the phrase list. At any level, if the child node (Cn) is a modifier (dependency tag 'prep'), then we will individually append it to the phrase list, followed by the subsequent exploration of the following hierarchy child nodes of Cn. This procedure continues recursively until we reach the leaf nodes for a branch. More details of various rules created by us for our unsupervised algorithm can be found in our shared source code.

### 5.3 Phase-II, Part 2: Triples Extraction

As there was little explicit section information in the provided parsed corpus, we classified each sentence into the 12 information units described above. We used a simple CNN-based neural architecture, and the model structure is shown in Fig 3. The first layer is the data input layer, followed by the embedded layer, which creates a numerical representation of the textual data. Then there are three parallel CNN models, each of which has a double convolution means a combination of a convolution layer and a pooling layer. To fully consider each word's information before and after, extract the size of the local characteristics of different sizes of 2x100,3x100,4x100. After the processing of the convolution layer, the characteristics of text classification are more advantageous. Based on this, the pooling layer is further screened from the global perspective where max pooling is used, followed by the merged layer, dense layer, dropout layer with a rate of 0.2. Finally, the text data is passed to a softmax function for outputting the classification

<sup>4</sup><https://spacy.io/>

result.

For triples creation, we created some rules. For research problems, triples are mainly in the form: "Contribution" followed by "has research problem" followed by the statement's scientific entity. For example:

*Contribution||has research problem||Text Comprehension*, is formed from the sentence "Gated - Attention Readers for Text Comprehension" belonging to a research problem.

We generate the triples in this format with the already extracted scientific phrases for the research problem information unit. Code triples are mainly in the form: "Contribution" followed by "code" followed by the URL of the available source code. For example:

*Contribution||Code||https://github.com/mandarjoshi90/coref*

We extract the URL using regular expression and generate the triples in the above format. We identified subjects along with their directly linked objects and predicates describing the relation between them for other triples. For example, if there is a sentence,

*ST Gumbel - Softmax estimator relaxes the discrete sampling operation to be continuous in the backward pass, thus our model can be trained via the standard backpropagation*

we form the triples as:

*(Contribution||has||Model),  
(Model||use||Straight-Through (ST) Gumbel-Softmax estimator)*

## 6 Evaluation

We report the evaluation results of all the three phases on Table 5. Average F1 score was to rank the participants in the competition. Precision, recall, and other details of the competition are available on leaderboard<sup>5</sup> of the competition. We also report the ablation analysis and the effect of filtering sentences in the extraction of contributing sentences of phase-1 in Figure 4. For phases-2 part-1, as were already provided by the gold label contributing sentences, the average F1-score of the contributing sentence is 1. Similarly, for phases-2 part-2, as were already further offered the gold label phrases, the average F1-score of the contributing sentence and the phases is 1. We reported a 0.32 average F1 for phase-1(end to end pipeline),

<sup>5</sup><https://competitions.codalab.org/competitions/25680#results>

0.52 for phase-2(phrases and triples extraction) and 0.59 for phase-3(triples extraction).

## 7 Error Analysis

As shown in Table 6 these sentences are non-contributing but misclassified as contributing sentences.

In phase 2, our model is based on rules, so it fails to capture unique or very different tree structures. For example as shown in Table 7, in sentence:-  
"For both models, we tuned the dropout rate to maximize validation set likelihood, obtaining optimal rates of 0.2 (discriminative) and 0.3 (generative).".

The phrases such as "0.3 (generative)" and "0.2 (discriminative)" was not captured. Our model also captured the single word phrase "maximize" instead of the true phrase "to maximize".

## 8 Conclusion and Future Work

With the NLPContributionGraph Shared Task, we have attempted to formalize the building of a scholarly contributions-focused graph over NLP scholarly articles as an automated task. Results and analysis on the gold test dataset show that our approach performed reasonably well in identifying contributing sentences and phrase extraction. However, we didn't perform well in triples extraction. In the future, we plan to improve the system, especially the triples extraction phase.

## Abstract

In this work, we present our approach for solving the SemEval 2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation (MCL-WiC). The task is a sentence pair classification problem where the goal is to detect whether a given word common to both the sentences evokes the same meaning. We submit systems for both the settings - Multilingual (the pair's sentences belong to the same language) and Cross-Lingual (the pair's sentences belong to different languages). The training data is provided only in English. Consequently, we employ cross-lingual transfer techniques. Our approach employs fine-tuning pre-trained transformer-based language models, like ELECTRA and ALBERT, for the English task and XLM-R for all other tasks. To improve these systems' performance, we propose adding a signal to the word to be disambiguated and augmenting our data by sentence pair reversal. We further augment the dataset provided to us with WiC, XL-WiC and SemCor 3.0. Using ensembles, we achieve strong performance in the Multilingual task, placing first in the EN-EN and FR-FR sub-tasks. For the Cross-Lingual setting, we employed translate-test methods and a zero-shot method, using our multilingual models, with the latter performing slightly better.

## 1 Introduction

A key challenge in lexical semantics is to identify or to encode the different senses of an ambiguous word. The Word Sense Disambiguation task (WSD) (Navigli, 2009) is a framework used to evaluate systems in their ability to identify different senses of the word. The task involves selecting the correct sense (meaning) of a target word from a list of senses listed in a sense inventory like WordNet (Fellbaum, 2012). Pilehvar and Camacho-Collados

(2018) proposed a novel benchmark (WiC - Word in Context Disambiguation) for the task casting the problem as a binary classification task, wherein it has to be identified whether a word common to a sentence pair is used in the same sense or not. The WiC task frees up the word sense disambiguation task from being tied to any sense inventory.

The SemEval 2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation (Martelli et al., 2021) extends the WiC framework proposed by Pilehvar and Camacho-Collados (2018) to more languages. The task is divided into two subtasks - the Multilingual task and the Cross-Lingual task. The sentence pair, with a word in common, which is to be disambiguated, is drawn from the same language in the MultiLingual task, whereas the pair is drawn from two different languages in the Cross-Lingual Task. The task is posed as binary classification task over a pair of sentence wide contexts  $sent1$  and  $sent2$ , containing word sequences  $w_1$  and  $w_2$  respectively. The word sequences,  $w_1$  and  $w_2$ , have a common word in lemmatized form  $lemma$ . When  $w_1$  and  $w_2$  invoke the same sense of the lemma in their respective contexts, it is to be labeled as 'T' (True) class, else it labeled 'F' (False). As mentioned before, for the Multilingual setting,  $sent1$  and  $sent2$  are from the same language; for the Cross-lingual setting,  $sent1$  is from English, and  $sent2$  is from a non-English language. The languages considered for the Task are Arabic (AR), English (EN), French (FR), Russian (RU), and Chinese (ZH). Therefore for the Multilingual evaluation, we have AR-AR, EN-EN, FR-FR, RU-RU, and ZH-ZH settings, and for the Cross-Lingual evaluation, we have EN-AR, EN-FR, EN-RU, and EN-ZH settings. An example of Cross-Lingual sentence pair is given in figure 1. This task provides an evaluation benchmark for word sense disambiguation systems in languages other than English, a direction that has been less

\* Authors equally contributed to this work.

explored.

For this task, the training data is only provided for the EN-EN setting, and the development sets are provided only for the Multilingual task. As we are proposing supervised systems, it is essential to consider if we have training data or not. Therefore, splitting the Multilingual task, we propose systems for three components - (i) EN-EN (train and dev data available), (ii) Non-English Multilingual (only dev data available), and (iii) Cross-Lingual (neither train nor dev data available). Our models and implementations are available here<sup>1</sup>.

## 2 Related Work

**Word Sense Disambiguation:** The techniques for the WSD task are broadly divided into knowledge-based and supervised approaches. The supervised approaches include fine-tuning BERT for sequence classification (Wang et al., 2019), EWISE (Kumar et al., 2019), and BiLSTM with attention (Raganato et al., 2017b). The knowledge-based methods use the information present in sense inventories such as WordNet (Fellbaum, 2012), BabelNet (Navigli and Ponzetto, 2012) and Wikipedia to derive semantic knowledge, assisting in the task of WSD. These include building sense embeddings for each sense of the word and disambiguate the target word using the nearest neighbour sense embedding: SensEmbBERT (Scarlini et al., 2020), (Loureiro and Jorge, 2019), or augmenting the pre-training objecting of BERT to take into account the sense information available in the WordNet: SenseBERT (Levine et al., 2019).

There are two existing benchmarks to evaluate the performance of WSD systems. One method is linked to the sense inventories, and the task is framed as a multi-class classification among the senses of a word listed in the inventory (Raganato et al., 2017a). The other is the WiC framework, not tied to any sense inventory, and asks if a target word has the same sense or not in the two given sentences.

<sup>1</sup><https://github.com/dipakamiitk/Crosslingual-WSD.git>

	Multilingual (EN-EN)	Multilingual (Others)	Cross-Lingual
Train Data	8000	✗	✗
Dev Data	1000	1000 (each)	✗

Table 1: Available data for this task. All datasets are balanced, that is, equal number of 'True' and 'False' pairs.

Recently, transformer-based architectures (Vaswani et al., 2017) (e.g., T5 (Raffel et al., 2019)) have outperformed all existing approaches when fine-tuned on the WiC task.

**Cross-Lingual NLP:** There are many NLP tasks for which the data is present in only some high resource language (often English), but the task needs to be solved for other languages. Some existing methods involve - (i) using multi-lingual language models (like mBERT (Devlin et al., 2018), XLM-R (Conneau et al., 2019)) to train on the high resource language and transfer the learning to other languages, or (ii) the translation approaches where we can translate train or test data to a target language and train a language-specific model. These methods have shown good performance on benchmarks like XGLUE (Liang et al., 2020) and XTREME (Hu et al., 2020), which have been designed to test this cross-lingual transfer performance of systems, with train data being present majorly in English, while the testing is to be done in other languages.

## 3 Corpus Description and Data Augmentation

A brief summary of the available data is shown in Table 1. This data is manually curated and covers four parts of speech - Nouns, Verbs, Adjectives, and Adverbs. In addition, we augmented the data by utilizing WiC, XL-WiC, and SemCor.

**WiC:** We use the data provided by the WiC task (Pilehvar and Camacho-Collados, 2018), which proposes the same problem as this task but only in English. They collected their data semi-automatically from WordNet (Fellbaum, 2012), and covered only Nouns and Verbs.

**XL-WiC:** It is a dataset that is an extension of the WiC dataset to multiple languages (equivalent to our multilingual setting) (Raganato et al., 2020). Again, the data was collected automatically from WordNet and Wiktionaries of various

languages. We are only interested in a few languages, from the WordNet development sets, the ones with good human performance, because we often note that this data does not accurately represent human distinguishable senses, which our manually collected task data set does. Specifically, we use Chinese(ZH), Danish(DA), Croatian(HR), and Dutch(NL). Farsi(FA) also has good human performance but we could not include it due to a pre-processing error.

**AuSemCor:** We created our own augmented dataset AuSemCor from the SemCor (Miller et al., 1993) dataset, which is a sense annotated corpora in English, with senses tagged using WordNet as its sense inventory. To generate data points for the same sense (T class), we pair up sentences containing a common lemma, whose WordNet senses are identical. For the other class (F class), we pair up sentences with a common lemma, but this lemma has different WordNet sense across the sentence pair. In addition, for the F class, we make sure that the WordNet supersense is also different for creating coarser sense distinctions as suggested by Pilehvar and Camacho-Collados (2018). We obtain 4986 datapoints with 2520 unique words. It is approximately balanced (2495 ‘F’ and 2491 ‘T’ pairs). Like WiC, it covers only Nouns and Verbs.

## 4 Proposed Approach

We shall now describe our proposed approaches for the two subtasks, multilingual and cross-lingual. We deal with English separately because training data is available in English and not in any other language. Since the data across the two tasks differ only in the language pairs, some general approaches apply to both settings. We finally submit an ensemble of models in all the tasks. The ensembling was done by taking average of the probability scores of the models (Probability Sum Ensemble).

### 4.1 Task Agnostic Proposals

**Signals:** We use a data preprocessing step of applying a signal to indicate the word to be disambiguated. This can be done in two ways - (i) *Signal 1:* encoding the target word (the word to be disambiguated) in both the sentences of a pair within double quotes (e.g., *Click the right “ mouse ” button*) as suggested by Huang et al. (2019), or (ii) *Signal 2:* append the target word at the end of the second sentence, similar to what was done by Wang et al. (2019). Note, for the former method;

we need the character spans of the target word to apply double quotes at the correct position.

**Sentence Reversal Augmentation:** For the models proposed in this task, the sentence pair is fed to the model in a manner such that the results do depend on which order the sentences are fed (i.e. the network parameters are not symmetric with respect to the two sentences). In such a case we propose the following augmentation - for every data point ( $sent1, sent2, lemma, label$ ), add another data point ( $sent2, sent1, lemma, label$ ) to the set of data points. A similar notion can be extended to making more robust predictions - at inference, before thresholding on the probability scores returned by the model, take into account the reversed sentence order, and average both the results. If such an averaging policy is followed for a particular model on the dev set, we follow the same policy on the test set. The *rev* subscript shall be used with dataset names to indicate that the data has been doubled using sentence reversal augmentation or with a model name to indicate that the model performs the reverse sentence averaging at inference for more robust predictions.

**Transformers+Logistic Regression:** Here we use the transformer-based pre-trained language model as an encoder network, feeding it with the sentence pairs concatenated with a separator token ( $[CLS]E(x_{sent1}^i[SEP]x_{sent2}^i[SEP])$ ). We then extract the word level embeddings (last layer hidden state) for each instance of the word (from both sentence 1 and sentence 2). If the word gets sub-tokenized, we pick the embedding of the first sub-token. We finally feed their concatenation to a logistic regression head, with binary cross-entropy as the loss function. The architecture can be seen in Figure 2. We used ELECTRA (Clark et al., 2020), ALBERT (Lan et al., 2019), XLM-R (Conneau et al., 2019) for English only data, and XLM-R for all other language data. Unless otherwise mentioned, we use the ‘*large*’ variant for ELECTRA and XLM-R, and the ‘*xxlarge*’ variant for ALBERT.

**Siamese Architecture:** Here, we cast our problem as a similarity problem. Similarity being measured by the closeness of the senses of the target word in each of the sentence. We, therefore, use a Transformer-based Pretrained Language Model to obtain the contextualized representations of the target word across the two sentences (using same model weights for both sentences), and optimize

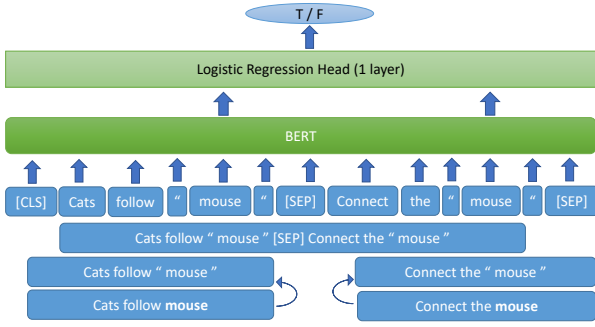

Figure 2: The Transformers + Logistic Regression Architecture (+ *Signal I*). This is our proposed architecture.

the contrastive loss (Hadsell et al., 2006) -

$$\mathcal{L} = \sum_i^{|T|} D_i^2 + \sum_j^{|F|} \max(0, m - D_j)^2$$

Where the set  $T$  is a set of same meaning sentence pairs, and  $F$  has different meaning pairs.  $D_i$  is the distance metric between the contextualized representations obtained for the target word by the language model for the pair of sentences. A small  $D_i$  would mean that the senses of the common word across the two sentences are the same.  $m$  is the margin parameter of the loss. We experiment with  $L_2$  and Cosine distances. We found this method to be good but not competitive with the Transformers+Logistic Regression method.

## 4.2 English (EN-EN) Task Proposal

For English language pair, we have dedicated training data (which we shall abbreviate as MCL-EN) that is used to train models. We used the proposed Transformers+Logistic Regression architecture and the preprocessing method of including signals using double-quotes.

In addition to sentence reversal augmentation, we augment the data using WiC and AuSemCor (Section 3). Both the WiC and the AuSemCor data have been automatically created using certain heuristics (Section 3), which make the sense distinctions in both the dataset a little different than what a human annotator would do. This is evidenced by the fact that human performance on the WiC benchmark is only 80%, while it is 97% on the Farsi dataset from the XL-WiC corpus, which was manually annotated. As this task’s data is human annotated, we do not use sentence reversal augmentation with WiC and AuSemCor data to avoid an

over-representation of the automatically annotated data in our training set.

## 4.3 Multilingual Task (except EN-EN) Proposal

For this task as well, we use Transformers+Logistic Regression architecture (the transformer being the multilingual XLM-R (Conneau et al., 2019)), with double-quote signal preprocessing and sentence reversal augmentation.

**Data:** For the four languages under this task, we have no training data. To address that, we split the development set for each of the language pairs into a 9:1 train-dev split. The split can be done in two ways - a random split or an out-of-vocabulary split (the 1 split will primarily have words not present in the 9 split). The latter’s motivation is to simulate the test set because the test set’s words will be unseen (not seen during training). The former may be useful as well because the model can see and learn more words during training. This distinction is based on Raganato et al. (2020)’s observation that models tend to perform better on seen words than unseen words during evaluation. We experiment using both split types. All languages’ data is concatenated together, and we solve the task for these four languages together by a single XLM-R model. We also use the EN-EN data of our task during this training. For development, we finally have  $100 \times 4$  data points, which we augment again by sentence reversal augmentation, thereby finally obtaining a dev set of 800 pairs. Since we perform sentence reversal on dev set, at test inference, we follow the reverse averaging policy as described before. This is denoted by a subscript *rev* in the model names. In our further discussion, we shall refer to this multilingual train data as MCL-MN<sup>rand</sup>, for the random split method, or MCL-MN<sup>oov</sup> for the out-of-vocabulary split method.

We augment our data using XL-WiC (Section 3). However, we do not use the XL-WiC data on all models, and whenever we do, we do not perform sentence reversal, to prevent higher representation of lower quality data. Sentence reversal is also not performed with English to have as much proportion of non-English data as possible in the training phase.

## 4.4 Cross-Lingual Task Proposal

For this task, we have no training or development data. We propose two methods - (i) Translate-Test, (ii) Multilingual Zero-Shot.

**Translate-Test:** In this method, we use Microsoft Translator<sup>2</sup> to translate the second sentence (in either AR, FR, RU, ZH) of the test set to English, thereby reducing it to an EN-EN task. However, this method is bound to introduce inaccuracies from translation, and we lose positional information about the target word in the translated sentence. So we cannot use word-level embeddings, and therefore the Transformer+Logistic Regression Model (Section 4.1) cannot be used. We, therefore tweak the Transformers+Logistic Regression architecture a little - we use the [CLS] token embedding instead of the word-level embeddings, keeping the Logistic regression head intact. For development, we use a back-translated EN-EN dev set (EN to FR to EN) for the second sentence to simulate inaccuracies of translation that will be induced in the second sentence in the test set. For training as well, we back translate 50% of the second sentence (12.5% to each AR, FR, RU, and ZH and back to en). Due to the loss of positional information about the target word after translation, we experiment with using *Signal 2* - appending the target word at the end of the second sentence. We use ELECTRA (Clark et al., 2020) as the encoder for this sub-task.

**Multilingual Zero-Shot:** In this method, we directly use the models obtained from our Multilingual task (section 4.3) on the Cross-Lingual test data.

## 5 Experiments and Results

We ran various experiments to test out the efficacy of the different approaches. All experiments have been carried out with a learning rate set at  $10^{-5}$ , using AdamW (Loshchilov and Hutter, 2017) optimizer, with batch sizes varying in  $\{8, 16, 32\}$ . We noticed that using a batch size of 32 was ideal. However, limited compute availability prevented us from trying it out. We trained our models for 10 epochs. To choose our best model, we performed validation multiple times during an epoch - 5 times an epoch for the EN-EN sub-task and 4 times an epoch for all other tasks. In all tables, we report accuracy, which is the task’s official evaluation metric.

The results and experimental set up of various models on the English set are summarized in Table 2. We obtain a total of 9 models for the EN-EN sub-task, four of them being *rev* variants. We submitted various ensembles, and the details are

<sup>2</sup><https://azure.microsoft.com/en-us/services/cognitive-services/translator/>

present in the lower half of the table. For the three listed ensembles, we violated our averaging policy; we do not average probability scores of the model with reverse sentence pair, even if the model was saved with such a policy on the dev set as these were overall best performing models on the dev set. At 93.3% on the test set, our model was the **best** performing model in the EN-EN task. Also noteworthy is an ensemble of models trained only on the data provided by the task, scoring 92.6% on the test set.

The results and experimental set up of various models on the Non-English Multilingual set are summarized in Table 5 for the development sets, and Table 3 for test set performance (where we show scores of various ensembles). As described in section 4.3, the OOV models refer to the models that were created by training on the out-of-vocabulary split method, while the RAND models refer to the models obtained by training on data created by the random split method. All models are based on XLM-R+Logistic Regression, with double quotes signal (indicated by + *Signal 1*). For evaluation on the test set, we ensemble a combination of models determined by the best performance on the joint dev set and language-wise dev set.

The performance of various translate-test models is shown in Table 4. We formed an ensemble of these models and submitted it to the leaderboard, which can be seen in Table 6. Also, in Table 6, we note that the best results are obtained by zero-shot application of the models trained in the multilingual sub-task to the cross-lingual sub-task.

## 6 Ablation Study

We perform an analysis of the various proposed approaches (Table 7), specifically paying heed to the EN-EN task, starting with a baseline of a BERT base model with a logistic regression head over the [CLS] token (the ‘cls’ models in the table). We see an improvement in performance by switching to target word embeddings (the last layer hidden state corresponding to the first sub-word token). Adding the signal in the form of double quotes (*Signal 1*) improves performance, probably by emphasizing the word to disambiguate, that, otherwise, the model does not know. *Signal 2* however, is not as effective, but it still improves performance over the non-signal model. Utilizing sentence reversal data augmentation, we see an improvement in performance. The model’s weights are not symmetric

Table 6: Final Ensembles Non-English Cross-Lingual Test. Translate Test models have been abbreviated as TT. The Dev column is only relevant to indicate the performance of TT models on the Back Translated EN-EN dev. The adjusted threshold model is purely for the purpose of analysis (Section 7).

and probably make better internal representations in the process. We do not observe a significant change in model performance on using the augmented data. In fact, for BERT<sub>base</sub>, it decays a little. Running models trained exclusively on WiC and AuSemCor, we note that the AuSemCor model performs better, but both models lag behind the model trained on MCL-EN. We note strong improvements in performance by ensembling various models (Table 2). The use of different transformers give us a diversity in our ensemble, with different models canceling each other’s mistakes. We also observe that the ensemble of models trained using only MCL data lag behind the ensemble of models trained using the augmented data (Table 2). This means that the augmented data is of benefit to our models. This was not clear with just a single model, BERT<sub>base</sub>, as mentioned before, with performance remaining around the same mark. As mentioned before, the Siamese models (83.5%) trail the Logistic Regression models (86.8%). Note that for Siamese models, the sentence order is irrelevant, so we cannot perform sentence reversal augmentation, and so 83.5% is their best with all our methods.

The analysis done on dev data is shown in Table 7. We finally took the models which were giving dev accuracy greater than 89% for the ensembles. That is XLM-R, ALBERT and ELECTRA. Another interesting point is that an XLM-R model trained for Non-English Multilingual subtask (using MCL-MN<sub>rev</sub> + MCL-EN) could also slightly improve itself (at the very least, it did not degrade) than when it trained on MCL-EN<sub>rev</sub> data.

For the Multilingual setting, we note that there is not much difference between the performance of OOV and RAND models (Table 3). The OOV

Model	Accuracy
cls BERT <sub>base</sub>	83.9

Sia. BERT <sub>base</sub> + Signal 1 , Cosine dist.	83.5

Table 7: An analysis of performance of models on EN-EN Dev. The training data was MCL-EN unless otherwise specified.

method works better for FR, while RAND works better for AR, RU, and ZH. On average, RAND scores are slightly better, but not by a large margin.

We note that some pre-trained language models perform better for this task, especially ELECTRA and ALBERT, which improve upon the scores of RoBERTa (Liu et al., 2019), and BERT. We also note that their ‘large’ variants are always better performers than the ‘base’ variants.

False	344	1656

Table 9: Confusion Matrix of Multi-Lingual (Non-English) Sub-Task (Model  $OOV_{rev}$ ).

## 7 Error Analysis

The confusion matrices for our best model are shown in Tables 8, 9, 10 and 11. On the Multilingual task, we found that number of false positives is higher than the number of false negatives for all languages.

In contrast, for the Cross-Lingual task, using the multilingual models in the zero-shot setting gives significantly lower false positives than false negatives (Table 10). The Translate-Test method offered a fairly balanced prediction, albeit with lower overall accuracy. (Table 11).

We observed that the probability scores returned by the multilingual models, when tested on the cross-lingual dataset, fell. We also observe a much lower number of false positives on this test data than the multilingual test data. This suggests that we need to tweak the prediction threshold value, in particular, to bring it down to adjust for the lower scores on this data set. Since we do not have a dev set for the cross-lingual sub-task, we perform the analysis on the test set itself. In Table 6, we can see a model’s performance in a threshold tuning experiment, where the threshold was brought down to 0.17 from 0.5 for all language pairs (i.e. 0.17 was used commonly for all language pairs). A significant spike in performance is observed (an average rise of 3.45% across all the cross-lingual language pairs). This suggests that models trained on multilingual data can competitively distinguish senses in the cross-lingual setting as well, provided we take into account the fall in probability scores, induced by the transfer, by threshold moving. As a control, a similar threshold tuning experiment for the same model on the multilingual test data

yielded only an average of 0.075% improvement for the four Non-English language pairs.

We also analyzed the Parts-Of-Speech (POS) wise performance of our English Model in Table 12. We see a lag in performance for Adverbs and Adjectives that have less number of training data points.

## 8 Conclusion

In this work, we presented our approach to solving the SemEval Task 2: Cross-Lingual and Multilingual Word in Context Disambiguation. We proposed different models based on transformers for the English, Non-English Multilingual and Cross-Lingual tasks. The application of signals and sentence reversal augmentation helped us improve performance across all tasks. Utilising the existing SemCor dataset, we created AuSemCor for the EN-EN sub-task. Due to the unavailability of training data in the Non-English Multilingual and Cross-Lingual task, we proposed methods to obtain the training data from the dev sets or external resources. We finally submitted ensembles for all tasks.

## Abstract

This paper presents the winning system that participated in SemEval-2021 Task 5: Toxic Spans Detection. This task aims to locate those spans that attribute to the text’s toxicity within a text, which is crucial for semi-automated moderation in online discussions. We formalize this task as the Sequence Labeling (SL) problem and the Span Boundary Detection (SBD) problem separately and employ three state-of-the-art models. Next, we integrate predictions of these models to produce a more credible and complement result. Our system achieves a char-level score of 70.83%, ranking 1/91. In addition, we also explore the lexicon-based method, which is strongly interpretable and flexible in practice.

## 1 Introduction

41% of American adults in 2020 are reported experiencing some form of harassment<sup>1</sup>. Increasing incidents of online harassment and cyber violence have spurred researchers to investigate the problem of identifying and filtering offensive speech on the Internet. Most previously published insult detection tasks (Davidson et al., 2017; Xu et al., 2012) and methods (Aroyehun and Gelbukh, 2018; Modha et al., 2018) classify an entire comment (or document) to discern whether the comment is offensive or not, but cannot identify specific pieces of the toxic comment. Unlike previous studies, SemEval-2021 Task5: Toxic Span Detection(Pavlopoulos et al., 2021) requires the identification of the specific toxic spans, which is more innovative and challenging, and a key step towards a successful semi-automatic review of comments.

<sup>†</sup> Authors equally contributed to this work.

More formally, toxic span detection is an extraction task, which is usually formalized as a Sequential Labeling (SL) problem, as shown in Figure 1(a), locating those spans by BIO tags. However, SL methods suffer from a huge search space due to the compositionality of labels (the power set of all sentence words), which has been proven in (Lee et al., 2016; Hu et al., 2019a). Therefore, in addition to SL formalization, we also formalize the task as a Span Boundary Detection (SBD) problem, as shown in Figure 1(b), locating those spans by start and end positions. Notice that, when there are multiple spans in a sentence, the matching of start and end positions may be ambiguous during decoding. This shows that theoretically, the SBD formalization is not consistently superior to the SL formalization. Hence, we choose to combine predictions of these two kinds of formalization to produce a more credible and complement result. Our system achieves a char-level score of 70.83%, ranking 1/91.

Besides, we also explore the lexicon-based methods, which usually have high precision but rather low recall, and are strongly interpretable and flexible in practice. First, we mine a toxic lexicon from the training set by a simple statistical strategy. Next, WordNet (Fellbaum, 2010) and GloVe (Pennington et al., 2014) are utilized to extend this lexicon further. With a toxic lexicon, we extract toxic spans through word-level matching.

## 2 Related Work

In recent years, cyber violence has become a widespread societal concern, and how to identify and filter hate speech has become an important topic in machine learning. TRAC proposes an aggression recognition task (Kumar et al., 2018) that provides a dataset of 15,000 annotated Facebook posts and comments in English and Hindi for

Figure 1: Comparison of SL and SBD, (a) denotes SL, (b) denotes SBD.

training and validation. The task aims to classify comments into three categories: non-aggressive, covertly aggressive, and overly aggressive. The Toxic Comment Classification Challenge 5<sup>2</sup> is an open competition in Kaggle that provides participants with comments from Wikipedia and defines six toxic categories: toxic, severe toxic, obscene, threat, insult, identity hate. In SemEval 2019 task 6 (Zampieri et al., 2019), in addition to whether the comment is offensive, the type of the attack and the target of the attack are also included. Based on this, Semeval 2020 task 12 (Zampieri et al., 2020) further extends the dataset to 5 languages: Arabic, Danish, English, Greek, and Turkish.

### 3 Methods

In the section, we describe how toxic span detection is formalized and corresponding solutions in detail.

#### 3.1 Sequence Labeling

The BIO tag scheme is utilized to locating toxic spans, where B (Begin) corresponds to the first token in a toxic span, I (Inside) corresponds to the inside and end tokens in a toxic span, and O corresponds to those no-toxic tokens. Following most existing work (Lample et al., 2016; Ma and Hovy, 2016), we leverage Conditional Random Fields (CRF) (Lafferty et al., 2001) for learning and inference.

In addition to token-level classification, CRF models the dependencies between tags in a tag sequence by the transition matrix  $A \in \mathbb{R}^{K \times K}$ , where  $K$  is the size of the tag space, i.e.  $K = 3$ . For the contextual representation  $\mathbf{x} \in \mathbb{R}^{n \times h}$ , the score of a tag sequence  $\mathbf{y} \in \mathbb{R}^n$  in CRF is defined as:

$$S(\mathbf{x}, \mathbf{y}) = h^1(y_1; \mathbf{x}) + \sum_{k=1}^{n-1} \left( h^{k+1}(y_{k+1}; \mathbf{x}) + A_{y_k, y_{k+1}} \right). \quad (1)$$

<sup>2</sup><https://www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge>

where  $h^k(y_k; \mathbf{x})$  is the score of the tag  $y_k$  at the  $k$  time step. Then, the conditional probability is obtained by a normalization operation:

$$P(\mathbf{y}|\mathbf{x}) = \frac{\exp(S(\mathbf{x}, \mathbf{y}))}{\sum_{\tilde{\mathbf{y}} \in \mathcal{Y}} \exp(S(\mathbf{x}, \tilde{\mathbf{y}}))}. \quad (2)$$

where  $\mathcal{Y}$  contains all possible paths of tag sequences. During inference, the predicted tag sequence  $\hat{\mathbf{y}}$  is obtained by:

$$\hat{\mathbf{y}} = \arg \max_{\mathbf{y} \in \mathcal{Y}} P(\mathbf{y}|\mathbf{x}). \quad (3)$$

We adopt BERT(Devlin et al., 2019) and BERT+LSTM(Hochreiter et al., 1997) as the language encoder respectively, resulting in two solutions: BERT+CRF and BERT+LSTM+CRF. The reason for adding LSTM is that we believe that the contextual representation refined by LSTM could be more sensitive to the position of tokens.

#### 3.2 Span Boundary Detection

Different from SL formalization, SBD formalization utilizes the start and end positions tagging scheme to represent toxic spans. SBD formalization was originally applied in the machine reading comprehension task (Seo et al., 2016; Wang and Jiang, 2016). In these works, two  $n$ -classifiers are employed to predict the start position and end position separately, where  $n$  denotes the length of the input sentence. However, this strategy can only output a single span for an input sentence. Later, Hu et al. (2019b) extended the two  $n$ -classifiers strategy by a heuristic multi-span decoding algorithm. But this is not a concise and efficient solution for multi-span scenario, as the decoding algorithm relies on two hyper-parameters: (1)  $\gamma$ , the minimum score threshold, (2)  $K$ , the maximum number of spans. In addition to the two  $n$ -classifiers strategy, a more recent and popular strategy is to employ two binary classifiers to determine whether each token is the start (end) position or not (Li et al., 2020; Wei et al., 2020; Yu et al., 2019). In this paper, we adopt the binary classifiers strategy for SBD formalization and describe the details below.

Split	Train	Dev	Test
Num	6894	1723	2000

Table 1: Data statistics.

Given the contextual representation  $\mathbf{x} = \{x_1, x_2, \dots, x_n\} \in \mathbb{R}^{n \times h}$ , for the location  $i$ , we calculate the probability of whether it is a start position by Equation (4) and the probability of whether it is an end position by Equation (5).

$$p_{\text{start}}(i) = \sigma(W_1^\top x_i + b_1), \quad (4)$$

$$p_{\text{end}}(i) = \sigma(W_2^\top [x_i; p_{\text{start}}(i)] + b_2), \quad (5)$$

where  $W_1 \in \mathbb{R}^{h \times 1}$ ,  $W_2 \in \mathbb{R}^{(h+1) \times 1}$  and  $b_1, b_2 \in \mathbb{R}$  are model parameters.

The predictions of start and end positions are obtained by:

$$\text{starts} = \{i | p_{\text{start}}(i) > 0.5, i = 1, \dots, n\}, \quad (6)$$

$$\text{ends} = \{i | p_{\text{end}}(i) > 0.5, i = 1, \dots, n\}. \quad (7)$$

Then we adopt the nearest start-end matching strategy: for each predicted start position  $s \in \text{starts}$ , the nearest predicted end position  $e$  to the right of  $s$  is selected to form a predicted span  $(s, e)$ .

Similarly, we adopt BERT as the language encoder, and we call this model as BERT+Span.

### 3.3 Ensemble Strategy

Voting method is applied to integrate the results. In detail, for  $k$  different models, if no less than  $k/2$  models consider a character to be in the toxic span, the character is retained.

## 4 Experimental Setup

### 4.1 Data

The given trial data and training data are merged and the duplicates are removed. In addition, we fix some annotation errors, such as the partially-labeled words. 80% of the processed data is utilized for training and the rest is the validation set. Table 1 shows the statistics of the data used.

### 4.2 Parameter Settings

We find that the parameter size of the pre-trained model does not have a significant effect on performance, and therefore we simply adopt BERT-base as our language encoder, which consists of 12 transformer blocks with 12 representation heads. Three models are trained separately. The learning

	P(%)	R(%)	F1(%)
BERT+LSTM+CRF	71.99	89.96	69.34
BERT+CRF	74.50	88.10	69.44
BERT+Span	76.29	86.77	69.34
Ensemble	75.01	89.66	70.83

Table 2: Performance of three benchmark models and ensemble approach.

rate of BERT is set to  $2e-5$ , the learning rate of CRF is set to  $5e-3$ , and the maximum encoding length is 128. The weight decay is set to 0.01.

### 4.3 Evaluation Metrics

We use the official metric, i.e. char-level  $F1$ -score, as the evaluation metric. In addition, for a more detailed analysis, we also introduce character-level Precision ( $P$ ) and Recall ( $R$ ). Note that  $F1/P/R$  is the average over the samples, so there is no  $F1 = 2PR/(P + R)$ .

## 5 Results

### 5.1 Ensemble Approach

Table 2 shows the performance of three benchmark models and the ensemble approach. The experimental results show that all three models achieve similar results on  $F1$ -score, and integrating them results in an improvement of more than 1%, indicating that the predictions of the three models have good complementarity.

To further analyze the differences and respective advantages of SL and SBD formalization, we list their performances in single-span scenario and multi-span scenarios in Figure 2. It could be found that SBD formalization is more advantageous in single-span scenario, while SL formalization is more advantageous in multi-span scenario, which is consistent with our claim.

### 5.2 Lexicon-based Approach

We also explore a lexicon-based approach for predicting toxic spans. A toxic lexicon is mined from training data by a simple statistical strategy. More specifically, the toxic score of a word  $w$  is defined as below:

$$\text{toxic\_score}(w) = \frac{\#w\_in\_toxic\_span}{\#w\_in\_whole\_corpus}, \quad (8)$$

where  $\#w\_in\_toxic\_span$  is the count of appearances of word  $w$  in toxic spans, and  $\#w\_in\_whole\_corpus$  is the count of appearances

	# of words	P(%)	R(%)	F1(%)
Ensemble	-	75.01	89.66	70.83
Lexicon <sup>1</sup> (Wiegand et al., 2018)	551	75.13	44.47	33.07
Lexicon <sup>2</sup> (Wiegand et al., 2018)	2989	66.22	72.01	50.98
Lexicon <sup>original</sup> (Our)	119	76.71	82.22	64.98
Lexicon <sup>wordnet</sup> (Our)	231	72.56	84.05	64.09
Lexicon <sup>glove</sup> (Our)	186	73.98	83.34	64.19

Table 3: Results of Lexicon-based approaches and ensemble model on Precision, Recall and F1. Lexicon<sup>1</sup> and Lexicon<sup>2</sup> are two external lexicons. Lexicon<sup>original</sup> is collected by ourselves from training set. Lexicon<sup>wordnet</sup> and Lexicon<sup>glove</sup> are expanded from Lexicon<sup>original</sup> with WordNet and GloVe.

Figure 2: Comparison of the performance of SL and SBD method for data with different numbers of Spans.

of word  $w$  in the whole corpus. Then those words with a toxic score greater than a given threshold  $\theta$  are selected from a lexicon.

When predicting, the words in the sentence that appear in that toxic lexicon are extracted as the predicted toxic spans. There are three lexicons in our experiment, two of which were collected by (Wiegand et al., 2018), another is collected by ourselves from the training set.

Table 3 shows the results of the lexicon-based approaches and the ensemble approach, and we can observe that our lexicon-based approaches obtain notable results in the  $F1$ -score. In addition, we also calculate the average precision and average recall values of different methods on the test set, and our original lexicon-based approach even outperforms ensemble approaches in average precision, but there is still a significant gap in an average recall. Since the lexicon-based approaches can only identify the toxic words in the lexicon, the recall can be improved by expanding the toxic lexicon.

To improve the recall, we use WordNet (Miller, 1995) and GloVe (Pennington et al., 2014) to ex-

Figure 3: Performances of Lexicon<sup>original</sup> model with different threshold.

pand the toxic lexicon. In detail, we collect synsets of each toxic from WordNet, and collect the nearest similar words by calculating cosine similarity of GloVe vectors. The performances of the two expanded approaches are shown in Table 3. Although the recall of two approaches improves over the original lexicon, the precision decreases significantly, which indicating that there are a considerable number of non-toxic words in the synonyms found through WordNet.

Besides, we explore the impact of threshold  $\theta$  when mining the original lexicon on performance. The performances with different threshold is shown on Figure 4. As the threshold  $\theta$  increases, the size of lexicon decreases,  $P$  decreases,  $R$  increases,  $F1$  increases and then decreases, reaching a maximum 64.98 when  $\theta = 0.5$ .

## 6 Conclusion

In this paper, we formalize the toxic span detection as two problems separately and employ three state-of-the-art models. The strengths of each model are analyzed and a more credible and complement result is obtained through a voting approach. Our re-

sults achieve a good score (ranking 1/91). Besides, we explore a lexicon-based approach. The lexicon is mined from the annotation of the training data and then expanded by WordNet and Glove. Experiments show that the lexicon-based approach has not yet achieved the performance of the ensemble approach. We believe that future work could move towards combining deep learning-based methods and lexicon-based methods.

## Abstract

This paper presents one of the top winning solution systems for task 7 at SemEval2021, "HaHackathon: Detecting and Rating Humor and Offense". The shared task 7 consists of two parts, task-1 with three sub-tasks 1a,1b, and 1c, and task-2. The goal of task-1 is to predict if the text would be considered humorous or not, then if it is yes, predict how humorous it is and whether the humor rating would be perceived as controversial. The goal of task-2 is to predict how the text is considered offensive for users in general. The proposed solution, SarcasmDet, has been developed using RoBERTa pre-trained model with ensemble techniques. The paper describes the submitted system's architecture with the experiments and the hyperparameter fine-tuning that led to this robust system. Our model ranked third and fourth places out of 50 teams in tasks 1c and 1a with F1-Score of 0.6270 and 0.9675, respectively. At the same time, the model ranked one of the top 10 models in task 1b and task 2 with RMSE scores of 0.5446 and 0.4469, respectively.

## 1 Introduction

In our daily life, the obstacles and difficulties in dealing with sarcasm, bullying, or even abuse of all kinds and ways are increasing day by day (Sheehan et al., 1999; Cleary et al., 2009; Tucker and Maunder, 2015; van Verseveld et al., 2021). Technically, sarcasm and bullying are among the most complex and challenging topics that major companies and institutes seek to address. Artificial intelligence and text processing techniques are the most potent current methods for detecting these problems within texts and images. Sarcasm and abuse are associated with attacking a specific person or group of people either through an unintended joke or, in many cases, by directly affecting the target's psyche. Irony and offensiveness are characterized by

their vocabularies that are peppered with humor to conceal the opposite (Lee and Katz, 1998).

Task 7 at SemEval-2021, "HaHackathon: Detecting and Rating Humor and Offense", provides two main tasks: task-1 with three sub-tasks (1a,1b, 1c) and task-2. The goal of task-1 is to predict if the text would be considered humorous or not, and if it is yes, then expect how funny it is and whether the humor rating would be perceived as controversial. The goal of task 2 is to predict how the text is considered offensive for users in general. Our solution, SarcasmDet, has been ranked among the top four teams in two sub-tasks. The proposed approach uses the provided dataset, which contains 10K of row text data. We have experimented with several pre-trained language models using the simple transformers library. It is worth mentioning that using the hard-voting ensemble technique has increased our score remarkably.

The paper is constructed as follows: Section 2 provides the related works. Section 3 and 4 describe the shared task and the provided dataset, respectively. Section 5 describes our system solution. Section 6 shows our experiments. Section 7 provides the results, and finally, the conclusion is in Section 8.

## 2 Related Works

In recent years, social media's development and growth have motivated the NLP research community to detect Humor and Offensiveness. In 2018, SemEval provided different shared tasks to detect emotions and irony in tweets (Mohammad et al., 2018; Van Hee et al., 2018). The top teams' proposed models mostly used LSTM and word embeddings (Abdullah and Shaikh, 2018; Badaro et al., 2018; Wu et al., 2018). In 2019, SemEval also introduced a shared task to discover offensive language in social media. Researchers in (Liu et al., 2019a)

used the dataset of the Offensive Language Identification Dataset (OLID) provided by (Zampieri et al., 2019). They ranked first in the task with an F1 (Macro) score of 0.8286 by applying linear model, LSTM, and BERT pre-trained model. In 2020, one of the shared tasks presented in SemEval was about how to change a chunk of text to make the text funnier. The authors (Mahurkar and Patil, 2020; Shatnawi et al., 2020) applied a pre-trained BERT model with different preprocessing for the presented dataset. This paper presents our solution to task 7 in SemEval2021, to detect humor and offensive simultaneously and explains it in detail.

### 3 Tasks Description

All subtasks of the SemEval2021 task 7 have different requirements. In this section, we have detailed the description for each task.

#### 3.1 Task 1a Humor Detection

Task 1a is a binary classification problem. The text should be classified as humor or not based on the answers of 20 participants to whether the particular text was intended to be funny or not. It is considered funny based on the majority of the participants' responses. Table 1 shows an example of the training dataset for task 1a.

#	Example	is humor
348	A baby's laughter can be the most beautiful sound you will ever hear. Unless it's 3 am. And you're home alone. And you don't have a baby.	1
6	Trabajo,' the Spanish word for work, comes from the Latin term 'trepariare,' meaning torture.	0

Table 1: Example for task 1a from the train dataset

#### 3.2 Task 1b Average Humor Score

Task 1b is a regression task; humor rating depends on the classified task 1a arguments. If the text was classified as funny (humor), then a question was raised about the level of humorous in the text on a scale of 1-5. Then, they took the average rating as a label. If not humorous text, they used 0 as a label. Table 2 shows an example of the training dataset for task 1b.

#	Example	humor rating
348	A baby's laughter can be the most beautiful sound you will ever hear. Unless it's 3 am. And you're home alone. And you don't have a baby.	3.1
15	Balsamic vinegar helps slowing the appearance of ageing signs healthy food health.	0

Table 2: Example for task 1b from the train dataset

#### 3.3 Task 1c Humor Controversy

Task 1c is a binary classification problem task; humor controversy depends on the classified arguments from task 1a. If the text was classified as funny (humor), then the task should determine whether the classification of the humor is controversial (1) or not (0). Table 3 shows an example of the training dataset for task 1c.

#	Example	humor controversy
348	A baby's laughter can be the most beautiful sound you will ever hear. Unless it's 3 am. And you're home alone. And you don't have a baby.	1
8000	Each ounce of sunflower seeds gives you 37% of your daily need for vitamin E vitamin health.	0

Table 3: Example for task 1c from the train dataset

#### 3.4 Task 2 Average Offensiveness Score

Task 2 is a regression problem task. The question was asked to determine whether the text is offensive in general, and how much general offensive is between 1-5. Table 4 shows an example of the training dataset for task 2.

### 4 Dataset Description

The dataset provided by (Meaney et al., 2021) SemEval 2021 organizers for task 7 contains 10,000 rows of text data and four columns of labels. The

#	Example	offense rating
27	How do the Chinese select their baby names? They chuck a tin can down the stairs Ping Wong ching Pang	3.8
1498	Today, I overslept and completely missed my 2nd nap.	0

Table 4: Example for task 2 from the train dataset

dataset is divided into three phases: training, development, and evaluation phase datasets. The dataset was collected by surveying US English native speakers of various ages between 18-70 and different genders, political situations, and income levels. The training set contains 8,000 rows of texts with four labels, every text in the data set have been classified based on four questions that were asked to the participants, and each question is related to a specific task. Each of the development set and the test set contain 1000 texts.

#### 4.1 Data Preprocessing

There was no need to implement preprocessing methods for the dataset of task1a and task2. However, the dataset for task1b and task1c contain null values. Therefore, we attempted to convert all null values into zeros, which lowered the data’s quality. Therefore, we used another technique, which is dropping the records with null. The later technique increased the data quality and gave better performances.

### 5 Systems Description

In our solution, we have used the pre-trained language model, RoBERTa (Liu et al., 2019b), that uses a robustly optimized NLP method to improve the Bidirectional Encoder Representations from Transformers. We have also used the BERT pre-trained model (Devlin et al., 2018). RoBERTa is built based on BERT’s language masking strategy, which learns to predict knowingly hidden sections of text within unannotated language examples. We have chosen RoBERTa pre-trained model because of the significant improvements in the performance by tuning the BERT training procedure and the architecture based on BERT-large. We have experimented with several deep learning models. In our

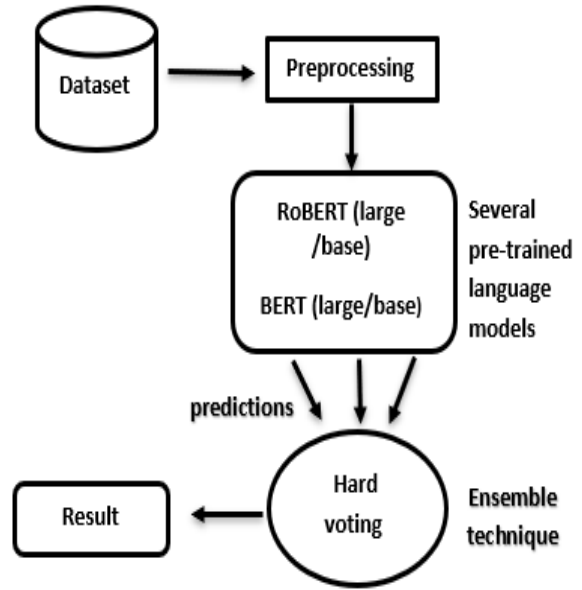

Figure 1: The architecture of our model.

best-performed solution system, we implemented ensemble technique (Chou et al., 2009) on the best-scored models that include RoBERTa-large, BERT-large trained on 24-layer, 1024 hidden, 16-heads, 355M parameters. We used RoBERTa model from HuggingFace(Wolf et al., 2019) and simpletransformers pre-trained models. More details about each subtask are as follows.

#### 5.1 Task 1a

We have applied RoBERTa (base/large) with different hyperparameters. Then, we have utilized the hard-voting ensemble technique to produce the best model that predicts the label in the test dataset. Our approach’s best result has scored 0.9513 F-score in the development phase and 0.9675 F-score in the test phase. The learning rate=1e-5, manual seed= 17, train batch size= 16, and num train epochs= 5.

#### 5.2 Task 1b

In this sub-task, we have applied BERT(base/large) cased with different hyperparameter. Then applied the hard-voting ensemble technique for the best model to predict the label in the test set (learning rate=1e-5, manual seed= 17, train batch size= 16, and num train epochs= 5).

#### 5.3 Task 1c

In this sub-task, we have applied several pre-trained NLP models, such as BERT(base-large), XINet(large), and RoBERTa(large), but the best solution was obtained from the two previous sub-

tasks (task 1a, task 1b). We used the best results of task 1a and task 1b to predict task 1c. If the result from task1a is 1, then that indicates it is humor. If the value of the Humer\_Ratting is equal or more than 3, then we consider that humor\_controversy to be 1. Otherwise, we assume humor\_controversy is 0.

#### 5.4 Task2

We have applied RoBERTa (large/base) with different hyperparameters. Then, we have used the hard-voting ensemble technique for the best model to predict the label in the test dataset (learning rate=1e-5, manual seed= 17, train batch size= 16, and num train epochs= 5).

## 6 Experiments

We have experimented with several pre-trained NLP models to detect Humor and Offensive through the development and evaluation phases. The pre-trained models include BERT(base/large) that is developed by Google researchers. Also, ALBERT(base/large)(Lan et al., 2019), which is a lite version of BERT to reduce parameters and increase the model speed by reducing memory consumption. Another pre-trained model is XLNet(base/large)(Yang et al., 2019), which introduced the automatic regressive pre-training method and outperformed BERT model in several tasks sentiment analysis, question answering and others. Finally, RoBERTa model, which outperformed most of the pre-trained models, if not all. We have implemented our experiments on google Colab using CPU and GPU. Using colab GPU increased the speed of the experiments by 100%. We used simple transformers library with various hyperparameters, learning rate=1e-5, manual\_seed= 17, train\_batch size=8-16-32 and epochs= 2-3-5. Our best results accomplished on all tasks was using hard-voting ensemble technique on top of best-scored results by RoBERTa-large and BERT-large-cased. The use of hard-voting technique increased the performance, and the accuracy, remarkably. In the development phase, our model ranked first place in three task1a, task1c, task2, and second place in task1c. However, for the evaluation phase, we have ranked 4th place in task1a, and 3rd place in task1c 3rd. Table 5 shows details of all hyperparameters used on all models for two phases.

Model	Epoch	Batch Size	LR	Manual Seed
RoBERTa-large	3,5	8,16,32	1e-5	17
RoBERTa-base	3,5	8,16	1e-5	17
BERT-base	2,3,5	8	1e-5	11,17
BERT-large	3,5	8,16,32	1e-5	11,17
XLNet-base	2,3	8,16	1e-5	17
XLNet-large	3,5	16	1e-5	17
ALBERT-base	2,3	8,16	1e-5	17
ALBERT-large	3,5	16	1e-5	17

Table 5: Hyperparameter was used in all experiments for two phases(development and evaluation) of all tasks.

## 7 Results

Our solution system results are divided into two phases development and evaluation phase. We experienced several pre-trained language models (RoBERTa, BERT, ALBERT, and XLNET) and implemented them using a simple transformers library in the development phase. In the evaluation phase(test phase), we improved our system solution's capabilities by using different hyperparameters with ensemble techniques. In the following sub-sections, we provided in detail all the results of the evaluation phase.

### 7.0.1 Task 1a

In task1a RoBERTa-large model outperformed all models with 0.9669 F-score and 0.9590 accuracies. We used the hard-voting ensemble technique to improve our results using the top best five achieved scores by RoBERTa-large and RoBERTa-base model with different hyperparameters. We have increased our solution performance and accomplished 4th place with a 0.9675 f-score and 0.9600 accuracies using this method. Table 6 shows the ensemble results and the top best results for RoBERTa model.

### 7.0.2 Task 1b

In task1b BERT-large-cased outperformed all models with 0.5468 RMSE. We improved the result

#	model	LR	Batch Size	F-Score	Accuracy
(1)	RoBERTa-base	1e-5	16	0.9654	0.9570
(2)	RoBERTa-base	1e-5	8	0.9660	0.9580
(3)	RoBERTa-large	1e-5	32	0.9661	0.9580
(4)	RoBERTa-large	1e-5	16	0.9663	0.9580
(5)	RoBERTa-large	1e-5	8	0.9669	0.9590
(6)	*	*	*	<b>0.9675</b>	<b>0.9600</b>

Table 6: Top best experiments used for task 1a in the evaluation phase by RoBERTa(large/base) model.\*Ensemble for 1,2,3,4,5

with the same method of ensemble and hyperparameters used in the previous sub-task. We have used the top best four achieved scores by BERT-large-cased and BERT-base-cased model, and we achieved 10th place with 0.5446 RMSE. Table 7 shows ensemble results and the top best results for the BERT model.

#	model	LR	Batch Size	RMSE
(1)	BERT-base	1e-5	8	0.5492
(2)	BERT-base	1e-5	16	0.5475
(3)	BERT-large	1e-5	16	0.5468
(4)	BERT-large	1e-5	8	0.5498
(5)	*	*	*	<b>0.5446</b>

Table 7: Top best experiments used for task 2 in the evaluation phase by BERT(large/base). \* Ensemble for 1,2,3,4

### 7.0.3 Task 1c

In task1c, we have implemented a method consisting of top of the best task1a and task1b results and using it. We accomplished third place with a 0.6270 F-score and 0.4699 Accuracy.

### 7.0.4 Task 2

Task2 RoBERTa-large outperformed all other models with 0.4559 RMSE. We have used hard-voting

ensemble technique and various hyperparameters with the top five best results by RoBERTa-large and RoBERTa-base. Using this technique, we achieved 10th place with 0.4469 RMSE. Table 8 shows ensemble results and top best results.

#	model	LR	Batch Size	RMSE
(1)	RoBERTa-base	1e-5	8	0.4828
(2)	RoBERTa-large	1e-5	32	0.4741
(3)	RoBERTa-large	1e-5	16	0.4609
(4)	RoBERTa-large	1e-5	8	0.4559
(5)	*	*	*	<b>0.4469</b>

Table 8: Top best experiments used for task 2 in the evaluation phase by RoBERTa(large/base) model. \* Ensemble for 1,2,3,4

## 7.1 Error Analysis

Our model was able to predict well in task 1a with an F1-score of 0.9675, but in task 1c, the prediction decreased with an F1-score of 0.52. Figures 2 and 3 show the confusion matrix for tasks 1a and 1c. The reason for this is due to the distribution of the datasets. In task 1a, the dataset was balanced, but in task 1c, the dataset was imbalanced as it contained null values.

Figure 2: confusion matrix for task 1a.

## 8 Conclusion

This paper presents and describes our solution system for the SemEval2021 Task7: HaHackathon

Figure 3: confusion matrix for task 1c.

detecting and rating humor and offense. We have applied several pre-trained language models, such as RoBERTa, BERT, ALBERT, and XLNET, with hard-voting ensemble technique to detect humor and offense mechanism. Our final solution was based on BERT-large-cased model and RoBERTa-large model, which showed remarkable improvements and a high overall outperformance. Our solution system ranked 4th place in task1a with a 0.9675 F-score, 10th place in task1b with a 0.5446 RMSE, 3rd place in task1c with a 0.6270 F-score, and 10th place in task2 with a 0.4469 RMSE.

## Abstract

Extracting semantic information on measurements and counts is an important topic in terms of analyzing scientific discourses. The 8th task of SemEval-2021: Counts and Measurements (MeasEval) aimed to boost research in this direction by providing a new dataset on which participants train their models to extract meaningful information on measurements from scientific texts. The competition is composed of five subtasks that build on top of each other: (1) quantity span identification, (2) unit extraction from the identified quantities and their value modifier classification, (3) span identification for measured entities and measured properties, (4) qualifier span identification, and (5) relation extraction between the identified quantities, measured entities, measured properties, and qualifiers. We approached these challenges by first identifying the quantities, extracting their units of measurement, classifying them with corresponding modifiers, and afterwards using them to jointly solve the last three subtasks in a multi-turn question answering manner. Our best performing model obtained an overlapping F1-score of 36.91% on the test set.

## 1 Introduction

Our world revolves around quantities and units of measurement present in all texts, ranging from scientific texts to recipes. Nevertheless, the process of automatically extracting measurements is not trivial, considering that, in most situations, the quantitative structures are ambiguous and are not present in the same area within the text. Therefore, parsing the semantic relations becomes a ubiquitous task, since proper quantity identification leads to transformations towards an easy to follow quantitative summary. Advantages of the previously mentioned process can be found in medical prescriptions (Adamo et al., 2015). As such, a system

that can robustly and confidently identify medication quantities, measurement units, as well as the medication itself has the potential to become a breakthrough for computer-based medicine and consultations. Another use case resides in ERP systems where proper parsing of resource descriptions facilitates the identification of similar or duplicate items.

The MeasEval - Counts and Measurements competition (Harper et al., 2021) organized by the 15th International Workshop on Semantic Evaluation (SemEval-2021) creates a new challenge in the area of Natural Language Processing, proposing five subtasks related to span identification, classification, as well as relation extraction, that aim to improve the state of the art for the current field of measurement information extraction. We created a cascaded system to solve the stated problem that is composed of: (1) a subsystem that identifies quantities in the input text; (2) a subsystem that classifies their value modifiers; (3) a subsystem that extracts their measurement unit; and (4) a subsystem that then finds the appropriate measured entities, measured properties, and qualifiers by asking questions related to entity-relations. Three pretrained Transformer-based (Vaswani et al., 2017) language models are experimented for subsystems (1) and (4) of the cascaded system by fine-tuning them on the specific task: Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019), Robustly Optimized BERT Pretraining Approach (RoBERTa) (Liu et al., 2019), and Science BERT (SciBERT) (Beltagy et al., 2019). A character-level bidirectional Long Short-Term Memory (BiLSTM) (Hochreiter and Schmidhuber, 1997) architecture was considered for subsystems (2) and (3).

The rest of the paper is structured as follows. The next section presents a series of solutions associated with relation extraction, span identification,

and measurement unit identification. The third section outlines our approaches related to the subtasks proposed by the competition. The fourth section presents a performance evaluation of our systems together with an error analysis, while the final section concludes our work and outlines potential future improvements.

## 2 Related Work

**Span Identification.** Papay et al. (2020) studied the performance of various models designated for different span identification tasks. Out of them, we mention Conditional Random Fields (CRFs) (Lafferty et al., 2001), LSTM cells with CRF, BERT+CRF, LSTM+BERT+CRF, or handcrafted features, usable with any of the previously mentioned models. At the same time, a language model was specifically developed for the span identification tasks, entitled SpanBERT (Joshi et al., 2020), by masking an entire sequence instead of masking a single word in its pretraining process. The authors argued that SpanBERT obtained substantial gains on span selection tasks, such as question answering and coreference resolution.

**Measurement Unit Identification.** Berrahou et al. (2013) proposed a two-step system for search space size reduction, followed by unit extraction from the previously obtained textual fragments. Also, Hundman and Mattmann (2017) presented a hybrid system composed of a CRF that identifies quantities values and their units, followed by a rule-based model to detect their corresponding entities.

**Relation Extraction.** Zhang and Wang (2015) adopted a model based on Recurrent Neural Networks (RNN) (Cho et al., 2014) composed of three main elements: an embedding layer, a bidirectional recurrent layer, followed by a max pooling layer that produces the feature vector used for relation classification. RNN-based models were also applied by Zhang et al. (2015) who adopted BiLSTMs, or by Xiao and Liu (2016) who proposed an architecture based on hierarchical RNNs alongside an attention mechanism. Furthermore, several convolutional neural network-based models with various approaches were proposed, for example: multi-level attention (Wang et al., 2016), attention-based context vectors (Shen and Huang, 2016), or multi-level features (word, lexical, sentence) (Zeng et al., 2014). BiLSTMs are also present in the work of Lee et al. (2019) who implemented a mechanism

based on entity-aware attention using latent entity typing. Jin et al. (2020) approached the relation extraction task by employing a Graph Neural Network system that modeled each relation as a node and learned the dependencies between the nodes.

## 3 Method

Our approach on MeasEval consisted of a cascade system composed of individual subsystems for each of the problems in the first two subtasks, and then jointly solving the last three subtasks with a single subsystem.

### 3.1 Quantity Identification

The subtask of identifying quantities in text was formalized as a sequence labeling problem with Inside–Outside–Beginning (IOB) tags (Ramshaw and Marcus, 1999) that were predicted by a pretrained language model with a CRF on top of predicted logits, as proposed by Avram et al. (2020). The architecture is depicted in Figure 1.

Figure 1: Quantity identification subsystem architecture.

More formally, we project each output embedding  $e_i$  produced by the pretrained language model into probability logits  $l_i$  by using a feed-forward network with a ReLU activation as  $l_i = ReLU(W_l^T e_i + b_l)$ , where  $W_l$  is the corresponding weight matrix and  $b_l$  is the corresponding bias. Then, we model the output conditional probabilities for each tag  $y_i$  by using the CRF learning algorithm, as depicted in Eq. 1:

$$p(y|l) = \frac{1}{Z} \exp \left\{ \sum_{i=1}^n W_{y_{i-1}, y_i}^T l_i + b_{y_{i-1}, y_i} \right\} \quad (1)$$

where  $W_{y_{i-1}, y_i}$  and  $b_{y_{i-1}, y_i}$  are the weight matrix and the bias of the CRF, and  $Z$  is a normalization constant such that the probabilities sum up to one.

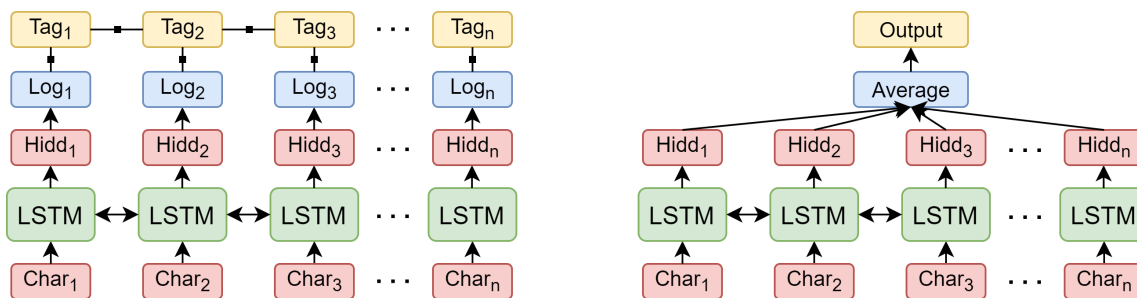

Figure 2: Architectures used in unit extraction (left) and value modifiers classification (right) subsystems.

The entire subsystem is trained to maximizing the log-likelihood of the data, while the Viterbi algorithm (Forney, 1973) is used during inference to find the most likely sequence of tags.

### 3.2 Unit Extraction and Value Modifier Classification

For the second subtask, a character-level BiLSTM extracts the units from quantities and classifies their corresponding value modifiers. We approached the unit extraction in a similar way as the quantity identification, by treating the problem as a sequence tagging; however, the pretrained language model was replaced with BiLSTM cells. Moreover, instead of predicting a label for each character (token), we instead averaged the BiLSTM hidden states and projected their average in an eleven-dimensional vector (i.e., number of possible value modifiers) for the classification. Then, a sigmoid activation function was applied to obtain a vector that contains the probability of the quantity to belong to a class at each index. The architectures used for unit extraction and value modifiers classification are depicted in Figure 2.

### 3.3 Joint Entity Identification and Relations Extraction

**Subtask Grouping.** The last three subtasks were grouped into a single subtask where a pretrained language model was fine-tuned to jointly identify three elements: the span of the measured entities, the measured properties, and their corresponding qualifiers. The model extracts the relations between the three elements and the previously extracted quantities using a multi-turn question answering (QA) architecture, as proposed by Li et al. (2019). The pretrained language models used for this task were identical to the ones from the quantity identification subtask.

**Question Templates.** The input to the subsystem is created by appending a question before the

text that denotes a possible relation between a given and a target entity. There are a total of six question templates that can be filled with the corresponding entities that cover all the possible relations, as depicted in Table 1. Then, the questions are asked in a specific order to correctly identify the relations and the span of the entities. First, starting with a given quantity, the model is asked to identify its measured properties. If a measured property is found, the model marks its span and links it to the quantity with the `HasQuantity` relation (question 1). Second, the model is asked to identify the measured entity with that corresponding measured property, linking the two with the `HasProperty` relation (question 2). Third, if no measured property is found for a given quantity, the model is asked to directly identify the measured entity, marking the relation between the measured entity and the quantity directly with `HasQuantity` (question 3). Finally, once all quantities, measured entities, and properties are identified, the model is asked to identify corresponding qualifiers and marks the relations accordingly (questions 4-6 in table).

**Model Output.** The architecture proposed in (Devlin et al., 2019) for SQuAD 2.0 (Rajpurkar et al., 2018) is employed to create the output of the subtasks; as such, two vectors are used for fine-tuning: a starting vector  $S$  and an ending vector  $E$ . The probability of token  $i$  to be the start of a span is computed as a dot-product between the embedding  $T_i$  and the start vector  $S$ , followed by a softmax applied over all the tokens of the input:  $P = \text{softmax}(T_i \cdot S)$ . An analogous formula computes the end probabilities of a span. Then, we take the indices  $i$  and  $j$  are taken to compute the most probable span for an entity, where  $i \leq j$  maximizes the sum of log-likelihoods  $T_i \cdot S + T_j \cdot E$ . We compare for each query the previously defined maximum sum with the sum of the start and end log-likelihoods of the `[CLS]` token  $s_{null}$  because

#	Relation Type	Question
1	HasQuantity	What is the <i>measured property</i> of the <i>quantity</i> ____?
2	HasProperty	What is the <i>measured entity</i> that has the <i>measured property</i> ____ of the <i>quantity</i> ____?
3	HasQuantity	What is the <i>measured entity</i> that has the <i>quantity</i> ____?
4	Qualifies	What is the <i>qualifier</i> corresponding to the <i>quantity</i> ____?
5	Qualifies	What is the <i>qualifier</i> corresponding to the <i>measured entity</i> ____?
6	Qualifies	What is the <i>qualifier</i> corresponding to the <i>measured property</i> ____?

Table 1: Question templates for each relation type.

there can be questions without an answer<sup>1</sup>. If this sum is higher, then there is no such type of relationship for that entity. A threshold added to the  $s_{null}$  is considered in order to provide a higher granularity between questions with or without answers, which was tuned on the development set to maximize F1-score.

Figure 3 introduces our architecture for entity recognition and relation extraction. The question tokens marked with Qst and the paragraph tokens marked with Tok are fed as input, while the start S and the end E logits are present at output.

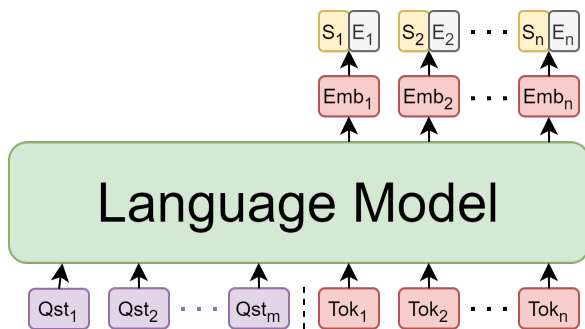

Figure 3: Joint entity recognition and relation extraction architecture as multi-turn question answering.

## 4 Performance Evaluation

### 4.1 Experimental Setup

**Dataset Analysis and Processing.** The provided corpus for the competition was quite scarce, counting 298 samples in both train and trial datasets. The corpus contained texts from the scientific domain, counting a total of 7,979 unique words with an average sentence length of approximately 160 words. For training our models, we merged the train and trial subsets and randomly split them into 90% training and 10% development.

**Pretrained Language Models.** An Adam optimizer (Kingma and Ba, 2014) with a learning rate

<sup>1</sup>Only measured properties and qualifiers related questions are allowed to not have an answer. Measured entity-related questions must always have an answer.

of  $2e-5$  was used for training the subsystem of the first and last three subtasks. We experimented with the large versions of BERT and RoBERTa, and with the base version of SciBERT because there are currently no implementations available online of its large variant. Each subsystem was fine-tuned for 10 epochs; the subsystems that employed large language model variants were trained with a batch size of 2 due to the computational constraints, whereas the subsystems that employed base language model variants used a batch size of 8.

**BiLSTM Networks.** An Adam optimizer was also employed for training the BiLSTM networks of the second subtask, but with a learning rate of  $1e-4$ . The models were trained for 25 epochs using a batch size of 16. We stacked the LSTM cells two times and used a hidden size of 64, with an embedding of 32 dimensions for the characters.

### 4.2 Results

The results of each subsystem on the development set are introduced in Table 3. SciBERT obtained the highest F1-score on both quantity identification and joint entity and relation extraction, although it is smaller when compared with the other two models. On the second subtasks, the model achieved a reasonable performance, 95.75% F1-score on unit extraction and 88.94% F1-score on value modifier classification.

The results of the cascaded system are presented in Table 2 that introduces the global precision, recall, and F1-scores averaged across all subtasks, as well as the exact match (EM) and overlap F1 scores<sup>2</sup> between the gold annotations and our predictions. As opposed to the performance of each subsystem on the development set where SciBERT was the best performing model, RoBERTa obtained the highest scores as a whole system, with an overlap F1-score of 39.05% on the development set and 36.91% on the test set, outperforming SciBERT

<sup>2</sup>The overlap F1-score was the metric by which the competition systems were ranked.

System	Avg. Precision		Avg. Recall		Avg. F1		EM		Overlap F1	
	Dev	Test	Dev	Test	Dev	Test	Dev	Test	Dev	Test
BERT-related	<b>61.10</b>	58.69	52.28	48.05	56.63	52.84	31.61	25.58	36.72	32.69
RoBERTa-related	60.04	<b>61.01</b>	<b>56.05</b>	<b>52.66</b>	<b>58.14</b>	<b>56.53</b>	<b>34.98</b>	<b>30.89</b>	<b>39.05</b>	<b>36.91</b>
SciBERT-related	56.73	54.35	54.61	46.12	55.65	49.90	30.82	23.71	35.89	30.30

Table 2: Results averaged across all five subtasks on the development and test sets.

Subsystem	Precision	Recall	F1
<i>Quantity identification</i>			
RoBERTa-CRF	90.77	92.85	91.26
BERT-CRF	<b>91.77</b>	93.72	92.38
SciBERT-CRF	91.60	<b>95.02</b>	<b>93.00</b>
<i>Unit extraction and value modifier classification</i>			
Unit Extraction	96.44	95.27	95.75
Value Modifiers	91.82	86.65	88.94
<i>Joint relation extraction and entity identification</i>			
RoBERTa-QA	71.04	71.26	71.14
BERT-QA	72.18	<b>71.09</b>	71.63
SciBERT-QA	<b>73.81</b>	70.71	<b>72.22</b>

Table 3: Performance analysis on the development set.

with over 6% and over 3%, respectively. More surprisingly, SciBERT also obtained a lower score than BERT on both sets, having an overlap F1-score lowered by 2% and 1%. We believe that these differences between the scores of RoBERTa and SciBERT were caused by the way the two models were evaluated as stand-alone subsystems or as a whole system.

### 4.3 Error Analysis

**Quantity Sensitivity.** The main drawback in our approach was that all other subtasks were highly dependent on the quality of the extracted quantities for the first subtask. To exemplify this, let us consider the case where a modifier like "approximate" is missed before a quantity; afterwards, it would be impossible to correctly classify its modifiers. Another use case is when the subsystem misses the measuring unit, with the same effect on the unit extractor. Moreover, we noticed that the joint entity and relation extraction was especially sensible to partially identified quantities, producing mostly bad outputs in these cases.

**Measured Unit Inference.** Another limitation of our approach emerges when the unit extractor does not identify all units in a sequence tagging style. This happened in cases when the unit was split across several places in the quantity, or when it had to be predicted from the context. For instance,

the correct unit would be "m<sup>2</sup>" when encountering a "300 m x 400 m" quantity; however, our model found only "m" as unit.

**Long Documents.** Finally, several documents had a longer sequence length than 512 tokens<sup>3</sup> when tokenized, which surpasses the maximum admitted length by the pretrained language models; the workaround was to simply remove the tokens after position 512. However, this solution has the obvious effect of missing identifiable entities that appear after this position.

## 5 Conclusions and Future Work

This paper introduces our approach that solves all the five subtasks of the 8th task of SemEval-2021 competition in a cascaded manner. First, quantities are identified as a sequence tagging task by using a pretrained language model with a CRF layer. Then, the measurement units are extracted and the modifiers are classified using BiLSTMs at character level on the identified quantities. Finally, the measured entities, measured properties, and qualifiers are jointly identified, together with their relations, by using a multi-turn question answering approach with hand-crafted questions specific to each relation type. Our best model obtained an F1-score of 36.91% on the test set. We further emphasized several limitations of our approach and showed that the overall performance was highly sensitive to the quality of the identified quantities.

A possible direction for future work is to test the system using language models that can process longer sequences, such as Longformer (Beltagy et al., 2020) or BigBird (Zaheer et al., 2020), in order to reduce the effect of missing entities simply due to the sequence length. We also consider creating an ensemble model using several pretrained language models to boost the overall performance, as reported by Ionescu et al. (2020).

<sup>3</sup>Approximately 4% of the documents had more than 512 tokens for each pretrained language model.

## Abstract

This paper describes our contribution to SemEval 2021 Task 1: Lexical Complexity Prediction. In our approach, we leverage the ELECTRA model and attempt to mirror the data annotation scheme. Although the task is a regression task, we show that we can treat it as an aggregation of several classification and regression models. This somewhat counter-intuitive approach achieved an MAE score of 0.0654 for Sub-Task 1 and MAE of 0.0811 on Sub-Task 2. Additionally, we used the concept of weak supervision signals from Gloss-BERT in our work, and it significantly improved the MAE score in Sub-Task 1.

## 1 Introduction

With the rapid growth in digital pedagogy, English has become an extremely popular language. Although English is considered an easy language to learn and grasp, a person’s choice of words often affects texts’ readability. The use of difficult words can potentially lead to a communication gap, thus hampering language efficiency. Keeping these issues in mind, many Natural Language Processing tasks for text simplification have been recently proposed (Paetzold and Specia, 2017; Sikka and Mago, 2020). Our task of lexical complexity prediction is an important step in the process of simplifying texts.

The SemEval 2021 Task 1 (Shardlow et al., 2021) focuses on lexical complexity prediction in English. Given a sentence and a token from it, we have to predict the complexity score of the token. The task has two Sub-Tasks-

**Sub-Task 1:** complexity prediction of single words

**Sub-Task 2:** complexity prediction of multi word expressions (MWEs).

A word might seem complex because of 2 major

factors-

a) The word is less common or complex in itself.

b) The context in which the word is used makes it hard to comprehend.

Observing the orthogonality of these two reasons, we captured the context-dependent features and independent features separately, trained models on them individually, and then combined the two using ensemble methods. We used the ELECTRA (Clark et al., 2020) model for extracting context-dependent features and GloVe embeddings (Pennington et al., 2014) for representing the word-level features.

Additionally, we propose a classification pipeline that is trained on GloVe embeddings of the tokens. This pipeline can be interpreted as a model for capturing different annotators’ thought processes: overconfidence, under-confidence and randomness. We are making our code available for our models and experiments via GitHub<sup>1</sup>.

## 2 Background

This task uses the CompLex dataset (Shardlow et al., 2020), which is a lexical complexity prediction dataset in English for single and multi word expressions (2-grams). Sentences in this task consists of sentences taken from 3 corpora- Bible, Biomed and Europarl. The train, validation and test split of the data was 9179, 520, 1103 respectively. We used the train data as the validation set.

The aim of the task is to predict how complex a given token in a given sentence is. More mathematically, given a tuple  $[s, t, c]$ , where  $s = [t_1, t_2, \dots, t_n]$  and  $t = t_j$ , we have to give an estimate of the function  $\sigma$ , such that  $\sigma(s, t) = c$ . ( $s$  is the sentence,  $t$  is the token and  $c$  is the complexity score).

The earlier focus on this task has been through

<sup>1</sup><https://github.com/neilrs123/Lexical-Complexity-Prediction>

\* Authors equally contributed to this work.

Figure 1: Solution Pipeline

the SemEval 2016 Task 11 (Paetzold and Specia (2016a)). However, it was a binary classification task. Most of the participating systems used Support Vector Machines such as Kuru (2016) and Choubey and Pateria (2016), decision trees and random forests (Choubey and Pateria (2016), Brooke et al. (2016), Ronzano et al. (2016)), and even basic threshold based approaches (Kauchak (2016), Malmasi et al. (2016)). Very few of them, including Bingel et al. (2016) used neural networks. The system by Wróbel (2016) achieved an F1 score very close to the winning solution using only single feature - word frequency from Wikipedia. Most of these systems use word embeddings, POS information and word frequencies as features. The winning system by Paetzold and Specia (2016b) however uses 69 morphological, semantic and syntactic features.

Another related shared task was presented at the BEA workshop at 2018 (Yimam et al., 2018). It had a probabilistic task as well as a binary classification task. Even there, the organizers conclude that feature engineering has worked better than neural networks. The winning system by Gooding and Kochmar (2018) uses feature engineering and later random forest and linear regression models.

### 3 System Overview

Our proposed pipeline can be divided into the following 4 main components-

- a) Feature Extraction
- b) Regression Pipeline
- c) Classification Pipeline
- d) Ensemble

The pipeline is shown in Figure 3.

#### 3.1 Feature Extraction

ELECTRA is a transformer based model, that is trained like a discriminator and not like generator. And in our case, this model performed exception-

Figure 2: Convergence of losses for finetuning ELECTRA with weak supervision

ally well on the validation data as compared to BERT (Devlin et al., 2019).

We extracted context-dependent features using embeddings generated from the ELECTRA model and captured context-independent word-level features using static 200-dimensional GloVe embeddings of the tokens.

In order to generate the embeddings of the target word through ELECTRA, we implemented the KMP pattern matching algorithm (Wikipedia, 2021) to find the indices of the sub-tokens of the target token in the tokenized sentence. Subsequently, we calculated an average across these sub-token embeddings generated by ELECTRA.

While using GloVe embeddings, in the case of multi-word expressions in Sub-Task 2, the average of the embeddings of both token words was taken as the feature vector. If a word was not present in the GloVe dictionary, the GloVe embedding was initialized to a 200-dimensional vector consisting of zeros.

#### 3.2 Regression Pipeline

The most natural way to look at the lexical complexity prediction task is to treat it as a regression task. The regression pipeline, a significant component of our system, is based on this idea. For Sub-task 1, in the regression pipeline, a pretrained ELECTRA model was finetuned with a linear layer on top of it. We leveraged the model directly available at the Huggingface library (Wolf et al., 2020). Only the last transformer layer of ELECTRA was kept trainable. The remaining ones were kept frozen. For Sub-task 2, a fixed ELECTRA model (non-trainable weights) was used to generate token embeddings and a linear regression model was trained with these extracted embeddings.

**Weak Supervision:** In order to have higher attention on the target word, the use of weak supervi-

sion signals proved useful. Inspired by GlossBert (Huang et al., 2019), the target word was wrapped with single inverted commas ( ' )s as a weak signal to the transformer (Vaswani et al., 2017) model. This technique significantly improved the results obtained using the regression pipeline in subtask I. However, the same technique applied to subtask II made the scores worse.

Method	Val MAE	Test MAE
+ signal	0.06516	0.06800
- signal	0.06990	0.07118

Table 1: Variation of MAE scores with and without the signalling technique for Sub-task 1: the single word task. ('+ signal' means weak supervision has been used and '- signal' means otherwise.)

### 3.3 Classification Pipeline

**Motivation from Annotation Procedure:** Another way to look at the task is via a novel classification pipeline that is inspired from the data annotation process that is explained in Shardlow et al. (2020). Even though the task is a regression task, each data annotator performed a 5 class classification-

Given a sentence and a token in the sentence, each annotator had to select one class from among Very Easy, Easy, Neutral, Difficult and Very Difficult. Each of these classes was mapped to a discrete label between 0 and 1- namely 0, 0.25, 0.5, 0.75 and 1 respectively. The final complexity score was an average of up to 20 such annotations.

The Classification Pipeline aims to model this data annotation procedure. The main idea of this process is to teach classification models how to annotate data tuples. The three main components of this scheme are-

**a)** Generating dummy annotations from complexity scores **b)** Training classification models on dummy annotations, and **c)** Aggregating all predicted annotations to generate predicted complexity scores.

**Generation of Dummy Annotations:** A given complexity score can be represented as a weighted average of its lower and upper target classes and the weights can be determined using the magnitude of the complexity score. These weights then determine the proportions of the two classes in the set of dummy annotations for that data tuple. For example, if the number of dummy annotators is  $n = 5$  and the complexity score of the training

example is  $c = 0.2$ , the lower and upper target classes are  $low = 0$  and  $high = 0.25$ , respectively. Let  $\alpha$  be the proportion of dummy annotations with the lower target class. Correspondingly,  $1 - \alpha$  will be the proportion with the upper target class. The number of dummy annotations with  $target\_class = low$  are given as  $floor(n * \alpha)$  and that with  $target\_class = high$  as  $n - floor(n * \alpha)$ .  $\alpha$  can be calculated using the equation-

$$c = \alpha * low + (1 - \alpha) * high$$

We get  $\alpha = 0.2$ . Hence, we have  $floor(n * \alpha) = 1$  dummy annotations with  $target\_class = low(0)$  and remaining 4 annotations with  $target\_class = high(0.25)$ . Hence, the dummy annotations set for  $c = 0.2$  is 0, 0.25, 0.25, 0.25, 0.25. Similarly, the dummy annotations set for  $c = 0.8$  is 0.75, 0.75, 0.75, 0.75, 1.

In this process, we also attempted to capture the impact of intentional human errors made during the data annotation procedure. Just like a weary or uninterested annotator who would have randomly selected for one of the five classes for a certain data tuple, a small fraction of the dummy annotations was assigned random values from the set containing 0, 0.25, 0.5, 0.75 and 1. This modification aims to model the small-scale randomness in annotation procedure.

Using this procedure, dummy annotation sets of size  $n$  can be generated for any value of  $c$ , where  $n$  can be treated as a hyperparameter. The value  $n$  can also be interpreted as the number of classification models that are being trained in the next step.

**Classification Models:** In a diverse set of annotators, there will be over-confident annotators who will select lower classes and there will be under-confident annotators who will select upper classes. Then there will be neutral annotators as well. By ensuring that the dummy annotations are sorted, we can say that the first classifier learns how to annotate like the over-confident annotator, the last classifier learns how to annotate like the under-confident annotator and the classifiers in between model the neutral annotators. We trained SVM classifiers with RBF kernels, using GloVe embeddings of token words as features.

**Aggregation of Predicted Annotations:** The annotations were aggregated by simply taking the average of all predicted class labels in order to obtain the final predicted complexity scores. Each of these models may have high individual variances,

Complexity Score	Dummy Annotations				
0.2	1	2	2	2	2
0.8	4	4	4	4	5
0.35	2	2	2	3	3
0.4	2	2	3	3	3

1st  
classifier

2nd  
classifier

3rd  
classifier

4th  
classifier

5th  
classifier

Figure 3: A few worked out examples of generating dummy annotations from complexity scores. For each of these cases, the continuous labels 0,0.25,0.50,0.75 and 1 are mapped to categorical labels 1,2,3,4,5 and then put into SVM. Clearly the labels of the 1st classifier is less than that of the second one. i.e. on a scale of confidence, the first classifier is at a lesser position. So it models a less confident person.

but the ensemble tends to have lower variance and bias. Also, any number of models can be inserted in the ensemble without leading to over-fitting on the train data.

### 3.4 Ensemble

In order to have a better bias variance trade off and also to exploit the “expertise” of different pipelines, the final approach incorporates both the regression and classification pipelines to form an ensemble. The final predicted complexity was obtained by taking an ensemble of the predictions from the regression and classification pipelines as described above. The classification pipeline for both the Sub-Tasks was based on GloVe embeddings as features and SVM classifiers. The regression pipeline for Sub-Task 1 was based on fine-tuning ELECTRA with weak supervision and that for Sub-Task 2 was based on features collected from ELECTRA model (non-trainable) with a linear regression trained on it.

## 4 Experimental Setup

The official evaluation metric for both the Sub-Tasks was Pearson Correlation (standard for regression tasks). For both sub-tasks, the train/test/val split as per the official release has been used. The ELECTRA finetuning was done with an NVIDIA GTX 1080 GPU with early stopping (93 epochs). We used the MAE loss function to train the model with an adam optimizer with  $lr = 1e^{-5}$ ,  $eps = 1e^{-8}$  and  $weightdecay = 0$ . Training set was shuffled and the batch size was kept at 64. In the ELECTRA model, the padding parameter was set

to True and maximum length was at 140. For the SVM models the value of slack was chosen to be 1 and for SVM and Linear regression the sklearn (Pedregosa et al., 2011) library was used. All the hyperparameters were tuned with a grid search method.

## 5 Results

**Results on Validation Data:** The comparison of the baseline results and our results obtained using the regression pipeline, the classification pipeline and the ensemble of the two models on the validation set (trial data) is given in Table 4.

Task	Baseline	Regression Pipeline	Classification Pipeline
Subtask 1	0.0853	0.0651	0.0641
Subtask 2	-	0.0840	0.0768

Table 2: Results on validation set (Mean Absolute Errors)

Task	MAE	Pearson	MSE
One	0.0623	0.8308	0.0065
Two	0.0727	0.8146	0.0087

Table 3: Results on Validation Set for final ensemble

**Results on Test Data:** Our results on the test data along with the best results obtained for each task are shown in Table 1.

The winning system’s pearson and MAE scores on the test data are as follows: 0.7886 and 0.0609 for subtask I(single word expressions), 0.8612 and 0.0616 for subtask II(multi word expressions).

Task	MAE	Pearson	MSE
One	0.0654	0.7511	0.0071
Two	0.0811	0.8277	0.0098

Table 4: Results on Test Set

## 6 Error Analysis

Analyzing all the experiments and the corresponding results, the following can be concluded: **a)** Word-level features as well as context-dependent features need to be considered while determining

complexity of a token. **b)** Approaches based on the data annotation scheme are well suited to tackle the lexical complexity prediction task. **c)** Ensemble of a large number of simple models is an effective way of tackling this task. **d)** Models with large number of parameters like BERT () suffer heavily due to overfitting, where as ELECTRA base prove to be much better.

The model architectures that were tried out in earlier stages showed similar trends. For example, ELECTRA finetuning produced much better scores than BERT finetuning. Also, simpler models like a simple linear regression on GloVe embeddings showed promise, proving that simpler models with lesser parameters worked better. All these trends across those models are visually shown in Figure 4. It was observed that the model was underperforming on the tuples from Biomed corpus. However the scores did not improve using BERT variants like BioBERT (Lee et al., 2019), BioMedBERT (Chakraborty et al., 2020) and a few other transformer based models pretrained on biomedical texts. A variant of ELECTRA on biomedical texts could have improve on this, however due to its unavailability it could not be tried out.

In majority of the prior work on LCP, there is abundance use of word frequency as a feature. However, in this system the scores got worse when frequency features were used along with others in ensemble. And the feature in itself could not produce competitive results. Previously, Gong et al. (2020) and Mu et al. (2018) have shown that frequency information causes significant distortion in the embedding space. We also hypothesize that the frequency information in GloVe embeddings help us in this regard.

## 7 Conclusion

In this paper we presented a system for lexical complexity prediction in the form of a regression task. The proposed system’s primary novelty is in treating it as a classification task and trying to model the annotation scheme. An ensemble of these classification models and vanilla fine-tuning of ELECTRA model proved to be very useful. Also the weak supervision based approach gave the scores a significant boost for the Sub-Task 1.

# LCP-RIT at SemEval-2021 Task 1: Exploring Linguistic Features for Lexical Complexity Prediction

Abhinandan Desai, Kai North, Marcos Zampieri, Christopher Homan

Rochester Institute of Technology

Rochester, NY, USA

ad2724@rit.edu, kn1473@rit.edu, mazgla@rit.edu, cmh@cs.rit.edu

## Abstract

This paper describes team LCP-RIT’s submission to the SemEval-2021 Task 1: Lexical Complexity Prediction (LCP). The task organizers provided participants with an augmented version of CompLex (Shardlow et al., 2020), an English multi-domain dataset in which words in context were annotated with respect to their complexity using a five point Likert scale. Our system uses logistic regression and a wide range of linguistic features (e.g. psycholinguistic features,  $n$ -grams, word frequency, POS tags) to predict the complexity of single words in this dataset. We analyze the impact of different linguistic features on the classification performance and we evaluate the results in terms of mean absolute error, mean squared error, Pearson correlation, and Spearman correlation.

## 1 Introduction

Lexical complexity prediction (LCP) is the task of predicting the complexity value of a target word within a given text (Shardlow et al., 2020). Complexity within LCP is used as a “synonym for difficulty” (Malmasi and Zampieri, 2016)<sup>1</sup>. A complex word is therefore a word that a target population may find difficult to understand. Various LCP systems have been designed to identify words that may be found to be complex for children (Kajiwara et al., 2013), language learners (Malmasi et al., 2016), or people suffering from a reading disability, such as dyslexia (Rello et al., 2013). These systems have been utilized within assistive language technologies, lexical simplification systems, and in a variety of other applications.

LCP is related to complex word identification (CWI) (Paetzold and Specia, 2016). CWI is modeled as a binary classification task by assigning each target word with a complex or non-complex

<sup>1</sup>The term “complex” within LCP is not necessarily related to the terms *simplex* and *complex* used in morphology.

label. The shortcomings of modeling lexical complexity using binary labels have been discussed in previous work (Zampieri et al., 2017; Maddela and Xu, 2018), motivating the organization of SemEval-2021 Task 1: Lexical Complexity Prediction.<sup>2</sup> LCP models complexity in a continuum and the goal is to predict a target word’s degree of complexity by assigning it a value between 0 and 1. This value may then correspond to one of the following labels: very easy (0), easy (0-0.25), neutral (0.25-0.5), difficult (0.5-0.75), or very difficult (0.75-1) (Shardlow et al., 2020).

In this paper, we describe (in detail in Section 4) the LCP-RIT entry to SemEval-2021 Task 1. We approached LCP from a feature engineering perspective with a particular focus on the adoption of psycholinguistic features, such as average age-of-acquisition (AoA), familiarity, prevalence, concreteness, and arousal, alongside the use of prior complexity labels. Our submitted system utilized a combination of these linguistic features, which we compared to a baseline model that only used statistical features: word length, word frequency and syllable count (Quijada and Medero, 2016; Mukherjee et al., 2016). On our training dataset, our submitted system achieved a mean absolute error (MAE) of 0.067, mean squared error (MSE) of 0.007, Person Correlation (R) score of 0.779, and a Spearman Correlation ( $\rho$ ) score of 0.724. This surpassed our baseline model’s performance by a MAE of 0.008, MSE of 0.003, as well as R and  $\rho$  scores of 0.075 and 0.062 respectively.

## 2 Related Work

Before SemEval-2021 Task 1: LCP, two CWI shared tasks were organized at one SemEval-2016 and the other at BEA-2018 (Paetzold and Specia, 2016; Yimam et al., 2018). While the first CWI provided participants with an English dataset, the

<sup>2</sup><https://sites.google.com/view/lcpsharedtask2021/home>

second provided a multilingual dataset. The systems submitted to the English track of the second shared task (Yimam et al., 2018) performed better overall than the previous task (Paetzold and Specia, 2016), probably due to the properties of the two datasets (Zampieri et al., 2017). State-of-the-art neural net models and word embedding models performed worse than conventional models such as decision trees (DTs) and random forests (RFs) (Yimam et al., 2018). Among the conventional models, the use of statistical, character  $n$ -gram, and psycholinguistic features was found to be highly effective in improving CWI performance (Malmasi et al., 2016; Zampieri et al., 2016; Paetzold and Specia, 2016; Yimam et al., 2018).

Among the best performing systems in CWI 2018, Gooding and Kochmar (2018) used an ensemble of classifiers. They found that during their system’s development, the boosting classifier AdaBoost, a random forest classifier, or a combination of both classifiers achieved the highest performance. These systems used multiple features such as the word’s grammatical category, Google character  $n$ -gram frequency as well as a range of psycholinguistic features (Gooding and Kochmar, 2018).

Of the remaining systems, Aroyehun et al. (2018) and Hartmann and Borges dos Santos (2018) utilized statistical features, such as word length and number of syllables, psycholinguistic features such as familiarity, age of acquisition, concreteness, and imagery scores, and word  $n$ -grams. Hartmann and Borges dos Santos (2018) compared the performance of tree ensembles to a convolutional neural network (CNN). They found that their tree ensembles performed better than their CNN, especially when the target expression contained more than three words (Aroyehun et al., 2018).

### 3 Task and Dataset

The LCP shared task organizers provided participants with the CompLex corpus, an English multi-domain dataset with sentences from the Bible, the European Parliament proceedings, and a collection of biomedical texts. A pool of annotators, using a five point Likert scale, labeled the complexity of single words and multi-word expressions in CompLex (Shardlow et al., 2020).

Taking advantage of the annotation of single words and multi-word expressions, the LCP shared task was divided into two sub-tasks as follows:

- **Sub-task 1:** predicting the complexity score for single words;
- **Sub-task 2:** predicting the complexity score for multi-word expressions.

We chose to participate in sub-task 1. Sub-Task 1’s training dataset contained 7,662 instances with its test dataset having 917 instances. 20% of the training dataset was used to test our system’s performance during development. Sub-Task 1 received 54 system submissions.

## 4 System Overview

### 4.1 Model

Taking inspiration from the CWI systems discussed in Section 2, we adopted a random forest regressor (RFR) to predict the complexity values of each word within the test dataset. To achieve this, we tested the impact a variety of linguistic features have on LCP performance during our system’s development. The RFR was taken from scikit-learn’s ensemble module (Pedregosa et al., 2011). The RFR used a maximum of 120 trees and 750 features.

### 4.2 Features

We constructed a baseline RFR using the following statistical features and character trigrams. We then used psycholinguistic and additional features to see whether its baseline performance could be improved.

**Statistical Features** include word length, word frequency and syllable count. Zipf’s Law implies that words that appear less frequently within a text are likely to be longer and therefore may be considered more complex than words that are more frequent and shorter (Quijada and Medero, 2016). In addition, words with a high number of syllables are difficult to pronounce and are subsequently hard to read (Mukherjee et al., 2016). As such, word length, word frequency and syllable count were considered to be good baseline statistical indicators of a word’s complexity value.

**Character N-grams** include the use of character bigram and trigram frequencies. These frequencies were calculated by counting each bigram’s and trigram’s presence in the target words provided in Sub-Task 1’s training dataset. Experimentation with bigrams and trigrams, along with a combination of both, found that the use of trigrams on their own was superior. This together with their use

within prior CWI systems justified their inclusion within our baseline model (Yimam et al., 2018).

**Psycholinguistic Features** include average age of acquisition (AoA), concreteness, familiarity, prevalence and arousal. AoA is the age at which a word’s meaning is first learned. Concreteness refers to “the degree to which the concept denoted by a word refers to a perceptible entity” (Brysbaert et al., 2013). Familiarity and prevalence are somewhat similar. Familiarity is how well known the word is to an individual and was obtained through self-report (Gilhooly and Logie, 1980). Prevalence was calculated in accordance to the percentage of people who knew the word (Brysbaert et al., 2019). Lastly, arousal is a measure of how active or passive a word’s meaning is interpreted as being<sup>3</sup>. For instance, the word “*nervous*” indicates more arousal than “*lazy*” (Mohammad, 2018). As such, grammatical categories such as adjectives, verbs, and adverbs may incite higher levels of arousal than nouns.

Average AoA was calculated by averaging the AoAs provided in the Living Word Vocabulary Dataset (Dale and O’Rourke, 1981) with an updated version of this dataset (Brysbaert and Biemiller, 2017). Both datasets consisted of AoA values for 44,000 English word meanings. Concreteness, familiarity and arousal values were taken from the MRC Psycholinguistic Database (Wilson, 1988) as well as three newer datasets each containing 37,058, 61,858 and 20,000 English words (Brysbaert et al., 2013, 2019; Mohammad, 2018).

**Additional Features** include part-of-speech (POS) tags as well as prior complexity labels. POS tags were generated by using the Python Natural Language Toolkit (Bird et al., 2009). Prior complexity labels were taken from the previous CWI shared tasks (Paetzold and Specia, 2016; Yimam et al., 2018) and the Word Complexity Lexicon (Maddela and Xu, 2018). A combined dataset was then created that contained a total of 26,088 English words each with a binary complexity value.

## 5 Evaluation

### 5.1 Features

To determine the effect each feature had on our baseline model’s performance, we used the fol-

<sup>3</sup>The terms “active” and “passive” do not refer to the use of *active* or *passive voice* but rather the emotional or physical intensity associated with a word’s meaning (Mohammad, 2018).

lowing scores: mean absolute error (MAE), mean squared error (MSE), Pearson Correlation (R) and Spearman Correlation ( $\rho$ ). Table 1 depicts each feature’s performance on the training dataset. These criteria have also been used in the SemEval LCP test set evaluation.

Average AoA decreased the baseline model’s MAE and MSE by 0.004 and 0.001 respectively. It likewise increased its R and  $\rho$  scores by 0.039. This generated the second highest R and  $\rho$  scores of 0.743 and 0.701 respectively. Average AoA is therefore a useful feature for LCP.

Brysbaert et al.’s prevalence and concreteness (Brysbaert et al., 2013, 2019) were also seen to improve the baseline model’s performance with prevalence being the most notable. Prevalence decreased baseline MAE and MSE scores by 0.005 and 0.002 respectively. It also surpassed baseline R by 0.054 and  $\rho$  by 0.047, yielding the highest increases among all features. Concreteness (Brysbaert et al., 2013) also caused a slight increase in the baseline model’s scores, being greater than that caused by MRC concreteness. Concreteness values (Brysbaert et al., 2013) increased the baseline model’s R and  $\rho$  scores by 0.032 and 0.024 respectively, whereas the MRC concreteness values resulted in a slightly less impressive increase of 0.019 in both its R and  $\rho$  scores. However, there was little-to-no difference in MAE and MSE produced by either set of concreteness values.

Features	Performance			
	R	$\rho$	MAE	MSE
Baseline Features	0.704	0.662	0.075	0.010
Average AoAs	0.743	0.701	0.071	0.009
<b>Prevalence</b>	<b>0.758</b>	<b>0.709</b>	<b>0.070</b>	<b>0.008</b>
MRC Familiarity	0.727	0.687	0.073	0.009
Concreteness	0.736	0.686	0.072	0.009
MRC Concreteness	0.723	0.681	0.073	0.009
Arousal	0.722	0.676	0.074	0.009
POS Tags	0.701	0.663	0.075	0.010
Complexity Labels	0.727	0.686	0.072	0.009

Table 1: Feature performance on training dataset. The baseline model uses the statistical features and character trigrams. Best results in bold.

Two possible conclusions can be drawn: 1). The difference in the calculation of prevalence versus that of familiarity likely causes prevalence to be a greater indicator of word complexity<sup>4</sup>, and 2). The

<sup>4</sup>Prevalence being the percentage of people who. know the word (Brysbaert et al., 2019). Familiarity being a self-reported

superior coverage of Brysbaert et al.’s prevalence (2018) and concreteness (2013) datasets (Brysbaert et al., 2019, 2013): being 52.62% and 57.51% respectively, compared to that of the MRC Psycholinguistic Database (Wilson, 1988): being 23.44%, suggests that there now exists larger and more up-to-date psycholinguistic datasets that are more useful for LCP feature engineering.

Arousal has never before been used for LCP or CWI. Due to its ability to differentiate grammatical categories, such as nouns and verbs, along with its ability to signify a word’s intensity, we had speculated that arousal would be able to help predict a word’s complexity. Arousal was found to have no significant effect on the baseline model’s performance. Nevertheless, once added to our submitted system, it slightly decreased its MSE by 0.001 and increased its R and  $\rho$  scores by 0.002 and 0.001 respectively.

POS tags was the worst performing feature as POS tags had little affect on improving our model’s performance. It achieved the same MAE and MSE values as our baseline model: 0.075 and 0.01 respectively. Regarding R score, only a slight increase of 0.001 was observed. POS tags was the only feature that saw a decrease in our model’s  $\rho$  score, worsening its performance by 0.003. This suggests that a word’s grammatical category may not impact its degree of complexity. This is also supported by Arousal’s lack of improved performance.

Given that prior complexity labels are directly related to complexity prediction, it was believed that they would be the most influential in improving overall performance. Instead, AoA, prevalence and concreteness were all found to be more beneficial with higher or identical MAE, MSE,  $\rho$ , and R scores. Complexity labels only saw a slight decrease in MAE and MSE by 0.003 and 0.001 respectively and a slight increase in  $\rho$  and R scores by 0.023 and 0.024 respectively. The binary nature of prior CWI datasets is likely responsible for this phenomenon, as binary 0 or 1 complexity values are not well suited for a regression-based task, such as LCP. This would have resulted in the same problem faced by previous CWI systems: the misclassification of words on the decision boundary.

measure of an individual’s awareness of the word (Gilhooly and Logie, 1980).

## 5.2 Models

The results for the three models on the training dataset are presented in Table 2. This is then followed by a short description of each model as well as our performance on the test dataset.

Model	Performance			
	R	$\rho$	MAE	MSE
Model 1	0.772	0.717	0.068	0.008
Model 2	0.777	0.724	0.067	0.008
LCP-RIT	<b>0.779</b>	<b>0.724</b>	<b>0.067</b>	<b>0.007</b>

Table 2: Model performance on training dataset.

**Model 1 - Top 3 Features:** Adding the top 3 features of average AoA, prevalence and concreteness to our baseline model reduced its MAE and MSE by 0.007 and 0.002 respectively and increased its R score by 0.068 and its  $\rho$  score by 0.055. It attained a new MAE of 0.068 which was noticeably better than our baseline model’s previous MAE of 0.075. This goes to show that inclusion of psycholinguistic features has a positive impact on the performance of an LCP system.

**Model 2 - Top 5 Features:** A small improvement was seen after adding the fourth and fifth best performing features to Model 1, namely, MRC familiarity and prior complexity labels. Model 2 increased Model 1’s R and  $\rho$  scores by 0.005 and 0.007. However, it failed to improve Model 1’s MAE or MSE. This small increase in performance was due to the prior top 3 features of average AoA, prevalence and concreteness already having captured those instances caught by MRC familiarity and prior complexity labels. This further proves the redundancy of the MRC Psycholinguistic Database (Wilson, 1988) as well as binary complexity labels for LCP feature engineering.

**LCP-RIT:** Our final model submitted to the official evaluation used the psycholinguistic features of average AoA, prevalence, concreteness and arousal together with our baseline model’s features of word length, syllable count, word frequency and character trigrams to predict the lexical complexity of single words. On the training dataset of SemEval-2021 Task 1: LCP, we achieved a MAE of 0.067, MSE of 0.007, R score of 0.779, and  $\rho$  score 0.724. We performed less well on the single word test dataset with an MAE and MSE of 0.072 and 0.009 respectively and  $\rho$  and R scores of 0.709 and 0.653 respectively. This reduced performance may be

indicative of our submitted system being overfit on our training dataset.

## 6 Conclusion

We carried out multiple experiments evaluating the impact of linguistics features in LCP using the CompLex dataset for English. We have shown that several psycholinguistic features help with LCP. Average AoA, prevalence and concreteness were all found to be beneficial, whereas MRC familiarity, MRC concreteness and prior complexity labels were proven to be redundant. We would like to explore other features described in [Shardlow et al. \(2021\)](#). In terms of performance, we believe that the multiple features we tested allowed us to get close to the maximum performance for this dataset using regression. A possible alternative for better performance is to test state-of-the-art transformer models. Furthermore, we are interested in looking at the performance of these features for LCP in languages other than English and for multilingual datasets.

## Acknowledgments

We would like to thank the LCP shared task organizers for proposing this interesting shared task and for making the data available.

# Alejandro Mosquera at SemEval-2021 Task 1: Exploring Sentence and Word Features for Lexical Complexity Prediction

Alejandro Mosquera  
Symantec Enterprise Division  
Broadcom Corporation  
alejandro.mosquera@broadcom.com

## Abstract

This paper revisits feature engineering approaches for predicting the complexity level of English words in a particular context using regression techniques. Our best submission to the Lexical Complexity Prediction (LCP) shared task was ranked 3rd out of 48 systems for sub-task 1 and achieved Pearson correlation coefficients of 0.779 and 0.809 for single words and multi-word expressions respectively. The conclusion is that a combination of lexical, contextual and semantic features can still produce strong baselines when compared against human judgement.

## 1 Introduction

Lexical complexity is a factor usually linked to poor reading comprehension (Dubay, 2004) and the development of language barriers for target reader groups such as second language learners (Saquete et al., 2013) or native speakers with low literacy levels, effectively making texts less accessible (Rello et al., 2013). For this reason, complex word identification (CWI) is often an important sub-task in several human language technologies such as text simplification (Siddharthan, 2004) or readability assessment (Collins-Thompson, 2014).

The Lexical Complexity Prediction (LCP) shared task of Semeval-2021 (Shardlow et al., 2021) proposes the evaluation of CWI systems by predicting the complexity value of English words in context. LCP is divided into two sub-tasks: Sub-task 1, predicting the complexity score for single words; Sub-task 2: predicting the complexity score for multi-word expressions. In our participation in both sub-tasks, we treat the identification of complex words as a regression problem, where each word is given a score between 1 and 5, given the sentence in which it occurs. In order to do this, we have evaluated sub-sets of word and sentence features against different machine learning models.

Our best submissions achieved Pearson correlation coefficients of 0.779 and 0.809 for single words and multi-word expressions respectively.

In Section 2 we review related work for this task. Section 3 and 4 introduce the data and feature engineering approaches respectively. In Section 5 the performance of different machine learning models is analysed. In Section 6 we present the obtained results. Finally, in Section 7 we draw our conclusions and outline future work.

## 2 Related Work

Previous CWI studies applied to the English language have relied mostly on word frequencies, psycholinguistic information (Devlin and Tait, 1998), lexicons and other word-based features such as number of characters or syllable counts (Shardlow, 2013), which considered in most cases the target word in isolation. In order to address the limitations of word-level approaches more recent work made use of contextual and sentence information such as measuring the complexity of word n-grams (Ligozat et al., 2012), applying language models (Maddela and Xu, 2018) or treating the problem as a sequence labelling task (Gooding and Kochmar, 2019).

In this paper, we not only evaluate many of the traditional word-based features found in the literature but we also pay attention to the context surrounding the target by generating additional bigram and sentence features. In the end, we demonstrate that a careful selection of simple features is still competitive against more novel approaches for this task.

## 3 Datasets

CompLex (Shardlow et al., 2020), which was the official dataset provided by the organizers, contains complexity annotations using a 5-point Likert scale

for 7,662 words and 1,517 multi-word expressions (MWE) from three domains: the Bible, Europarl, and biomedical texts.

External datasets and models are historically allowed and used in SemEval as a way of complementing the original training set. Likewise, based on previous experiences, external resources can also correlate better with the evaluation labels than the official task resources in certain scenarios (Mosquera, 2020). For this reason, related datasets from previous CWI shared tasks such as CWI 2016 (Paetzold and Specia, 2016) and CWI 2018 (Štajner et al., 2018) were considered and evaluated as both extra training data and for deriving additional features. However, the performance of our models during the validation step not only didn't improve but worsened when attempting to use them.

## 4 Feature Engineering

The 51 features used in order to detect the complexity of single words and each component of MWEs are as follows:

**Word length** (word\_len): The length in characters of the target word.

**Syllable count** (syl\_count): Target word syllable count.

**Morpheme length** (morpheme\_len): Number of morphemes for the target word.

**Google frequency** (google\_freq): The frequency of the target word based on a subset Google ngram corpus<sup>1</sup>.

**Wikipedia word frequency** (wiki\_freq1): The frequency of the target word based on Wikipedia<sup>2</sup>.

**Wikipedia document frequency** (wiki\_freq2): The number of documents in Wikipedia where the target word appears.

**Complexity score** (comp\_lex): Complexity score for the target word from a complexity lexicon (Maddela and Xu, 2018).

**Number of morphemes** (morpheme\_len): Number of morphemes in the target word.

**Zipf frequency** (zip\_freq): The frequency of the target word in Zipf-scale as provided by the wordfreq (Speer et al., 2018) Python library.

**Kucera-Francis word** (kucera\_francis): Kucera-Francis (Kucera et al., 1967) frequency of the target word.

**Kucera-Francis lemma** (st\_kucera\_francis): Kucera-Francis (Kucera et al., 1967) frequency of the target word lemma.

**Is stopword** (stop): True if the target word is an stopword.

**Is acronym** (acro): Heuristic that is set to True if the target word is a potential acronym based on simple casing rules.

**Average age of acquisition** (age): At what age the target word is most likely to enter someone's vocabulary (Kuperman et al., 2012).

**Average concreteness** (concrete): Concretedness rating for the target word (Brysbaert et al., 2014).

**Lemma length** (lemma\_len): Lemma length of the target word.

**Word frequency (COCA)** (word\_freq): Frequency of the target word based on the COCA corpus (Davies, 2008).

**Lemma frequency (COCA)** (lemma\_freq): Frequency of the lemmatized target word based on the COCA corpus (Davies, 2008).

(consonant\_freq): Frequency of consonants in the target word.

**Number word senses** (wn\_senses): Number of senses of the target word extracted from WordNet (Fellbaum, 2010).

**Number of synonyms** (synonyms): Number of synonyms of the target word from WordNet.

**Number of hypernyms** (hypernyms): Number of hypernyms of the target word from WordNet.

**Number of hyponyms** (hyponyms): Number of hyponyms of the target word from WordNet.

**WordNet min-depth** (wn\_mindepth): Minimum distance to the root hypernym in WordNet for the target word.

**WordNet max-depth** (wn\_maxdepth): Maximum distance to the root hypernym in WordNet for the target word.

**Number of Greek or Latin affixes** (greek\_or\_latin\_affix): True if the target word contains Greek or Latin affixes<sup>3</sup>.

**Bing frequency** (bing\_counts): The frequency of the target word based on the Bing n-gram corpus (Wang et al., 2010).

**Bi-gram frequency** (ph\_mc2): Bi-gram frequency for the target and its preceding word in Google Books Ngram Dataset obtained via the phrasefinder API<sup>4</sup>.

<sup>1</sup><https://github.com/hackerb9/gwordlist>

<sup>2</sup>[https://github.com/alex-pro-dev/english-words-by-frequency/blob/master/wikipedia\\_words.zip](https://github.com/alex-pro-dev/english-words-by-frequency/blob/master/wikipedia_words.zip)

<sup>3</sup><https://github.com/sheffieldnlp/cwi>

<sup>4</sup><https://phrasefinder.io/api>

**Volume count** (ph\_vc2): The number of books where the target and its preceding word appeared in the Google Books Ngram Dataset obtained via the phrasefinder API.

**Year of appearance** (ph\_fy2): The first year where the target and its preceding word appeared in the Google Books Ngram Dataset obtained via the phrasefinder API.

**SUBTLEX-US frequency** (FREQcount): Target word frequency based on SUBTLEX-US corpus (Brysaert et al., 2012).

**SUBTLEX-US number of films** (CDcount): Number of films in which the target word appears in the SUBTLEX-US corpus.

**SUBTLEX-US frequency lowercase** (FREQlow): Number of times the target word appears in the SUBTLEX-US corpus starting with a lowercase letter

**SUBTLEX-US number of films lowercase** (Cdlow): Number of films in which the target word appears starting with a lower-case letter in the SUBTLEX-US corpus.

**SUBTLEX-US frequency per million** (SUBTLWF): Target word frequency per million words in the SUBTLEX-US corpus.

**SUBTLEX-US log frequency** (Lg10WF): The base-10 logarithm of the absolute frequency of the target word plus one in the SUBTLEX-US corpus.

**SUBTLEX-US percentage of films** (SUBTLCD): The percentage of the films where the target word appears in the SUBTLEX-US corpus.

**SUBTLEX-US log number of films** (Lg10CD): The base-10 logarithm of the number of films in which the target word appears in the SUBTLEX-US corpus.

**SUBTLEX-UK frequency** (LogFreqZipf): The base-10 logarithm of the target word frequency in Zipf-scale for the SUBTLEX-UK corpus (Van Heuven et al., 2014).

**SUBTLEX-UK Cbeebies frequency** (LogFreqCbeebiesZipf): The base-10 logarithm of the target word frequency in Zipf-scale for the Cbeebies subset of SUBTLEX-UK corpus

**SUBTLEX-UK CBBC frequency** (LogFreqCBBCZipf): The base-10 logarithm of the target word frequency in Zipf-scale for the CBBC subset of SUBTLEX-UK corpus

**SUBTLEX-UK BNC frequency** (LogFreqBNCZipf): The base-10 logarithm of the target word frequency in Zipf-scale for the BNC subset of SUBTLEX-UK corpus

**ANC word frequency** (anc): Frequency of the target word based on the American National Corpus (ANC) (Ide and Macleod, 2001).

**Kincaid grade level** (sentence\_Kincaid): Kincaid grade level of the whole sentence.

**ARI score** (sentence\_ARI): Automated readability index (Senter and Smith, 1967) of the whole sentence.

**Coleman-Liau score** (sentence\_Coleman-Liau): Coleman-Liau readability score (Coleman and Liau, 1975) of the whole sentence.

**Flesch score** (sentence\_FleschReadingEase): Flesch reading ease score (Flesch, 1948) of the whole sentence.

**Gunning-Fog** (sentence\_GunningFogIndex): Gunning-Fog readability index (Gunning et al., 1952) of the whole sentence.

**LIX score** (sentence\_LIX): LIX readability score (Anderson, 1983) of the whole sentence.

**SMOG index** (sentence\_SMOGIndex): SMOG readability index (Mc Laughlin, 1969) of the whole sentence.

**RIX score** (sentence\_RIX): RIX readability score (Anderson, 1983) of the whole sentence.

**Dale-Chall index** (sentence\_DaleChallIndex): Dale-Chall readability index (Chall and Dale, 1995) of the whole sentence.

All the readability features were calculated using the readability Python library <sup>5</sup>.

## 5 Machine Learning Approach

Since the labels in the training dataset were continuous we have modelled both sub-tasks as regression problems. For sub-task 1, we made use of LightGBM (LGB) (Ke et al., 2017) implementation of gradient tree boosting. Minimal hyper-parameter optimization was performed against our development set, using a 0.01 learning rate and limiting the number of leaves of each tree to 30 over 500 boosting iterations.

For sub-task 2, the complexity score of each MWE component was obtained by using a linear regression (LR) model and averaged with equal weights.

By examining the feature importance for both the LGB model in Figure 2 and the LR model in Figure 3 we can observe several sentence readability features being identified as top contributors. While some degree of correlation between the complexity of the sentence and the target word was expect

<sup>5</sup><https://github.com/andreasvc/readability>

a priori, a machine learning model can also use sentence-level complexity as a predictor of formality and genre (Mosquera and Moreda, 2011), thus being able to differentiate between the different sub-corpora present in the training data as seen in Figure 1.

Figure 1: Example of differences in readability across the CompLex sub-corpora as measured by the Dale-Chall index.

Figure 2: LGB feature importance as the number of times the feature is used in the model.

Figure 3: Linear regression weights.

Model	Dev	Trial	Test
Sub-task 1 LR	0.789	0.798	0.760
Sub-task 1 RF	0.792	0.824	0.766
Sub-task 1 LGB	0.801	0.841	<b>0.779</b>
Sub-task 2 LR	0.771	0.780	<b>0.809</b>
Sub-task 1 winner			<b>0.788</b>
Sub-task 2 winner			<b>0.861</b>

Table 1: Performance comparison of different models for each sub-task and evaluation set using Pearson’s r.

## 6 Results

For sub-task 1, we have evaluated the performance of both linear and tree ensembles using the provided trial set and a randomly selected holdout with 30% of the training data as development set. The best performing model was gradient boosting. See Table 1.

## 7 Conclusion and Future Work

In this paper, we present the system developed for the Lexical Complexity Prediction task of SemEval 2021. Even though most of the features we made use of are relatively common in previous works, we demonstrate that a careful selection of lexical, contextual and semantic features at both target word and sentence level can still produce competitive results for this task. In a future work we would like to explore different neural network architectures and automated machine learning (AutoML) approaches.

## Abstract

This paper describes the CompNa model that has been submitted to the Lexical Complexity Prediction (LCP) shared task hosted at SemEval 2021 (Task 1). The solution is based on combining features of different nature through an ensembling method based on Decision Trees and trained using Gradient Boosting. We discuss the results of the model and highlight the features with more predictive capabilities.

## 1 Introduction

Complex Word Identification (CWI) is a task focused on the detection of complex (not easy to understand) words or expressions. One of the challenges of natural language-based systems is to provide informative content that is tailored to the needs of users in terms of content and level of understanding. For this aim, predicting Lexical Complexity plays a crucial role in simplifying the text so that it can be more easily understood by people with low literacy levels (for example children) or non native speakers (Shardlow, 2013). The interest of the Computational Linguistics community on this topic has grown in recent years. Indeed, SemEval 2016 presented a challenge specifically on CWI (Paetzold and Specia, 2016a; Zampieri et al., 2017). The task proposed to build models capable of predicting whether a word was easy or not for non-native English speakers. In this case, the proposed dataset was annotated with a binary label.

In 2018 the CWI task was re-proposed at the workshop for Building Educational Applications (BEA) (Yimam et al., 2018). The data was again annotated with binary labels but samples from more languages were considered, specifically English, German and Spanish. In addition to the word classification task, a sub-task where the participants had to predict the probability of a word being complex was added.

The best performing models for both tasks were based on ensembling techniques using features that were carefully selected (Paetzold and Specia, 2016b; Gooding and Kochmar, 2018).

In this context, the Lexical Complexity Prediction (LCP) shared task hosted at SemEval 2021 proposes a challenge where the data is annotated according to the degree of complexity (Shardlow et al., 2021). This type of annotation allows regression models that predict a complexity index rather than just a binary label. This task is split into two sub-tasks, the first one is about the prediction of the complexity of single words and the second is about the prediction of the complexity of multi word expressions.

In this work we present our submission to both the sub-tasks with a model that aggregates a large set of heterogeneous features that can capture a wide variety of linguistics aspects (morphological, semantic, distributional and lexicon-based) in a regression model based on Gradient Boosting. We also present an in-depth analysis of which features are more important for the model.

In Section 2 we present a description of the task and the data available. In Section 3 we introduce the model. In Section 4 we show an analysis of the most relevant features for the model. In Section 5 we present the results. Finally, in Section 6 we draw some conclusions.

## 2 Task and data

The data released for sub-task 1 is made of 9000 sentences where the complexity of a single word was annotated considering its context. The complexity has been annotated using a 5-point Likert scale (from 1 to 5 corresponding to Very Easy, Easy, Neutral, Difficult and Very Difficult) with the values scaled in the range 0-1. Here is one example of a sentence annotated in the dataset:

“The structural Gh gene itself and Stat5b are excellent candidates.”

In this sentence, the word “candidates” is annotated with a complexity of 0.11 (the average in the dataset is 0.30). The goal of sub-task 1 is to predict the complexity of a single word given the sentence and the word to evaluate. The data for sub-task 2 is made of 1800 sentences where expressions of two words are annotated as already described. Here is one sample extracted from the dataset:

“I invite the President to ask all Members who are in the pension fund to say so orally, in plenary, immediately, because they have a direct interest in what is to be discussed.”

In this sentence, the expression “direct interest” is annotated with a complexity of 0.40 (the average in the dataset is 0.42). The goal of sub-task 2 is to predict the complexity of an expression like the one above given the sentence and the expression to evaluate.

For both sub-tasks, the data was selected from three different corpora:

- The World English Bible, translation from Christodouloupoulos and Steedman (2015).
- A selected portion of the European Parliament proceedings in English.
- Selected articles from the biomedical domain.

Having data from sources so diverse is a unique aspect of this task. This dataset was introduced in (Shardlow et al., 2020).

### 3 CompNA model

The main idea behind our model is to aggregate many diverse features that can capture a wide variety of linguistics aspects in a regression model that offers the ability to interpret which of them are more influential.

#### 3.1 Features

In this section we list the features used for the two sub-tasks.

##### 3.1.1 Features for sub-task 1

The following sets of features were used to capture morphological aspects of the text:

- Part of speech tag and Syntactic dependency of the word to evaluate and surrounding words in a window of three words. The library

Spacy with the model `en_core_web_sm` (Honnibal and Montani, 2017) has been used to extract these features.

- Syllables in the word. Number of syllables in the word. Minimum, maximum and average number of syllables in the sentence.
- Length of the word. Minimum, maximum, and average of the lengths of all the words in the sentence.
- Desinence of the word, first and last letter of the word.
- Number of unique characters.
- A Boolean value that is 1 only if all the characters in the word are uppercase.

To take into account distributional characteristic of the word to evaluate we used:

- GloVe embedding of the word, we used the version pre-trained on Wikipedia 2014 and Gigaword 5 with size 50 (Pennington et al., 2014).
- Frequency of the word and of the part of the sentence of three words that include the word in the wordfreqs dataset (Speer et al., 2018).

Semantic aspects were encoded considering the number of synsets and hyponyms of the word in WordNet.

We also considered a set of binary features that report if the word is in one of the following lexicons: Obscure words (Chrisomalis, 1996), Medical words, Simple English words (Ogden and Halász, 1935).

##### 3.1.2 Features for sub-task 2

For sub-task 2 we have used the same features considered for sub-task 1 computing them for each word in the expression to evaluate. We have also restricted the part of speech tags to the target words and added the frequency of the entire expression.

#### 3.2 Regressor

Our final regressor is composed of 120 Decision Trees with a maximum depth of 5 layers. The model was trained using Gradient Boosting (Friedman, 2001) with a learning rate of 0.047 and taking a sub-sample of 75% of the original data at each boosting iteration. The final prediction is computed averaging the output of each tree. The library XGBoost (Chen and Guestrin, 2016) was used for our experiments. The parameters were selected via a grid search performed using the library Scikit-Learn (Pedregosa et al., 2011).

Figure 1: Frequency of the word in Zipf scale versus the complexity. The points in red represent words for which the model has an error higher than a quarter of a point. The chart was made splitting the train data for sub-task 1 in half. The first half has been used to train the model and the second to evaluate the error.

Features group	Importance	N. features
Syllables	19.1%	2260
GloVe	17.8%	50
Desinences	10.2%	898
All frequencies	8.7%	6
Starting letters	5.8%	52

Table 1: Importance of the top 5 groups of features for the model (on single words).

#### 4 Features importance

In order to bring insights into how the model works, we study the contribution of the features. Tables 1 and 2 report the importance of the features that are influential for the prediction, respectively, per group and single feature. The feature importance reflects the number of times a feature is selected for a split for one of the decision trees in the model, weighted by the improvement as a result of the split, and averaged over all the trees in the model (Elith et al., 2008).

Looking at the importance of the features grouped by type we find morphological and distributional ones at the top. While the morphological

Feature	Importance	Type
All uppercase letters	9.47%	binary
Word frequency	7.93%	float
In medical lexicon	3.03%	binary
POS PROP	1.85%	binary
Word length	1.47%	integer
Syllable “ca”	1.19%	binary
Ends with “s”	1.10%	binary
Desinence “ess”	0.84%	binary
Ends with “e”	0.75%	binary
Desinence “ing”	0.71%	binary
GloVe 32th position	0.68%	float
Syllable “ver”	0.67%	binary
Syllable “ro”	0.64%	binary
Desinence “ium”	0.63%	binary
GloVe 29th position	0.62%	float

Table 2: Importance of the top 15 single features for the model (on single words).

group (syllables, desinences and starting letters) add up to almost 3000 features, the distributional group, made of GloVe and word frequencies, only presents 56 features.

Going into details and inspecting the importance

Sub-task	Team	Pearson	Spearman	MAE	MSE	R2
1	JUST Blue	0.7886	0.7369	0.0609	0.0061	0.6172
1	CompNa	0.7552	0.7153	0.0641	0.0070	0.5701
1	<i>baseline</i>	0.6920	0.6533	0.0737	0.0091	0.4387
2	DeepBlueAI	0.8612	0.8526	0.0616	0.0063	0.7389
2	CompNa	0.7931	0.7800	0.0783	0.0093	0.6160
2	<i>baseline</i>	0.7503	0.7435	0.0848	0.0111	0.5386

Table 3: Results of the CompNA model compared a baseline and the best performing model in the competition. The baseline is given by the values on the 20th percentile of the leaderboard.

of single features we note that two of them stand out covering more than 15% of importance. The first is the binary variable representing if the word to evaluate is made of only capital letters and the second is the frequency of the word. In Figure 1 we see the frequency of the word in Zipf scale versus the complexity annotated. The frequency of a word in Zipf scale is the base-10 logarithm of the number of times it appears per billion words (Van Heuven et al., 2014). The Figure shows in red the words for which the model achieves an error greater than 0.25. It is easy to see that the relation between the two features in the chart is well covered by the model as significant errors happen mostly in samples that can be considered outliers. Specifically, we see that many acronyms tend to be outliers in this space. It is interesting to note that acronyms highlighted in the chart are annotated with a score much higher than the average.

Looking again at the table of individual features importance, we find the desinence “ess” which is associated with simple words (such as “darkness”, “kindness” and “business”) and the desinence “ium” which is associated with words that have a complexity more than the average (such as “epithelium”, “cadmium”, “medium”).

Considering the most important syllables, we notice the syllable “ca” which is associated with words from a wide range of complexities (the most complex “cause”, and the least complex “catalepsy”). And the syllable “ver” which is associated with low complexity words (the most complex being “reversal”, and the least complex being “river”).

This analysis further confirms the hypothesis outlined in (Zampieri et al., 2016) that distributional and morphological aspects of the words have a tight bond with the complexity.

The analysis also highlights one of the weak points of the model, it overlooks features related to

the context of the word.

## 5 Results

In Table 3 we summarize the results comparing our model with the best performing model in the competition and a baseline given by the values on the 20th percentile of the leaderboard. The proposed model largely outperforms the baseline in all the measures considered. Notice that the baseline considered here is more challenging than the one proposed in the description of the data (Shardlow et al., 2020). Regarding sub-task 1, the results of the proposed model are comparable to the ones of the winner of the competition in all the measures apart from the  $R^2$  where the two models have a difference of almost 18%. While for sub-task 2 the model beats the baseline but it is far from the winning model. For sub-task 1 the model ranked 26th achieving above average performances and for sub-task 2 it ranked 24th achieving average performances.

## 6 Conclusions

In this paper, we presented a solution to predict the complexity of single and multi word expressions combining a large number of features from a diverse nature.

The model achieves average results and, more importantly, offers the ability to quantify the relevance of the features for the prediction. Thanks to this ability we have shown that the frequency of occurrence and the morphology of the words are key predictors of complexity for the data considered.

From our analysis, it is clear that our model overlooks features related to the context of the word and we would like to improve it under this point of view in our future efforts.

## Abstract

In this contribution, we describe the system presented by the PolyU CBS-Comp Team at the Task 1 of SemEval 2021, where the goal was the estimation of the complexity of words in a given sentence context.

Our top system, based on a combination of lexical, syntactic, word embeddings and Transformers-derived features and on a Gradient Boosting Regressor, achieves a top correlation score of 0.754 on the subtask 1 for single words and 0.659 on the subtask 2 for multiword expressions.

## 1 Introduction

The notion of *complexity* has often been debated in linguistics and, depending from the disciplines, it might have different meanings.

In linguistic typology, for example, complexity is generally studied as a property of the language system as a whole, it is conceived as the number of (morphological, syntactic, semantic etc.) distinctions that a speaker has to master, and it is assessed by comparing different languages (McWhorter, 2001; Parkvall, 2008). On the other hand, in the perspective of psycholinguistics and cognitive science, the notion of complexity can be described as the *difficulty* encountered by language users while processing concrete linguistic realizations (sentences, utterances etc.) (Blache, 2011; Chersoni et al., 2016, 2017, 2021; Iavarone et al., 2021; Sarti et al., 2021). Finally, in the Computational Linguistics community, the assessment of complexity at the lexical level is often related to readability

applications (Shardlow et al., 2020), with the goal of determining if a word in a given text will be difficult to understand for the language users. Such applications are extremely useful for second language learners, for speakers with relatively low literacy and for people with reading disabilities, helping to tailor the difficult level of the texts to the needs of the target users.

Task 1 of SemEval 2021 (Shardlow et al., 2021) aims at the development of systems for the estimation of lexical complexity in context, both for single words and for multiword expressions. The organizers provided two datasets with the target words in a sentence context, with annotations consisting of a mean of the complexity ratings assigned by humans. In our paper, we present the system developed by the PolyU CBS-Comp team for the competition. Our top system achieves a Pearson correlation of, respectively, 0.754 on the single words dataset and 0.659 on the multiword expressions one.

## 2 Related Work

In the earliest shared task on the lexical complexity problem, organized in 2016 (Paetzold and Specia, 2016), complexity was defined as a binary variable: given a word in context, the word will be judged as complex or not. Of course, this was a simplifying assumption, since there might be many situations where the boundary is not a clear-cut one, and annotators would rather indicate a value in a continuous scale. Moreover, the "complex" words in the data only needed to be categorized as such by just one

of the annotators. A further study by [Zampieri et al. \(2017\)](#) analyzed the output of the participating systems, showing that modeling complexity as binary actually hindered their performance.

A second iteration of the shared task was organized in 2018 ([Yimam et al., 2018](#)), this time features two separate subtasks: the traditional binary classification task, where systems had to predict whether one word was complex or not, and a regression task, where systems had to estimate the probability that an annotator would have considered a given word as complex.

Recently, [Shardlow et al. \(2020\)](#) have introduced CompLex, a new gold standard for the estimation of lexical complexity in context for English: the corpus, including sentences from different textual genres, is annotated with the mean complexity ratings for the target words. As a preliminary evaluation, the authors presented the results of a linear regression model trained on sets of features including word and sentence embeddings and some hand-crafted features that are traditionally associated to complexity, such as frequency, word length and syllable count. The best scores, in terms of mean absolute error, were obtained when using only the latter set of features, while models based on the dimensions of the embeddings were lagging behind.

### 3 Datasets

The datasets for the shared task are part of the CompLex corpus, which has been published and described by [Shardlow et al. \(2020\)](#). The annotated sentences were collected using three different corpora: the Europarl corpus ([Koehn, 2005](#)), which includes the proceedings of the European Parliament; the CRAFT biomedical corpus ([Bada et al., 2012](#)); and the Bible, in the modern version of the World English Bible translation ([Christodouloupoulos and Steedman, 2015](#)).

The organizers selected targets as either single words (Sub-Task 1) or multiword expressions (Sub-Task 2), and the datasets include also multiple examples with the same target, as different contexts can determine different complexity values. As for the multiword expressions, they were identified via syntactic patterns, being either adjective-noun or noun-noun phrases.

20 annotations per data instance were collected, with annotators coming from different English-speaking countries (US, UK and Australia): the possible ratings ranged from 1 → Very Easy to 5

Dataset Instance	Corpus	Score
This was the <b>length</b> of Sarah’s life.	Bible	0.125
... <b>dissenters</b> by definition excluded.	Europarl	0.688
...due to reduction in <b>adipose</b> tissue...	CRAFT	0.813

Table 1: Examples of the instances from the different corpora, together with the mean complexity scores for the target words in bold.

→ Very Difficult. Mean scores were then normalized in the 0-1 range.

In a first phase, the organizers released a training data of 7661 samples for the single words track and 1517 samples for the multiword expressions track, together with a trial/validation dataset of 420 and 99 samples, respectively. Later, they released a test set of 917 samples for the single words track and 184 samples for the multiword expressions track.

Examples of the instances are shown in Table 1.

## 4 Evaluation

For both the single words and the multiword expressions track, we used the same set of features as input for a regression algorithm. In the multiword expressions track, we computed the value of the features for each of the two words in the target expression and then we took the average.

### 4.1 Features

As hand-crafted features, we adopted the same ones used by [Shardlow et al. \(2020\)](#) in the original evaluation of their dataset: **Logarithmic Frequency**, **Word Length** and **Syllable Length**. The latter two have been extracted using the Python `textstat` for each target word. As for the frequency feature, we extracted a general, out-of-domain frequency for each target word using the SUBTLEX database ([Brysbaert and New, 2009](#)) and the `wordfreq` Python package ([Speer et al., 2018](#)), and then we extracted the frequency of the word in each one of the three corpora composing CompLex. In total, we obtained 6 features (4 frequency + 2 length features) for each instance. We also added two Boolean features for **Capitalization**: the first was equal to 1 if the first letter of the target word was upper case and 0 otherwise; the second one was equal to 1 if all the letters of the target word were upper case and 0 otherwise. The latter feature was added because we noticed that some of the target words in the dataset are acronyms.

Apart from the lexical information, **Syntactic Features** were explored for both single words and

multiword expressions. The StanfordNLP tools (Manning et al., 2014) were first used to acquire both the part-of-speech (POS) tags and dependency trees. POS tags of target words were manipulated using one-hot encoding, for a total of 20 POS-based features. On the other hand, directed and path from the target word to the root were extracted as dependency features. We concatenated all dependency tags to the root, using one-hot encoding once again to encode every distinct path as a single feature. In total, we generated 267 dependency paths features with this mechanism.

Another feature was based on **Word Embedding similarity**: first, we computed the sum of the embeddings for all the words preceding the target, as a sort of general representation of the sentence context<sup>1</sup>, and then we measured the cosine similarity with the embedding of the target word. If the target was a multiword expression, we summed the embeddings of the words composing it. As word embeddings, we used the publicly available Fast-Text vectors, pre-trained on the Wikipedia corpus (Bojanowski et al., 2017).<sup>2</sup>

We added one feature based on the **BERT Transformer Model** (Devlin et al., 2019)<sup>3</sup> by masking the target word in the original sentence and taking the probability value provided in output by the Softmax. For multiword expressions, we sequentially masked the words composing the target and took the average value.

Similarly, we used the **GPT-2 Transformer Model** (Radford et al., 2019)<sup>4</sup> to obtain a probability score for the full sentence, computed as the product of the probabilities of the single tokens.

The total number of extracted features is 300. Finally, we decided to generate polynomial features from our set, in order to exploit potential interactions. We used the PolynomialFeatures functionality of the scikit-learn Python package to generate interaction features of order 2, so that the final number of features that was fed to the regressors was 45151.

<sup>1</sup>The use of vector sum as a compositional function has been used in Distributional Semantics since Mitchell and Lapata (2010).

<sup>2</sup><https://fasttext.cc/docs/en/pretrained-vectors.html>.

<sup>3</sup>We used the BERT-large-cased model, in the implementation of the Happy Transformer library: <https://github.com/EricFillion/happy-transformer>.

<sup>4</sup>We used the GPT2-xl model, in the implementation of the lm-scorer package: <https://pypi.org/project/lm-scorer/>.

## 4.2 Regressors

We tested several regression algorithms, using the implementations in the scikit-learn Python package. The adopted scikit-learn API and the main hyper-parameters are listed below:

- **RR Ridge**: Ridge Regression solves a regression model where the loss function is the linear least squares function and regularization is given by the l2-norm. `alpha=1.0, normalize=True`.
- **MLP MLPRegressor**: Multi-layer Perceptron regressor optimizes the squared-loss using LBFGS or stochastic gradient descent. `hidden_layer_size=5, activation=identity, solver=adam`.
- **PLSR PLSRegression**: PLS Regression implements the PLS2 blocks regression in case of one dimensional response. `components=5`.
- **BRR BayesianRidge**: a Bayesian Ridge model implements the optimization of the regularization parameters lambda and alpha. `alpha_1, alpha_2==1.0e-6, lambda_1, lambda_2=1.0e-6`.
- **LR LinearRegression**: Linear Regression is trained based on ordinary least squares function. `normalize=True`.
- **RF RandomForestRegressor**: a Random Forest is a meta estimator that fits a number of classifying decision trees on various sub-samples of the dataset and uses averaging to improve the predictive accuracy and control over-fitting. `min_samples_split=2, min_samples_leaf=1`.
- **GBR GradientBoostingRegressor**: Gradient Boosting builds an additive model in a forward stage-wise fashion which allows for the optimization of arbitrary differentiable loss functions. `learning_rate=0.1, min_samples_split=2, min_samples_leaf=1`.

## 4.3 Metrics

The performance of the participating systems was evaluated in terms of Pearson correlation ( $r$ ) between the outputs and the human mean ratings. In the Results section, we also report the scores

for Spearman correlation ( $\rho$ ), Mean Absolute Error ( $MAE$ ), Mean Squared Error ( $MSE$ ) and R-Square ( $R^2$ ).

## 5 Results

We evaluated our system for two subtasks based on given trial datasets. For each regressor, we tuned hyper-parameters according to each subtask. Performance evaluation has been carried out in two aspects: the assessment of the overall correlation with human ratings and the analysis of the contribution of the features.

### 5.1 Complexity Prediction

Evaluation metrics are reported ranking by Pearson correlation in Table 2 and 3 for single words and multiword expressions, respectively.

Regressor	$r$	$\rho$	$MAE$	$MSE$	$R^2$
RR	0.34	0.36	0.100	0.017	0.097
MLP	0.39	0.46	0.099	0.017	0.083
PLSR	0.46	0.53	0.093	0.015	0.206
BRR	0.47	0.51	0.094	0.015	0.181
LR	0.48	0.54	0.092	0.015	0.208
RF	0.49	0.65	0.078	0.010	0.472
GBR	0.75	0.72	0.070	0.008	0.561

Table 2: Performance on single words prediction (Sub-Task 1).

Regressor	$r$	$\rho$	$MAE$	$MSE$	$R^2$
RR	0.26	0.28	0.128	0.021	0.083
MLP	0.28	0.37	0.117	0.019	0.091
BRR	0.40	0.42	0.112	0.017	0.151
PLSR	0.40	0.42	0.109	0.017	0.178
LR	0.41	0.42	0.110	0.016	0.183
RF	0.44	0.51	0.105	0.015	0.424
GBR	0.66	0.66	0.090	0.013	0.427

Table 3: Performance of multiword expressions prediction (Sub-Task 2).

Features	$r$	$\rho$	$MAE$	$MSE$	$R^2$
Hand-crafted	0.73	0.69	0.072	0.009	0.527
+Synt.	0.73	0.69	0.073	0.009	0.528
+Embs.	0.73	0.69	0.073	0.009	0.530
+Trans.	0.74	0.71	0.071	0.009	0.545
+ALL	0.75	0.72	0.070	0.008	0.561

Table 4: Ablation study of feature groups.

It can be observed that predicting the complexity of single words is naturally less difficult than multiword expression. Concerning the regression algorithm, gradient boosting regression outperforms other investigated methods by a large gap, while PLS regression, Bayesian ridge regression, linear

regression and random forest regression perform very similarly. Though PLSR has a worse Pearson correlation than BRR, its  $R^2$  and Spearman correlation are slightly better. Further studies about regressors brought some unexpected results for our feature based approaches: based on the features we selected, Ridge Regression performs worse than linear regression, suggesting that some features are not suitable for applying L2-norm.

### 5.2 Feature Study

As our proposed method heavily relies on feature selection, the acquired features are investigated in four groups: *Hand-crafted* (including Logarithmic Frequency, Word and Syllable Length and Capitalization), *Syntactic* (including the POS- and the Dependency-based features), *Embedding* and *Transformer* features. We adopted the features of the *Hand-crafted* group as baseline, and present a comparison between the performance of systems using the other features as add-on components. The scores in Table 4 refer to the performance on the single words dataset, by using GBR as a regressor.

According to Table 4, syntactic, embedding and transformer based features can all contribute to improve the prediction results. As expected, the combination of all feature type groups can achieve the best predicting capability.

Comparing with the baseline of hand-crafted features, syntactic and embedding features have very marginal contribution. Yet, it should not be neglected supplementing only transformer based features cannot achieve the maximum performance gain. This indicates that the interaction of the individual features can bring latent useful information to model, further revealing the complexity values of the target words.

## 6 Conclusion

In this paper, we presented the PolyU CBS-Comp system for lexical complexity prediction, which took part in the SemEval shared task 1. Our method, based on a combination of lexical, syntactic, embeddings and Transformers features, achieved a 0.754 correlation on single words and 0.659 on multiword expressions, when using Gradient Boosting as a regression algorithm.

Traditional hand-crafted features, followed by Transformer-based ones, seem to give the strongest contribution to the classification performance, which is further improved by adding feature in-

teractions to the input for the regressor.

For future studies on lexical complexity, we plan to further exploit the text genre information, for example by adding domain-adapted language model features (Van Schijndel and Linzen, 2018) to the information available to our models.

# LAST at SemEval-2021 Task 1: Improving Multi-Word Complexity Prediction Using Bigram Association Measures

Yves Bestgen

Laboratoire d'analyse statistique des textes - LAST  
Institut de recherche en sciences psychologiques  
Université catholique de Louvain  
Place Cardinal Mercier, 10 1348 Louvain-la-Neuve, Belgium  
yves.bestgen@uclouvain.be

## Abstract

This paper describes the system developed by the Laboratoire d'analyse statistique des textes (LAST) for the Lexical Complexity Prediction shared task at SemEval-2021. The proposed system is made up of a LightGBM model fed with features obtained from many word frequency lists, published lexical norms and psychometric data. For tackling the specificity of the multi-word task, it uses bigram association measures. Despite that the only contextual feature used was sentence length, the system achieved an honorable performance in the multi-word task, but poorer in the single word task. The bigram association measures were found useful, but to a limited extent.

## 1 Introduction

For more than half a century, many studies have been carried out to collect norms about formal and semantic properties of words, such as frequency of use, spelling regularity, familiarity, age of acquisition, or emotional valence (Proctor and Vu, 1999). Some of these properties can be easily harvested through automatic counting procedures applied to corpora. Other properties, such as familiarity or emotional valence, are obtained by requiring participants, often more than ten, to rate the words on these dimensions. In psycholinguistics, these norms have been mainly used for selecting experimental materials (Wilson, 1988). In computational linguistics, they are used in opinion mining, in the evaluation of foreign language skills and in text simplification for instance (Pang and Lee, 2008; Kyle et al., 2018). Obtaining lexical norms that require human evaluations is extremely costly in time and resources, which greatly reduces their size. However, huge norms are essential in applications (Bestgen, 1994). This observation has led to the development of automatic techniques to extend such

norms (Bestgen, 2002; Kamps et al., 2004; Esuli and Sebastiani, 2006; Bestgen and Vincze, 2012).

The Lexical Complexity Prediction (LCP) shared task at SemEval-2021 requires exactly the development of such techniques (Shardlow et al., 2021a). It is indeed a question of estimating the lexical complexity, the degree of difficulty of the words in a text. This dimension is important in NLP applications for simplifying texts and assisting specific populations such as people with reading disabilities or who are learning a foreign language. A specificity of the LCP task is that it relates not only to words but also to multi-word expressions which are very rarely taken into account in norms and in automatic extension techniques (Bestgen, 2014). Another important feature of the task is that the target tokens were presented to human judges in context and that a significant number of them were presented in several different contexts. Human annotations are therefore likely to reflect the impact of the linguistic context on lexical complexity.

This paper describes the system proposed for this task by the Laboratoire d'analyse statistique des textes (LAST). It is based on a LightGBM model fed with features obtained from many word frequency lists, published lexical norms and psychometric data. For tackling the specificity of the multi-word task, it uses bigram association measures (such as Mutual Information) from research in lexicography (Church and Hanks, 1990) and in the automatic evaluation of texts written by English learners (Durrant and Schmitt, 2009; Bestgen and Granger, 2014). Despite that the only contextual feature used was sentence length, the system achieved an honorable performance in the multi-word task, ranking 9th out of 37 teams, but poorer in the single word task, ranking 26th out of 54 teams.

In the next section, the main characteristics of this challenge are summarized. The following sec-

tion describes in detail the developed system. Finally, the results in the challenge are reported along with several analyzes performed to get a better idea of the factors that affect the system performance.

## 2 Task and Materials

The organizers of the challenge have made available an updated version of the CompLex dataset (Shardlow et al., 2020) to the participating teams for developing their systems (i.e., the learning set). It consists of 8,083 single words and 1,616 bigrams, all of them presented in a one-sentence context. These sentences were taken from three English sources in almost equal proportion: biblical text, biomedical articles and proceedings of the European Parliament. The target words and bigrams were evaluated by several judges on a 5-point Likert scale depending on whether it seemed more or less easy to understand in this context. There were on average 25.75 annotations per instance (Shardlow et al., 2021b). The complexity score for each target is the mean of these ratings. In this materials, a non-negligible proportion of the targets were presented several times in different sentences in order to assess the impact of this context on the complexity assessment. The test set, collected in the same way, consisted of 917 single words and 184 bigrams of which none of the targets were present in the learning set. The challenge measure was Pearson’s linear correlation coefficient between human ratings and system predictions.

## 3 System

The first part of this section presents the features used to predict lexical complexity starting with those common to both tasks and ending with those specific to predicting the complexity of the multi-word expressions. Next, the procedure used to build the predictive models is described.

### 3.1 Features

**Frequency Lists:** I used the frequency of spelling forms calculated from corpora, but also a series of lists established by other researchers:

- The frequency in the Corpus of Contemporary American English (COCA), a balanced, 425-million word corpus of American English collected from 1990 to 2011 (<http://corpus.byu.edu/coca/>).

- The frequency in the British National Corpus (BNC), a 100-million word collection of samples of written and spoken language designed to represent a wide cross-section of British English from the latter part of the 20th century (<http://www.natcorp.ox.ac.uk/corpus/>).
- The Facebook frequency norms for American English and British English of Herdagdelen and Marelli (2017), based on approximately 1 billion tokens for each English variety, obtained from publicly available English posts collected between November 2014 and January 2015.
- The Rovereto Twitter Corpus frequency norms based on 75 millions tweets, for more than 1 billion tokens collected between December 2010 and July 2011 (Herdagdelen and Marelli, 2017).
- The USENET Orthographic Frequencies derived by Shaoul and Westbury (2006) from a corpus of 7,781,959,860 words of USENET postings collected between October 2005 and August 2006.
- The Hyperspace Analogue to Language (HAL) frequency norms provided by (Balota et al., 2007) for more that 40,000 words.
- The frequency word list derived from the Google’s ngram corpus available at <https://github.com/hackerb9/gwordlist>.

I also obtained the frequency of each target in each of the three corpora provided by the organizers as materials.

**Lexical Norms and Psychometric Data:** Lexical norms were mainly taken from the Glasgow Norms (Scott et al., 2019). They contain the evaluation by human raters of 5,553 English words on the psycholinguistic dimensions of age of acquisition, arousal, concreteness, dominance, familiarity, gender association, imageability, semantic size and valence. I also used SemD, a measure of the semantic ambiguity of a word based on variability in its contextual usage (Hoffman et al., 2013). The psychometric data were taken from the English Lexicon Project (Balota et al., 2007), a database that contains, for more than 40,000 words, the reaction time and average accuracy during lexical decision and naming tasks performed by many participants.

**Other Features:** Three binary features were used to encode the corpus from which the sentence is extracted, the initial analyzes having shown that it was more efficient than building three models, one per corpus. The only contextual feature taken into account was the sentence length in tokens.

**Bigram Association Measures:** These features, used only for the multi-word task, inform about the degree of association between the two target words according to a series of indices calculated on the basis of the frequency in a reference corpus of the bigram and that of the two words that compose it: pointwise mutual information and t-score (Church and Hanks, 1990), z-score (Berry-Rogghe, 1973), log-likelihood Chi-square test (Dunning, 1993), simple-ll (Evert, 2009), Dice coefficient (Kilgariff et al., 2014) and the two delta-p (Kyle et al., 2018). Bestgen and Granger (2014) refer to these features as *collgrams* because they combine the strengths of both collocations (by using association scores) and n-grams (by using contiguous pairs of words). The justification for their use in the LCP task is given by works in foreign language learning which has shown that these indices can be used to assess the lexical richness of multi-word expressions present in texts written by English learners (Bestgen and Granger, 2014; Somasundaran et al., 2015; Bestgen, 2018, 2019).

### 3.2 Supervised Learning Software

The regression models were built by the LightGBM open software (Ke et al., 2017), a well-known implementation of the gradient boosting decision tree approach. Compared to the multiple linear regression used for this task by Shardlow et al. (2020), this type of model has the advantages of not requiring any feature preprocessing, such as a logarithmic transformation, since it is insensitive to monotonic transformations. It also allows a very effective overfit control thanks to its many parameters.

### 3.3 Procedure

The sentences were first lemmatized by the Tree-Tagger (Schmid, 1994). The scores on the different lexical lists were attributed to the targets by a two-step procedure: on the basis of the orthographic form if it is found in the list or by using the lemma. The handling of missing values, which occurs when a word is not in a frequency list for example, has been left to the LightGBM default procedure. A large number of multi-word targets were given two

	Test	CV
	r	r
Full System	0.753	0.810
	Diff.	Diff.
Length	-0.002	-0.001
Frequencies	-0.013	-0.012
Normes	-0.022	-0.027

Table 1: Difference in Pearson’s r from the full system for the single word task when a set of features is removed (ablation approach).

values for many features by this procedure, one for each word. The corresponding features were doubled: the first encoding the minimum value and the second the maximum value.

The features used in the final models as well as LightGBM parameters were optimized by a 9-fold cross validation procedure. This led to the selection of the following features:

- For task 1, the length of the sentence and 12 features from the frequency lists, 10 from the lexical norms, and 8 from the psychometric data (i.e., average response latencies (raw and standardized), standard deviations, and accuracies for the lexical decision and naming tasks).
- For task 2, the same features as in task 1 plus 3 features for the corpus of origin and 8 from the bigram association measures.

The same LightGBM parameters were used for both tasks. They were left at their default values except the followings: *num\_iterations: 4800*, *max\_bin: 64*, *min\_data\_in\_bin: 10*, *lambda\_l2: 0.0175*, *bagging\_freq: 5*, *bagging\_fraction: 0.66*, *feature\_fraction: 0.09*, *learning\_rate: 0.0035*, *max\_depth: 7*, *min\_data\_in\_leaf: 7*, *num\_leaves: 11*.

## 4 Analyzes and Results

### 4.1 System Performance

The system built to predict the lexical complexity of single words scored 0.7534 on the test material, ranking it 26th out of 54 teams, down 0.0352 from the best team. In the multi-word subtask, the system finished 9th out of 37 teams with a score of 0.8417. The best team got 0.8612.

Line Id	Sent. Length	Corpus Id	Norms	Freq.	Bigram	Test	CV
						r	r
1	x	x	x	x	x	0.842	0.799
						Diff.	Diff.
2		x	x	x	x	-0.002	-0.001
3	x		x	x	x	-0.011	-0.003
4	x	x		x	x	-0.031	-0.015
5	x	x	x		x	-0.012	-0.004
6	x	x	x	x		-0.014	-0.014
7			x			-0.096	-0.055
8				x		-0.066	-0.054
9					x	-0.176	-0.161

Table 2: Difference in Pearson’s r from the full system for the multi-word task using the ablation approach.

The comparison of the results obtained on the test sets with those obtained by cross validation shows an unexpected difference between the two tasks. In the single word task, the correlation on the test set was lower by 0.053 compared to that obtained in CV (0.8064) while in the multi-word task this same correlation is higher by 0.042 compared to that obtained in CV (0.7996). It is also observed that the best systems which participated in the two tasks had superior performance on the multi-word task. If the difference in performance between the test sets and the CVs is not specific to the present system, this would suggest that the performance achieved in the multi-word task is rather overestimated, the test set being for some unknown reason relatively easy to predict. Although this is only a hypothesis which requires additional analyzes, it leads to not considering the multi-word task as being almost solved.

#### 4.2 Usefulness of the Different Types of Features

In this section, the impact of the different types of features on the system performance is assessed using an ablation procedure. As the previous section indicated important differences between performance on the test set and by the CV approach, results are presented for these two evaluation procedures.

**Single Word Task:** Table 1 shows that the sentence length, the only contextual feature, is of little use. Norms and psychometric data are more useful than frequencies in corpora, but above all, these two sets of features provide very similar informa-

tion since the removal of one as well as the other harms very little the model performance. These conclusions apply equally to the test set as to the CV.

**Multi-Word Task:** The system for multi-word expressions is based on five sets of features whose roles in its effectiveness are shown in Table 2. The absence of an "x" in a column indicates that this set of features has not been used in this version of the model. The first line of the table gives the performance of the system submitted for the challenge.

The length of the sentences [2] is much less useful than the features which identify the corpus [3]. The comparison of the usefulness of the psychometric norms and data and the frequencies in corpora shows a contrast. When these sets are in turn excluded from the system, psychometric norms and data [4] are more useful than frequencies in corpora [5]. On the other hand, when used alone, frequencies [8] are more effective than psychometric norms and data [7]. It will be concluded that a greater part of the contribution of the frequency data is shared with other indices, most probably the bigram association measures.

The specific contribution of the bigram association measures [6] to the performance of the system is slightly greater than that of the frequencies in corpora. These features provide a gain of 0.014. Without it, the system would have been ranked 15th instead of 9th in this task. When used alone, however, bigram association measures [9] are much less effective than norms or frequencies.

The effects of the different types of features are almost always more important when estimated on

Frequency of the target	Task	
	Single	Multi
1	49.2	87.4
2	19.9	7.8
3	10.2	2.2
4	6.2	0.8
5	13.5	1.8
6 or +	4.0	0.0
Total (%)	100.0	100.0
Total nbr.	3,850	1,479

Table 3: Percentage of the target frequency in the two tasks.

Figure 1: Distribution of the range for the repeated targets in the single-word task.

the test set rather than by CV. This could result from the initial difference in effectiveness between the two approaches. However, this phenomenon was not observed in the single-word task in which a difference in effectiveness was also observed. It is especially noted that the norms seem much more useful for the test set than for the CV.

**Potential Importance of the Context:** The results presented above indicate that, in both tasks, sentence length is of little use. Taking better account of the context is undoubtedly a way to improve the system. This hypothesis is all the more likely as the role of context could explain the difference in performance between the two tasks of this system, but also of those of the other teams. Two observations support this hypothesis. Firstly, an analysis of the target frequencies in the two tasks, presented in Table 3, shows that there are much more repeated targets in the single-word task than in the multi-word task, a statistically significant difference for a Chi-square test ( $p < 0.0001$ ).

Second, there are important differences between the human evaluations for the same target shown in different contexts. Figure 1 displays the distribu-

tion of the range (the difference between the maximum and the minimum values) of the complexity score for the repeated targets in the single-word task. The mean range is 0.125 and that 10% of the repeated targets have a range greater than 0.224. Being able to take these differences into account in the single-word task could significantly improve the system, provided that the differences in evaluation for the same target are not just noise. Only an analysis of the inter-rater reliability for the repeated targets would make it possible to choose between these two options.

## 5 Conclusion

The models proposed for the LCP task were built by the LightGBM software mainly fed with norms and frequency features. It obtained an acceptable performance on the test set in the multi-word task on the basis of little contextual information, but less so in the single word task. The analyzes carried out by a CV approach showed, on the other hand, that the system is no better in the multi-word task. It is therefore possible or even probable that the better performance results from an overestimation of its effectiveness. The bigram association measures (aka CollGrams) have proven to be useful, but to a limited extent.

Taking the context into account would probably have improved the system, especially for the single word task in which more than half of the targets were repeated. This hypothesis, however, is based on the assumption that differences between human ratings for the same target in different contexts are as reliable as their ratings for different targets. More generally, it would be interesting to explain the origin of the very important difference in performance between the two tasks, but that does not seem possible on the basis of the data I have access to.

## Abstract

Lexical complexity plays an important role in reading comprehension. lexical complexity prediction (LCP) can not only be used as a part of Lexical Simplification systems, but also as a stand-alone application to help people better reading. This paper presents the winning system we submitted to the LCP Shared Task of SemEval 2021 that capable of dealing with both two subtasks. We first perform fine-tuning on numbers of pre-trained language models (PLMs) with various hyperparameters and different training strategies such as pseudo-labelling and data augmentation. Then an effective stacking mechanism is applied on top of the fine-tuned PLMs to obtain the final prediction. Experimental results on the Complex dataset show the validity of our method and we rank first and second for subtask 2 and 1.

## 1 Introduction

Lexical complexity is one of the main reasons leading to overall text complexity and thus result in poor reading comprehension for readers (DuBay, 2004). Different from the Complex Word Identification (CWI) (Shardlow, 2014) task, which aims to predict whether a given word is complex or not, the goal of **lexical complexity prediction** (LCP) is to predict the complexity value of the given parts from contexts as shown in Figure 1. The underlined parts of the sentence are the words that need to be predicted and the same words in different contexts may have different complexity scores. LCP plays an important role in the usual Lexical Simplification (LS) (Bott et al., 2012) pipeline since it can help simplifiers find the challenging words and replace them with appropriate alternatives that easy to understand. Either LCP or CWI can not only be used as a component of LS systems but also as a stand-alone application within intelligent

Single word	Multi-words
<i>Context1:</i> They shall be to you for a <u>refuge</u> from the avenger of blood. <i>Complexity score:</i> 0.3475	<i>Context1:</i> SEM confirmed many of the observations made by <u>confocal microscopy</u> . <i>Complexity score:</i> 0.64473
<i>Context2:</i> There will be a pavilion for a shade in the daytime from the heat, and for a <u>refuge</u> and for a shelter from storm and from rain. <i>Complexity score:</i> 0.075	<i>Context2:</i> SJ and SVJ carried out <u>confocal microscopy</u> on whole-mounts of stria vascularis. <i>Complexity score:</i> 0.7750

tutoring systems for second language learners or in reading devices for people with low literacy skills (Gooding and Kochmar, 2018).

In this paper, we introduce our system for the lexical complexity prediction task of the SemEval-2021 (Matthew et al., 2021). We fulfill this task by leveraging multiple pre-trained language models (PLM) with different training strategies. There are two main steps for our system: (i) fine-tuning numbers of heterogeneous PLMs, including BERT (Devlin et al., 2019), ALBERT (Lan et al., 2019), RoBERTa (Liu et al., 2019) and ERNIE (Zhang et al., 2019), with various hyperparameters and training strategies, obtaining diverse models; (ii) applying an effective stacking mechanism on top of these PLMs to predict the final complexity scores.

Our experiments, merging PLMs in total, indicate that our method successfully utilizes weaker PLMs as well as high-performing PLMs. As a result, our system ranks second and first for Subtask 1 and 2 of LCP 2021, SemEval-2021.

## 2 Related Work

### 2.1 Lexical Complexity Prediction

There has been some work for the creation and evaluation of automatically graded vocabulary lists

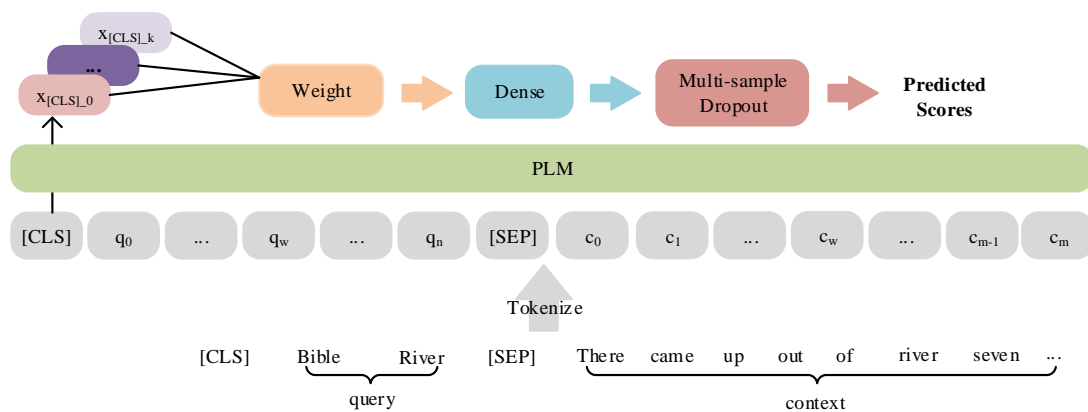

Figure 2: The overall architecture for predicting complexity scores.

for analyzing lexical complexity. François et al. (2014) present the first graded lexicon for French as a foreign language that reports word frequencies by difficulty level and Gala et al. (2014) train two SVM classifiers with 49 features, one for L1 learners and one for learners of French as a foreign language. Alfter and Volodina (2018) map the use of previously created word lists to a single CEFR scale (Common European Framework of Reference for Languages) (De l’Europe, 2003), then they add topics as additional features to predict the complexity level for learners of Swedish as a second language. Shardlow et al. (2020) point out the limitation of treating lexical complexity as a binary classification task. Therefore, they present the first English dataset for continuous lexical complexity prediction and develop a linear regression-based method with various features.

## 2.2 Complex Word Identification

A related area of LCP is CWI. Early studies on CWI either attempt to simplify all words (Thomas and Anderson, 2012) or set a frequency-based threshold (Biran et al., 2011). Shardlow (2013) indicates that a classification-based method to CWI is the most promising one. Most of the teams participating in two CWI shared tasks also use classification approaches with extensive feature engineering. In CWI 2016 (Paetzold and Specia, 2016a), complexity was defined as whether or not a word is difficult to understand for non-native English speakers and the words in the dataset are tagged as complex or non-complex by 400 non-native English speakers. The results highlight the effectiveness of Decision Trees (Quijada and Medero, 2016; Mukherjee et al., 2016) and Ensemble methods (Paetzold and Specia, 2016b; Malmasi et al., 2016) for the task.

In CWI 2018 (Yimam et al., 2018), a multilingual dataset was provided containing English, German, Spanish and French and there were two subtasks: binary classification and probabilistic classification. The submitted systems mainly use traditional machine learning classifiers (e.g. SVM, Random Forests) with features (Butnaru and Ionescu, 2018; Kajiwara and Komachi, 2018), deep learning methods (Hartmann and Dos Santos, 2018; De Hertog and Tack, 2018) and ensemble methods (Gooding and Kochmar, 2018; Aroyehun et al., 2018). More recently, (Gooding and Kochmar, 2019) propose a new perspective by treating CWI as a sequence labeling task that can detect both complex words and phrases. All these methods are different from ours which utilizes heterogeneous PLMs with various training strategies.

## 3 Background

**Task Definition** There are two subtasks in the LCP task. For subtask 1, the goal is to predict the complexity score for a single word from the given context. As an example shown in Figure 1, the ‘refuge’ is the word that needs to be predicted and since the meaning of it is harder to get in the first context, its complexity score in the first context is much higher. For subtask 2, the goal is to predict the complexity score for a multi-word expression from the given context. An example is also shown in the right part of Figure 1.

**Dataset** Shardlow et al. (2020) introduce a new English corpus, Complex, as the dataset for the LCP task of SemEval-2021. Instead of assigning binary scores for lexical complexity, they use crowdsourcing to annotate 8979 instances covering three genres with lexical complexity scores using

Parameters	BERT <sub>LARGE</sub>	ALBERT <sub>XXLARGE</sub>	RoBERT <sub>LARGE</sub>	ERNIE <sub>LARGE</sub>

Table 1: Parameter settings for different base models

a 5-point Likert scale: one for very easy, two for easy, three for neutral, four for difficult, and five for very difficult. The numerical labels were transformed to a 0-1 range as shown in Figure 1. To add further variation to the data, three corpora were selected including Bible, Europarl (Koehn, 2005) and Biomedical (Bada et al., 2012). Each corpus has its own unique language features and styles. In addition to single words, multi-word expressions were also selected for annotating. In the end, there were 9476 annotated contexts with 5166 unique words.

## 4 System

### 4.1 PLMs-based Method

PLMs such as BERT (Bidirectional Encoder Representations from Transformers) use the encoder structure of the Transformer (Vaswani et al., 2017) for deep self-supervised learning, which requires task-specific fine-tuning. In this paper, the downstream task is to predict the complexity scores, a real-value in the range of [0,1], of given words. Our method is capable of dealing with both subtask 1 and 2. Figure 2 shows the main architecture of our BERT-based model for predicting complexity scores.

Since PLMs can process multiple input sentences, we add a query sentence before the context to emphasize the words (e.g. river) that need to be predicted and the corpus (e.g. Bible) they come from. We add special tokens [CLS] and [SEP] to separate the query and the context as shown in Figure 2. BERT first tokenizes the input contents and then generates contextualized vector representations for each token in multiple hidden layers. We focus on the output of only the first position that we passed the special [CLS] token to. The last  $k$  hidden layers are selected to get the final representation of token [CLS] through a weighted calculation function as below,

$$x_{[CLS]} = \sum_{i=1}^k W_i x_{[CLS]i}$$

where  $W_i$  is the learning weight for each hidden layer. The calculated representation is then fed into a dense layer, and the technique of multi-sample dropout (Inoue, 2019) is utilized to accelerate training and finally obtain the predicted complexity scores. The loss function can be chosen among several options including Mean Square Error (MSE), Root Mean Square Error (RMSE), and Mean Absolute Error (MAE).

### 4.2 Training strategies

In order to further improve the diversity of trained models, we incorporate two training strategies as depicted below.

**Pseudo-Labeling** Pseudo-labeling is the process of using a labeled data model to predict labels for unlabeled data. We predict the unlabeled test dataset and mix these pseudo labels with the training set together to train the new model.

**Data augmentation** Data augmentation is the technique used to increase the amount of data by adding slightly modified copies of already existing data or newly created synthetic data from existing data. It acts as a regularizer and helps reduce overfitting when training a machine learning model. In this paper, data augmentation consists of two parts. We first add the dataset released by CWI 2018 into the training set. Besides, for subtask 2, since its training dataset is small which only contains one thousand samples, we add the dataset of subtask 1 to train the model for subtask 2. Then, for a given sentence in the training set, we perform the operations containing synonym replacement, random insertion, random swap, and random deletion introduced by Wei and Zou (2019).

### 4.3 Stacking Trained Models

Model stacking is an efficient ensemble method to improve model accuracy. The main procedure of stacking trained models in our method including five steps. First, we use heterogeneous PLMs including BERT, RoBERTa, ALBERT, and ERNIE as base models. Second, we generate multiple

Scheme	Model	R	Rho	MAE	MSE	R2

Table 3: Comparison of different pre-trained language models of subtask 2

hyperparameter sets by setting different values of dropout, selecting different numbers of last hidden layers, and using different loss functions. Since our purpose here is not only to find the best hyperparameter sets but also to collect diverse sets with reasonable performances, we keep all the training results from different sets. Third, we perform 7-fold cross-validation during the whole training process to avoid overfitting or selection bias. Fourth, we adopt several training strategies including using pseudo-labelling (Iscen et al., 2019) and data augmentation to further improve the diversity of trained models.

Ultimately, we train a simple linear regression model as the final estimator. Suppose that the complexity score predicted by a based model with one hyperparameter set is  $\hat{y}_j$ , then the final complexity scores will be calculated as below,

$$\hat{y} = \sum_{j=1}^N W_j \hat{y}_j$$

where  $N$  is the total number of various fine-tuned PLMs with different hyperparameters sets and  $W_j$  is the weight for each predicted score from different PLMs learned by a linear regression model.

## 5 Experiments

### 5.1 Evaluation Metrics

As mentioned in the official evaluation procedure of LCP 2021, several evaluation metrics are chosen including Pearson correlation (R), Spearman correlation (Rho), Mean absolute error (MAE), Mean

squared error (MSE), and R-squared (R2). The final results are ranked using Pearson correlation.

### 5.2 Parameter settings

All models are implemented based on the open-source transformers library of hugging face (Wolf et al., 2020), which provides thousands of pre-trained models that can be quickly downloaded and fine-tuned on specific tasks. Table 1 shows the four employed PLMs and different parameters we set for each PLM including different numbers of hidden layers, different dropout pairs, and different loss functions.

## 6 Results

### 6.1 Ablation Study

**PLMs with Training Strategies** For subtask 1, we use different PLMs including ERNIE<sub>LARGE</sub>, ALBERT<sub>XXLARGE</sub>, BERT<sub>LARGE</sub>, RoBERTa<sub>LARGE</sub> as shown in Table 2. The results are the average scores of 7-fold cross-validation on the training dataset. Since RoBERTa<sub>LARGE</sub> performs best on this task, we further incorporate the training strategies including pseudo-labelling (PL) and data augmentation (DA) with it. However, for the training dataset, we find that by adding the training strategies, the results decrease a little bit.

For subtask2, we use two types of PLMs which are RoBERTa<sub>LARGE</sub> and ALBERT<sub>XXLARGE</sub>. The results shown in Table 3 are also obtained by averaging the scores of 7-fold cross-validation on the training dataset. Since we have added the dataset of subtask 1 into subtask 2, we also show the results

Figure 3: Comparison of Pearson Correlation values for stacking different models of subtask 1.

Subtask 1		Subtask 2	
System	R	System	R
qusaibanyismail	0.7886	<b>DeepBlueAI</b>	<b>0.8612</b>
<b>DeepBlueAI</b>	<b>0.7882</b>	rg_pa	0.8575
amsqr	0.7790	xiang_wen_tian	0.8571

abdelkader	0.7779	ren_wo_xing	0.8541

Table 4: Leaderboard

of doing this in Table 3 and we can find that it is very effective by increasing 0.02 from base models.

**Stacking trained models** We use a linear regression (LR) model to stack different pre-trained models. We train the weights of each model in LR on the training set and then use the learning weights to predict the final scores of the test set.

Figure 3 shows the comparison of Pearson Correlation values for stacking different models of subtask 1. The columns in blue are the values computed by averaging predicted scores of different models while the columns in orange are the values through the LR function. We can clearly observe that the LR-based ensemble method outperforms those with the mean-based method, which verifies the validity of using the LR mechanism. Besides, although we find that adding training strategies to the base models would decrease performance according to Table 2, the performance will be improved when stacking them all. This indicates the positive effect of increasing model diversity.

## 6.2 Official Ranking

For both subtask 1 and subtask 2, among all the pre-submission experiments, we find that the scores obtained from stacking all the models performed best. The official ranking is presented in Table 4 and it demonstrates that our system is ranked first in subtask 2 and ranked second in subtask 1.

## 7 Conclusion

In this paper, we propose a top-performing model for the task of lexical complexity prediction. We fine-tune several pre-trained language models including BERT, ALBERT, RoBERTa, and ERNIE with different training strategies such as pseudo-labelling and data augmentation and stack them with a simple linear regression model. Experimental results show the effectiveness of this ensemble method and we win first place and second place for subtask 2 and 1.

## Abstract

Lexical Complexity Prediction (LCP) involves assigning a difficulty score to a particular word or expression, in a text intended for a target audience. In this paper, we introduce a new deep learning-based system for this challenging task. The proposed system consists of a deep learning model, based on a pre-trained transformer encoder, for word and Multi-Word Expression (MWE) complexity prediction. First, on top of the encoder's contextualized word embedding, our model employs an attention layer on the input context and the complex word or MWE. Then, the attention output is concatenated with the pooled output of the encoder and passed to a regression module. We investigate both single-task and joint training on both Sub-Tasks data using multiple pre-trained transformer-based encoders. The obtained results are very promising and show the effectiveness of fine-tuning pre-trained transformers for LCP tasks.

## 1 Introduction

Text Simplification (TS) is a fundamental task for improving text readability, and presents a wide variety of use cases, including assisting children with reading difficulties and native speakers with low literacy levels (De Belder and Moens, 2010; Aluísio and Gasperin, 2010), increasing accessibility for people with intellectual disabilities (Saggion, 2017), and facilitating certain aspects of language for language learners (Paetzold and Specia, 2016). TS may involve modifications to the syntactic structure of a sentence, its lexical units or both (Shardlow, 2014).

Lexical Simplification (LS), as a sub-task of TS, focuses on simplifying complex words of an input sentence. It first identifies complex words in a sentence, known as Complex Words Identification (CWI) or Lexical Complexity Prediction (LCP)

task. Then, it replaces them with other alternatives of equivalent meaning. Those substitutions should be more simplistic while preserving the semantic and the grammatical structure of the input sentence (Paetzold and Specia, 2017; Qiang et al., 2020).

Most of the previous research has modeled LCP as a binary classification task (Paetzold and Specia, 2017; Zampieri et al., 2016; Ronzano et al., 2016). A recent research study has introduced a multi-domain dataset, annotated using a 5-point Likert scale scheme (Shardlow et al., 2020). The aim is to label the complexity of a word or a Multi-Word Expression (MWE), in a more fine-grained manner, from very easy to very difficult. Hence, the lexical complexity of words is expressed on a continuous scale.

In this paper, we introduce our submitted system to the SemEval-2021 LCP 1 and 2 Sub-Tasks (Shardlow et al., 2021). The proposed system consists of a deep learning model for word and MWE complexity prediction. Our model employs a residual attention block and a regression module on top of a pre-trained transformer encoder, as follows:

- The encoder is fed with the concatenation of the context and the complex word or MWE, using the SEP token of the encoder's tokenizer.
- The residual attention block is a layer on top of the encoder's Contextualized Word Embedding (CWE) of the input context (sentence) and the complex word or MWE. The aim is to leverage the encoder's CWE to extract the relevant features of the inputs.
- The attention layer output is concatenated with the pooled output of the encoder and passed to the regression module for complexity prediction.

Figure 1: Domains and complexity distributions of the datasets sentences

The proposed model is trained to minimize both the Root Mean Square Error (RMSE) and the auxiliary loss associated to the negative Pearson Correlation. The two losses are combined using the uncertainty loss weighting (Kendall et al., 2017). We investigate two pre-trained transformer networks, namely BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019). Moreover, we evaluate both single-task and joint training of word and MWE complexity prediction sub-tasks. The best performances are achieved using RoBERTa-large encoder while performing joint training on both Sub-Tasks data. The obtained results are very promising and show the effectiveness of our system, which was ranked among the top 10 submitted systems to both LCP 1 and 2 Sub-Tasks.

The rest of this paper is organized as follows. Section 2 describes the dataset and the sub-tasks of SemEval-2021 Task 1. In Section 3, we present our system overview. Section 4 summarizes and discusses the obtained results for both Sub-Task 1 and Sub-Task 2. Finally, Section 5 concludes the paper.

## 2 Task Description

### 2.1 Dataset Description

The dataset of the Lexical Complexity Prediction shared task (Shardlow et al., 2021) is an augmented version of the Complex dataset (Shardlow et al., 2020). In addition to complex word annotation, the data also include MWEs along with their context sentences and complexity scores. The dataset is annotated using a 5-point (1-5) Likert scale scheme and covers sentences from three domains: Bible, EuroParl, and Biomedical texts. The dataset is labeled by a group of annotators from English-speaking countries. It is compiled from sentences with at least four valid annotations. The aggregation of annotations is performed ensuring that

the normalized complexity is in the interval  $[0, 1]$ . The complexity scores are on a 5-point Likert scale and correspond to five levels of complexity ranging from "Very Easy" to "Very difficult" (Shardlow et al., 2020).

### 2.2 Sub-tasks Description

The LCP shared task consists of two sub-tasks (Shardlow et al., 2021):

- **Sub-Task 1:** predicting the complexity score of single words.
- **Sub-Task 2:** predicting the complexity score of multi-word expressions.

The training set consists of 7,662 samples for single word complexity prediction (Sub-Task 1), while the training set of MWE sub-task contains 1,517 samples (Sub-Task 2). Figure 1a presents the number of samples per domain. The dataset is almost balanced for all three domains in the two LCP sub-tasks. Figure 1b and 1c show the complexity distribution of single words and MWEs, respectively. The Figures (1b and 1c) illustrate that most single words have a complexity score less than 0.5, whereas for MWEs, the complexity scores are between 0.25 and 0.75.

## 3 System Overview

The proposed system uses a residual attention block and a regression module on top of the pre-trained transformer encoder network. In the following, we describe each component of our system.

### 3.1 Transformer Encoder

In order to encode the input context and the complex word or MWE, we employ two state-of-the-art pre-trained transformer encoder networks, namely BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019). First, the context (sentence) and the

complex word or MWE are concatenated using the special token (SEP or /s) of the encoder’s tokenizer, as follows:

- BERT case:

Input = [CLS] context [SEP] word/MWE

- RoBERTa case:

Input = < s > context < /s > word/MWE

Then, the tokenizer of the encoder splits the input into wordpieces  $[T_1, T_2, \dots, T_n]$  and encodes them using its vocabulary. The transformer encoder is fed with these encoded inputs. As a result, it outputs:

- The pooled embedding  $h_{pooled} \in \mathbb{R}^{1 \times d}$  (the embedding of [CLS] and < s > tokens for BERT and RoBERTa encoders, respectively).
- The contextualized word embedding (CWE)  $H = [h_1, h_2, \dots, h_n] \in \mathbb{R}^{n \times d}$  ( $d$  is the embedding dimension).

### 3.2 Attention block

Our model applies an attention layer on top of the CWE, output by the encoder (Bahdanau et al., 2015; Yang et al., 2016). The aim is to reward CWEs according to their relevance to the complexity prediction task. Using the CWE, the attention layer extracts a features vector  $v$ , representing the weighted sum of  $H$  vectors:

$$\begin{aligned} C &= \tanh(HW_a) \\ \alpha &= \text{softmax}(C^T W_\alpha) \\ v &= \alpha \cdot H^T \end{aligned}$$

where  $W_a \in \mathbb{R}^{d \times 1}$  and  $W_\alpha \in \mathbb{R}^{n \times n}$  are the learnable parameters of the attention layer,  $C \in \mathbb{R}^{n \times 1}$  is the context vector of the attention mechanism, and  $\alpha \in [0, 1]^n$  weights the CWEs according to their relevance to the task.

### 3.3 Regression Module

The regression module  $F$  consists of one hidden layer and one output layer.  $F$  is fed with the concatenation of the encoder’s pooled output  $h_{pooled}$  and the output attention block  $v$ .  $F$  outputs the  $\hat{y}$ , the predicted complexity:

$$\hat{y} = F([h_{pooled}, v])$$

The proposed system is trained to minimize both the Root Mean Square Error (RMSE) and the auxiliary loss associated to the negative Pearson Correlation:

- The RMSE loss:

$$\mathcal{L}_{rmse}(\hat{y}, y) = \sqrt{\frac{1}{N} \sum_{i=1}^N (y_i - \hat{y}_i)^2}$$

- The auxiliary loss associated to the negative Pearson Correlation:

$$\mathcal{L}_{aux}(\hat{y}, y) = 1 - \frac{\sum_{i=1}^N (y_i - \bar{y})(\hat{y}_i - \bar{\hat{y}})}{\sqrt{\sum_{i=1}^N (y_i - \bar{y})^2} \sqrt{\sum_{i=1}^N (\hat{y}_i - \bar{\hat{y}})^2}}$$

where  $N$  is the number of samples,  $y$  is the ground truth complexity,  $\hat{y}$  is the predicted complexity, and  $\bar{y}$  (resp.  $\bar{\hat{y}}$ ) is the mean of  $y$  (resp.  $\hat{y}$ ). In order to combine both  $\mathcal{L}_{rmse}$  and  $\mathcal{L}_{aux}$ , we use the uncertainty loss weighting (Kendall et al., 2017). The latter aims to combine multiple losses according to their uncertainty and to avoid manual tuning of the loss weights. Finally, our model is trained to minimize the total loss, given by:

$$\mathcal{L}_{total} = \frac{1}{2\sigma_1^2} \mathcal{L}_{rmse} + \frac{1}{2\sigma_2^2} \mathcal{L}_{aux} + \log(\sigma_1 \sigma_2)$$

where  $\sigma_1$  and  $\sigma_2$  are two parameters for learning the relative weight of  $\mathcal{L}_{rmse}$  and  $\mathcal{L}_{aux}$ .

## 4 Results

This section describes the experiment settings and the obtained results.

### 4.1 Experiment Setting

We investigate the performance of our system using both the *base* and the *large* models of BERT and RoBERTa encoders:

- **BERT-base**: 12 transformer blocks,  $d = 768$ , 12 attention heads, and 110M parameters.
- **BERT-large**: 24 transformer blocks,  $d = 1024$ , 16 attention heads, and 336M parameters.
- **RoBERTa-base**: 12 transformer blocks,  $d = 768$ , 12 attention heads, and 125M parameters.
- **RoBERTa-large**: 24 transformer blocks,  $d = 1024$ , 16 attention heads, and 355M parameters.

We implement a simple text preprocessing pipeline that normalizes the contractions<sup>1</sup>. All models are trained using Adam optimizer (Kingma and

<sup>1</sup>We have employed the package contractions for this purpose. <https://github.com/kootenpv/contractions>

Table 2: Ablation study of our model’s component using joint training and RoBERTa-large as encoder (symbol w/o denotes without the corresponding component). **w/o uncertainty loss weighing** corresponds to the simple combination of model losses ( $\mathcal{L}_{total} = \mathcal{L}_{rmse} + \mathcal{L}_{aux}$ ).

Ba, 2015) with a learning rate of  $1 \times 10^{-5}$ . The batch size and the number of epochs are fixed to 16 and 5, respectively. We investigate both single-task training and joint training of both Sub-Task 1 and Sub-Task 2 (training a single model on both sub-tasks data). All models are trained on the full train sets, validated on the trial sets, and evaluated on the test set of each Sub-Task. For evaluation purpose, we use the shared task’s evaluation metrics, namely the **Pearson** correlation, the **Spearman** correlation, the Mean Absolute Error **MAE**, the Mean Squared Error **MSE**, and the coefficient of determination **R2**.

## 4.2 Experiment Results

Table 1 presents the obtained results of our model for both single-task and joint training, using the four transformer-based encoders. The overall results show that training joint models for both Sub-Tasks (1 and 2) outperform their single-task counterparts. The Use of deep encoders (large encoders) in our model yields better correlation performances. The best results for the correlation metrics are obtained using joint training and RoBERTa-large. For Sub-Task 1, the best MAE, MSE and R2 performances are achieved using single-task training and RoBERTa-large encoder. For Sub-Task 2, the best performances of all evaluation measures are obtained using joint training. In accordance with

Sub-Task 1, the best correlation performances are attained using RoBERTa-large encoder. Besides, the best R2 is achieved using BERT-large, while the top MAE and MSE performances are obtained using RoBERTa-base.

To sum up, the best performances are obtained by joint training of our model on top of a deep encoder. These results can be explained by the fact that deep encoders yield better input representation for both Sub-Tasks. The joint training helps to leverage signals from both Sub-Tasks.

## 4.3 Ablation Experiment

In order to assess the effectiveness of each component of our model, we perform an ablation study using joint training and RoBERTa-large encoder. Table 2 illustrates the results of our model’s ablation study. The results show that all components in our model improve the system performance. The auxiliary loss improves the performances of correlation measures, while it degrades MAE, MSE, and R2 performances. Combining RMSE and auxiliary losses using uncertainty loss weighting slightly improves the performance of correlation measures.

## 5 Conclusion

In this paper, we have presented our submitted system to the SemEval-2021 Task 1. The pro-

posed system consists of a deep learning model for word and MWE complexity prediction. Our model employs a residual attention block and a regression module on top of a pre-trained transformer encoder. We have trained the model to minimize the uncertainty weighted loss of the RMSE and the auxiliary loss associated to the negative Pearson correlation. Experiments are performed using the base and the large variants of the pre-trained BERT and RoBERTa encoders. The best performance is obtained using RoBERTa-large encoder while performing joint training on both Sub-Tasks data.

# Cambridge at SemEval-2021 Task 1: An Ensemble of Feature-Based and Neural Models for Lexical Complexity Prediction

Zheng Yuan Gladys Tyen David Strohmaier

ALTA Institute, University of Cambridge, United Kingdom

Department of Computer Science and Technology, University of Cambridge, United Kingdom  
{firstname.lastname}@cl.cam.ac.uk

## Abstract

This paper describes our submission to the SemEval-2021 shared task on Lexical Complexity Prediction. We approached it as a regression problem and present an ensemble combining four systems, one feature-based and three neural with fine-tuning, frequency pre-training and multi-task learning, achieving Pearson scores of 0.8264 and 0.7556 on the trial and test sets respectively (sub-task 1). We further present our analysis of the results and discuss our findings.

## 1 Introduction

Predicting which words are considered hard to understand for a given target population has many applications. For example, it can be used to identify texts appropriate for language learners or included in a pipeline for automatic text simplification for people with low literacy skills or reading disabilities (Xia et al., 2016; Shardlow, 2014; Gooding and Kochmar, 2019b). In this paper, we describe our submission to the SemEval-2021 shared task on Lexical Complexity Prediction (LCP) (sub-task 1), where participating teams are expected to predict the complexity score of single words in context (Shardlow et al., 2021). Compared to previous shared tasks on Complex Word Identification (CWI), which have primarily focused on binary classification as systems were expected to identify words as complex or not (Paetzold and Specia, 2016a; Yimam et al., 2018); a new multi-domain English dataset was used for the purpose, which was annotated using a 5-point Likert scale (Shardlow et al., 2020). We approached LCP as a regression problem and proposed a traditional feature-based model, as well as three neural models exploring fine-tuning, frequency pre-training and multi-task learning (MTL).

The remainder of this paper is organised as follows. Section 2 presents related work in the area.

In Section 3, we describe our approach to the task and detail the four models included in our final ensemble system. In Section 4, we turn to the experiments, describing the data and evaluation metrics used, and presenting our results on the shared task trial set. Section 5 presents our official results on the shared task test set, and offers a discussion of the results and the performance of our submitted system. Finally, we conclude the paper and provide an overview of our findings in Section 6.

## 2 Related work

The SemEval-2016 shared task on CWI (Paetzold and Specia, 2016a) was framed as a binary classification problem, where complexity was defined as whether or not a word is difficult to understand for non-native English speakers. A set of 400 non-native speakers annotated the data in a binary fashion and a word was labelled as complex if it was annotated as complex by at least one annotator. The study performed by Zampieri et al. (2017) showed that most systems performed poorly due to the way the data was annotated. They also found out that words that were annotated as complex by the majority of human annotators tend to be easier for systems to identify, arguing that lexical complexity should be seen as a continuum on a spectrum rather than a binary value.

The second CWI shared task was organized as part of the BEA-2018 workshop (Yimam et al., 2018). It extended the previous one by introducing a new probabilistic classification sub-task where participants were asked to assign the probability that an annotator would find a word complex. The continuous complexity value for each word was calculated as the proportion of annotators that found a word complex. The results of the shared task showed that traditional feature engineering approaches (mostly based on length and

Linguistic feature	Pearson			Importance

Table 1: Features used in the random forest regressor and the corresponding Pearson’s correlation with complexity in the training (train), trial, and test data; as well as the corresponding mean permutation importance ( $n = 50$ ). Bold Pearson values are significant ( $p < 0.001$ ).

frequency features) performed better than neural network and word embedding approaches, including the winning system **Camb-2018** from Gooding and Kochmar (2018). However, this system was subsequently outperformed by a sequence labeller approach to CWI that incorporated word context (Gooding and Kochmar, 2019a). In both shared tasks, the top-performing systems demonstrated the strength of ensemble models (Paetzold and Specia, 2016b; Gooding and Kochmar, 2018).

### 3 Approach

#### 3.1 Random forest regression

As a baseline, we began with training a simple random forest regressor based on 15 manually selected linguistic features. The regressor was trained with 100 trees, and we used mean absolute error (MAE) to measure the quality of each split. Most of our features were inspired by psycholinguistic studies and readability metrics. The full list of features can be found in Table 1.

**Frequency** Based on the psycholinguistic findings that the frequency of a word is strongly correlated with the speed at which it is processed (Preston, 1935; Monsell et al., 1989; Brysbaert et al., 2011), we introduced six features which are based on frequencies found in the Simple English

Wikipedia (SimpleWiki).<sup>1</sup> We selected SimpleWiki for its standardised form, relatively low frequency of complex words, and coverage of a large number of topics. Two of our frequency-based features were calculated based on the frequency of words that match both the surface form and the syntactic role - this was done as a coarse form of word sense disambiguation, but also to capture syntactic complexity.

**Syntax** Psycholinguistic studies have shown that syntactic complexity is linked to processing speed (Ferreira, 1991) and working memory limitations (Norman et al., 1992), which may affect participants’ perception of lexical complexity. In a similar vein, we added three syntactic features: the number of compounds and modifiers in the phrase containing the target word, and the number of child dependencies linked to the target word.

**Readability** We included syllable-based<sup>2</sup> and character-based metrics, which were inspired by traditional readability metrics such as the Flesch-Kincaid readability tests (Kincaid et al., 1975)

<sup>1</sup>The Simple English Wikipedia data can be accessed at <https://simple.wikipedia.org/>. For this shared task, we used a preprocessed version at <https://github.com/LGDoor/Dump-of-Simple-English-Wiki>.

<sup>2</sup>The number of syllables were estimated using the Syllables library: <https://github.com/prosegrinder/python-syllables>.

and the Coleman-Liau index (Coleman and Liau, 1975).

### 3.2 Fine-tuning BERT

Fine-tuning pre-trained language models via supervised learning has become the key to achieving state-of-the-art performance in various natural language processing (NLP) tasks. Our approach builds upon this, where we used BERT (Devlin et al., 2019) as the underlying language model and added a linear layer on top that allows for regression.

We treated it as a *sequence regression* problem and constructed the input by concatenating the target word  $w_t$ , the complexity of which was to be determined, and its context sentence:

$$[CLS]; w_t; [SEP]; w_1, \dots, w_t, \dots; [SEP] \quad (1)$$

We then fed the  $[CLS]$  representation into the output layer for regression.

We used the L1-loss, which measures the MAE for the prediction, i.e.:

$$Loss = mean(\{l_1, \dots, l_N\}); l_n = |x_n - y_n| \quad (2)$$

where  $x$  and  $y$  are respectively the output of the model and the target value.  $N$  is the batch size.

During training, the whole model was optimised in an end-to-end manner.

### 3.3 Frequency pre-training

We proposed an extension to the fine-tuning BERT system by introducing a pre-training step. We constructed a new pre-training set with 20,000 sentences extracted from SimpleWiki, filtering for whole sentences by detecting the presence of verbs, and removing sentences that are longer than 256 words, as this is the length of the longest sentence in the training data.

Frequency of each word and part-of-speech (POS) combination in SimpleWiki was counted and converted into a value between 0 and 1:

$$1 - \frac{\ln(f)}{\ln(h)} \quad (3)$$

where  $f$  is the original frequency value and  $h$  is the highest frequency found (excluding stop words). This conversion makes use of the Zipfian distribution observed in natural language (Zipf, 1935), allowing the model to be pre-trained on output values that match the range in the shared task dataset (see Section 4.1 for more details).

Data	Train	Trial	Test
Bible	2,574	143	283
Biomedical	2,576	135	289
Europarl	2,512	143	345
Total	7,662	421	917

Table 2: Number of single word instances in the training (train), trial and test subsets of the Bible, Biomedical and Europarl datasets.

We chose this particular frequency feature because it is the most strongly correlated one with the complexity values in the training data among the 15 features used in the random forest regressor (see Table 1 #12).

### 3.4 Neural multi-task learning

MTL allows models to use information from related tasks and learn from multiple objectives, which leads to performance improvement on individual tasks (Rei and Yannakoudakis, 2017; Yuan et al., 2019; Taslimipoor et al., 2020; Andersen et al., 2021). Instead of only predicting the complexity value of word in context, we extended the model to incorporate auxiliary objectives. We used a joint learning approach trained on in-domain data only and experimented with three related tasks to boost model performance:

- POS tagging
- Grammatical Relations (GR) prediction: We included as an auxiliary objective the prediction of the GR type of a dependent with its head.
- Genre classification: A classification task was introduced to predict the genre of the text.

Model weights were shared between the main and auxiliary training objectives. We used pre-trained DistilBERT (Sanh et al., 2020) for language representation as the basis for our neural network and added additional layers on top of the Transformer (Vaswani et al., 2017) architecture for fine-tuning.

The final layer for the LCP objective is a fully connected layer that performs regression. Different from the first two neural systems, we treated it as a *token regression* problem, where we only input the context sentence, and fed the vector representation of the target word  $w_t$  into the output layer for

Hyper-parameter	BERT	BERT <sub>freq.</sub>	MTL
Language model	bert-base-uncased	bert-base-uncased	distilbert-base-uncased
Max. length	190	160	304
Batch Size	40	8	1
Epochs	5	7	4
Decay rate	0.01	0.01	0.01
Learning rate	5e-06	2e-05	1e-05
Schedule	linear	linear	linear
Warm up steps	80	90	7662

Table 3: Hyper-parameters used for experiments.

regression:

$$[CLS]; w_1, \dots, w_t, \dots, w_N; [SEP] \quad (4)$$

For those cases where the target word was split into multiple sub-tokens, we took the averaged representation.

Additionally, a new output layer was introduced to perform the auxiliary task. For the first two token-level auxiliary tasks (POS and GR), the token representations were fed into the output layer. The model only predicted labels for auxiliary objectives on the first token of a word, in an identical fashion to Devlin et al. (2019). For genre classification, we used the  $[CLS]$  representation. The overall loss function is a weighted sum of the main LCP loss (measured as MAE) and the auxiliary loss (as cross-entropy):

$$Loss = \lambda Loss_{LCP} + (1 - \lambda) Loss_{aux} \quad (5)$$

## 4 Experiments

### 4.1 Dataset and evaluation

The data used in this shared task is an augmented version of CompLex (Shardlow et al., 2020), a multi-domain English dataset with sentences annotated using a 5-point Likert scale with 1 being very easy and 5 being very difficult. The final complexity labels were normalised in the range of  $[0, 1]$ . The dataset contains texts of three genres (Bible, Biomedical and Europarl) and both single words (sub-task 1) and multi-word expressions (sub-task 2). Since we focused on sub-task 1, we used only single word instances in our experiments. Corpus statistics are given in Table 2.

Systems were evaluated using Pearson correlation. We also report scores for the following metrics: Spearman correlation, MAE, mean squared error (MSE) and R-squared (R2).

### 4.2 Training details

We used spaCy<sup>3</sup> to preprocess the data and automatically generated lemma, POS and GR labels to be used in our experiments.

For the feature-based system, we used the random forest regressor in the *scikit-learn* library.<sup>4</sup> For the neural systems, we used pre-trained language models provided by *huggingface* (Wolf et al., 2020).<sup>5</sup> All neural systems were trained using the AdamW variant (Loshchilov and Hutter, 2019) of the Adam stochastic optimisation algorithm (Kingma and Ba, 2015). Detailed hyper-parameters are listed in Table 3. Each neural model was trained on one NVIDIA Tesla P100 GPU.

### 4.3 Individual system performance

Individual system performance on the trial set is reported in Table 4, where **RandomForest** refers to the feature-based random forest regression system, **BERT** refers to the fine-tuned BERT system, **BERT<sub>freq.</sub>** refers to the fine-tuned BERT system with frequency pre-training, and **MTL<sub>x</sub>** refers to the MTL system with the subscript ‘x’ representing the auxiliary task (POS, GR, or genre). We also report results from the winning system **Camb-2018** in the BEA-2018 CWI shared task, a feature-based, context-independent linear regression model.

We can see that our feature-based **RandomForest** system achieved comparable performance to the heavily feature-engineered **Camb-2018** system, despite using only 15 features. This may be due to the fact that linguistic features are often highly interdependent and capture very similar information.

We also notice that all our neural systems outperformed both feature-based systems by large margins (+0.1 Pearson). This contradicts the findings

System	Pearson	Spearman	MAE	MSE	R2
RandomForest	0.7043	0.6746	0.0751	0.0096	0.4934
BERT	0.7907	<b>0.7579</b>	0.0647	0.0072	0.6191
BERT <sub>freq.</sub>	<b>0.8089</b>	0.7546	<b>0.0646</b>	<b>0.0068</b>	<b>0.6397</b>
MTL <sub>POS</sub>	0.8000	0.7528	0.0662	0.0075	0.6052
MTL <sub>GR</sub>	0.7936	0.7208	0.0654	0.0070	0.6290
MTL <sub>genre</sub>	0.7982	0.7272	0.0656	0.0070	0.6300
Camb-2018	0.7079	0.6885	0.0746	0.0095	0.4957

Table 4: Performance of individual systems on the trial set (sub-task 1). The best results are marked in bold. **Camb-2018** is the winning system in the BEA-2018 CWI shared task.

Ensemble	Pearson	Spearman	MAE	MSE	R2
MTL <sub>All</sub>	0.8129	0.7471	0.0634	0.0065	0.6542
MTL <sub>All</sub> + BERT + BERT <sub>freq.</sub>	0.8228	0.7641	<b>0.0621</b>	<b>0.0063</b>	0.6684
MTL <sub>All</sub> + BERT + BERT <sub>freq.</sub> + RandomForest	<b>0.8264</b>	<b>0.7676</b>	0.0623	<b>0.0063</b>	<b>0.6688</b>

Table 5: Performance of ensemble systems on the trial set (sub-task 1). The best results are marked in bold.

from the BEA-2018 CWI shared task where traditional feature-based approaches performed better than neural network and word embedding approaches. This could possibly be explained by the use of pre-trained Transformer-based language models in our neural systems, as well as a different annotation scheme employed when constructing the CompLex dataset used for this shared task. Nevertheless, our findings appear to match the general trend in NLP where neural systems are overtaking feature-based models as the state of the art. All our neural systems produced comparable results: **BERT<sub>freq.</sub>** yielded the best Pearson, MAE, MSE and R2 scores; while **BERT** yielded the best Spearman score.

#### 4.4 Ensemble performance

We further averaged the outputs from individual systems to obtain an ensemble. Table 5 shows results for different system combinations. Overall, the best system consists of all our individual systems proposed in Section 3, including the feature-based **RandomForest** system; and achieved the best Pearson score of 0.8264, Spearman of 0.7676, MSE of 0.0063, and R2 of 0.6688. The ensemble of all neural systems yielded the best MAE of 0.0621.

## 5 Official results and discussion

Our submission to the LCP shared task (sub-task 1) is the result of our best system (in terms of Pearson), an ensemble of three neural and one feature-based systems **MTL<sub>All</sub> + BERT + BERT<sub>freq.</sub> +**

**RandomForest**. The official results are reported in Table 6. Our final system achieved a Pearson score of 0.7556.

### 5.1 Per-genre performance

Using the Pearson correlation metric, the highest performance is obtained on the Biomedical data, followed by the Bible and Europarl data. On the MAE metric, however, the worst performance is found for the Biomedical data (see Table 6). We hypothesise that this might result from differences in the distribution of the lexical complexity scores. In particular, the scores for the Biomedical data appear to have a slightly larger interquartile range (see Appendix A, Figure A.1c).

### 5.2 Individual system contribution

To measure the contribution of each individual system to the overall performance, a number of ablation tests were performed, where one system was removed at a time. Results in Table 6 suggest that all neural systems have positive effects on the overall performance. Among them, **MTL<sub>All</sub>** is the most effective one, whose absence is responsible for a 0.02 decrease in Pearson, followed by **BERT<sub>freq.</sub>** and **BERT**. Interestingly, removing **RandomForest** yielded a better Pearson score of 0.7560, indicating that it is detrimental and brought performance down. This is inconsistent with our results on the trial set (see Table 5), where all systems contributed to the final system.

		Pearson	Spearman	MAE	MSE	R2
Official		0.7556	0.7105	0.0646	0.0070	0.5705
<b>Genre</b>	Bible	0.7475	0.7154	0.0662	0.0076	0.5493
	Biomedical	0.7763	0.7274	0.0745	0.0088	0.6025
	Europarl	0.7195	0.6699	0.0551	0.0049	0.5169
<b>Ablated system</b>	RandomForest	0.7560	0.7126	0.0647	0.0070	0.5685
	BERT	0.7523	0.7069	0.0650	0.0070	0.5655
	BERT <sub>freq.</sub>	0.7515	0.7067	0.0652	0.0071	0.5633
	MTL <sub>All</sub>	0.7371	0.6920	0.0669	0.0076	0.5335

Table 6: Official results of our submitted system on the test set (sub-task 1). Per-genre performance and ablation test results are included.

**Analysis of RandomForest** To understand why the feature-based regressor performed worse on the test data, we examined the correlation between each feature and the complexity scores in the training (train), trial, and test sets. Results in Table 1 show that several linguistic features (particularly #3, #4, and #10) are more strongly correlated with scores in the trial data compared to the test data, which may explain the discrepancy in our results. Although most features appear to have a small but significant correlation with complexity in the training data, many are not significant in the test data, likely due to the smaller sample size. This suggests that, while there may be some weak, overall correlation between these features and complexity, there is sufficient noise in the data that the relationship is negligible and unreliable when used to predict the complexity of a given word.

Additionally, we investigated the importance of each feature in the random forest regressor, as measured by the mean permutation importance (Breiman, 2001) - see Table 1. Our analysis reveals that the frequency of the target lemma (#8) is the most important one, followed by the frequency of the target word itself (#7). Both of these features are more strongly correlated with complexity in the trial data than either the training or test data, which also contributes to the inconsistency described above.

## 6 Conclusion

This paper presents our contribution to the SemEval-2021 shared task on LCP. We competed in sub-task 1 (single words) with an ensemble system combining three neural models and one feature-based model. Our analysis reveals that even though all three neural systems perform comparably, the MTL system contributed the most to the ensemble

system. Adding the feature-based model improved the performance on the trial data, but brought performance down on the test data. In addition to the mismatch between the trial and test data, the noise in the data further contributed to this inconsistency. The comparatively lower performance of the feature-based system is especially interesting in light that such systems were competitive for CWI until relatively recently (Gooding and Kochmar, 2018). When looking at different genres, our submitted system yielded the highest performance in Pearson, but worst performance in MAE in Biomedical domain, compared to the other genres. We hypothesise that this is due to differences in data distribution between genres.

## Acknowledgments

We thank Sian Gooding and Ekaterina Kochmar for support and advice. This paper reports on research supported by Cambridge Assessment, University of Cambridge. This work was performed using resources provided by the Cambridge Service for Data Driven Discovery operated by the University of Cambridge Research Computing Service, provided by Dell EMC and Intel using Tier-2 funding from the Engineering and Physical Sciences Research Council (capital grant EP/P020259/1), and DiRAC funding from the Science and Technology Facilities Council. ## Abstract

In this paper, we propose a method of fusing sentence information and word frequency information for the SemEval 2021 Task 1-Lexical Complexity Prediction (LCP) shared task. In our system, the sentence information comes from the RoBERTa model, and the word frequency information comes from the Tf-Idf algorithm. Use Inception block as a shared layer to learn sentence and word frequency information. We described the implementation of our best system and discussed our methods and experiments in the task. The shared task is divided into two subtasks. The goal of the two subtasks is to predict the complexity of a predetermined word. The evaluation index of the task is the Pearson correlation coefficient. Our best performance system has Pearson correlation coefficients of 0.7434 and 0.8000 in the single-token subtask test set and the multi-token subtask test set, respectively.

## 1 Introduction and Background

Language and writing are the main ways we transmit knowledge and information. An accurate and efficient understanding of the meaning expressed in the text is of great significance to our learning and production. Vocabulary complexity and reading comprehension are inextricably linked, and overly complex terms may bring bad results (DuBay, 2004). The research of Leroy et al. showed that the use of vocabulary simplification technology is one of the ways to effectively improve readers' reading comprehension ability (Leroy et al., 2013). Accurately predicting lexical complexity can make the system better guide users to use appropriate text, or customize text according to their needs. Especially when some ordinary readers are reading technical text content (Wei et al., 2009). Lexical complexity detection and complex lexical simplification have attracted the attention of the NLP community, and

systems have been developed to simplify the text of second language learners (Shardlow, 2014), native speakers with low literacy levels (Specia, 2010), and people with dyslexia (Rello et al., 2013).

The topic of the shared task of SemEval 2021 Task 1 is "Lexical Complexity Prediction (LCP)". The task data set uses English text data in a single language (Shardlow et al., 2020). There are two subtasks in the task, which are the subtasks for predicting the complexity of a single token and multiple tokens (Shardlow et al., 2021). In this article, we give the method and task result of predicting word complexity. Our system uses a method that combines sentence, word frequency, and context information. The acquisition of sentences and context information uses the RoBERTa model (Liu et al., 2019b). The word frequency information comes from the Tf-Idf algorithm (Ramos et al., 2003). The complexity is a continuous value, so the whole task can be regarded as a regression task. We provide the model code used in this task <sup>1</sup>.

## 2 Related Work

Previously held similar to this shared task are SemEval 2016 task 11: Complex Word Identification (CWI2016) (Paetzold and Specia, 2016a), Complex Word Identification Shared Task 2018 (CWI2018) (Yimam et al., 2018).

In CWI2016, the system voting method used by Paetzold et al. has achieved excellent results in sharing tasks (Paetzold and Specia, 2016b). In CWI2018, Butnaru uses a kernel-based learning method for complex word identification (Butnaru and Ionescu, 2018). Sian and other methods using integrated voting have also achieved good scores (Gooding and Kochmar, 2018). In addition to the above methods, some common methods are applied to these tasks. For example, SVM, random forest,

ture. The structure of the Inception Block used in our system is an improvement based on the solution implemented by Szegedy et al. (Szegedy et al., 2015). In the Inception block, we use the Conv1d convolution provided by Pytorch to adapt to our needs in the task. Inception Block has convolution kernels of different sizes, and can use windows of different sizes to extract non-continuous semantic features. At the same time, the parallel structure of Inception Block can save training time. The structure of the transformer allows interaction between the input sentence and the input token. We use the output of RoBERTa and the output of Tf-Idf weighted RoBERTa as different inputs of Inception Block, so that Inception Block can capture different information. Different classifiers are used to process the output results from different inputs of the Inception Block.

In step 1, we spliced the text data (Sentence) and the target word (Token) in the data with (SEP). Then the spliced result is used as the input of RoBERTa and Tf-Idf. In step 2, we use the output of Tf-Idf to weight the output of RoBERTa. In step 3, we use the weighted result of the previous step and the output result of RoBERTa as the input of the Inception Block. Here, the Inception Block is used as a shared layer to learn the output results of RoBERTa and the output results of RoBERTa weighted by Tf-Idf. In step 4, two linear classifiers are used to process the output from the Inception Block. In step 5, the output results of the two linear classifiers are averaged. In step 6, the average value is output as the final prediction result of the system.

## 4 Experiment and Results

In this section, we will introduce the data preprocessing methods and experimental settings we used in the task and the final results.

### 4.1 Data Preprocessing

In the part of data processing, we deleted the stop words in the text data. For the stop word list, we

use the stop word package provided by NLTK. To use the Tf-Idf algorithm to obtain a weighted output, and to ensure that the shape of the text code processed by the Tf-Idf algorithm is consistent with the shape of the RoBERTa output, we removed the part of the text code that exceeded the maximum sentence. For those text encodings that are less than the maximum sentence length, we perform zero padding. The encoding of Tf-Idf is obtained using the toolkit provided by gsim (Řehůřek and Sojka, 2010)<sup>2</sup>. For the validation set, we randomly select 20% from the pre-processed training set as our validation set during the training process. The remaining 80% of the training set is used as our training set during the training process.

### 4.2 Experiment setting

During our training model, we designed 4 different models and observed the result scores of different models on the validation set. We adjust the parameters as much as possible to obtain the best results for each different model, so different systems may have different parameter combinations. The overall design and data flow of the BERT+Tf-Idf+Inception system is the same as the system we introduced in Figure 2. The difference is that we replace the RoBERTa model in Figure 2 with the BERT model. In all experiments, we use Radam (Liu et al., 2019a) as the optimizer and MSELoss as the loss function.

- RoBERTa+Tf-Idf+CNN: The epoch, batch size, maximum sequence length, and learning rate for the model are 4, 32, 60, and 4e-5, respectively.
- BERT+Tf-Idf+CNN: The epoch, batch size, maximum sequence length, and learning rate for the model are 4, 32, 60, and 3e-5, respectively.
- RoBERTa: The epoch, batch size, maximum

Table 2: The scores of the top three teams and our team on the test set announced by the task organizer. Mean absolute error (MAE), Mean squared error (MSE), R-squared (R2). 61 and 38 different teams submitted results for subtask 1 and subtask 2, respectively.

sequence length, and learning rate for the model are 4, 32, 60, and 3e-5, respectively.

- BERT: The epoch, batch size, maximum sequence length, and learning rate for the model are 4, 32, 60, and 3e-5, respectively.

## 5 Results and Analysis

According to the Pearson correlation coefficient, the results submitted by the teams participating in the two subtasks are ranked. In the published results, the task organizer team also announced some other evaluation indicators. These evaluation indicators are Spearman correlation (Rho), Mean absolute error (MAE), Mean squared error (MSE), R-squared (R2). We compare the scores of Pearson correlation coefficient results obtained by several different methods proposed in the experimental part. The results of these different methods can be found in Table 3.

Compare our result scores on the validation set of the two subtasks. First of all, our system can predict the word complexity required in the task. Secondly, under the same data and parameters, the score obtained by the RoBERTa model is higher than the score obtained by the BERT model. Then, the scores we get on the RoBERTa+Tf-Ifd+Inception and BERT+Tf-Ifd+Inception systems are higher than the single use of the RoBERTa model and the use of the BERT model. Finally, the above performance proves the feasibility of the improved method we used.

After comparing the result scores of different systems on the verification set, we used the RoBERTa+Tf-Ifd+Inception system to predict the results of the test set and successfully submitted it to the task organizer team. Our test set prediction result scores are 38th and 22nd respectively in the

Method	Pearson(1)	Pearson(2)
RoBERTa+Tf-Ifd+Inception	0.7651	0.8072
BERT+Tf-Ifd+Inception	0.7426	0.7850
RoBERTa	0.7327	0.7846
BERT	0.7255	0.7644

Table 3: The scores of the Pearson correlation coefficient results obtained by our different systems on the validation set. The validation set comes from 20% of the training set provided by the task organizer. Pearson(1) is the result score of the Pearson correlation coefficient of subtask 1. Pearson(2) is the result score of the Pearson correlation coefficient of subtask 2.

ranking lists of the two subtasks. Table 2 shows the test set result scores of the top three teams and our team announced by the task organizer team.

## 6 Conclusion

In this article, we describe the system our team has developed for shared tasks in SemEval 2021 task1 LCP. The system combines lexical, syntactic, and contextual semantic features. We describe and analyze the tasks, data, experiments, and results. We compared the results of the RoBERTa model and the BERT model. In the final test set prediction result score ranking, our results in the competition ranked middle. In future work, we will study how the complexity of the phrase is affected by the context in the sentence. For our model and method, we can also try to introduce other types of word embedding, and use different models to fuse the output of RoBERTa and the output of word embedding.

## Abstract

We present two convolutional neural networks for predicting the complexity of words and phrases in context on a continuous scale. Both models utilize word and character embeddings alongside lexical features as inputs. Our system displays reasonable results with a Pearson correlation of 0.7754 on the task as a whole. We highlight the limitations of this method in properly assessing the context of the target text, and explore the effectiveness of both systems across a range of genres. Both models were submitted as part of LCP 2021, which focuses on the identification of complex words and phrases as a context dependent, regression based task.

## 1 Introduction

Complex Word Identification (CWI) involves identifying words that the reader may find difficult to understand. A word’s complexity can depend on many factors and differ according to context. Further, assessment of the complexity of named entities can require some degree of general knowledge, making CWI a challenging task (Shardlow, 2013). Accurately identifying complex words is important for many downstream simplification tasks, making literature more accessible for people with conditions such as dyslexia (Rello et al., 2013), and the assessment of a text’s readability as a whole (Dubay, 2004).

Our methodology plans to extend on previous convolutional network based approaches to CWI (Aroyehun et al., 2018; Sheang, 2019). With the goal of producing a system that is able to better model the complexities of phrases and unfamiliar words, within the English language.

Previous shared tasks on CWI addressed the problem as a binary and probabilistic classification type task, although human judgements on word complexity are not binary and exist on a continuous

scale. Lexical Complexity Prediction (LCP) 2021 tries to address this and uses an augmented version of CompLex (Shardlow et al., 2020), a dataset annotated with a 5-point Likert scale. CompLex also features context-specific annotation, with words receiving different annotations depending on their context. The dataset provides annotations from three different domains: Bible, Biomed and Europarl (Shardlow et al., 2021).

The code for this task is available on GitHub<sup>1</sup>.

## 2 Related Work

Word frequency is a commonly used feature in CWI (Gooding and Kochmar, 2018; Kajiwara and Komachi, 2018); words that appear frequently in language are more likely to be recognised and understood by the reader (Carroll et al., 1998). For the purpose of identifying medical terminology that may be unfamiliar to the lay reader, Elhadad (2006) leveraged lexical frequencies while also exploring the potential of other features such as word familiarity ratings from the MRC Psycholinguistic Database (Coltheart, 1981).

More recently lexical and psycholinguistic features have been utilized by machine learning tools, resulting in improved accuracy on these tasks. Through the use of an ensemble-based voting method the CAMB system (Gooding and Kochmar, 2018) achieved state-of-the-art results in the 2018 CWI shared task (Yimam et al., 2018), employing a total of 27 lexical, morphological and psycholinguistic features. The CAMB system however does not consider the target words context, opting for a “greedy” approach towards phrase classification, marking all phrases as complex.

Aroyehun et al. (2018) explored the use of convolutional neural networks (CNN) for CWI using only

<sup>1</sup><https://github.com/robflynnh/CNN-LCP-Shared-Task-2021>

the word embeddings of the target words and the averaged embeddings of the left and right contexts as inputs. They contrasted the results against a feature engineering approach using decision tree learning finding that both methods achieved competitive results. However, their decision tree method was marginally more accurate than their CNN for most of the datasets. Integrating lexical features alongside word embeddings can lead to further improvements in accuracy making this a more competitive approach, and outperforming many previous deep learning methods for CWI (Sheang, 2019).

By framing CWI as a sequence labelling task, Bi-directional long short-term memory (BiLSTM) networks have produced state-of-the-art results on the CWIG3G2 dataset (Yimam et al., 2017; Gooding and Kochmar, 2019). BiLSTM networks are able to capture long-term word and character level dependencies allowing these models to consider a large amount of contextual information. Modelling the complexity of phrases has proven to be a more challenging and complex task compared to individual words (Gooding and Kochmar, 2019).

### 3 Implementation

#### 3.1 Features

Below a description of the features used by both models is given:

**Frequency:** Word frequencies are taken from the SUBTLEX-UK word frequency database (van Heuven et al., 2014). Logarithmic Zipf frequency values were chosen based on previous results from this metric (Zampieri et al., 2016) and the Zipfian distribution that is displayed in language (Zipf, 1949).

**Age of Acquisition:** Age of Acquisition (AoA) values, estimating the age at which a word is typically acquired. (Kuperman et al., 2012; Brysbaert, 2012).

**Word-level Features:** Target word length and number of syllables are used as features (Brysbaert, 2012).

**Corpus Type:** As the dataset includes extracts from three different sources of potentially varying complexity, the corpus type was included and represented as a one-hot embedding.

**Pre-trained Embeddings:** 50d GloVe (Pennington et al., 2014) word embeddings, and 50d chars2vec<sup>2</sup> embeddings representing a word's char-

acter sequence are used. 50d GloVe embeddings were chosen as embeddings with more dimensions showed worse performance on the training data. Which suggests that the 50d embeddings capture sufficient information needed for this task. Character embeddings allow inferences to be made between words with similar morphologies.

#### 3.2 Preprocessing

Firstly min-max normalization is applied to the features taken from datasets, and word length is divided by 10. Non-alphanumeric characters are removed from the sentences before any features are extracted.

Both models take as inputs the features for the target word, and the averaged features for the left and right contexts of the target text. If the target word or words are positioned at the beginning or end of the sentence a zero vector of size 107 is used for the left or right context. For out-of-vocabulary words a zero vector is used for the word embedding and other features are imputed using mean values from their respective datasets. Finally the vectors for the target text and its context are stacked to produce a 3x107 matrix (left context — token — right context) for single words or a 4x107 matrix for MWEs (left context — token 1 — token 2 — right context).

#### 3.3 Models

This section provides a description of the architecture and hyperparameters used for both models. The models were produced using the Keras library version 2.4.3. Each of the models were trained with a batch size of 50, early stopping of 1000 and model checkpointing based on the validation loss.

##### 3.3.1 Single Word Model

For single words a 1D convolutional network followed by three fully connected layers is used. The model takes three inputs, an average of the features for left and right contexts is used for the first and third inputs respectively, and the features of the target word is used as the second input. The convolutional layer pads the inputs and uses a kernel size of 3 with 150 output filters and ReLu as the activation function. Global Max Pooling and a flatten layer followed by batch normalization is then applied to the output of this layer. Three dense layers with sizes of 150 (ReLu), 50 (ReLu) and 1 (Linear) are then used with a Dropout of 0.5 applied before each dense layer. Mean Squared Error

<sup>2</sup><https://github.com/IntuitionEngineeringTeam/chars2vec>

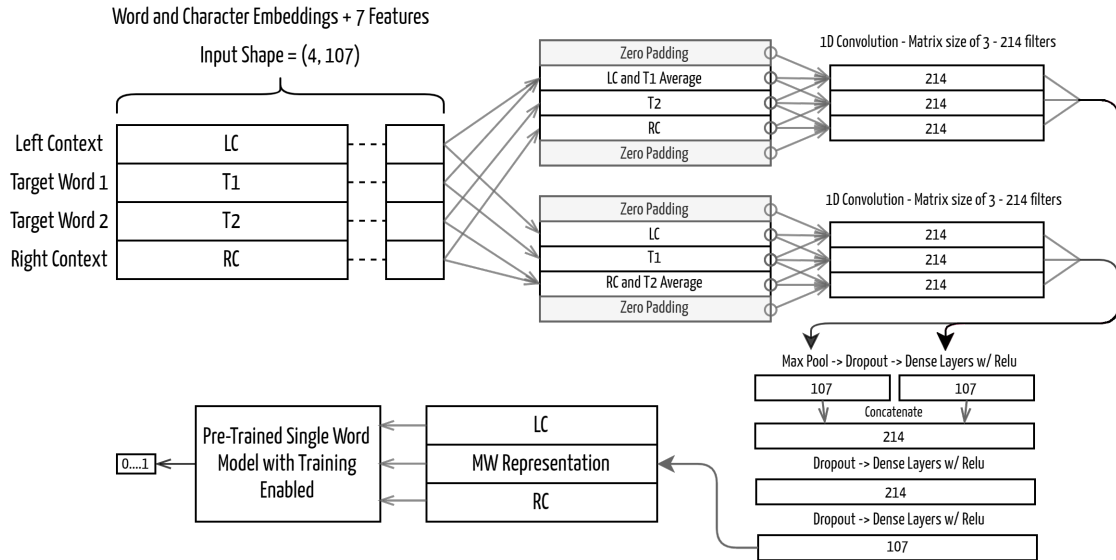

Figure 1: Depiction of multi-word model architecture

(MSE) is used as the loss function and Stochastic Gradient Descent as the optimizer, with a learning rate of 0.01 and momentum of 0.6 with Nesterov accelerated gradient enabled.

### 3.3.2 Multi-Word Model

For multi-words a second model is used to assess the complexity of two word phrases. This model acts as an adapter with the output being fed into a pre-trained single word model, allowing the model to take advantage of the data for single words and MWEs. Figure 1 gives an overview of the model architecture.

Features for the averaged left context, target word one, target word two and the averaged right context are used as input for the model. A convolutional layer with a similar architecture to task one is used for each of the target words. For the two convolutional layers the other target word is averaged with either the left or right context depending on its positioning, weighting the other target word higher than the rest of the context.

Each convolutional layer uses a filter size of 214 but is otherwise the same as in task one. Global Max Pooling followed by Dropouts of 0.3 and dense layers with 107 neurons and ReLu activation are applied to the outputs of the convolutions which are then concatenated along the last axis. Two dense layers with ReLu activation and sizes of 214 and 107 are then applied with a Dropout of 0.5 before each layer. This final output of size 107 is then concatenated along the first axis with the original left and right contexts to form the input

for a pre-trained single word model with training enabled. This model uses the Adam optimizer with default parameters and MSE as the loss function.

## 4 Results

Task	Pearson	MSE	R2
Task 1	0.7389	0.0074	0.5398
Task 2	0.7754	0.0079	0.5989

Table 1: Results for both tasks

This section will discuss and evaluate the performance of both models. Participants were ranked according to the Pearson correlation coefficient of their submissions. Table 1 presents the results for each of the tasks with task 1 evaluating individual words and task 2 covering both single and two word Multi-Word Expressions (MWEs).

### 4.1 Single Word Model Results

Figure 2: MSE across different complexities

As shown in Figure 2 the single word model struggles to accurately predict values for words of a high complexity, and also displays difficulties for words of a complexity of less than 0.1. The training and evaluation data features less examples of very simple or complex words. The complexity of these extremities is often highly dependant on the context, making them more challenging to assess.

Corpus	Pearson	MSE	R2
All	0.7389	0.0074	0.5398
Bible	0.7085	0.0085	0.4948
Biomed	0.7828	0.0087	0.6050
Europarl	0.6807	0.0055	0.4562
<b>JUST-BLUE</b>	0.7886	0.0062	0.6172

Table 2: Results for individual words

Table 2 presents the results for this task on each of the domains and the task as a whole. The prediction accuracy varies significantly across the different sources. Results from the best performing team are given for comparison (Shardlow et al., 2021).

As the model only uses an average of the features present in the left and right context of the target word, it is unable to differentiate between tokens that are influential to the target words complexity and ones that are not. Because of this equal weighting of words in the context, the models accuracy can be negatively affected by an abundance or lack of stop words in the sentence. Very complicated or simple words in sentence that are not related to the target word, and don't share a similar complexity can also cause the model to over- or under-predict the target word's complexity. The mechanism by which the model assesses the context may partly explain the variance in accuracy on each domain.

Interestingly, our sub-analysis showed that the model shows a better correlation for those tokens without a word embedding, yielding a Pearson correlation of 0.7804 and a MSE of 0.0071. Generally these out-of-vocabulary words are more complex so the model is using the lack of a word embedding as a feature when making predictions. Although this shows a better correlation overall it could lead to false positives in specific cases where the out-of-vocabulary word is of a low complexity.

## 4.2 Multi-Word Model Results

As shown in Figure 2 the multi-word model is much less accurate for very simple MWEs of a complexity less than 0.1. However, for more complex words

the predictions remain fairly accurate. This model is able to assess the way in which the words in a phrase interact with each other and to some degree the rest of the sentence. This additional contextual information may increase the model's capacity to evaluate more complex words. Only 1.65 percent of phrases in the training data were of a complexity of less than or equal to 0.1 which could explain the inaccuracy in this range.

Corpus	Pearson	MSE	R2
All	0.7611	0.0102	0.5770
Bible	0.7173	0.0113	0.5106
Biomed	0.7980	0.0141	0.6317
Europarl	0.5799	0.0060	0.3089
<b>DeepBlueAI</b>	0.8612	0.0063	0.7389

Table 3: Results for MWEs

MWE Type	Pearson	MSE	R2
A-N (115)	0.7654	0.0115	0.5801
N-N (56)	0.7414	0.0091	0.5293

Table 4: Results for the different MWE formations. A-N: Adjective-Noun. N-N: Noun-Noun.

Table 3 presents the results across each of the different domains present in the dataset. The model used for MWEs makes use of a fine-tuned instance of the single-word model; consequentially incorrect associations from the single-word model may have been carried over to this model. The results show a similar variance across domains to task 1, although it struggles more significantly on the Europarl sub-corpus. Compared to the other domains, Europarl's complexity values show a much smaller standard deviation than the other sub-corpora (0.093 compared to 0.196 and 0.152, on biomed and bible). The variation of complexities may play a role in the models effectiveness at making accurate predictions across the domains.

Table 4 presents the results across different MWE formations. The number of occurrences of each part-of-speech formation is denoted in brackets, MWE types with less than 10 occurrences were omitted from the table. The model performs marginally better on Adjective-Noun MWE formations.

## 5 Discussion

In this paper, we presented two convolutional neural networks used as an approach to single-word and multi-word complex word identification. Both models achieved reasonable results, achieving scores in a comparable range to the majority of other submissions.

Multi-Word CWI is a more challenging task compared to the assessment of single words; the multi-word model was able to utilize the datasets of both tasks, and its predictions show a Pearson's correlation score of 0.7611. Our system is only able to process two-word MWEs, which for this task is not an issue. However, in other use cases the ability to assess longer MWEs would be useful. Given a dataset with annotations for longer MWEs the model could potentially be adapted to work with three or four word sequences.

Both models are able to assess the context of the target text when making predictions; although, as the left and right contexts are given as an average, all words are weighted equally regardless of their relevance to the target text. Because of this equal weighting of words, the models are able to adjust their predictions based on the general complexity of the sentence but are unable to fully capture the relevant context. Adding a mechanism that could weight each word in the context based on certain features may offer some improvements in this area. Attention based models such as BERT (Devlin et al., 2019) are able to attend to each token in a sequence to produce embeddings that capture large amounts of contextual information. Fine-tuning such a model on CWI tasks could produce embeddings that contain more useful and relevant information.

## Abstract

Reading is a complex process which requires proper understanding of texts in order to create coherent mental representations. However, comprehension problems may arise due to hard-to-understand sections, which can prove troublesome for readers, while accounting for their specific language skills. As such, steps towards simplifying these sections can be performed, by accurately identifying and evaluating difficult structures. In this paper, we describe our approach for the SemEval-2021 Task 1: Lexical Complexity Prediction competition that consists of a mixture of advanced NLP techniques, namely Transformer-based language models, pre-trained word embeddings, Graph Convolutional Networks, Capsule Networks, as well as a series of hand-crafted textual complexity features. Our models are applicable on both subtasks and achieve good performance results, with a MAE below 0.07 and a Person correlation of .73 for single word identification, as well as a MAE below 0.08 and a Person correlation of .79 for multiple word targets. Our results are just 5.46% and 6.5% lower than the top scores obtained in the competition on the first and the second subtasks, respectively.

## 1 Introduction

Reading is a complex process due to the mental exercise readers are challenged to perform, since a coherent representation of the text needs to be projected into their mind in order to grasp the underlying content (Van den Broek, 2010). For non-native speakers, the lack of text understanding hinders knowledge assimilation, thus becoming the main obstacle that readers need to overcome. Complex words can impose serious difficulties, considering that their meaning is often dependant on their context and cannot be easily inferred. In order to facilitate text understanding or to perform text simplification, complex tokens first need to be detected.

This can be performed by developing systems capable of identifying them by individual analysis, as well as contextual analysis.

There are two main approaches regarding the complexity task. Tokens can be binary classified as complex or non-complex, a procedure that helps users separate problematic words from the others. Words can be also labeled with a probabilistic complexity value, which in return can be used to simplify the text. Words with lower degrees of complexity can be easily explained, whereas more complex tokens can be replaced with simpler equivalent concepts.

The Lexical Complexity Prediction (LCP) shared task, organized as the SemEval-2021 Task 1 (Shardlow et al., 2021a), challenged the research community to develop robust systems that identify the complexity of a token, given its context. Systems were required to be easily adaptable, considering that the dataset entries originated from multiple domains. At the same time, the target structure evaluated in terms of complexity could contain a single word or multiple words, depending on the subtask.

The current work is structured as follows. The next section presents the state-of-the-art Natural Language Processing (NLP) approaches for LCP (probabilistic) and complex word identification (CWI). The third section outlines our approaches for this challenge, while the fourth section presents the results. Afterwards, the final section draws the conclusions and includes potential solutions that can be used to further improve performance.

## 2 Related Work

**Probabilistic CWI.** Kajiwara and Komachi (2018) adopted for the CWI task a system based on Random Forest regressors, alongside several features, such as the presence of the target word in certain

corpora. Moreover, they conducted experiments to determine the best parameters for their regression algorithms.

De Hertog and Tack (2018) introduced a deep learning architecture for probabilistic CWI. Apart from the features extracted by the first layers of the network, the authors also included a series of hand-crafted features, such as psychological measures or frequency counts. Their architecture included different Long Short-Term Memory (LSTM) modules (Hochreiter and Schmidhuber, 1997) for the input levels (i.e., word, sentence), as well as the previously mentioned psychological measures and corpus counts.

**Sequence labeling CWI.** Gooding and Kochmar (2019) introduced a technique based on LSTMs for CWI, which obtained better results on their sequence labeling task than previous approaches based only on feature engineering. The contexts detected by the LSTM offered valuable information, useful for identifying complex tokens placed in sequences.

Changing the focus towards text analysis, Finnimore et al. (2019) extracted a series of relevant features that supports the detection of complex words. While considering their feature analysis process, the greatest influence on the overall system performance was achieved by the number of syllables and the number of punctuation marks accompanying the targeted tokens.

A different approach regarding CWI was adopted by Zampieri et al. (2017), who employed the usage of an ensemble created on the top systems from the SemEval CWI 2016 competition (Paetzold and Specia, 2016). Other experiments performed by the authors also included plurality voting (Polikar, 2006), or a technique named Oracle (Kuncheva et al., 2001), that forced label assignment only when at least one classifier detected the correct label.

Zaharia et al. (2020) tackled CWI through a cross-lingual approach. Resource scarcity is simulated by training on a small number of examples from a language and testing on different languages, through zero-shot, one-shot, and few-shot scenarios. Transformer-based models (Vaswani et al., 2017) achieved good performance on the target languages, even though the number of training entries was extremely reduced.

## 3 Method

### 3.1 Dataset

CompLex (Shardlow et al., 2020, 2021b) is the dataset used for the LCP shared task that was initially annotated on a 5-point Likert scale. Moreover, the authors performed a mapping between the annotations and values between 0 and 1 in order to ensure normalization. The dataset has two categories, one developed for single word complexity score prediction, while the other is centered on groups of words; each category has entries for training, trial, and testing. The single word dataset contains 7,662 entries for training, 421 trial entries, and 917 test entries. The multi-word dataset contains a considerably smaller number of entries for each category, namely 1,517 for training, 99 trial entries, and 184 for testing.

All entries from the LCP shared task are part of one of three different English corpora (i.e., Bible - biblical entries, Biomed - biomedical entries, and Europarl - political entries), evenly distributed, each one representing approximately 33% of its corresponding set. As such, the task is even more challenging when considering the vastly different domains of these entries.

### 3.2 Architecture

During our experiments, we combined features obtained from multiple modules described later on in detail, and then applied three regression layers, alongside a *Dropout* layer, to obtain the complexity score of the input (see Figure 1 for our modular architecture). The permanent components are represented by the target word embeddings and the Transformer features, which are concatenated and then fed into the final linear layers, designated for regression. The other components (i.e., character-level embeddings, GCN, and Capsule) are enabled in particular setups; similarly, the adversarial training component can also be disabled. At the same time, a series of hand-crafted features can be concatenated before the last layer with the aim to further improve the overall performance.

### 3.3 Pre-trained Word Embeddings

Pre-trained word embeddings were used as features for the final regression as an initial representation of the input. Throughout our experiments, three types of pre-trained word embeddings were consid-

Figure 1: The overall model architecture used in our experiments.

ered, namely: GloVe<sup>1</sup>, FastText<sup>2</sup>, and skip-gram<sup>3</sup>. Out of the three previous options, GloVe performed best in our experiments. As such, the results section exclusively reports the performance obtained by our configurations alongside GloVe embeddings for the target word.

### 3.4 Transformer-based Language Models

Considering that Transformers achieve state-of-the-art performance for most NLP tasks (Wolf et al., 2020), all our setups include a Transformer-based component. However, they are pre-trained in different manners; thus, we experimented with several variants, as follows:

- **BERT** (Devlin et al., 2019) - Extensively pre-trained on English, BERT-base represents the baseline of Transformer-based models;
- **BioBERT** (Lee et al., 2020) - Considering that some of the most difficult to understand entries are part of the Biomed corpus, we also experimented with a model pre-trained on biomedical data;
- **SciBERT** (Beltagy et al., 2019) - Similarly to BioBERT, SciBERT is pre-trained on scien-

tific data and becomes a good candidate for fine-tuning on the scientific entries from the dataset;

- **RoBERTa** (Liu et al., 2019) - RoBERTa improves upon BERT by modifying key hyperparameters, and by being trained with larger mini-batches and learning rates; RoBERTa usually has better performance on downstream tasks.

### 3.5 Adversarial Training

We also aimed to improve the robustness of the main element of our architecture, the Transformer-based component. Therefore, we adopted an adversarial training technique, similar to Karimi et al. (2020). The adversarial examples generated during training work on the embeddings level, and are based on a technique that uses the gradient of the loss function.

### 3.6 Character-level Embeddings

Alongside the previously mentioned word embeddings for the target word, we also employ character-level embeddings for the same word, such that its internal structure, as well as its universal context, can be properly captured as features in our architecture.

<sup>1</sup><https://nlp.stanford.edu/projects/glove/>

<sup>2</sup><https://fasttext.cc/>

<sup>3</sup><http://vectors.nlpl.eu/repository/>

### 3.7 Graph Convolutional Networks

Besides the previous Transformer-based models, we also explored the relations between the dataset entries, as well as the vocabulary words. Therefore, Graph Convolutional Networks (GCN) (Kipf and Welling, 2016) were also considered for determining node embedding vectors, by taking into account the properties of the neighboring nodes. By stacking multiple GCN layers, the information embedded into a node can become broader, inasmuch as it incorporates considerably larger neighborhoods. Similar to Yao et al. (2019), we consider the graph to have several nodes equal to the number of entries (documents) in the corpus plus the vocabulary size of the corpus.

### 3.8 Capsule Networks

Alongside the relational approach derived from GCN and Transformer embeddings, we intended to further analyze our inputs by passing them through a Capsule Network (Sabour et al., 2017). This approach enables us to obtain features that reflect aspects specific to different levels of the inputs, as Capsule Networks increase the specificity of features, while the capsule layers go deeper.

### 3.9 Hand-crafted Features

Similar to Gooding and Kochmar (2018), we integrated a series of hand-crafted features for the target word: **Syllables**, **Synset length**, **Hyponyms length**, **Hyponyms length**, **Number of dependencies** obtained using NLTK<sup>4</sup> alongside CoreNLP<sup>5</sup>, **SubIMDB presence**<sup>6</sup>, **SimpWiki presence** (Coster and Kauchak, 2011), **CEFR level** obtained from the Cambridge English dictionary<sup>7</sup>, **MRC features** (Wilson, 1988) (*Age of acquisition*, *Concreteness rating*, *Imageability rating*, *Word familiarity rating*, *Number of phonemes*), **Semantic Diversity** (Hoffman et al., 2013), **Sensorimotor Norms** (Lynott et al., 2019).

**Character n-grams** - The character n-gram approach consists of two steps: first, a vectorizer is applied on the inputs to select a maximum number of 5,000 most frequent n-grams; second, Tf-Idf scores for these elements are computed. The obtained values are then normalized in the  $[0, 1]$  range

<sup>4</sup><https://www.nltk.org/>

<sup>5</sup><https://stanfordnlp.github.io/CoreNLP/>

<sup>6</sup><http://ghpaetzold.github.io/subimdb/>

<sup>7</sup><https://dictionary.cambridge.org/dictionary/learner-english/>

and used as features.

**ReaderBench indices** - The ReaderBench framework (Dascalu et al., 2017) was used to extract additional textual complexity features reflective of writing style. Out of the 1311 features obtained by running ReaderBench on our inputs, we selected 278. The choice was made by considering only the features with a high linguistic coverage (i.e. were non-zero for at least 50% of the entries).

### 3.10 Traditional Machine Learning Baseline

Several machine learning algorithms, such as *Logistic regression*, *Random Forest Regressors*, *XGBoost regression*, or *Ridge regression* were experimented using the aforementioned handcrafted features.

We then switched to a ridge regression approach and trained it with a multitude of features, including Transformer-based embeddings (BERT, BioBERT, SciBERT, RoBERTa), pre-trained word embeddings (GloVe, fastText, Skip-gram), and handcrafted features.

### 3.11 Preprocessing and Experimental Setup

Text preprocessing is minimal and consists of removing unnecessary punctuation, such as quotes. The experimental hyperparameters for all modules are presented in Table 1.

## 4 Results

Table 2 introduces the results obtained using our deep learning architecture, while Table 3 focuses on the traditional machine learning baseline. The best results for the deep learning approaches applied on the single target word dataset are obtained using RoBERTa as Transformer model. The setup which maximizes performance considers RoBERTa, GCN, and Capsule features, obtaining a Pearson score of 0.7702 and a mean absolute error (MAE) of 0.0671 on the trial dataset. Moreover, the high performance is maintained on the test dataset, with a Pearson correlation coefficient of 0.7237 and a MAE of 0.0677. BERT, SciBERT, and BioBERT have similar results with marginal differences; GCN, Capsule, and adversarial training improve performance for all models, while character-level embeddings do not provide a boost in performance.

Table 3 presents the results obtained using the features described in Section 3, namely Transformer-based contextualized embeddings (BERT, RoBERTa, BioBERT, SciBERT), pre-

\* The models marked with \* are the ones used in our submissions.

Table 2: Results for the Deep Learning approaches.

trained word embeddings (GloVe, fastText, skip-gram), and hand-crafted features, all combined using various regression algorithms. Logistic regression, Random Forrest and XGBosst yield lower performance when compared to the previous deep learning approaches. However, we managed to increase the scores on the single target word dataset, with Pearson coefficients of 0.7738 and 0.7340 on the trial and test datasets, by combining the results obtained from training several instances of ridge regression. Nevertheless, the best results for the multiple target word task are still obtained by the deep learning approaches (RoBERTa, GCN, Capsule, adversarial training), which surpass the Ridge Regression + pre-trained word embeddings + Transformer embeddings + handcrafted features approach by a low margin of 0.0074 Pearson on the trial dataset and 0.0033 on the test dataset.

## 5 Discussion

The entries with the largest difference when compared to the gold standard are represented by the ones that are part of the Biomed category. This discrepancy is valid for both subtasks (i.e, single target word and multiple target words). The Biomed entries employ the usage of more complex terminology, quantities, or specific scientific names. Therefore, it becomes more difficult for standard pre-trained Transformer systems, such as BERT or RoBERTa, to adapt to the Biomed entries. In contrast, corpora with easier to understand language (i.e., Bible and Europarl) are not properly represented when using BioBERT or SciBERT, considering that the Transformers are mainly pre-trained for scientific or biomedical texts.

Moreover, a considerable part of the Biomed entries contains large amounts of abbreviations, while other entries from the same domain have

## 6 Conclusions and Future Work

This work proposes a modular architecture, as well as different training techniques for the Lexical Complexity Prediction shared task. We experimented with different variations of the previously mentioned architecture, as well as textual features alongside machine learning algorithms. First, we used different word embeddings and Transformer-based models as the main feature extractors and, at the same time, we examined a different training technique based on adversarial examples. Second, other different models were added, such as character-level embeddings, Graph Convolutional Networks, and Capsule Networks. Third, several hand-crafted features were also considered to create a solid baseline covering both deep learning and traditional machine learning regressors.

For future work, we intend to experiment with altering the modular architecture such that the models are trained similar to a Generative Adversarial Network (Croce et al., 2020), thus further improving robustness and achieving higher scores in terms of both Pearson correlation coefficients and MAE.

# UTFPR at SemEval-2021 Task 1: Complexity Prediction by Combining BERT Vectors and Classic Features

Gustavo Henrique Paetzold

Universidade Tecnológica Federal do Paraná - Campus Toledo

Toledo-PR, Brazil

ghpaetzold@utfpr.edu.br

## Abstract

We describe the UTFPR systems submitted to the Lexical Complexity Prediction shared task of SemEval 2021. They perform complexity prediction by combining classic features, such as word frequency, n-gram frequency, word length, and number of senses, with BERT vectors. We test numerous feature combinations and machine learning models in our experiments and find that BERT vectors, even if not optimized for the task at hand, are a great complement to classic features. We also find that employing the principle of compositionality can potentially help in phrase complexity prediction. Our systems place 45th out of 55 for single words and 29th out of 38 for phrases.

## 1 Introduction

Accurately measuring the complexity of words can be useful in many ways. It facilitates the creation of text simplification technologies that could, for example, help in identifying and adapting challenging excerpts of literary pieces targeting specific groups, such as children (De Belder and Moens, 2010) and second language learners (Paetzold and Specia, 2016e), and make news articles and official documents more accessible to the general population (Paetzold and Specia, 2016a).

This task has received a considerable amount of attention in the past few years, especially due to the popularity of the Complex Word Identification (CWI) shared tasks of 2016 (Paetzold and Specia, 2016c) and 2018 (Yimam et al., 2018), where dozens of teams were challenged to judge the complexity of words in context. While the CWI 2016 task used a simple binary complex/not complex classification setup for English only, the CWI 2018 task explored both a binary classification and a regression setup and multiple languages.

The majority of the most successful systems submitted to these shared tasks combined ensemble

methods, such as Random Forests (Ho, 1995) and AdaBoost (Freund and Schapire, 1997) with numerous linguistic features, including word frequencies, n-gram frequencies, word length, number of senses, number of syllables, psycholinguistic metrics, and word embeddings (Konkol, 2016; Malmasi et al., 2016; Paetzold and Specia, 2016d; Gooding and Kochmar, 2018; Hartmann and Dos Santos, 2018). However, because these tasks were held prior to the ascension of transformer-based masked language models, such as BERT (Devlin et al., 2019) and ROBERTA (Liu et al., 2019), we could not find any systems that exploited the power of the features produced by them.

In this paper, we describe the UTFPR systems for the Lexical Complexity Prediction shared task of SemEval 2021 (LCP 2021), which combine classic complexity prediction features with contextual word and phrase representations extracted from transformer-based models. In our experiments, we explore the efficacy of a number of different machine learning models, feature combinations, and corpora sources for our features. In what follows, we present the task being addressed (Section 2), our approach (Section 3), some preliminary experiments (Section 4), our final shared task results (Section 5), and our conclusions (Section 6).

## 2 Task Description

We address the LCP 2021 shared task (Shardlow et al., 2021), held at SemEval 2021. The shared task is split into two sub-tasks: predicting the in-context lexical complexity of single words and phrases for the English language. Participants could choose to submit systems to either or both sub-tasks.

The organizers provided training, trial and test sets for both sub-tasks. Each instance of these datasets is composed of an ID, a source identifier,

a sentence, a target word or phrase within the sentence, and a complexity score calculated based on judgments made by 20 English speakers from the USA, UK and Australia. The source identifier describes from where the sentence came from, the possibilities being the Bible, biomedical documents and the Europarl corpus. The task’s dataset is an extended version of the CompLex dataset (Shardlow et al., 2020).

The training, trial, and test sets for single words have 7662, 421, and 917 instances, respectively. The training, trial and test sets for phrases have 1517, 99, and 184 instances, respectively. Participants were allowed and encouraged to use any external resources they saw fit.

### 3 Approach

Our approach consists of using modern ensemble models to learn from a combination of commonly used complexity estimation features, such as word frequencies, word length, and number of senses, with contextual representations extracted from large pre-trained BERT-like models, which have been widely used to create state-of-the-art solutions to numerous tasks. While it has been observed that word frequencies (especially those extracted from spoken text) tend to drive the performance of effective complexity prediction systems (Paetzold and Specia, 2016c), we hypothesize that the wealth of knowledge present in transformer-based models such as BERT can help in extracting complementary contextual complexity clues.

#### 3.1 Features

We explore a set of 779 total features in our approach. They are:

- **Frequency:** We use not only word/phrase frequency, but also n-gram frequencies as well. We consider a total of 9 configurations  $(i, j)$ , where  $i$  represents the number of tokens to the left of the target word/phrase to be considered and  $j$  the number of tokens to the right. The configurations we consider are (0, 0), (0, 1), (1, 0), (1, 1), (0, 2), (2, 0), (1, 2), (2, 1), (2, 2).
- **Length:** We use the number of characters that compose the word/phrase. For phrases, instead of using its overall length, we use the average number of characters of all individual words. We motivate this decision in the experiments of Section 4.2.
- **Number of senses:** We use the word/phrase’s number of senses catalogued in the WordNet database (Miller et al., 1990). In line with our setup for word length, for phrases, we use the average number of senses of all individual words.
- **BERT vector:** We use the numerical representation of 768 dimensions produced by the pre-trained BERT model (Devlin et al., 2019). For phrases and out-of-vocabulary words that were fragmented during tokenization, we average the representations produced for all fragments. More specifically, we used the bert-base-uncased model from the Hugging Face’s transformers library (Wolf et al., 2020).

In the experiments of Section 4.3, we conduct an ablation study that reveals the performance impact of adding/removing some of these features from our models.

#### 3.2 Models

We explore 5 different machine learning models in our experiments:

- Ridge Regression (Ridge) (Tikhonov, 1943)
- Support Vector Machines (SVM) (Boser et al., 1992)
- AdaBoost Regression (AdaBoost) (Freund and Schapire, 1997)
- Gradient Boosting (GBoost) (Friedman, 2001)
- Random Forests (Forests) (Ho, 1995)

The final configuration we chose to submit to LCP 2021 is described in Section 5. In the following section, we explain how we got to that configuration.

### 4 Preliminary Experiments

In this section, we describe the preliminary experiments we conducted in an effort to engineer our final systems for the LCP 2021 shared task. In these experiments, all machine learning models were trained and optimized on the training set and tested on the trial set provided by the organizers. All models were implemented using the Scikit-Learn library (Pedregosa et al., 2011) and optimized using grid search and 5-fold cross validation.

Split	Size	(0, 0)	(0, 1)	(1, 0)	(1, 1)	(0, 2)	(2, 0)	(1, 2)	(2, 1)	(2, 2)

Table 1: Trial set Pearson correlations between complexity scores and frequencies for all SubIMDB splits and n-gram configurations on the single words sub-track.

#### 4.1 Corpora Analysis

Arguably the most important features we use are frequencies. These must be calculated based on a language model trained on a specific corpus, so, as a first step in our engineering process, we decided to conduct an experiment to choose a corpus for the shared task in question.

As evidenced and discussed by Brysbaert et al. (2012) and Paetzold and Specia (2016b), frequencies extracted from spoken text corpora tend to correlate better with word complexity, so we decided to choose the SubIMDB corpora (Paetzold and Specia, 2016b) for our experiment. SubIMDB is a structured corpus extracted from 38,102 subtitles of children, family and comedy movies and series. We created 12 SubIMDB splits for this experiment: Children movies (Chi-M), children series (Chi-S), children movies and series (Chi-MS), family movies (Fam-M), family series (Fam-S), family movies and series (Fam-MS), comedy movies (Com-M), comedy series (Com-S), comedy movies and series (Com-MS), all movies (Movies), all series (Series), and the entire corpus (All). We calculate the Pearson correlation between the trial set complexity scores and n-gram frequencies for all n-gram configurations described in Section 3.1. To do so, we trained 5-gram language models over these splits using KenLM (Heafield, 2011).

The results illustrated in Table 1 are absolute correlation scores for the trial set of the single words sub-track (original values were negative, given that complexity inversely correlates with word frequency). We chose absolute scores to make the table more compact. It can be observed that the (0,

0) configuration (no context) yields the best correlations in every scenario. It can also be noted that, while the family movies split (Fam-M) is best for (0, 0), the remaining configurations tend to benefit from larger splits. Based on that observation, in the experiments that follow, we use family movies to calculate frequencies for single words/phrases and the whole SubIMDB corpus for the remaining n-grams.

#### 4.2 Phrase Compositionality

The next step in our engineering process was to optimize the performance of our submission for the phrases sub-track. For that, we tested the hypothesis that the complexity of a phrase can be more reliably modelled if addressed as a product of the complexity of its words. To do so, we first calculated 3 features from our feature set using 4 different composition functions, then calculated the Pearson correlation between them and the reference complexity scores from the trial set.

The features calculated are: Phrase/word frequency, length, and number of senses. The composition functions are: None (addressing the phrase as a single word), averaging, maximum, and minimum. Frequencies were calculated using a 5-gram language model trained over the entire SubIMDB corpus.

The results in Table 2 show that, overall, employing the principle of compositionality in feature calculation for phrases increases the correlation between classic complexity features and human complexity scores. This is especially true for word senses, given that Wordnet has very few phrases

	None	Avg.	Max.	Min.
Frequency	-0.617	-0.641	<b>-0.650</b>	-0.547
Length	0.482	<b>0.482</b>	0.370	0.461
Senses	-0.125	<b>-0.460</b>	-0.430	-0.420

Table 2: Trial set Pearson correlations for different compositionality settings on the phrases sub-track.

catalogued.

In the subsequent experiments, we employ averaging as the compositionality function in feature calculation for phrases.

### 4.3 Feature Selection

The last step in engineering our submissions was to select a set of features and a machine learning model from the ones described in Section 3. To do so, we conducted a thorough ablation analysis with all models and multiple feature subsets.

Each feature subset is identified by a set of IDs. Each ID describes a feature or group of features. The identifiers are:

- Word/phrase frequency (**F**)
- N-gram frequencies (**N**)
- Word/phrase length (**L**)
- Number of senses (**S**)
- BERT vector (**V**)

The F identifier represents the (0, 0) configuration described in Section 3.1, while the N identifier represents all others. For example, the subset FNLSV contains all features, while the subset FNS does not contain length or the BERT vector.

The results in Table 3 show the results for the feature configurations that we feel were the most relevant for our engineering process. It can be seen that the best performing variant for both single words and phrases is an SVM trained over all features except n-gram frequencies. Models tend to benefit from the inclusion of word length, number of senses, and especially the BERT vector to the feature set. Interestingly, discarding n-gram frequencies tends to improve the models’ performance, especially for single words. This was observed not only in the results of Table 3, but also in many other comparisons we tested, such as FNLSV versus FLSV and FNLS versus FLS.

## 5 Task Results

We based the creation of the final UTFPR systems on the experiments of the previous section. Our final systems are SVMs trained with word/phrase frequencies, word/phrase length, number of senses, and BERT vector (no n-gram frequencies). Compositionality in phrases was handled through averaging. Frequencies were calculated using a 5-gram language model trained over family movies from SubIMDB. Due to a limitation in time availability, the BERT model was used in its original pre-trained form and not optimized for the task at hand.

Table 4 showcases our shared task performance in comparison to the top 3 and bottom 3 systems with respect to Pearson correlation. Our systems for single words and phrases placed 45th out of 55 and 29th out of 38, respectively. Inspecting the instances that featured most discrepancy between gold labels and predictions, we found that our systems had a tendency of both underestimating the complexity of some of the most complex words and phrases (above 0.7 complexity) and overestimating the complexity of the simplest ones (below 0.2). The conservative nature of their predictions seems to be the main reason why our systems did not place higher.

## 6 Conclusions

We presented the UTFPR systems submitted to the Lexical Complexity Prediction shared task of SemEval 2021. Although the placing of our systems were not impressive, we do showcase through our preliminary experiments that employing compositionality can potentially improve the predictions for phrases. We also show that including word length, number of senses, and non-optimized BERT vectors to complexity prediction models can noticeably improve their predictions for both words and phrases. In the future, we intend to test the efficacy of adding BERT vectors optimized for the task at hand to the pool of features of our models.

## Abstract

In this paper we propose a contextual attention-based model with two-stage fine-tune training using RoBERTa. First, we perform the first-stage fine-tune on corpus with RoBERTa, so that the model can learn some prior domain knowledge. Then we get the contextual embedding of context words based on the token-level embedding with the fine-tuned model. And we use Kfold cross-validation to get K models and ensemble them to get the final result. Finally, we attain the 2nd place in the final evaluation phase of sub-task 2 with Pearson correlation of 0.8575.

## 1 Introduction

LCP is an augmented version of Complex Word Identification(CWI) (Shardlow et al., 2020), predict complexity score for each target word in a sentence. The dataset is a multi-domain English dataset annotated with a 5-point Likert scale (1-5). The annotation model in CompLex addresses complexity as a continuum instead of a binary feature. Previous studies of CWI treat the task as a binary classification, predict a complexity label (complex vs. non-complex) for a set of target words in a sentence.

In this paper, we exploratory data analysis(EDA) for the dataset, and found that the distribution of the single task and multi task dataset are very inconformity, so should bulid two models for every dataset great than one model for merge two task dataset.

Several key technologies as follows:

- Train a RoBERTa based fine-tune corpus classifier. It use the data of all single and multi

---

with train, trial and test dataset as train data, no dev and test, and only train 1 epoch, which enable the RoBERTa model ahead of time learning the domain knowledge.

- At each layer, calculate target vector and context tokens embedding attention, the layer context vector is average the context tokens embedding with soft alignment.
- Weighted the RoBERTa last 12 layers context vector and target vector. They use the same weights, and it's sum equals to 1.
- The degeneration of gradual unfreezing (Howard and Ruder, 2018). At first epoch freeze the pretrained model parameter only learning the head layers parameter, then unfreeze all model parameter.
- Multi-Sample Dropout at last layer (Inoue, 2019)

## 2 Background

Previous approaches to CWI typically refer to binary identification of complex words, two shared tasks on CWI topic have been organized so far. SemEval-2016 Task 11 (Paetzold and Specia, 2016) and BEA workshop 2018 (Yimam et al., 2018). The two tasks approache a number of different model to classification, ranging from traditional machine learning classifiers such as support vector machines (SVM), decision trees, random forest, and maximum entropy classifiers to deep learning classifiers, such as recurrent neural networks. A wide range of features were used such as word embeddings, word and character n-grams, word frequency, Zipfian frequency distribution, word length, morphological, syntactic, semantic, and psycholinguistic.

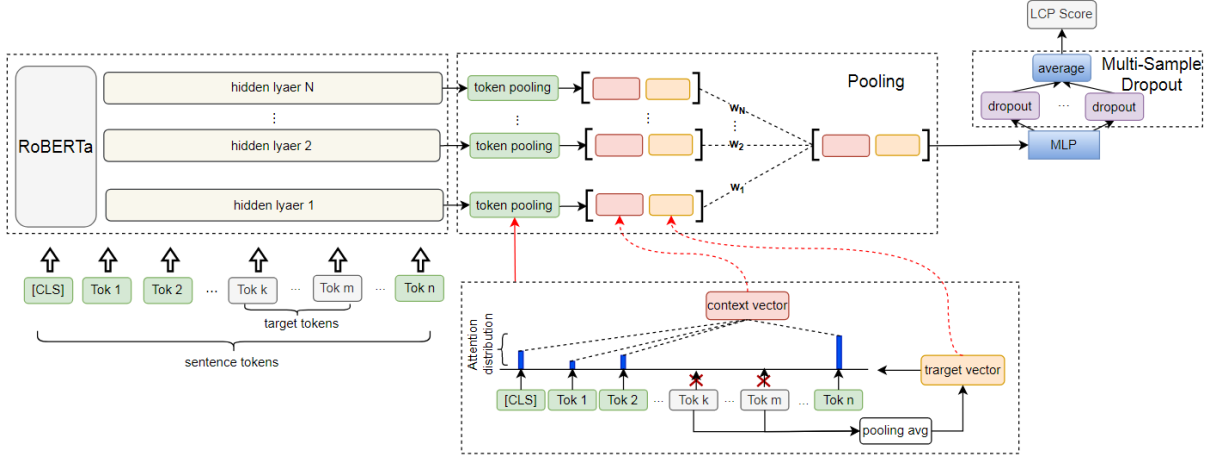

Figure 1: Attention Based Context Representation for LCP

BERT is a new language representation model, and stands for Bidirectional Encoder Representations from Transformers (Devlin et al., 2018). Since BERT appear, fine-tuned pre-trained model with just one additional output layer to create state-of-the-art models for a wide range of tasks. A number of Transformers series models are proposed, such as GPT-2, RoBERTa (Liu et al., 2019), XLM, DistilBert, XLNet. In this papaer we focus on use RoBERTa to slove the tasks.

### 3 System overview

We propose a RoBERTa with attention based model to solve the LCP task, Figure 1 outlines our proposed model framework. First, use Byte-Pair Encoding (BPE) to tokenize the input sentence, which is an effective subword technique to relieve the Out-of-Vocabulary (OOV) problem. For every RoBERTa hidden layer, we apply token pooling that is average the target words tokens embedding as the target vector. Then we calculate the attention between target vector and context tokens vector which are sentence tokens masked the target tokens, After that, context tokens embedding multiply attention weight as the context vector, then concatenate the context vector and target vector. Second, pooling the RoBERTa last 12 layers context vector and target vector, Finally, connect the MLP layer to predict the LCP Score.

#### 3.1 Pooling

The input sentnct is tokenized to  $n$  tokens  $t_i, i = 1, 2, \dots, n$ , and the target tokens index are  $l_t = \{k, k + 1, \dots, m\}$ , the context tokens index are  $l_c = \{1, \dots, k - 1, m + 1, \dots, n\}$ , which exclude

the target tokens.  $E_i^j$  denotes the  $i_{th}$  token embedding of hidden layer  $j$ ,  $T^j$  denotes the target vector of the hidden layer  $j$ .

$$T^j = \frac{1}{m - k + 1} \sum_{i \in l_t} E_i^j \quad (1)$$

The attention weight between context tokens embedding and target vector of layer  $j$  is compute by.

$$\alpha_i^j = softmax(s(E_i^j, T^j)) = \frac{exp(s_i^j)}{\sum_i exp(s_i^j)}, i \in l_c \quad (2)$$

where

$$s_i^j = s(E_i^j, T^j) = (E_i^j)^T T^j \quad (3)$$

After that, we compute the weighted summation for  $c^j$

$$c^j = \sum_{i \in l_c} \alpha_i^j E_i^j \quad (4)$$

Finally, calculate the pooling target vetor  $\bar{t}$ , and context vector  $\bar{c}$ , they are weighted last  $N$  layers target vector and context vector of RoBERTa, the weight  $w_1, w_2, \dots, w_N$  is the model parameters and equals to 1.

$$\bar{t} = \sum_j^N w_j t^j \quad (5)$$

$$\bar{c} = \sum_j^N w_j c^j \quad (6)$$

$$\sum_{j=1}^N w_j = 1 \quad (7)$$

Quantile	Single		Multi	
	train	trial	train	trial
Q1	0.2115	0.2143	0.3026	0.3090
Q2	0.2794	0.2667	0.4091	0.4219
Q3	0.3750	0.3594	0.5294	0.5140

Table 1: Single and Multi DataSet Quantile

## 4 Experiments

### 4.1 Data

Table 1 shows the single and multi dataset quantile. From the table we found that the single and multi words Complexit Score distribution are very different. Single is easy to understand but multi words are difficult. So we build different model to adjust the dataset.

We use 5-fold cross validation, first generate a new feature score\_bin which is binning the LCP score by quantile. Because the dev dataset commonly used to search the optimal hyper parameters, in this experiment we only use dev dataset to found the best epoch, in order to prevent overfitting by early stop, but we found that pretrained model only train 5-6 epochs could be convergence on the task dataset, so not need deliberately generate the dev dataset, only let dev dataset as same as test dataset. Train and test dataset are splited use stratified KFold by the features domain corpus and score\_bin.

### 4.2 Corpus information

The dataset give the sentences domain corpus, but how to use this information? At first, we build the multi-task learning. The auxiliary task is the corpus classification which use the last 12 layers average CLS token embedding. But the auxiliary task not improve the LCP task, and the accuracy of corpus classifier is quite low. It's not conform to the actual, because of the sentences corpus come from Bible Europarl and Biomedical, and they are very easy to distinguish.

Since that, we build a corpus classification model separately which is a RoBERTa fine-tune model (Sun et al., 2019). Benefit from the dataset are easy to classify, the model only need to train 1 epoch, and could get 0.99 accuracy. We merge the single and multi trial, train and test dataset as new train dataset, this can let the model see all data include test dataset. After train, the RoBERTa learning the domain knowledge, and in advance learning part of the test dataset.

Then, export the RoBERTa model as the pre-trained model of LCP task.

### 4.3 Single LCP Task

First merge the single train and trial dataset, then process stratified 5-fold, compare the origin pre-trained model(RoBERTa-large) and fine-tune by the corpus classification(pre-RoBERTa-large).

For train, we use the Mean squared error(MSE) loss function and adam optimizer (Kingma and Ba, 2014). At first epoch we freeze the RoBERTa parameters, only training the head layers. Apply learning rate linear schedule with warmup,  $lr = 2e - 5$ ,  $warmup\_steps = 200$ , and use early stop.

Table 2 shows the single task result, the metric is Pearson correlation (R). The **fold-x** column is the metric of CV model evaluate on the fold-x dataset. The **mean** column is the average of the fold-\* column. Pre-trained corpus classification with fine-tune RoBERTa-large is a little outperformance than origin RoBERTa-large. The single model result is the average of all 5-fold models's predict result for single task test data, and **model result** column is the metric of the the model result. The task final result is the average of all models result, and **final result** column is the metric of the the final result. The two model can achieve 0.7586 and 0.7618, but use simple average ensemble could get 0.7629. It's quite effective.

### 4.4 Multi LCP Task

The merged dataset of multi train and trial only have 1616 examples, In single task, the pre-RoBERTa-large is outperformance than origin RoBERTa-large. In order to augment the multi task examples, Fisrt use the data which merge all sigle and multi train trial dataset, use 5-fold cross validation, splited data use stratified KFold as same as single task. Then use pre-RoBERTa-large train the LCP task. After that, inference the vector  $\bar{h} = [\bar{c}, \bar{t}]$  for all merge data, the final  $\bar{h}$  is average of all 5-fold models. Finally, use the vector to calculate cosine similarity of the multi dataset with single dataset, then recall single examples add to the multi train example with threshold. Here we use  $sim\_threshold = 0.75$ , and recall 2707 single examples.

Then split dataset and train strategy are as same as singe task. The results are in Table 3. gen-RoBERTa-large is the origin RoBERTa model with Data Augmentation, pre-gen-RoBERTa-large is the RoBERTa model fine-tune by the corpus with Data

model	the result of 5-fold cross validateion					LCP single task		
	fold-1	fold-2	fold-3	fold-4	fold-5	mean	model result	final result

pre-gen-RoBERTa-large	0.7614	0.7646	0.7616	<b>0.7920</b>	0.7791	<b>0.7717</b>	0.8355	

Table 3: Multi Task Result

Augmentation. Results shows model fine-tune by the corpus classification are outperformance than origin model, The final result 0.8575 is fusioned by average of the four models cv results, and rank the 2nd in test phrase.

## 5 Conclusion

This paper presents a method to predicting lexical complexity, which apply RoBERTa-large as the backbone language model. First fine-tune backbone model for corpus classification. Then build model with attention based context representation. make vector recall for multi task data augmentation. Finally, we carry out a multi-model average ensemble strategy to enhance the model performance. In the future, we will exploit better model for text representation, and utilizing data augmentation for all task.

## Abstract

Lexical complexity prediction (LCP) conveys the anticipation of the complexity level of a token or a set of tokens in a sentence. It plays a vital role in the improvement of various NLP tasks including lexical simplification, translations, and text generation. However, multiple-meaning of a word in multiple circumstances, grammatical complex structure, and the mutual dependency of words in a sentence make it difficult to estimate the lexical complexity. To address these challenges, SemEval-2021 Task 1 introduced a shared task focusing on LCP and this paper presents our participation in this task. We proposed a transformer-based approach with sentence pair regression. We employed two fine-tuned transformer models including BERT and RoBERTa to train our model and fuse their predicted score to the complexity estimation. Experimental results demonstrate that our proposed method achieved competitive performance compared to the participants' systems.

## 1 Introduction

Lexical complexity prediction (LCP) has become an important task in this globalization age, especially for second language learners (Przybyła and Shardlow, 2020). LCP is a little bit expansion of complex word identification (CWI) task (Paetzold and Specia, 2016; Štajner et al., 2018), where CWI is a binary classification of a word that is complex or not and LCP is finding the complexity level of a word in continuous labelling in a sentence (Shardlow et al., 2020). LCP plays a vital role in many NLP applications such as lexical simplification (Paetzold, 2016; Paetzold and Specia, 2017; Qiang et al., 2020), text generation, and machine translation (Wang et al., 2016). Besides, it helps those people who are suffering from

Dyslexia (Rello et al., 2013a), Aphasia (Rello et al., 2013b), and those with low literacy levels (Aluisio and Gasperin, 2010).

LCP is a very challenging task (Zampieri et al., 2017), especially because the non-identical target audiences will have distinct needs. For example, speakers of one language usually less familiar with different subsets of the vocabulary of a second language. Besides, the grammatical shape of a sentence and the ambiguous meaning of a word in different places make this task more challenging and important to explore. A single word may portray different lexical complexity because of its non-identical usage, position, tense form, and redundancy in different sentences or in the same sentence. To estimate multi-word complexity, we need to consider the dependency between tokens.

Sentence	Token	Complexity
Sub-task 1		
His head is like the purest gold.	gold	0.210
Sub-task 2		
They shall eat it with bitter herbs.	bitter herbs	0.25

Table 1: Example of sub-task 1 and sub-task 2.

To address the challenges of lexical complexity prediction of words in sentences, (Shardlow et al., 2021a) proposed a shared task at SemEval-2021 Task 1. The task is divided into two subtasks. In sub-task 1, a system needs to determine the complexity level of a word in the sentence, whereas in sub-task 2, a system needs to determine the overall complexity level of multiple words in the sentence. To explain the definition of both sub-tasks, we articulate a few examples in Table 1.

\*\*The first two authors have equal contributions.

Taking part in the LCP shared task of SemEval-2021, we exploit the pairwise contextual information of sentence and token. In this regard, we proposed a combined transformer based framework with sentence pair regression. We make a pairwise learning framework with the sentence-token pair to train the two state-of-the-art transformers model including BERT and RoBERTa.

We organize the rest of the paper as follows: Section 2 presents the details of our proposed framework. Whereas in Section 3, we present our experimental settings and analyze the performance of our model against the various settings and related methods. Finally, we conclude our paper in Section 4 with some future directions.

## 2 Proposed Lexical Complexity Prediction Framework

In this section, we describe our proposed lexical complexity prediction framework. Our goal is to predict the complexity score of a token or a set of tokens in the given sentence. We depict the overview of our framework in Figure 1.

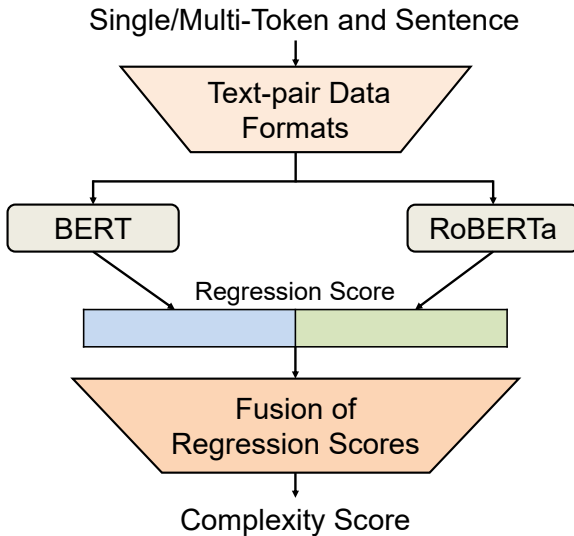

Figure 1: Overview of our proposed framework.

In our framework, we use a sentence pair regression concept in transformer models to perform lexical complexity prediction where input sentence and target word pairs are packed together into a single sequence. After performing sentence-token pair regression through BERT and RoBERTa models, we estimate each model’s regression score. Subsequently, we fuse these models’ predictions by taking the mean of these scores to determine the final complexity score.

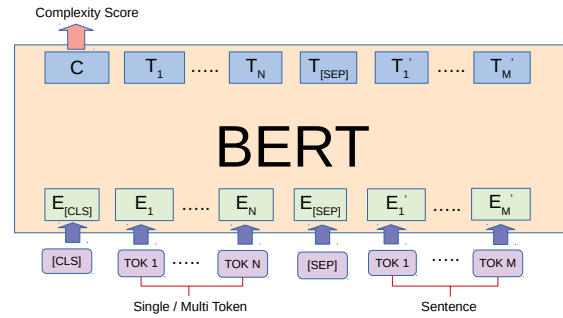

Figure 2: Pairwise learning using BERT model.

### 2.1 Fine-tuned Transformer Models

We fine-tune the transformer models to perform sentence pair regression for LCP through BERT and RoBERTa. We describe the details in the subsequent sections.

#### 2.1.1 Input Representation

We train with the sentence-word pair for better understanding their contextual relation which in turn helps to estimate the complexity of the target word in the sentence. It is important for an LCP system to predict both single and multi-words complexity. We exploit Huggingface transformers library (Wolf et al., 2020) with pairwise training where input target words and sentence make pair as a single sequence and detached with the [SEP] token. We utilize two pre-trained transformer models including RoBERTa and BERT. For LCP tasks training, each model’s first token is the special [CLS] token at the beginning of every sequence which is also responsible for the final layer regression score of each model. For each sequence, we separate every pair with [SEP] token (as presented in Figure 2) where the target words belong to text.a and sentence belongs to text.b. We fine-tune the architecture with the pre-trained BERT and RoBERTa models to estimate the complexity score.

#### 2.1.2 BERT

BERT (Devlin et al., 2019) stands for bidirectional encoder representations from transformers, is a new method of pre-training sentence representations which achieves state-of-the-art results on many NLP tasks including question-answering, text classification, and sentence-pair regression. We take advantage of the bert fast tokenizer and bert-base-uncased model for sentence-pair regression where target words and sentence make pair as a single sequence.

### 2.1.3 RoBERTa

RoBERTa (Liu et al., 2019) is an extension to the original BERT model which is named as a robustly optimized BERT pre-training approach. It focuses on the key hyper-parameters choices and removing the next sentence prediction (NSP) objective. Besides, it is training with much larger mini-batches and learning rates. We exploit the roberta fast tokenizer and roberta-base model for sentence-pair regression to get the complexity score where target word and sentence are trained as pairwise training.

## 2.2 Fusion of Transformer Models

To ameliorate the performance of individual models, we fuse the predicted complexity score of two models to generate a unified score. We use the arithmetic mean to average both model’s regression scores to determine the final complexity score. The estimation is computed as follows:

$$C_i = \frac{x_i + y_i}{2}$$

where  $x_i$  and  $y_i$  correspond to the BERT and RoBERTa regression score, respectively.

## 3 Experiment and Evaluation

### 3.1 Dataset Description

The organizers of the lexical complexity prediction (LCP) task 1 at SemEval-2021 (Shardlow et al., 2021a) provided a multi-domain English benchmark dataset (Shardlow et al., 2020, 2021b) to evaluate the performance of the participants’ systems. The dataset was collected from three different corpora including the Bible, europarl, and biomedical. The proposed task is divided into two subtasks, sub-task 1 focused on single word instances whereas sub-task 2 focused on multi-word instances. The training set for sub-task 1 contains 7662 instances where 2574 instances from Bible, 2576 instances from biomed, and 2512 instances from europarl. The training set of sub-task 2 comprises 1517 instances (505 Bible, 514 biomed, and 498 europarl). The validation set consists of 99 multi-word expressions (29 Bible, 33 biomed and 37 europarl) and 421 single word instances (143 Bible, 135 biomed and 143 europarl). The organizer provided 917 single word instances (283 Bible, 289 biomed, and 345 europarl) for sub-task 1 and 184 multi-word instances (66 Bible, 53 biomed, and 65 europarl) for sub-task 2 as a test set.

### 3.2 Experimental Settings

We now describe the set of parameters that we have used to design our proposed lexical complexity prediction model. In our CSECU-DSG system, we utilize two state-of-the-art Huggingface transformer models with fine-tuning, including BERT and RoBERTa. We use simpletransformers API (Rajapakse, 2019) to implement our system. We train our system with the provided training data. We trained BERT and RoBERTa model using 5 epochs and set the learning rate of 2.99e-5, save\_steps = 767, and evaluate\_during\_training\_steps = 40. We used the CUDA-enabled GPU and set the manual\_seed = 4 to generate the reproducible results. Default settings were used for the other parameters.

### 3.3 Evaluation Measures

To evaluate the performance of participants’ lexical complexity prediction systems, SemEval-2021 task 1 organizers used different strategies and metrics for sub-task 1 and sub-task 2 (Shardlow et al., 2020). For both sub-task, standard evaluation metrics including Pearson correlation (R), Spearman correlation (Rho), mean absolute error (MAE), mean squared error (MSE), and R-squared (R<sup>2</sup>) were applied to estimate the performance of a system. However, Pearson correlation (R) is considered as the primary evaluation measure for both subtasks of this task.

### 3.4 Results and Analysis

The comparative results of our proposed CSECU-DSG system along with top-5 performing systems (Shardlow et al., 2021a) in sub-task 1 and sub-task 2 are presented in Table 2 and Table 3, respectively. Following the benchmark of SemEval-2021 task 1, participants’ systems are ranked based on the primary evaluation metric Pearson correlation (R) score.

At first, we presented the performance of our proposed method. We also presented the performance of top-5 ranked participating systems and LCP baselines. Here, we see that our proposed method obtained competitive performance against the other top-performing systems. In comparison to the other participants’ methods, we have seen that our system demonstrated a similar kind of performance on both sub-task. This deduces the applicability and generalizability of our system for the complexity estimation of both the single and multi-words.

Team (Rank)	Pearson	Spearman	MAE	MSE	R <sup>2</sup>

Table 3: Comparative results with other selected participants (Sub-task 2).

### 3.5 Discussion

In order to estimate the effect of each component of our CSECU-DSG model, we estimated the performance of the individual model. The summarized experimental results for sub-task 1 and sub-task 2 are presented in Table 4.

From the results, it can be observed that RoBERTa based model performed better compared to the BERT model when considering individual model’s performances. However, combining two models regression scores by using mean increased Pearson correlation score by more than 1% on both subtasks. This deduced the importance of our model fusion.

All three models performed better for multi-words complexity estimation compared to the single word complexity. We have seen a similar kind of trend in other models’ performances reported in Table 2, and Table 3. This demonstrated that estimating the single word complexity is more challenging compared to the multi-words expression. This is because a multi-word expression contains more words, therefore, contains more contextual information that helps the model for complexity estimation compared to the single word.

Method	Single Word	Multi Word
	Pearson	Pearson
CSECU-DSG	0.7716	0.8311
Performance of Individual Model		
–BERT	0.7514	0.8077
–RoBERTa	0.7634	0.8211

Table 4: Performance analysis of individual model.

## 4 Conclusion and Future Directions

In this paper, we presented our approach to the lexical complexity prediction task. We tackled the problem by performing sentence pair regression using two SOTA transformer models including BERT and RoBERTa in a unified architecture. By using pairwise learning, we exploited the contextual relation between sentence-word pairs to estimate the complexity score. Our method achieved competitive scores compared to other participants.

In the future, we have a plan to incorporate various handcrafted features with state-of-the-art neural methods to distill the relationship of sentence-word pairs for complexity estimation.

## Abstract

This paper presents the system we submitted to the first Lexical Complexity Prediction (LCP) Shared Task 2021. The Shared Task provides participants with a new English dataset that includes context of the target word. We participate in the single-word complexity prediction sub-task and focus on feature engineering. Our best system is trained on linguistic features and word embeddings (Pearson's score of 0.7942). We demonstrate, however, that a simpler feature set achieves comparable results and submit a model trained on 36 linguistic features (Pearson's score of 0.7925).

## 1 Introduction

Lexical complexity relates to complexity of words. Its assessment can be beneficial in a number of fields, ranging from education to communication. For instance, lexical complexity studies can assist in providing language learners with learning materials suitable for their proficiency level or aid in text simplification (Siddharthan, 2014). These studies are also a central part of reading comprehension, as lexical complexity can predict which words might be difficult to understand and could hinder the readability of the text. Lexical complexity studies typically make use of Natural Language Processing and Machine Learning methods (Paetzold and Specia, 2016).

Previous similar studies focus on Complex Word Identification (CWI), which is a process of identifying complex words in a text (Shardlow, 2013). In this case, lexical complexity is assumed to be binary - words are either complex or not. LCP Shared Task 2021 addresses this limitation by introducing a new dataset designed for *continuous* rather than *binary* complexity prediction (Shardlow et al., 2021).

In this paper, we describe a *single-word* lexical complexity prediction system. Our goal is to

demonstrate that a simple system can achieve results comparable to more complex ones. Therefore, we focus on feature engineering rather than model tuning.

## 2 Related Work

### 2.1 Lexical Complexity

Over the years, studies on lexical complexity have ranged from research on the overall *readability* enhancement and *text simplification* to studies focusing specifically on lexical complexity.

Some of the earlier work on lexical complexity targeted communication enhancement of medical documents by assessing the familiarity of medical terminology (Zeng et al., 2005). Paetzold and Specia (2013) showed that the absence of lexical simplification in Automatic Text Simplification (ATS) systems yielded texts that readers might still find too complex to understand.

CWI has then gained more interest, and two Shared Tasks have been organised with the goal of establishing state-of-the-art performance in the field. SemEval-2016 Task 11 approached CWI as a *binary* classification task and collected a dataset for English which was annotated by non-native speakers (Paetzold and Specia, 2016). Zampieri et al. (2017) showed that such data annotation approach was not optimal. The second Shared Task addressed the limitations by introducing a multi-lingual dataset for Spanish, German, English and French and approaching the problem as both, a *binary* and a *probabilistic* complexity prediction task (Štajner et al., 2018).

### 2.2 Feature and Model Selection

In lexical complexity prediction tasks, linguistic features and word frequency measures have been proven to be among the most effective features. The winning systems developed for the CWI 2018

Shared Task (Yimam et al., 2018) use various lexical features, such as word N-gram, POS tags, and syntactic dependency parse relations. Moreover, they also include different variants of word frequency features, CEFR levels, and a few more.

As for the choice of algorithms, Gooding and Kochmar (2018) has achieved the best performing systems in English monolingual tasks using classifiers with ensemble techniques, such as AdaBoost with 5000 estimators and the aggregation classifier of Random Forest. The winning systems for multilingual tracks (Kajiwara and Kochi, 2018) also employ random forest models.

### 3 LCP Shared Task 2021 Setup

The LCP Shared Task 2021 aims to predict the complexity value of words in their context. It is divided into two sub-tasks: predicting the complexity score of 1) *single words* and 2) *multi-word expressions*. In this paper, we present a system for the first sub-task.

The Shared Task uses the CompLex corpus (Shardlow et al., 2020). In addition to the target word, it includes contextual information which is represented by a sentence where the word appears and its source or domain: *Bible* (Christodouloupoulos and Steedman, 2015), *Europarl* (Koehn, 2005) or *biomedical texts* (Bada et al., 2012). Each word in the dataset is evaluated by around 7 annotators from English speaking countries. The complexity labels are based on a 5-point Likert scale scheme (*very easy* to *very difficult*). The final dataset consists of 7,662 training and 917 testing instances.

The Shared Task baseline system uses a linear regression model. It is trained on log relative frequency and word length features, resulting in a Mean Absolute Error (MAE) of **0.0867**.

## 4 Methodology

In this section, we describe the methodology that we follow in the design of our system, including the used data, feature engineering and the training steps. The study relies on an in-depth experimentation with features. We aim to find out which linguistic information is the best predictor of lexical complexity.

### 4.1 Data Collection

For the computation of some features, we use additional data sources. We extract word frequencies from nine corpora that cover different do-

main and complexity levels: *BNC corpus*<sup>1</sup>, *Simple Wikipedia and English Wikipedia*<sup>2</sup>, *SubIMDB*<sup>3</sup> and English monolingual corpora from the *OPUS project*<sup>4</sup>: *bible-uedin*<sup>5</sup>, *EMEA*<sup>6</sup>, *Europarl*<sup>7</sup>, *News-Commentary*<sup>8</sup> and *OpenSubtitles 2018*<sup>9</sup>. We additionally use two word lists with annotated CEFR levels (Common European Framework of Reference for Languages, which organises language proficiency in six levels, A1 to C2)<sup>10</sup> and the *Age of Acquisition* dataset<sup>11</sup>.

### 4.2 Features

We consider a) word and sentence-level features (or *linguistic* features), b) *frequency* features and c) *word embeddings*.

On a word level, we compute the linguistic information, i.e. *character*, *syllable* and *phoneme counts*, *universal part-of-speech* tag and *named entity* tag (extracted with Stanza NLP toolkit) (Qi et al., 2020). We also compute scores that pertain to language learning such as *age of acquisition*, *percentage of population that knows the word* and *word prevalence* (Kuperman et al., 2012). Finally, we use two CEFR word lists and split them into five subsets each (one per CEFR level). Each word is assigned a *boolean value* depending whether it appears in one of the subsets.

On a sentence level, lexical complexity is represented by *lexical diversity rate* (*unique* words divided by *all* words). Syntactic complexity and readability are represented by the *average sentence length* and the *Linsear Write* score, which is a readability measure used to assess the difficulty of U.S. military manuals (Klare, 1974). We also make special use of the *OpenSubtitles* frequencies: *vocabulary percentage per CEFR level* is computed by splitting the corpus into five subsets and represents the distribution of words among the five frequency ranges; *difficult word percentage* relates to words containing two and more syllables that do not appear in top 200 most common words in the corpus; *unknown word percentage* represents

<sup>8</sup>News-Commentary

<sup>9</sup>OpenSubtitles 2018

<sup>10</sup>The Oxford 5000 and Kelly list for English

<sup>11</sup>AoA

the percentage of words that do not appear in the corpus at all. The final *text complexity score* is a normalised sum of all sentence-level scores.

Additionally, we calculate different types of *frequencies*, i.e. log relative, absolute (raw), frequency rank (word rank in a frequency list) and ZIPF frequency (Zipf, 1949), from the nine corpora.

Finally, we experiment with pre-trained *word embeddings*, including fastText for English and BERT’s embeddings (Mikolov et al., 2018; Devlin et al., 2018). However, we ablate fastText word embeddings from the final feature set as they slightly degrade the overall performance.

### 4.3 Training, Tuning & Testing

The focus of our study is to achieve the best results through feature engineering rather than model hyperparameter tuning. During all experiments, we utilise the open source Machine Learning software WEKA (Frank et al., 2016) with the default algorithm hyperparameter settings and apply 10-fold cross-validation.

#### 4.3.1 Models

First, we select several Machine Learning algorithms for further experiments with the features. During this step, we use *word* and *sentence-level* features with a subset of *frequency* features.

Due to the nature of the dataset target values, we employ classifiers suitable for regression tasks. Specifically, we use `linear regression` and `Multi-Layer Perceptron`, meta classifiers, such as `Bagging`, `Stacking` and `Random Subspace`, and decision trees, such as `M5P` and `Random Forest`. We obtain the best result and benchmark our approach with `M5P` - a model tree algorithm used for numeric prediction (Table 1). We reach MAE of **0.0638** (Pearson’s score of 0.7811), outperforming the baseline model of the Shared Task (Section 3).

Next, we experiment with different feature groups and combinations with the goal to select the optimal feature subset. We train with the five best performing algorithms in each step but report only the results of the best model.

#### 4.3.2 Ablation Studies

We narrow down the selection for the best performing features based on the three feature groups: *frequency* features, *linguistic* features and *word embeddings*.

Classifier	Pearson	MAE
M5P	<b>0.7811</b>	<b>0.0638</b>
Random SubSpace	0.77	0.0657
Bagging	0.7693	0.0657
Random Forest	0.7655	0.0661
Decision Table	0.7601	0.0665

Table 1: 10-fold cross-validation results on the training set for the top 5 classifiers

We pay special attention to frequency features since the previous work shows that word frequencies are usually among the most informative features (Yimam et al., 2018). First, to figure out the best way to represent frequencies of lower cased word forms, we train the M5P model on different frequency representations: *log relative*, *raw*, *ZIPF* and *frequency rank*. We use only the best frequency representation, log relative frequency, in the following steps. We then test the models with frequencies from various sources.

We also conduct experiments to understand the impact of word embeddings using 300-dimension pre-trained word vectors<sup>12</sup>, and BERT<sup>13</sup> embeddings, where we concatenate layers 7 and 11 (Chronis and Erk, 2020) which gives better results than concatenating or summing the last four hidden layers.

We then conduct the final ablation study. Given the complete set of features, we employ WEKA’s feature selection algorithms and remove the least informative features, one feature at a time. In case it does not result in an improvement, the feature is added back and we continue with the next available feature.

## 5 Results

In this section, we present our results and discuss the key findings. All discussed systems are trained with the `Random Forest` classifier.

### 5.1 Frequency Features

We find that a combination of frequency features from different sources alone can result in high performance (Table 2). In this case, daily spoken language sources, such as film subtitles, seem to be the most informative. However, adding more frequency features does not necessarily improve the results (Tables 2 and 3).

<sup>12</sup>fastText for English

<sup>13</sup>We use `bert-base-uncased` from Hugging Face (Wolf et al., 2020)

Above - harmonicMeanDiff (36 features)	<b>0.7925</b>
Above + best BERT 7-11 (76 features)	<b>0.7942</b>

Table 3: Feature Ablation Experiments

## 5.2 Linguistic Features

During the experiments with the linguistic features, we obtain the best results using a reduced 36 feature combination (Table 4). We find out that syntactic features such as target word *distance* to the syntactic head of the sentence and its *syntactic relation* to the head of the sentence seem to worsen the performance (Table 3). The full list of ablation steps can be found in Appendix A.

Furthermore, removing the *sentence-level* features results in a slight decrease of the overall performance (from Pearson’s score of 0.7925 to 0.7791). It indicates that either word-level information remains the most informative for this task or that a single sentence does not provide sufficient contextual information.

## 5.3 Word Embedding Features

Table 4 shows results for the best systems that are trained on *linguistic* features only, *word embedding* features only and the *combined* set of features.

The system trained on the word embeddings performs significantly worse than the other two systems. BERT embeddings only improve the result if we select a subset of 76 out of the 1536 embedding features with WEKA’s `CfsSubsetEval` (Hall, 1999). The model trained on the combined set of features performs the best, reaching Pearson’s score of **0.7942**. However, the difference between this system and the one trained on linguistic fea-

Feature Combination	#Features	Pearson
36 Linguistic + 76 Embedding	112	<b>0.7942</b>
Linguistic	36	0.7925
BERT Embeddings	1536	0.6999

Table 4: Best systems trained on linguistic, word embedding and the combined features

tures is statistically insignificant. These results indicate that word embeddings are less informative than the linguistic information. Additionally, word embedding computation can be costly in terms of the added complexity and the computational resources. We, therefore, argue that a simpler feature combination is sufficient and submit our second best model to the Shared Task.

## 5.4 Test Set

The submitted system that is trained on 36 linguistic features (Appendix B) is evaluated on the official Shared Task test set and reaches Pearson’s score of **0.7588**, ranking in the upper half of the submitted systems.

## 6 Conclusion

In this paper, we have described the design of our system submitted to the LCP Shared Task 2021 and discussed the key findings of our feature engineering approach. We aimed to design a simple system that would not require much classifier tuning or complex feature computations. Our two best models are trained on the Random Forest classifier with the default hyperparameters. The best system is trained on a 112 feature set which includes word embeddings. The second best system is trained on a simple 36 linguistic feature set. We submit the simple system since the performance difference between the two systems is not significant. The model is placed in the upper half of the Shared Task rankings for the single-word prediction subtask (Pearson’s score of 0.7588), demonstrating how a simple approach can achieve high performance results.

Further analysis of the feature ablation studies confirms that word frequencies seem to be the most informative among all features. We also observe that even though including contextual information does improve the overall result, the performance differences are small. Future research might therefore look into including more contextual information than one sentence. In addition, the perception

of word complexity differs from reader to reader. Future work could target specific reader groups, such as people with dyslexia or second language learners. In this case, the relevant background information of the readers should be included in the annotation and experimentation processes.

## Abstract

We present the technical report of the system called RS\_GV at SemEval-2021 Task 1 on complexity prediction of English words. RS\_GV is a neural network using hand-crafted linguistic features in combination with character and word embeddings to predict the target words' complexity. For the generation of the hand-crafted features, we set the target words in relation to their senses. RS\_GV predicts the complexity well of biomedical terms but it has problems with the complexity prediction of very complex and very simple target words.

## 1 Introduction

Text simplification is the process of modifying a text so that it becomes easy for the reader to understand the meaning of the text without any loss of information. A main part of text simplification is lexical simplification. In lexical simplification, complex words are replaced with easier or more frequent synonyms. Following [Shardlow \(2014\)](#), the process of lexical simplification can be split as follows: I.) identification of complex words in a given text, II.) substitution generation, III.) word sense disambiguation, IV.) synonym ranking, V.) substitution of complex word with the best synonym in correct morphological form.

Following [Shardlow \(2014\)](#), the most common errors in lexical simplification are that the words are not identified as complex or that words are incorrectly identified as complex. One reason might be the approach to predict complex words. So far, in the task called *complex word identification* (CWI), a word in a sentence was labeled as either complex or simple without any range in between. [Shardlow et al. \(2020\)](#) criticize this approach because there is no clear threshold when a word starts to be complex. Hence, they propose a new task called *lexical complexity prediction* (LCP). The aim of

LCP is to predict the complexity of a single word or a multi-word expression on a scale of 0 to 1.

This paper proposes RS\_GV, a model for LCP in the context of the SemEval-2021 task 1 ([Shardlow et al., 2021a](#)). RS\_GV uses hand-crafted features relative to their WordNet senses, Flair embeddings and a neural regressor in a cross-domain and within-domain setting.

## 2 Related Work

Lexical complexity prediction is a new sub-task of lexical text simplification. The aim is to predict the complexity of a single word or a multiword expression on a scale of 0 to 1. The most similar task is CWI. In contrast to LCP, CWI aims at binary classification that determines whether a word is complex or not. As LCP has been mentioned for the first time in the context of this shared task ([Shardlow et al., 2020, 2021a,b](#)), no other related work exists yet. Hence, we outline the state of the art in CWI.

**SemEval-2016 Task 11: CWI** [Paetzold and Specia \(2016\)](#) collated 9200 sentences from the CW Corpus ([Shardlow, 2013](#)), the LexMTurk Corpus ([Horn et al., 2014](#)), and the Simple Wikipedia corpus ([Kauchak, 2013](#)). All these corpora were based on the Simple English Wikipedia (SEW). CWI was treated as a binary classification task, wherein 400 non-native speakers annotated content words in English text. It was observed from the annotations that complex words were shorter, less ambiguous and had a low occurrence in SEW. F-score and G-score were used as the evaluation metrics. The features incorporated by the submitted systems can be seen in [Figure 1](#).

It is shown that the word frequency, lexical, semantic and morphological features play a dominant role in CWI. Besides these, n-gram features were also experimented with by a few systems. Word embeddings were not used extensively.

**CWI Shared Task 2018** Another shared task on complex word identification was organized in 2018 (Yimam et al., 2018). Yimam et al. (2018) collected data from three sources, i.e., professionally written news, WikiNews and Wikipedia, and in four languages, i.e., English, German, French, and Spanish. The shared task was composed of two sub-tasks. Sub-task 1 approached the problem as a binary classification problem and sub-task 2 treated it as a probabilistic classification problem, wherein the score between 0 and 1 indicated the proportion of annotators who considered a word as complex. Native as well as non-native readers annotated the dataset created by Yimam et al. (2017). A word was deemed to be complex if at least one out of twenty annotators labeled it as complex. Based on annotations, it was observed that the systems might perform better when trained on domain-specific data. It was also found that traditional feature engineering-based approaches performed better than neural network and word embedding based approaches. The features incorporated by the submitted systems of 11 teams can be seen in Figure 1.

Figure 1: Features incorporated by the systems submitted to CWI Shared Task 2016 (Paetzold and Specia, 2016) and 2018 (Yimam et al., 2018).

The graph reinstates the fact that frequencies, lexical, semantic and morphological features play a key role in CWI. However, it was observed that as compared to 2016, in 2018, word embeddings were more commonly used.

### 3 Experimental Setup

#### 3.1 Data

The corpus (Shardlow et al., 2020, 2021b) contains 9,476 annotated instances in three new CWI/LCP domains, i.e., bible, political and biomedical texts. For every instance, one target word, its target complexity value and its containing sentence are given.

The complexity value is based on crowd-sourced human ratings of at least 4 and at most 20 persons with residence in the UK, USA, or Australia. Each instance was rated on a 5-point Likert scale from 1 (very easy) to 5 (very difficult). Afterwards, the ratings were averaged and normalized on a continuous scale between 0 and 1, where 0 is easy and 1 is complex.

Each target word occurs in multiple instances and may capture different senses so that each word can be assigned to different complexity values in different instances. For example, *vision* occurs in all sub-domains with different meaning, e.g., ability to see, supernatural experience, and foresight.

Following the corpus description (Shardlow et al., 2020), a target word should only occur in a different sentence but not in the same sentence twice. Unfortunately, in our corpus analysis, we found a few doubled instances but with varying complexity values. For example, *body* is rated within in the same sentence in the biomedical part of the set with complexity values of 0.05 and 0.32 (see Appendix C, Table 9). This variation underlines that LCP is a subjective task, and, hence, a difficult NLP task (see section 5.3).

More details regarding the data, including the data split in training, trial, and test can be found in the shared task paper (Shardlow et al., 2021a).

As a preprocessing step we tokenized the sentences and annotated the tokens with their lemma, part-of-speech, and morphological information using spaCy (Honnibal and Montani, 2017). This linguistic information is the basis of our features.

#### 3.2 Evaluation

The lexical complexity prediction is evaluated, following the shared task instructions (Shardlow et al., 2021a), with e.g., Pearson’s correlation ( $r$ , mainly reported here) and Mean Absolute Error ( $MAE$ ).

#### 3.3 Baselines

We use the baseline results reported by the organizers<sup>1</sup> as comparative results. They use linear regression models with the following features, complexity-average, word length, log word frequency from SUBTLEX and log word frequency combined with word length.

<sup>1</sup>[https://competitions.codalab.org/competitions/27420#learn\\_the\\_details-evaluation](https://competitions.codalab.org/competitions/27420#learn_the_details-evaluation)

## 4 System Description

Our system’s main characteristics are a combination of hand-crafted features, contextualized character embeddings (see subsection 4.1), a sense relative normalization (see subsection 4.2), and a neural network for regression (see subsection 4.4).

### 4.1 Features

Based on the survey of features previously used for complexity estimation of words (see section 2), we decided to combine hand-crafted features and contextualized embeddings. A list of all language resources used for feature generation is provided in Appendix B (see Table 7).

#### 4.1.1 Word and Character Embeddings

Similar as proposed in Gooding and Kochmar (2019); Hartmann and dos Santos (2018), and De Hertog and Tack (2018) we use word and character embeddings. We compare pre-trained non-contextualized word embeddings, i.e., GloVe (Pennington et al., 2014), pre-trained contextualized word embeddings, i.e., ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019), with pre-trained contextualized character embeddings, i.e., stacked Flair (Akbik et al., 2018, 2019a) –a combination of GloVe and Flair– and PooledFlair (Akbik et al., 2019b).

We suggest that the contextualized embeddings perform better on LCP as the context of the target word and the meaning of the sentence are important for words’ complexity. To the best of our knowledge contextualized character embeddings have not been used for CWI or LCP before.

The embeddings are extracted using FLAIR (Akbik et al., 2019a). Details regarding the settings of the word and character embeddings are provided in Appendix B (see Table 8).

#### 4.1.2 Hand-crafted Features

An overview of all hand-crafted features used is visualized in Table 1.

**Readability Assessment Features.** We use the sentence’s readability as a feature because we assume that a token would be perceived as more complex if the entire sentence is complex. We implemented the readability using readability scores which are mainly applicable on texts such as Kincaid et al. (1975), Gunning (1952), Coleman and Liau (1975), Dale and Chall (1948) and Senter and Smith (1967) using textstat (Bansal and Aggarwal,

category	feature	category	feature
Readability Assessment	flesch kincaid grade	Morphological	proper noun
	gunning fog		singular
	coleman liau index		plural
	dale chall readability score		famsize
	automated readability index		HAL frequency
	difficult words		number morphemes
Lexical	*frequency	number prefixes	
	*word length	number roots	
	*number consonants	number suffixes	
	*number vowels	suffix length	
	*number syllables	prefix length	
WordNet	*number hypernyms	*familiarity	
	*number hyponyms	*concreteness	
	*number senses	*imagery	
Lexicon	in wordlists	Psycholinguistic	*m.fullness colorado
Other	named entity		*m.fullness pavio
	word position		*age of acquisition

Table 1: List of all used features sorted by category. An asterisk (\*) indicates whether the feature is normalized relative to its senses or not.

2014). We do not consider readability scores that are applicable on sentences as we could not reproduce certain sentence-level readability methods.

**Lexical Features.** Word length, word frequency and number of syllables are included in the set of lexical features following the methodology explained in Shardlow et al. (2020). The word frequency values are obtained from Sharoff (2006) and the GoogleWeb1T resource (Brants, Thorsten and Franz, Alex, 2006). Besides these, the number of consonants and vowels are also calculated.

**WordNet Features.** Paetzold and Specia (2016) use the number of senses, synonyms, hypernyms and hyponyms among other features to identify complex words. In our study, the number of hypernyms, hyponyms and senses are retrieved from the English WordNet (Fellbaum, 1998).

**Psycholinguistic Features.** Similarly as proposed in Davoodi and Kosseim (2016), we generate psycholinguistic features, e.g., word familiarity and age of acquisition, using the Medical Research Council (MRC) Psycholinguistic Database version 2.0 (Wilson, 1988).

**Morphological Features.** As seen in the survey of CWI shared task, morphological features are often used for this task. Hence, we also use a few morphological features derived by the morphological database MorphoLex-EN (Sánchez-Gutiérrez et al., 2018), e.g., number of prefixes, morphemes, and suffixes. We assume the more morphological rich, the more complicated the word.

**Lexicon-based Features.** As, for example, proposed in AbuRa’ed and Saggion (2018), and Wani et al. (2018), we check if the target word is con-

tained in the Oxford 3000 word list (Dictionaries, 2021) with commonly used words. We assume the more common a word is, the simpler it would be.

**Other Features.** Since it is expected that the corpus contains a lot of named entities, such as person names in the bible subcorpus, we check if a target word is a named entity, as also suggested in Gooding and Kochmar (2018).

The last feature is the position of the target word in the sentence. If a target word occurs more than once in a sentence, we consider the word’s last occurrence. In contrast to AbuRa’ed and Saggion (2018), who normalize the word position by the sentence length, we use the absolute word position because we normalize all features afterwards.

## 4.2 Normalization

The hand-crafted features described above all range on different scales, hence, normalizing is required. The normalization is performed as follows: I.) the synsets of the target word are identified, II.) the values of features for every word in the synset are calculated, III.) the values are normalized using min-max normalization. This is being done to compare words that are related to each other, rather than comparing, for instance, frequencies of unrelated words (glee and joyous as opposed to glee and table). In this manner, we are normalizing all the values within a range of 0-1, but by comparing each word with a related word in the synset in which it is present. For words that appear in multiple synsets, we take an average of the normalized values.

As not all features could be normalized relative to their sense (see Table 1), e.g., readability features, we normalized them using scikit-learn’s MinMaxScaler (Pedregosa et al., 2011).

## 4.3 Feature Sets

We create different feature sets considering the normalizing strategies in combination with all character and word embeddings. For the hand-crafted features, we either used the 14 sense relative features, all 34 minmax normalized features, or the 14 sense relative features combined with the missing 20 features minmax normalized (both). All feature sets are listed in Table 2.

## 4.4 Model

RS\_GV’s structure is a more simple version of the structure proposed in De Hertog and Tack (2018), containing linear layers instead of convolutional

layers. Our model is a simple feed-forward neural network with two input layers –one for the hand-crafted features and one for the embedding features–, both followed by a linear hidden layer. Both feature layers are concatenated in another hidden linear layer. It is finally followed by a linear output layer which is activated using the rectified linear unit function (ReLU). We also use stochastic gradient descent (SGD) optimization function. L1Loss as implemented in scikit-learn (Pedregosa et al., 2011) or another mean absolute error loss function seems best for our purpose of predicting continuous labels in a regression task. Following easy stopping, we chose 250 epochs for our model. All hyperparameters with which our model performs best are listed in Appendix A (see Table 5).

RS\_GV can be trained either across all domains at once (*cross-domain*) or on each domain separately (*within-domain*).

## 4.5 Implementation

The system is implemented in Python 3.8 and PyTorch 1.6 (Paszke et al., 2019) using the packages listed in Appendix B (see Table 6). The code of the system is available in our GitHub repository: <https://github.com/gayatrivenugopal/SharedTask-LPC2021>.

## 5 Results

### 5.1 Ablation Tests / Error Analysis

In this section, we report on different approaches made during developing RS\_GV. We compare the results on the trial data using the different feature sets, and a within and a cross domain approach. In the following, we report the average of Pearson correlation on 10 system runs.

#### 5.1.1 Feature Sets

The system’s performance considering all different feature sets is summarized in Table 2.

Embed.	HCF	$r$	SD	Embed.	HCF	$r$	SD
GloVe	sense rel.	0.7654	0.0123	Flair	sense rel.	0.8002	0.0056
GloVe	minmax	0.7721	0.0114	Flair	minmax	0.8007	0.0039
GloVe	both	0.7689	0.0073	<b>Flair</b>	<b>both</b>	<b>0.8027</b>	0.0051
ELMo	sense rel.	0.7648	0.0103	PooledFlair	sense rel.	0.7331	0.0050
ELMo	minmax	0.7667	0.0119	PooledFlair	minmax	0.7685	0.0068
ELMo	both	0.7752	0.0118	PooledFlair	both	0.7537	0.0051
BERT	sense rel.	0.7204	0.0085				
BERT	minmax	0.7260	0.0088				
BERT	both	0.7178	0.0134				

Table 2: Results of all feature sets reporting Pearson correlation  $r$  (average of 10 runs) on the trial data set. The standard deviation is provided in the last column.

**Hand-crafted Feature Sets.** Considering all embedding feature sets (see Table 2), RS\_GV performs often best and with a comparative low standard deviation (see Table 2) with the hand-crafted feature set `both` (e.g.,  $r_{flair}=0.8027, \pm 0.0051$ ) compared to `sense relative` (e.g.,  $r_{flair}=0.8002, \pm 0.0056$ ) and `minmax` (e.g.,  $r_{flair}=0.8007, \pm 0.0039$ ). Hence, in the following, we report the results only on the hand-crafted feature set `both`.

**Embedding Feature Sets.** A comparison between the character embeddings and the word embeddings (see Table 2) shows that `PooledFlair` ( $r=0.7537, \pm 0.0051$ ) could outperform BERT ( $r=0.7178, \pm 0.0134$ ) but `ELMo` could also outperform `PooledFlair` ( $r=0.7752, \pm 0.0118$ ). `Flair` ( $r=0.8027, \pm 0.0051$ ) could outperform all other embedding feature sets.

Surprisingly, RS\_GV with the non-contextualized embeddings feature set (`GloVe`,  $r=0.7689, \pm 0.0073$ ) could outperform all systems with contextualized embeddings except `Flair` ( $r=0.8027, \pm 0.0051$ ) and `ELMo` ( $r=0.7752, \pm 0.0118$ ). It seems that the impact of the contextualization of the embeddings is not as high as expected.

As a compromise of contextualized vs non-contextualized and character vs word embeddings, we use stacked `Flair` embeddings. They combine the forward and backward versions of `Flair` contextualized character embeddings with `GloVe` non-contextualized word embeddings.

### 5.1.2 Cross-domain vs. within-domain

In contrast to the insight of Yimam et al. (2018), RS\_GV performs on average better using the cross-domain approach ( $r=0.8027, \pm 0.0051$ ) than the within-domain approach ( $r=0.7823, \pm 0.0235$ ). The standard deviation of the within-domain approach implies that the model is not as robust as the cross-domain approach. Roughly 3000 instances per domain might be too less to train a robust LCP model with a neural network.

### 5.1.3 Deep Learning vs. Machine Learning

We compare the results of our deep learning approach of RS\_GV with a machine learning regression, i.e., linear regression of scikit-learn. As a result, the neural network and `Flair` ( $r=0.8027, \pm 0.0051$ ) significantly improve LCP compared to the machine learning regression ( $r=0.6945$ ) using only hand-crafted features. Hence, we can confirm the results of the CWI shared task 2018, character embeddings and neural networks do improve LCP.

## 5.2 Submitted Results

Following the previously described ablation tests, we chose to submit the results of the cross-domain approach and the within-domain approach. Both use a deep learning regressor and stacked `Flair` embeddings in combination with the hand-crafted feature set `both`. This section presents the official results of our system RS\_GV on the test set at SemEval 2021 Task 1 sub-task 1 (see also Table 3).

With a Pearson correlation coefficient of  $r=0.7478$  our system with the within-domain outperforms the cross-domain approach on the test data ( $r=0.7316$ ). Officially, RS\_GV ranks on place 34 of 54. The best system proposed by the team *JUST BLUE* achieved  $r=0.7886$ .

Comparing our submitted results with the results on an average of 10 runs (see Table 3), the cross-domain approach can outperform the within-domain approach on the test and trial data.

Overall, both approaches achieve better results than each of the baselines.

Setting or Team	Version	trial $r$	test $r$
within-domain	submission	<b>0.8156</b>	<b>0.7478</b>
cross-domain	submission	0.7978	0.7316
within-domain	average	0.7823	0.7287
cross-domain	average	<b>0.8027</b>	<b>0.7408</b>
Complexity-average	baseline	-	
Length	baseline	0.1589	
Log Frequency	baseline	0.5287	
Log Frequency & Length	baseline	<b>0.5376</b>	
JUST BLUE ()	best team	<b>0.8340</b>	<b>0.7886</b>

Table 3: Results using the trial (3rd) and test dataset (4th column) using Pearson correlation  $r$  for evaluation. The first block contains our submitted and averaged results of 10 runs using `Flair` and `both`. The second block reports the results of the baselines and the third block the results of the best performing system.

## 5.3 Error Analysis

The submitted results reveal that RS\_GV cannot stick with the shared task’s best performing systems. This section presents insights regarding the problems and strengths of RS\_GV on the test data.

**Domain-specific Results.** The subcorpora differ regarding their lexical complexity: The biomed subcorpus has the highest average of lexical complexity in the single word dataset (0.325) and the europarl subset the lowest average (0.286). When we train and predict the lexical complexity per domain,

we can observe the same ranking of the complexity prediction per domain as in [Shardlow et al. \(2020\)](#): The lexical complexity of the europarl domain is most difficult to predict for RS\_GV, whereas the biomedical subcorpus is most easy (see [Table 4](#)).

Domain	Feature set	$r$ (n=10)	SD
all	Flair + both	0.7823	0.0235
bible	Flair + both	0.7177	0.0182
biomed	Flair + both	0.8585	0.0042
europarl	Flair + both	0.7444	0.0089

Table 4: Results of within-domain approach and results per domain using the [trial](#) dataset for evaluation. The Pearson correlation  $r$  is an average of 10 system runs. The standard deviation is provided in the last column.

**High vs. Low Complexity.** It seems that our system can predict complex words better than easy words. However, when splitting the test dataset by complexity value and not by domain, RS\_GV performs poorly on very complex words (complexity value  $> 0.666$ ,  $r=0.0125$ ,  $\pm=0.0542$ ,  $n=12$ ), which might be again due to too less training samples ( $n=105$ ) for the neural network.

Furthermore, the system performs poorly for very easy words (complexity value  $<0.2$ ,  $r=0.0873$ ,  $\pm=0.0272$ ,  $n=188$ ) although roughly 20% of the training samples ( $n=1600$ ) are in this complexity area. We have not found a reason for it yet.

**Homonym-specific Results.** This SemEval task aims at predicting word complexity of tokens in different context including different meanings. Looking more closely on homonyms, on the one hand, different complexity values are assigned to different meanings of a homonym, e.g., vision, but on the other hand, similar complexity values are assigned to a homonym, e.g., resolution. Hence, there is no clear interpretation of how to predict their complexity. This problem is reflected in RS\_GV, our system predicts only slightly different complexity values per homonyms. It seems, that RS\_GV can somehow differentiate the different meaning of the words but overall it differentiate not good enough to perform well in their lexical complexity prediction.

The examples also show the importance of the multi-word LCP task, hence "account" is part of light verb constructions as "to give account" and "to take into account".

**Context-specific Results.** A few samples contain the same token in the (nearly) same sentence, but the complexity values of them are varying (see [Appendix C, Table 9](#)). Removing these 6 out of overall 917 samples of the test data, the system output already improve from 0.7316 to 0.7334. This underlines that LCP is a subjective task and, hence, difficult to predict for machines.

**Linearity.** We tested the data for linearity in order to justify the usage of linear regression. We could not find any linearity between the individual features and the complexity value. The missing linearity might be a reason why RS\_GV could not keep with other systems of the shared task.

## 6 Discussion and Conclusion

We described our model named RS\_GV which was submitted to SemEval Task 2021: Task 1 regarding lexical complexity prediction. We propose a neural network with a combination of hand-crafted and word/character embeddings to approach the task. Our analysis shows that normalization of hand-crafted features using WordNet senses achieves better results than using only a minmax normalization. Furthermore, we figured out that RS\_GV predicts lexical complexity best using a combination of non-contextualized word embeddings and contextualized character embeddings.

In contrast to other shared tasks results, our cross-domain approach achieves better results than the domain-specific approach. A domain-specific approach may need more data to perform reliably.

Furthermore, our neural regressor seems problematic, since it shows some variance in the results on average and the current dataset might be too small for regression with neural networks.

## 7 Future Work

In future works, we plan to improve the character and word embeddings. We could fine-tune the embeddings on our data or use domain-specific pre-trained embeddings, which fits the datasets' domains, e.g., BioFlair ([Sharma and Jr, 2019](#)).

Furthermore, we could calculate more hand-crafted features or edit the current ones. For example, the implementation of sentence readability formulas seems more promising than the misuse of text readability formulas on sentences.

The current neural network contains only a few linear layers, an extension using, e.g., convolutional layers for feature selection seems promising.

## Acknowledgements

We thank the SemEval-2021 Task 1 organizers for preparing and organizing the shared task.

This research is part of the PhD-program "Online Participation", supported by the North Rhine-Westphalian (German) funding scheme "Forschungskolleg".

We gratefully acknowledge NVIDIA Corporation's support with the donation of the Titan Xp GPU used for this research.

## Abstract

In this paper, we present three supervised systems for English lexical complexity prediction of single and multiword expressions for SemEval-2021 Task 1. We explore the use of statistical baseline features, masked language models, and character-level encoders to predict the complexity of a target token in context. Our best system combines information from these three sources. The results indicate that information from masked language models and character-level encoders can be combined to improve lexical complexity prediction.

## 1 Introduction

SemEval 2021 Task 1 (Shardlow et al., 2021) focuses on predicting the complexity of a target token in an English sentence on a scale from 0 (not very complex) to 1 (very complex). For example, the token *land* in the example below is judged to have a low complexity of 0.19.

1. Our land will yield its increase.

On the other hand, the token *doxycycline* in the following example is judged to have a relatively higher complexity of 0.75.<sup>1</sup>

2. The reason these two lines were unresponsive to doxycycline is unknown.

The dataset for this task was originally proposed in Shardlow et al. (2020), and includes sentences from three sources: a translated bible, European Parliament proceedings, and a biomedical corpus. This shared task contains two sub-tasks with the first focusing on lexical complexity for single words,

<sup>1</sup>These example sentences and complexity scores are taken from the dataset provided for the shared task.

which will be referred to as *SINGLE*, and the second focusing on complexity of multiword expressions, which will be referred to as *MULTI*.

In this paper, we explore the use of statistical baseline features, masked language models, and character-level encoders to predict the complexity of a target token in context. We first consider these approaches individually and then consider supervised methods for combining them. We evaluate our models with Pearson correlation (R), Spearman correlation (Rho), mean absolute error (MAE), mean square error (MSE), and R-squared (R2). We apply all our models to both sub-tasks and find that we achieve our best results with a model that combines all three sources of information — baseline features, masked language modeling, and character-level encoding. Specifically, we achieve our best results with respect to Pearson correlation — the evaluation measure used for the official shared task system ranking — using a model that combines complexity predictions from two approaches, one based on a character-level encoder, and the other based on a masked language model, which further incorporates the baseline features, using support vector regression. Although we achieve our best results using this approach on both *SINGLE* and *MULTI* with respect to Pearson correlation, we note substantial variation in performance with respect to the other evaluation metrics on *SINGLE*. This suggests that future work could further explore the variation in performance of this model on single and multiword expressions

## 2 Model components

In this section, we describe three approaches to lexical complexity prediction. In Section 3 we then describe how these approaches are combined into systems that we submitted as official runs to the shared task.

## 2.1 Baseline features

We extract a set of seven statistical baseline features. These features include the length of the target token, the frequency of the token in SubtlexUS (Brysbaert and New, 2009), the frequency of the token in SubtlexUK (van Heuven et al., 2014), a binary feature indicating whether the token is an MWE, and a binary feature for each text type the instances were taken from (i.e., biomedical text, European Parliament proceedings, and the bible) indicating whether the instance is from that corpus. For MWEs, the frequency features are calculated as the average of the frequencies of the component words in the MWE. In the case that frequency information is not available for a word in SubtlexUS or SubtlexUK, the frequency of that word is set to the average frequency for words in the dataset for which frequency information is available. These features are combined with the approach described in Section 2.3, and the systems presented in Section 3.

## 2.2 Character-level encoder

This approach is based on a character-level encoder, which has three parts. The first part is a pre-trained character-level language model which gets a sentence containing a target expression as its input and its last hidden state is used as an embedding representing the input sentence. This language model uses a bi-directional GRU with a hidden layer size of 256. It is trained on the sentences in the trial and training data provided for the shared task.

The second part is a similar pre-trained GRU bi-directional character-level language model, which receives the target word as its input and the first hidden state is initialized with the embedding of the input sentence. The last hidden state is then passed to the systems described in Section 3 for complexity prediction.

In this approach, our hypothesis is that the hidden state of the first language model provides a representation for the input sentence, and the language model can encode the complexity of the target word by having access to a representation of the sentence in which the target word appears. Figure 1 shows a diagram of this model.

## 2.3 Masked language model

In this approach, we recruit BERT (Devlin et al., 2019) as a masked language model to estimate the probability for the target token in context. Collins-

Thompson and Callan (2004) show that language modeling can be used to predict reading difficulty, and therefore we hypothesize that language modeling can also be useful for predicting lexical complexity.

We use the large uncased pretrained BERT model, which consists of 16 heads and 24 layers of 1024 hidden units each. Given a sentence, we replace the target token with the special *[MASK]* token and use the modified sentence as input to BERT to obtain the probability of the target token. BERT’s tokenizer can split tokens into multiple pieces. The probability of a target token (single word or multiword expression) is therefore calculated by averaging the probabilities of its parts.

The probability of the target is then used as a feature, alongside the baseline features from Section 2.1, in a support vector regressor (SVR) to predict complexity. The SVR uses an rbf kernel, with a kernel coefficient of 0.1, epsilon of 0.1, and a regularization of 1/100. The output of the SVR is used as a feature in the systems described in Section 3. Figure 2 shows a diagram of this model.

## 3 Submitted Systems

In this section, we describe how we combine the approaches discussed in Section 2 to form systems that were submitted as official runs to the shared task. We selected these systems because they achieved the best performance in a ten-fold cross-validation experiment on the combined trial and training data, in terms of Pearson correlation (R), the evaluation metric used to rank systems in the shared task. The performance of each submitted system, a baseline in which we train logistic regression on the baseline features from Section 2.1, and the masked language model approach described in Section 2.3 (our best-performing model that was not submitted to the shared task), are shown in Tables 1 and 2 for *SINGLE* and *MULTI*, respectively.

### 3.1 System 1

In this system, we concatenate the output of the character-level encoder approach discussed in Section 2.2 with the baseline features from Section 2.1. This representation is then used as input to a feed-forward network to predict the complexity. The feed-forward network has two fully connected hidden layers with sizes 128 and 64, and ReLU activation functions. We train this network using Adam optimizer (Kingma and Ba, 2015) with a

Figure 1: The character-level encoder model.

Figure 2: A diagram of the masked language model.

Model	R	Rho	MAE	MSE	R2
<i>Baseline</i>	0.618	0.633	0.080	0.011	0.378

learning rate of 0.001 for 100 epochs. This system is referred to as *System<sub>1</sub>* from heron.

### 3.2 System 2

In this system, we concatenate the feature from the masked language model approach described in Section 2.3 with the output from the system described in Section 3.1 to create a 2-dimensional vector. This vector is then used as input to an SVR to predict complexity.

We perform a grid search to tune the hyperparameters of the SVR via evaluating its performance on the validation set. We achieve our best results with an SVR using a polynomial kernel with a degree of 3, a kernel coefficient of 1, a regularization parameter of 100, a stopping tolerance of 1, and a gamma value of  $1/\text{number of training instances}$ . We use these parameters for all further experiments with this system, which we refer to *System<sub>2</sub>*.

### 3.3 System 3

In this system, similar to *System<sub>1</sub>*, we concatenate the output of several approaches from Section 2, and then pass this representation to a fully connected network to predict the complexity. Here we concatenate the baseline features with the output of both the character-level encoder approach (Section 2.2) and the masked language model approach (Section 2.3). We use the same fully-connected net-

work structure, and training settings, as for *System<sub>1</sub>*. We refer to this approach as *System<sub>3</sub>*.

## 4 Results

In this section we present our results with respect to the five evaluation metrics. We evaluate our models on the single word sub-task (*SINGLE*) first and then on the multiword expressions sub-task (*MULTI*). Each system is trained on all training instances from both *SINGLE* and *MULTI*.<sup>2</sup> We include the performance of our baseline to show that all submitted systems continue to outperform this baseline model on the test data.

In Table 3, we show the performance of our systems on *SINGLE*. *System<sub>2</sub>* achieves the best results with respect to *R*, which is the metric used to rank submissions in the shared task. Interestingly, however, this is the only metric for which *System<sub>2</sub>* outperforms the other systems. *System<sub>3</sub>* — which like *System<sub>2</sub>* incorporates information from both the character-level encoder and masked language model approaches — performs worst of these three systems with respect to *R*, but achieves the best performance amongst these systems for MSE, MAE, and R2.

In Table 4, we show the performance of our models on *MULTI*. In contrast to the results on *SINGLE*, these results show *System<sub>2</sub>* consistently performs

<sup>2</sup>The training data for the approach described in Section 2.3 also includes instances from the provided trial data from both *SINGLE* and *MULTI*.

best for all evaluation metrics. The improvement of *System*<sub>2</sub> — which uses information from both the character-level encoder and masked language model approaches — over *System*<sub>1</sub> in particular — which does not incorporate information from the masked language model — suggests that these two sources of information can be combined to improve lexical complexity prediction.

## 5 Conclusions

We evaluated three systems for lexical complexity prediction of single and multiword expressions for SemEval 2021 Task 1. These systems incorporated information from statistical baseline features, a character-level encoder approach, and a masked language model approach. We found that a system that combined the complexity predictions of the character-level encoder approach and the masked language model approach, which further incorporates the statistical baseline features, using support vector regression performed best amongst our submitted systems with respect to Pearson correlation on both the single word and multiword expressions sub-tasks. This approach further performed best of our submitted systems with respect to all evaluation metrics on the multiword expression sub-task, although this was not the case for the single word sub-task.

In future work, the relationship between the sub-tasks, models, and evaluation metrics warrants further exploration, including studying the effect that the type of the target expression, i.e., single word or multiword expression — has on the performance of the models with respect to the various evaluation metrics.

# ANDI at SemEval-2021 Task 1: Predicting complexity in context using distributional models, behavioural norms, and lexical resources

Armand Rotaru  
Independent researcher  
armand.rotaru@gmail.com

## Abstract

In this paper we describe our participation in the Lexical Complexity Prediction (LCP) shared task of SemEval 2021, which involved predicting subjective ratings of complexity for English single words and multi-word expressions, presented in context. Our approach relies on a combination of distributional models, both context-dependent and context-independent, together with behavioural norms and lexical resources.

## 1 Introduction

In our day-to-day life, outside the laboratory, we almost never come across single words or pairs of words, in isolation. Instead, such verbal stimuli are typically embedded within sentences or phrases, and our understanding of individual words and word pairs is influenced by their linguistic contexts (e.g., by disambiguating their intended meaning). However, almost all behavioural norms collected so far focus only on single words or word pairs (Johns, Jamieson, & Jones, 2020).

Therefore, the Lexical Complexity Prediction (LCP) shared task (Shardlow, Evans, Paetzold, & Zampieri, 2021), hosted at SemEval 2021, constitutes a timely and valuable contribution to the study of context-dependent semantics. The task requires competitors to predict subjective ratings of complexity for words or pairs of words, presented within sentences. As mentioned by the organisers, being able to automatically estimate contextualised complexity ratings would have several practical applications, such as detecting and simplifying portions of text that might be particularly difficult

to understand for second language learners, and people with low literacy levels (e.g., as a result of suffering from a reading impairment).

The dataset for the competition is CompLex 2.0 (Shardlow, Cooper, & Zampieri, 2020; Shardlow, Evans, & Zampieri, 2021), consisting of passages from the Bible, the proceedings of the European Parliament, and biomedical journal articles. The training data covers 7,662 single words (2,574 bible, 2,512 europarl, and 2,576 biomed), and 1,517 multi-word expressions (505 bible, 498 europarl, and 514 biomed). The test data covers 917 single words (283 bible, 345 europarl, and 289 biomed), and 184 multi-word expressions (66 bible, 65 europarl, and 53 biomed).

In this paper we describe our submission to the competition, based on distributional models, both context-dependent and context-independent, as well as behavioural norms/lexical resources<sup>1</sup>. The best results are obtained by combining the three classes of predictors. However, the improvement in performance over using just context-independent models is small, and, in practice, might be compensated by their impressive vocabulary size and ease of use.

## 2 General Description

In order to predict word complexity in context, we combined information from three type of sources, namely behavioural norms/lexical resources, and distributional models. With respect to the latter, we included two distinct classes of models:

- context-independent models, which output the same vector representation for a given word, regardless of the context in which the word is encountered;

---

<sup>1</sup> <https://github.com/armandrotaru/TeamAndi-LCP>

- context-dependent models, which output a potentially different representations for a given word, as a function of the context in which the word is presented.

Our approach was very similar to that employed in (Rotaru, 2020), for predicting ratings of concreteness in context.

Firstly, we used behavioural norms collected for a wide variety of psycholinguistic factors, as well as lexical resources. More specifically, we focused on norms for concreteness (Brysbaert, Warriner, & Kuperman, 2014; Paetzold & Specia, 2016), imageability (Paetzold & Specia, 2016), semantic diversity (Hoffman, Lambon Ralph, & Rogers, 2013), age of acquisition (Kuperman, Stadthagen-Gonzalez, & Brysbaert, 2012; Paetzold & Specia, 2016), familiarity (Paetzold & Specia, 2016), emotional dimensions (i.e., valence, arousal, and dominance; Mohammad, 2018), and sensorimotor dimensions (i.e., modality strengths for the tactile, auditory, olfactory, gustatory, visual, and interoceptive modalities; interaction strengths for the mouth/throat, hand/arm, foot/leg, head excluding mouth/throat, and torso effectors; Lynott, Connell, Brysbaert, Brand, & Carney, 2019). We also included complexity ratings (Maddela & Xu, 2018), lexical decision response times and accuracies (Keuleers, Lacey, & Brysbaert, 2012), contextual diversity counts (Van Heuven, Mandera, Keuleers, & Brysbaert, 2014), frequency counts (Van Heuven et al., 2014; Lin et al. 2012), prevalence counts (Brysbaert, Mandera, McCormick, & Keuleers, 2019), and CEFR word lists (Council of Europe, 2001). Nearly all these measures are correlated with word complexity.

Secondly, we employed context-independent distributional models, namely Skip-gram (Mikolov, Chen, Corrado, & Dean, 2013), GloVe (Pennington, Socher, & Manning, 2014), and ConceptNet NumberBatch (Speer, Chin, & Havasi, 2017). Such models have been used in order to accurately predict a range of psycholinguistic variables (e.g., Hollis, Westbury, & Lefsrud, 2017; Utsumi, 2020), which suggests that they could be useful in accounting for complexity ratings.

Thirdly, we employ context-dependent distributional models, namely BERT (Devlin, Chang, Lee, & Toutanova, 2019), RoBERTa (Liu et al., 2019), ELECTRA (Clark, Luong, Le, & Manning, 2020), ALBERT (Lan et al., 2020), and DeBERTa (He, Liu, Gao, & Chen, 2020). Given that such models achieve human-level

performance in various linguistic tasks (e.g., those in the GLUE benchmark; Wang et al., 2018), and that they were designed to process rich contextual information, they could be a valuable tool for predicting ratings of complexity in context.

### 3 System Description

We tested three groups of predictors, both in isolation and combined. The first group was obtained from comprehensive datasets of subjective ratings (concreteness, age of acquisition, etc.), task performance measures (i.e., response times and accuracies in the lexical decision tasks), as well as frequency, contextual diversity, and prevalence counts, plus CEFR word lists (see the references from the beginning of the previous section). In order to extend the coverage of the subjective ratings, we did not use the original data, but instead relied on extrapolated ratings for more than 70,000 words. The extrapolation was based on the Skip-gram, GloVe, and ConceptNet NumberBatch models, using linear regression over the concatenated vector dimensions. For the (already extrapolated) ratings from (Paetzold & Specia, 2016), as well as for the frequency, contextual diversity, and prevalence counts, we employed only the normed values, as they already have very good coverage. We also used only the original lexical decision data, given that response times and accuracies are difficult to extrapolate, and did not try to extend the CEFR word lists, due to methodological difficulties. For the single word datasets, we employed all the previously mentioned factors, whereas for the multi-word expression datasets, we only employed our own extrapolated factors.

The second group was generated from Skip-gram, GloVe, and ConceptNet NumberBatch embeddings. The vocabulary of the models was that described in the discussion above.

For the first two sources of information, and for each selected variable  $V$  (e.g., semantic diversity), we generated either four predictors, in the case of the single word datasets, or nine predictors, in the case of the multi-word expression datasets. The single word predictors consisted of  $V(w)$ ,  $V(c)$ ,  $V(w) * V(c)$ , and  $\text{abs}(V(w) - V(c))$ , while the multi-word expression predictors consisted of  $V(w_1)$ ,  $V(w_2)$ ,  $V(c)$ ,  $\text{abs}(V(w_1) - V(c))$ ,  $\text{abs}(V(w_2) - V(c))$ ,  $\text{abs}(V(w_1) - V(w_2))$ ,  $V(w_1) * V(c)$ ,  $V(w_2) * V(c)$ ,  $V(w_1) * V(w_2)$ , where:

- $V(w)$  denotes the value of  $V$  corresponding to the single word  $w$  (e.g.,  $w = \text{“sons”}$ ). If  $w$  is not present in our norms/models, we set  $V(w)$  to the average value of  $V$ , computed over the entire vocabulary;
- $V(w_1)$  and  $V(w_2)$  denote the values of  $V$  corresponding to the words  $w_1$  and  $w_2$  (e.g.,  $w_1 = \text{“skillful”}$ ,  $w_2 = \text{“workman”}$ ), that make up the multi-word expression  $w_1 w_2$  (i.e.,  $w_1 w_2 = \text{“skillful workman”}$ ). As before, if  $w_1$  and/or  $w_2$  are not present in our norms/models, we set  $V(w_1)$  and/or  $V(w_2)$  to the average value of  $V$ , computed over the entire vocabulary;
- $V(c)$  denotes the value of  $V$  corresponding to the context  $c$  in which the single word  $w$ , or multi-word expression  $w_1 w_2$ , are encountered (e.g.,  $w = \text{“sons”}$ ,  $c = \text{“The ____ of Perez: Hezron, and Hamul.”}$ ; or  $w_1 w_2 = \text{“skillful workman”}$ ,  $c = \text{“He made it the work of a ____.”}$ ). Computing this value involves calculating the average  $V(c) = \frac{\sum_{i=1}^N V(c_i)}{N}$ , where  $V(c_i)$  is the value of  $V$  corresponding to the  $i$ -th context word, calculated as described previously, and  $N$  is the number of context words.

These predictors allowed us to include both the individual contributions of the single word  $w$ , or the multi-word expression  $w_1 w_2$ , and the context  $c$ , as well as certain interactions between the former and the latter.

The third group was derived from the BERT, RoBERTa, ELECTRA, ALBERT, and DeBERTa models. We used the standard (base) versions of each model (i.e., without task-specific fine-tuning), as described in the original papers, with the exception of ELECTRA, where we employed the small, base, and large versions of the model. The implementations of the models were all obtained from the Hugging Face repository (Wolf et al., 2020). The predictors consisted only of the activations for the single word  $w$ , or the multi-word expression  $w_1 w_2$ , averaged over the last four hidden layers.

To predict ratings of complexity in context, we employed ridge regression ( $\lambda = 3000$ ), for the single word dataset, and a combination of ridge regression ( $\lambda = 1250$ ) and gradient-boosted decision trees, for the multi-word expression dataset, after zero centering all the aforementioned predictors.

## 4 Results and Discussion

The results for English are shown Figure 1, for various sets of predictors and regularization strengths. For reasons of space, we only present the results for ridge regression, but note that similar patterns of performance are obtained for gradient-boosted decision trees and other types of models, such as shallow neural networks. Results are averaged over 10 rounds of 10-fold cross-validation, using only the training dataset.

The results indicate that context-independent models (Fig. 1b) outperform behavioural norms (Fig. 1a), and context-dependent models (Fig. 1c-f). A likely reason for the superiority of context-independent models over context-dependent models is the fact that the former were trained on huge corpora (i.e., 100-840 billion tokens), while the latter were trained on considerably smaller corpora (i.e., 3-33 billion tokens). However, in spite of this significant training disadvantage, context-dependent models produce competitive levels of performance, a finding which can likely be attributed to several factors, such as the highly non-linear integration of contextual information, the use of self-attention mechanisms, and that of more sophisticated learning objectives.

Combining the three classes of predictors produces a relatively small improvement in predictive performance, as compared to relying on any single class. This reflects a very high degree of redundancy between the complexity-related information present in the three types of predictors.

Interestingly, even for the largest set of predictors, consisting of 13,400 variables per 1,517 data points, the degree of regularization does not appear to matter much, indicating little overfitting.

Finally, there is a small, but systematic difference in performance between single words and multi-word expressions, in favour of the latter, even though the training set for single word stimuli is roughly five times larger than that for multi-word stimuli. A potential explanation for this finding might be that the individual variability in meaning for multi-word expressions is smaller than that for single words, given that expressions should be more informative than single words, in virtue of their length (i.e., two words vs one word).

Within the competition, our models ranked 4<sup>th</sup> ( $r = .78$ ,  $\rho = .73$ ,  $MAE = .064$ ), in the single word sub-task, and 6<sup>th</sup> ( $r = .85$ ,  $\rho = .84$ ,  $MAE = .067$ ), in the multi-word expression sub-task.

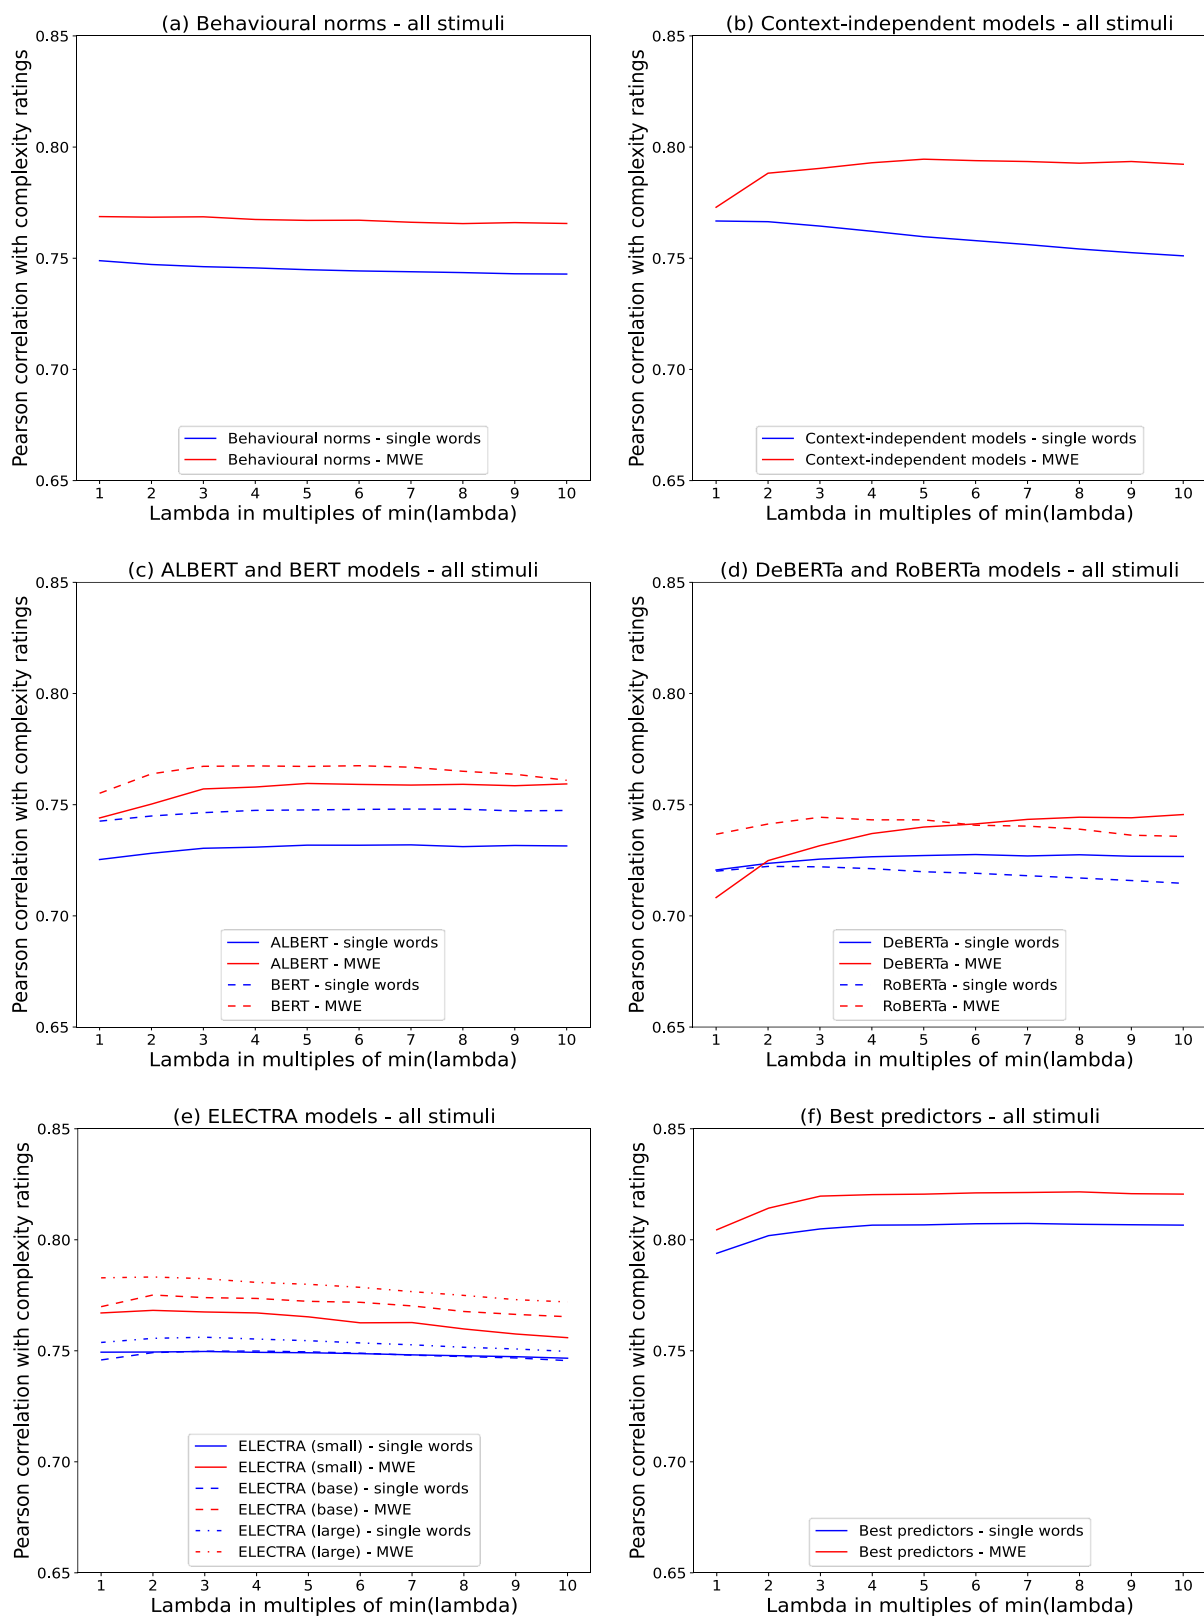

Figure 1. Pearson correlations between predicted and actual complexity ratings, for various groups of predictors and regularization strengths (i.e., values of  $\lambda$ ). For single words, in subfigures (a)-(e),  $\min(\lambda) = 100$ , while in subfigure (f),  $\min(\lambda) = 400$ . For multi-word expressions, in subfigures (a)-(e),  $\min(\lambda) = 50$ , while in subfigure (f),  $\min(\lambda) = 200$ .

## 5 Conclusions

Our results suggest that several approaches can be quite successfully employed in order to predict ratings of complexity in context, for both single words and multi-word expressions. In terms of performance, the best predictors are those derived from context-independent models (e.g., Skip-gram), but relatively good results can be obtained also by using context-dependent models (e.g., BERT) and behavioural norms (e.g., subjective ratings of familiarity). Moreover, given that their vocabulary covers a remarkable number of words (i.e., more than 500 thousand, for each of the Skip-gram, GloVe, and ConceptNet NumberBatch models), and that they are very easy to use off-the-shelf, context-independent models represent a particularly promising approach to predicting ratings of complexity in context.

## Abstract

Predicting the complexity level of a word or a phrase is considered a challenging task. It is even recognized as a crucial step in numerous NLP applications, such as text rearrangements and text simplification. Early research treated the task as a binary classification task, where the systems anticipated the existence of a word's complexity (complex versus uncomplicated). Other studies had been designed to assess the level of word complexity using regression models or multi-labeling classification models. Deep learning models show a significant improvement over machine learning models with the rise of transfer learning and pre-trained language models. This paper presents our approach that won the first rank in the SemEval-task1 (sub task1). We have calculated the degree of word complexity from 0-1 within a text. We have been ranked first place in the competition using the pre-trained language models BERT and RoBERTa, with a Pearson correlation score of 0.788.

keywords: Neuro-linguistic programming (NLP), Lexical Complexity Prediction(LCP), Deep Learning, RoBERTa, BERT.

## 1 Introduction

Lexical complexity plays a significant role in the readability level and comprehension. The precise anticipation of lexical complexity can help systems direct the user to an acceptable simple text accurately or modify the text to be more fluid (Brothers and Traxler, 2016). Predicting the complexity of words is a subjective and challenging problem, while it is conjectural, too. Yet, mapping words into their complexity is an essential task to understand natural language. Numerous components can influence the prediction of lexical complexity. Several approaches were proposed to solve or mitigate this type of study using Machine and Deep learn-

ing methods (Sengupta et al., 2020; Gooding and Kochmar, 2019; Bahja, 2020).

This paper describes the JUST-BLUE team's model that participated in the SemEval 2021-task1, Lexical Complexity Prediction (LCP) (Shardlow et al., 2021). The task provides participants with an augmented version of CompLex, a multi-domain English dataset with sentences annotated using a 5-point Likert scale (1-5) (from very easy to very difficult) (Shardlow et al., 2020). The task is to predict the complexity value of words in context. It is worth mentioning that our model, JUST-BLUE, has been ranked first in this task. We have used the pre-trained language models, BERT and RoBERTa Which have proven their effectiveness in this area (Liu et al., 2019), along with the ensemble method (weighted averaging) to achieve the highest Pearson correlation score of 0.788.

The rest of this paper is organized as follows: Section 2 sheds light on related work. Section 3 describes the methodology proposed in this research. Section 4 discusses the experimentation setup and evaluation results. Whereas Section 5 concludes this research.

## 2 Related work

One of the most prominent challenges in the current era is the prediction of lexical complexity. Prediction of the word complexity in machine learning can be binary; the word is complex or not complex. It also can be a non-binary prediction, as a probabilistic prediction with the measurement of complexity within a particular scale (0.6 the probability that the word is complex). SemEval 2016 introduced the first shared task of predicting word complexity with a mission limited to the word orders being complex or non-complex (binary prediction) (Paetzold and Specia, 2016). Decision Tree classifiers achieved the best results (Zampieri

et al., 2017). It has been noted that word length is a good indication of word complexity (De Hertog and Tack, 2018).

The authors in (Shardlow, 2013) discussed the importance of frequency and length of words. They used the Keras deep learning library to predict whether an English or Spanish word is complex or not. They used character embedding, word length, frequency count, word embedding, and psychological measures as features to predict complex words and achieved 0.872 as F1-score. The authors in (Yimam et al., 2018) worked on various languages, such as English, Spanish, French and German. They worked on two different methods for predicting complex words. The first method is to find if the word orders are either complex or simple. The second is to find the probability that the word is complex. The complex levels depended on the average of the annotators' answers. For example, if the number of annotators who expected the word to be complex is 6 out of 10, then the probability is 0.6. A claim stated that this annotating method is considered impractical since the probability of 0.5 cannot be considered complex or not complex. So the authors in (Shardlow et al., 2020) suggested a Likert scale with 5-point. The authors asserted that this method is more accurate scale instead of calling the word complex and non-complex. We can divide the word into being very easy, easy, neutral, difficult, and very difficult. This scale is beneficial to our work.

The deep learning pre-trained language models, BERT and RoBERTa, are considered state-of-the-art for NLP. Teams in the previous shared tasks of SemEval 2020 had used these models to obtain the best results for different NLP tasks (Al-Khdour et al., 2020; Shatnawi et al., 2020; Jurkiewicz et al., 2020). Our approach experimented with these models using different hyperparameters and weighted averaging methods that lead to the best result in the competition for predicting lexical complexity.

### 3 Methodology

This section describes our approach methodology and goes as follows: First, we describe the task's dataset. Then, the preprocessing step. Finally, we describe the JUST-BLUE approach to predict the word's complexity.

#### 3.1 Data

The SemEval-task 1 competition has provided the contestants with three files (trial, train, and test data). The files contain several columns as follows:

- id: the identification number for each entry.
- corpus: the sources from which the words were being collected. It was extracted from three sources: the bible, biomedical, and The European Parliament.
- sentence: the set of words for which complexity needed to be measured.
- token: the single word in which complexity needed to be measured.
- complexity: the degree of complexity of the word, ranging from 0 to 1.

#### 3.2 Pre-Processing Step

First, we cleaned the data and removed all single and double quotations manually. This step helped to separate some of the merged rows. Next, we deleted any row where columns contain the NaN value because it will not be effective in the training process.

#### 3.3 JUST-BLUE Architecture

We have used the pre-trained language models, BERT and RoBERTa models. We have imported the BERT model using BERT-sklearn library as it includes SciBERT and BioBERT models for the scientific and biomedical fields. We also have used simple transformers; classification libraries to import the RoBERTa model. As we mentioned earlier, the goal of the task is to determine the complexity of the word. Knowing that the word's complexity changes slightly based on the complexity of the sentence, we have used both the token (word) and the sentence to predict the word's complexity. We have fed BERT and RoBERTa models with the 'token,' and the 'complexity' label to be trained. We have also inserted 'sentence' and 'complexity' columns to both models for training as a second strategy. The results have been combined using an ensembling voting method, Weighted Averaging. Our experiments show that the 80:20 ratio for weights can achieve the best results. The highest voting rate is for the "token" model (model 1) since we need to calculate the degree of complexity for a single word. On the other hand, the complexity of a

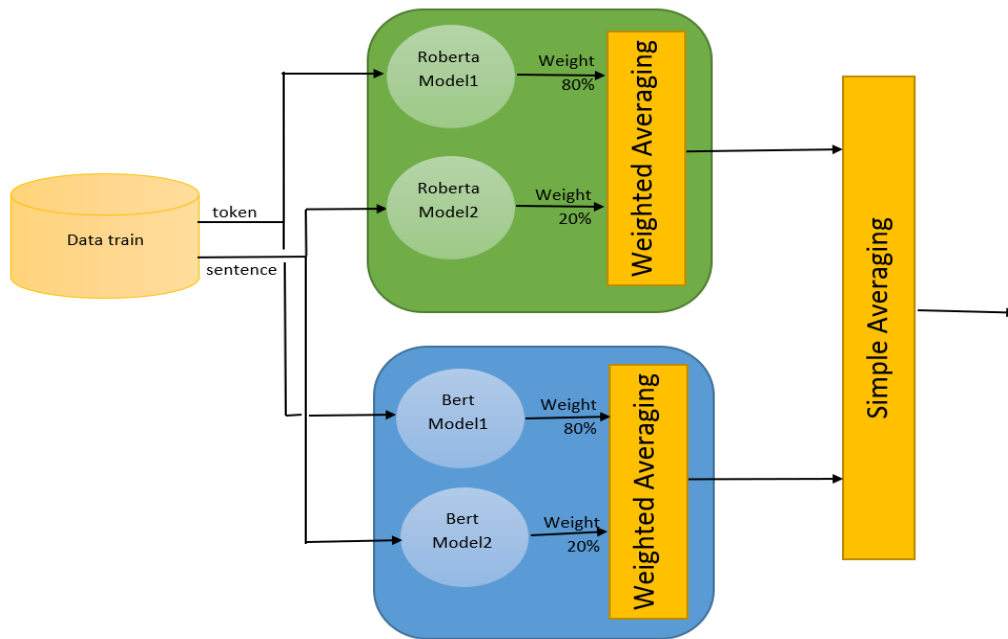

Figure 1: JUST-BLUE workflow

word is affected by the complexity of the sentence in which it is included. So, we gave a 20

The Simple Averaging method has been used as the ensembling technique to merge BERT and RoBERTa’s models’ results. Figure 1 illustrates the methodology used.

For more clarification, suppose we have the word ‘sea’ for which we want to calculate the complexity. The ‘sea’ word exists in this sentence ”and they entered into the boat, and were going over the sea to Capernaum.” First, we feed the word sea to model1 using RoBERTa. We also feed the sentence that contains the word sea to RoBERTa model2. Then, we combine the two results obtained using Weighted Averaging. Suppose that the RoBERTa model1 result is 0.01 (the word sea has a 0.01 complexity degree) and RoBERTa model2 is 0.13 ( the sentence has a 0.13 complexity degree). The resulted RoBERTa models is  $0.01 \times 80\% + 0.13 \times 20\%$ , which is equal to 0.034. We repeat these steps for BERT’s models. If the BERT model has a result of 0.052, then the final step is to calculate the average of the RoBERTa and BERT model. The complexity is  $(0.034 + 0.052)/2$ , equal to 0.043, as shown in Figure 2.

#### 4 Results and Discussion

We used Python version 3.6 on the Colab environment to execute our codes. We have experimented

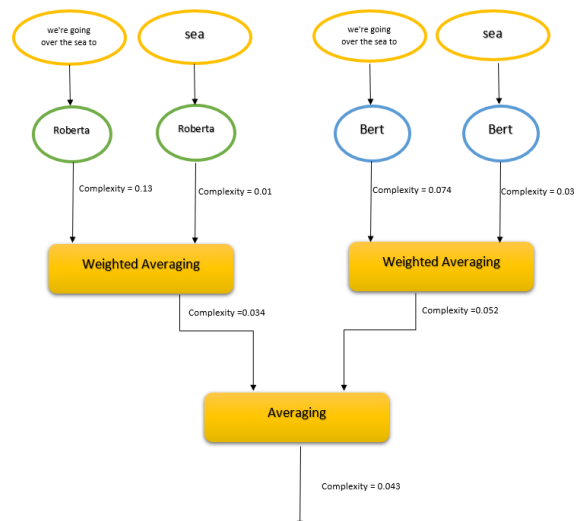

Figure 2: Example Description

with several models to determine which models are suitable for this task. We have experimented with BERT and RoBERTa pre-trained models. We also examined SVM and Random Forest machine learning models. Table 1 shows the results we have obtained throughout our experiments.

The challenging step was to find the best weights for the models that used tokens (single words) and sentences to get the best result (Table2). As we mentioned earlier, some words have a different complexity degree, depending on their location in the sentences. Therefore, it was necessary to insert

Table 1: Results of different models

Models	score
SVM	0.3472
Random Forest	0.4503
BERT	0.8199
RoBERTa	0.8268
BERT and RoBERTa	0.8190

Table 2: Different weights (tokens and sentences)

model		score
Token %	Sentence %	
90	10	0.8258
80	20	0.8268
70	30	0.8252

each of the words and sentences for the training to verify the best weight. Table 2 shows the best weight, which is 80% for words and 20% for sentences.

The next step was to explore BERT and RoBERTa’s best hyperparameters, such as learning rate, batch size, epochs, and max sequence length. Table 3 shows the description of these hyperparameters, and Table 4 shows example results of fine-tuning JUST-BLUE hyperparameters.

Finally, we thought of determining the effects of the base size and large size models of BERT and RoBERTa on the accuracy. It is shown by our experiments that the large sizes decreased the accuracy.

In the testing phase, we noticed that the words (tokens) in the file were new. Therefore, we decided to limit the number of arguments to avoid overfitting. We just changed ”num-train-epochs”=3 in BERT and RoBERTa’s model, but the other arguments had the default values. We have used three different models. The first was the BERT model, the second was the RoBERTa model, and the third was BERT and RoBERTa together as described in the Methodology Section. Table 5 shows the results we received from the different models we used.

JUST-BLUE approach achieved the best result using RoBERTa and BERT’s models with a Pearson correlation of 0.788 scores. We have also achieved the least Mean Absolute Error(MAE) with 0.0609. Our model is ranked first the LCP-sub task1 of a single word. The Spearman’s Rho (Rho) and R-squared (R2) scores are 0.7369 and 0.6172, respectively. The number of teams in the shared

task Lexical Complexity Prediction (LCP) was 54 teams. This shared task is considered a high level of CWI 2016 and CWI 2018 with a larger number of words from various sources.

## 5 Conclusion

Predicting the complexity of words is one of the most prominent tasks that the NLP research community strives to solve. It is worth noting that in 2016 and 2018, two tasks were issued to determine whether the word was complex or not. SemEval 2021 introduced task 1, Lexical Complexity Prediction (LCP) that aims to predict the word’s complexity from 0 to 1. This paper described the top-ranked team’s model, JUST-BLUE. The JUST-BLUE model obtained the highest Pearson Correlation score of 0.788 using the pre-trained language models BERT and RoBERTa. Our strategy depends on the ensembling methods, Simple and Weighted Averaging.

# BigGreen at SemEval-2021 Task 1: Lexical Complexity Prediction with Assembly Models

Aadil Islam, Weicheng Ma, Soroush Vosoughi

Department of Computer Science

Dartmouth College

{aadil.islam.21, weicheng.ma.gr, soroush.vosoughi}@dartmouth.edu

## Abstract

This paper describes a system submitted by team `BigGreen` to LCP 2021 for predicting the lexical complexity of English words in a given context. We assemble a feature engineering-based model with a deep neural network model founded on BERT. While BERT itself performs competitively, our feature engineering-based model helps in extreme cases, eg. separating instances of easy and neutral difficulty. Our handcrafted features comprise a breadth of lexical, semantic, syntactic, and novel phonological measures. Visualizations of BERT attention maps offer insight into potential features that Transformers models may learn when fine-tuned for lexical complexity prediction. Our ensembled predictions score reasonably well for the single word subtask, and we demonstrate how they can be harnessed to perform well on the multi word expression subtask too.

## 1 Introduction

Lexical simplification (LS) is the task of replacing difficult words in text with simpler alternatives. It is relevant in reading comprehension, where early studies have shown infrequent words lead to more time spent by a reader fixated on it, and that ambiguity in a word’s meaning adds to comprehension time (Rayner and Duffy, 1986). Complex word identification (CWI) is believed to be a fundamental step in the automation of lexical simplification (Shardlow, 2014). Early techniques for conducting CWI suffer from a lack of robustness, from simplifying all words to *then* study its efficacy (Devlin, 1998), to applying thresholds on features like word frequency (Zeng et al., 2005).

This year’s Lexical Complexity Prediction (LCP) shared task (Shardlow et al., 2021) forgoes the treatment of word difficulty as a binary classification task (Paetzold and Specia, 2016a; Yimam et al.,

2018) and instead measures degree of complexity on a continuous scale. This choice is intriguing as it mitigates a dilemma with previous approaches of having to treat words extremely close to a decision boundary (suppose a threshold deems a word’s difficulty) identically to those that are far away, ie. extremely easy or extremely difficult.

Teams are asked to submit predictions on unlabeled test sets for two subtasks: predicting on English single word and multi word expressions (MWEs). For each subtask, `BigGreen` presents a machine learning-based approach that fuses the predictions of a feature engineering-based regressor with those of a feature learning-based deep neural network model founded on BERT (Devlin et al., 2018). Our code is made available on GitHub.<sup>1</sup>

## 2 Related Work

Previous studies have looked at estimating the readability of a given text at the sentence-level. Mc Laughlin (1969) regresses the number of polysyllabic words in a given lesson against the mean score for students quizzed on said lesson, yielding the SMOG Readability Formula. Dale and Chall (1948) offer a list of 768 (later updated to 3,000) words familiar to grade-school students in reading, which they find correlates with passage difficulty. An issue with traditional readability metrics seems to be the loss of generality at the word-level.

Shardlow (2013) tries a brute force approach where a simplification algorithm is applied to each word of a given text, deeming a word complex only if it is simplified. However, this suffers from the assumption that a non-complex word does not require further simplification. They also try assigning a familiarity score to a word, and determining whether the word is complex or not by applying a threshold.

<sup>1</sup><https://github.com/Aadil101/BigGreen-at-LCP-2021>

Corpus	Subtask	Train	Trial	Test
Bible	Single Word	2574	143	283
	Multi Word	505	29	66
Biomed	Single Word	2576	135	289
	Multi Word	514	33	53
Europarl	Single Word	2512	143	345
	Multi Word	498	37	65

Table 1: LCP train, trial, and test sets.

We avoid thresholding our features in this study as we find it unnecessary, since raw familiarity scores can be used as features in regression-based tasks.

Results from CWI at SemEval-2016 (Zampieri et al., 2017) suggest vote ensembling predictions of the best performing models as an effective strategy, while several top-performing models (Paetzold and Specia, 2016b; Ronzano et al., 2016; Mukherjee et al., 2016) appear to use linguistic information beyond just word frequency. This inspires our use of ensemble techniques, and a foray into phonological features as a new point of research. Results from CWI at SemEval-2018 show feature engineering-based models outperforming deep learning-based counterparts, despite the latter having generally better performances since SemEval-2016.

### 3 Data

#### 3.1 CompLex Dataset

Shardlow et al. (2020) present CompLex, a novel dataset in which each target expression (a single word or two-token MWE) is assigned a continuous label denoting its lexical complexity. Each label lies in range 0-1, and represents the (normalized) average score given by employed crowd workers who record an expression’s difficulty on a 5-point Likert scale. We define a sample’s *class* as the bin to which its complexity label belongs, where bins are formed using the following mapping of complexity ranges:  $[0, 0.2) \rightarrow 1$ ,  $[0.2, 0.4) \rightarrow 2$ ,  $[0.4, 0.6) \rightarrow 3$ ,  $[0.6, 0.8) \rightarrow 4$ ,  $[0.8, 1] \rightarrow 5$ . Target expressions in CompLex have 0.395 average complexity and 0.115 standard deviation, reflecting an imbalance in favor of class 2 and 3 samples.

Each target expression is accompanied by the sentence it was extracted from, drawn from one of three corpora (Bible, Biomed, and Europarl). A summary of the train, trial,<sup>2</sup> and test set samples is

<sup>2</sup>In our study we avoid the trial set as we find it to be less representative of the training data, opting instead for training set cross-validation (stratified by corpus and complexity label).

provided in Table 1.

#### 3.2 External Datasets

We use four additional corpora to extract term frequency-based features from:

- **English Gigaword Fifth Edition** (Gigaword): this comprises articles from seven English newswires (Parker et al., 2011).
- **Google Books Ngrams, version 2** (GBND): this is used to count occurrences of phrases across a corpus of books, accessed via the PhraseFinder API (Trenkmann).
- **British National Corpus, version 3** (BNC): this is a collection of written and spoken English text (Consortium et al., 2007).
- **SUBTLEXus**: this consists of American English subtitles, offering a multitude of word frequency lists (Brysaert and New, 2009).

### 4 BigGreen System & Approaches

In this section, we overview features fed to our feature engineering-based model, as well as training techniques for the feature learning-based model. We describe our features in detail in Appendix A. Note that fitted models for the single word subtask are then harnessed for the MWE subtask.

#### 4.1 Feature Engineering-based Approach

##### 4.1.1 Feature Extraction

We aim to capture a breadth of information pertaining to the target word and its context. Most features follow heavily right-skewed distributions, prompting us to also consider the log-transformed version of each feature. For the MWE subtask, features are extracted independently for head and tail words.

##### 4.1.1.1 Lexical Features

These are features based on lexical information about the target word:

- **Word length**: length of the target word.
- **Number of syllables**: number of syllables in the target word, via the Syllables library.<sup>3</sup>
- **Is acronym**: whether the target word is a sequence of capital letters.

<sup>3</sup><https://github.com/prosegrinder/python-syllables>

#### 4.1.1.2 Semantic Features

These features capture the target word’s meaning:

- **WordNet features:** the number of hyponyms and hypernyms associated with the target word in WordNet (Fellbaum, 2010).
- **GloVe word embeddings:** we extract 300-dimension embeddings pre-trained on Wikipedia-2014 and Gigaword (Pennington et al., 2014) for each (lowercased) target word.
- **ELMo word embeddings:** we extract for each target word a 1024-dimension contextualized embedding pre-trained on the One Billion Word Benchmark (Peters et al., 2018).
- **GloVe context embeddings:** we obtain the average 300-dimension GloVe word embedding over each token in the given sentence.
- **InferSent context embeddings:** we obtain 4096-dimension InferSent embeddings (Conneau et al., 2017) for each sentence.

#### 4.1.1.3 Phonetic Features

These features compute the likelihood that soundable portions of the target word would arise in English language. We estimate ground truth transition probabilities between any two units (phonemes or characters) using Gigaword:

- **Phoneme transition probability:** we consider the min/max/mean/standard deviation over the set of transition probabilities for the target word’s phoneme bigrams.
- **Character transition probability:** analogous to that above, over *character* bigrams.

#### 4.1.1.4 Word Frequency & N-gram Features

These features are expressly included due to their expected importance as features (Zampieri et al., 2017). Gigaword is the main corpus from which we extract word frequency measures (for both lemmatized and unlemmatized versions of the target word), summed frequency of the target word’s byte pair encodings (BPEs), as well as summed frequencies of bigrams and trigrams. We complement these features with their IDF-based analogues. Lastly, we use the GBND, BNC, and SUBTLEXus corpora to extract secondary word frequency, bigram, and trigram measures.

#### 4.1.1.5 Syntactic Features

These are features that assess the syntactic structure of the target word’s context. We construct the constituency parse tree for each sentence using a Stanford CoreNLP pipeline (Manning et al., 2014).

- **Part of speech (POS):** tag is assigned using NLTK’s `pos_tag` method (Bird et al., 2009).
- **Depth of parse tree:** the parse tree’s height.
- **Depth of target word:** distance (in edges) between target word and parse tree’s root node.
- **Is proper:** whether the target word is a proper noun/adjective, detected using capitalization.

#### 4.1.2 Training

Prior to training, we Z-score standardize all features. For the single word subtask, we fit Linear, Lasso (Tibshirani, 1996), Elastic Net (Zou and Hastie, 2005), Support Vector Machine (Platt et al., 1999), K-Nearest Neighbors (Wikipedia, 2021), and XGBoost (Chen and Guestrin, 2016) regression models.

After identifying the best performing model by Pearson correlation, we seek to mitigate the imbalanced nature of the target variable, ie. multitude of class 1,2,3 and lack of class 4,5 samples: we devise a sister version of our top-performing model, fit upon a *reduced* training set. For the *reduced* set, we tune percentages removed from classes 1-3 by performing cross-validation on the full training set.

#### 4.2 Approach based on Feature Learning

Our handcrafted feature set relies heavily on target word-specific features. Beyond N-gram and syntactic features, it is a cursory analysis of the context surrounding the target word. We seek an alternative, automated approach using feature learning.

##### 4.2.1 Architecture

LSTM-based approaches have been used to model the contexts of target words in past works (Hartmann and Dos Santos, 2018; De Hertog and Tack, 2018). An issue with a single LSTM is its ability to read tokens of an input sentence sequentially only in a single direction (eg. left-to-right). It inspires us to try a Transformer-based approach (Vaswani et al., 2017), architectures that process sentences as a whole (instead of word-by-word) by applying *attention* mechanisms upon them. Attention weights

are useful as they can be interpreted as learned relationships between words. BERT (Devlin et al., 2018) is one such model used for a variety of natural language understanding (NLU) tasks.

Multi-Task Deep Neural Network (MT-DNN) proposed by Liu et al. (2019) offers state-of-the-art results for multiple NLU tasks by incorporating benefits of both multi-task learning and language model pre-training. We are able to initialize MT-DNN’s shared text encoding layers with a pre-trained BERT base model (cased), and fine-tune its later layers for 5 epochs, using a mean squared error loss function and default hyperparameters. Such hyperparameter settings are provided in Appendix B. Note that the model is fine-tuned on only the CompLex corpus.

#### 4.2.2 Input Layer

Data is fed to the model’s input layer in *Premise-AndOneHypothesis* format, premise and hypothesis being sentence and target word/MWE, respectively. The data is preprocessed by a BERT tokenizer, backed by Hugging Face (Wolf et al., 2020).

#### 4.2.3 Output Layer

Our model’s output layer produces the predicted lexical complexity for a given target word/MWE. Additionally, we extract *attention maps* across each of the model’s attention heads, for each test set sample. These will be assessed in Section 6.3.

#### 4.3 Ensembling

Our best performing feature engineering-based regression model yields two sets of predictions (from fitting on *full* and *reduced* training sets, respectively). We default to using the *full* predictions, then tune a threshold, where predictions higher than the threshold (likely of class 4,5 samples) are overwritten with the *reduced* predictions. We compute a weighted average ensemble of these predictions with those of our MT-DNN model to obtain a final set of predictions for the single word subtask.

For the MWE subtask, the fitted models from the previous subtask are harnessed to predict lexical complexities for the head and tail words. We then compute a weighted average ensemble of these predicted complexities *and* the predictions of an MT-DNN model trained on MWEs.

### 5 Results

We present the performances of BigGreen’s system on each subtask in Tables 2 and 3.

Model	Pearson	Rank
XGBoost <sub>full</sub>	0.7589	-
XGBoost <sub>reduced</sub>	0.7456	-
XGBoost <sub>full+reduced</sub>	0.7576	-
MT-DNN	0.7484	-
Ensemble (submission)	0.7749	8/54
Best competition results	0.7886	

Table 2: Test set results for single word subtask.

Model	Pearson	Rank
XGBoost <sub>full+red.</sub> (head)	0.7164	-
XGBoost <sub>full+red.</sub> (tail)	0.7188	-
MT-DNN	0.7890	-

## 6 Analysis

### 6.1 Performance

For feature selection, we find success in selecting the top-300 features by mutual information and removing quasi-constant features. The pruned feature set is passed to wrapper/embedded methods and a variety of regressors for model comparison. We find an XGBoost regressor (with hyperparameters tuned via grid search) to excel consistently for the single word subtask. As shown in Table 2, we rank in the top 15% by Pearson correlation.

For the MWE subtask, performances are reported in Table 3. Note that our submitted predictions differ from post-competition predictions. We *previously* used a training procedure resembling that for the single word subtask: (1) filter methods for feature selection, (2) XGBoost for regression, (3) ensembling with MT-DNN. We had passed the entire MWE as input to our XGBoost and MT-DNN models. We hypothesize that the fewer number of training samples available for this subtask contributed to the prior procedure’s lackluster performance. This inspired us to incorporate the predictive capabilities of our fitted single word subtask models by applying them *independently* on the MWE’s constituent head and tail words. This gives us predicted complexities for the head and tail words each, which when ensembled with the predictions of our MT-DNN model (that, mind you, is trained on the *entire* MWE) yields superior results to those submitted to competition.

Figure 1: Feature importances for XGBoost<sub>full</sub>. Definitions of the features are shown in Appendix A.

Figure 3: Head 3-9 attention map for a random sample.

Figure 2: Attention head correlation between word frequency and total attention received by word, averaged across 100 random test set samples.

## 6.2 Feature Contribution

In total we consider 110 features, in addition to our multidimensional embedding-based features and log-transformed features. We inspect the estimated feature importance scores produced by the XGBoost<sub>full</sub> model to find that term frequency-based features (eg. unigrams, bigrams, trigrams) are of overwhelming importance (see Figure 1). This raises concern for whether the MT-DNN model too relies on term frequencies to make *its* predictions, and if not, the linguistic features it may have learned upon fine-tuning. Of the remaining features having non-zero feature importances, most appear to be dimensions of target word-based semantic features (ie. GloVe or ELMo embeddings).

## 6.3 BERT Attention

Attention maps have in previous works been assessed to demonstrate linguistic phenomena learned by a Transformer’s specialized attention heads (Voita et al., 2019; Clark et al., 2019). We extract attention maps from MT-DNN’s underlying fine-tuned BERT architecture. For each sample in the single word test set, we obtain an attention map from each of the BERT base model’s 144 attention heads (ie. 12 heads per 12 layers).

Based on the precedence given to term frequency features by the XGBoost<sub>full</sub> model, we hypothesize that for certain attention heads, the degree to which BPEs attend to one another varies relative to their word’s rarity in lexicon. This follows the findings of Voita et al. (2019), who identify heads in which lesser frequent tokens are attended to semi-uniformly by a majority of sentence tokens.

To test our hypothesis, we estimate for each attention head the Pearson correlation between word frequency and average attention given to each word in the context.<sup>4</sup> As illustrated in Figure 2, we find multiple attention heads appearing to specialize at directing attention towards the most or least frequent words (depending on sign of the correlation). Vertical stripe patterns like that in Figure 3 emerge as a result of attention originating from a spectrum of tokens. The findings seem to affirm the fundamental relevancy of word frequency to lexical complexity prediction, corroborating our intuition.

<sup>4</sup>We compute attention given to a *word* as the sum of attention given to its constituent BPEs. We use the GBND corpus to extract word frequencies, though any large corpora would suffice.

## 7 Conclusion

In this paper, we report inspirations for a system submitted by BigGreen to LCP SharedTask 2021, performing reasonably well for the single word subtask by adapting ensemble methods upon feature engineering and feature learning-based models. We see potential in future deep learning approaches, acknowledging the need for complementary word frequency-based handcrafted features for the time being. We surpass our submitted results for the MWE subtask, by utilizing the predictive capabilities of our single word subtask models.

Avenues for improvement include better data aggregation, as a relative lack of class 4,5 samples seems to hurt Pearson correlation across extremely complex samples. An approach may involve synthetic data generation using SMOGN (Branco et al., 2017). Shardlow et al. (2020) acknowledge a reader’s familiarity with a genre may affect perceived word complexity. However, the CompLex dataset lacks information on each annotator’s expertise or background, which may offer valuable new insights.

## A Feature Descriptions

Here, we describe in greater detail the various features that were experimented with for our feature engineering-based model. Note that while this discussion regards the single word subtask, for the MWE subtask we compute the same features but for each of the head and tail words, respectively.

### A.1 Lexical Features

`word_len`

- Character length of the target word.

`num_syllables`

- Number of syllables in the target word, via the Syllables library.

`is_acronym`

- Boolean for whether the target word is all capital letters.

### A.2 Semantic Features

`num_hyperyms`

- Number of hyperyms associated with the target word. The target word is initially disambiguated using NLTK's implementation of the Lesk algorithm for Word Sense Disambiguation (WSD) (Lesk, 1986), which finds the WordNet Synset with the highest number of overlapping words between the context and different definitions of each Synset.

`num_hyponyms`

- Number of hyponyms associated with the target word. Procedure for finding this is analogous to that for `num_hyperyms`.

`glove_word`

- 300-dimension embedding for each target word, pre-trained on Wikipedia-2014 and Gigaword. Target word is lowercased for ease.

`elmo_word`

- 1024-dimension embedding for each target word, pre-trained on the One Billion Word Benchmark corpus.

`glove_context`

- 300-dimension average of GloVe word embeddings (see `glove_word` above) for each word in the given context. Each word is lowercased for simplicity.

`inferred_embeddings`

- 4096-dimension embedding for the context.

### A.3 Phonetic Features

`char_transition_min`

- Minimum of the set of character transition probabilities for each character bigram in the target word. Ground truth character transition probabilities between any two English characters are estimated over Gigaword.

`char_transition_max`

- Maximum of the set described above.

`char_transition_mean`

- Mean of the set described above.

`char_transition_std`

- Standard deviation of the set described above.

`phoneme_transition_min`

- Minimum of the set of phoneme transition probabilities for each character bigram in the target word. Ground truth phoneme transition probabilities between any two phonemes are estimated over the Gigaword corpus. The phoneme set considered is that of the CMU Pronouncing Dictionary.<sup>5</sup>

`phoneme_transition_max`

- Maximum of the set described above.

`phoneme_transition_mean`

- Mean of the set described above.

`phoneme_transition_std`

- Standard deviation of the set described above.

### A.4 Word Frequency & N-gram Features

#### A.4.1 Gigaword-based

`tf`

- Target word term frequency. Note that all term frequency-based features are computed using Scikit-learn library's `CountVectorizer` (Pedregosa et al., 2011).

`tf_lemma`

- Term frequency of the lemmatized target word. Lemmatization is performed using NLTK's `WordNetLemmatizer`.

<sup>5</sup><http://speech.cs.cmu.edu/cgi-bin/cmudict>

tf\_summed\_bpe

- Sum of term frequencies of each BPE in the target word. BPE tokenization is performed using Hugging Face’s BERT Tokenizer.

tf\_ngram\_2

- Sum of the term frequencies of each bigram in the context containing the target word.

tf\_ngram\_3

- Sum of the term frequencies of each trigram in the context containing the target word.

tfidf

- Term frequency-inverse document frequency.

tfidf\_ngram\_2

- Sum of the term frequency-inverse document frequencies of each bigram in the context containing the target word.

tfidf\_ngram\_3

- Sum of the term frequency-inverse document frequencies of each trigram in the context containing the target word.

#### A.4.2 Google N-gram-based

google\_ngram\_1

- Term frequency of the target word.

google\_ngram\_2\_head

- Term frequency of leading bigram in the context containing the target word.

google\_ngram\_2\_tail

- Term frequency of trailing bigram in the context containing the target word.

google\_ngram\_2\_min

- Minimum of the set of term frequencies of bigrams in context containing the target word.

google\_ngram\_2\_max

- Maximum of the set described above.

google\_ngram\_2\_mean

- Average of the set described above.

google\_ngram\_2\_std

- Standard deviation of the set described above.

google\_ngram\_3\_head

- Term frequency of leading trigram in the context containing the target word.

google\_ngram\_3\_mid

- Term frequency of middle trigram in the context containing the target word.

google\_ngram\_3\_tail

- Term frequency of trailing trigram in the context containing the target word.

google\_ngram\_3\_min

- Minimum of set of term frequencies of trigrams in the context containing target word.

google\_ngram\_3\_max

- Maximum of the set described above.

google\_ngram\_3\_mean

- Average of the set described above.

google\_ngrams\_3\_std

- Standard deviation of the set described above.

#### A.4.3 SUBTLEXus-based

FREQcount

- Number of times target word appears in corpus.

CDcount

- Number of films in which target word appears.

FREQlow

- Number of times the lowercased target word appears in corpus.

CDlow

- Number of films in which the lowercased target word appears.

SUBTLWF

- Number of times the target word appears per million words.

SUBTLCD

- Percent of films in which target word appears.

#### A.4.4 BNC-based

bnc\_frequency: Target word term frequency.

#### A.5 Syntactic Features

parse\_tree\_depth

- Height of context's constituency parse tree. Parse trees are obtained using a Stanford CoreNLP pipeline.

token\_depth

- Depth of the target word with respect to root node of the context's constituency parse tree.

num\_words\_at\_depth

- Number of words at the depth of the target word (see `token_depth` above) in the context's constituency parse tree.

is\_proper

- Boolean for whether target word is a proper noun/adjective, based on capitalization.

POS\_{CC, CD, DT, EX, FW, IN, JJ, JJR, JJS, LS, MD, NN, NNP, NNPS, NNS, PDT, POS, PRP, PRP\$, RB, RBR, RBS, RP, SYM, TO, UH, VB, VBD, VBG, VBN, VBP, VBZ, WDT, WP, WP\$, WRB}

- Booleans indicating the target word's part-of-speech tag. Tags considered are those used in the Penn Treebank Project.<sup>6</sup> Tags are estimated using NLTK's `pos_tag` method.

#### A.6 Readability Features

automated\_readability\_index,  
avg\_character\_per\_word,  
avg\_letter\_per\_word,  
avg\_syllables\_per\_word,  
char\_count, coleman\_liau\_index,  
crawford, fernandez\_huerta,  
flesch\_kincaid\_grade,  
flesch\_reading\_ease,  
gutierrez\_polini,  
letter\_count, lexicon\_count,  
linsear\_write\_formula, lix,  
polysyllabcount, reading\_time,  
rix, syllable\_count,  
szigriszt\_pazos, SMOGIndex,  
DaleChallIndex

- Algorithms applied using Textstat library implementations, most being readability metrics.

<sup>6</sup>[https://www.ling.upenn.edu/courses/Fall\\_2003/ling001/penn\\_treebank\\_pos.html](https://www.ling.upenn.edu/courses/Fall_2003/ling001/penn_treebank_pos.html)

#### A.7 Other Features

ppl

- Perplexity metric, as defined by the Hugging Face library.<sup>7</sup> For each token in the context, we use a pre-trained GPT-2 model to estimate the log-likelihood of the token occurring *given its preceding tokens*. A sliding-window approach is used to handle the large number of tokens in a context. The log-likelihoods are averaged, and then exponentiated.

ppl\_aspect\_only

- Similar approach to that described above, where only log-likelihoods of tokens comprising the target word are averaged.

num\_OOV

- Number of words in the context that do not exist in the vocabulary of Gigaword.

corpus\_bible, corpus\_biomed,  
corpus\_europarl

- Booleans indicating the sample's domain.

## B Model Hyperparameters

Here we provide optimized hyperparameter settings that may help future developers with reproducing results, namely with training our models.

### B.1 XGBoost

Below are tuned parameters used for all of our XGBoost models. Parameters not listed are given default values as specified in documentation.<sup>8</sup>

```
colsample_bytree: 0.7  
learning_rate: 0.03  
max_depth: 5  
min_child_weight: 4  
n_estimators: 225  
nthread: 4  
objective: 'reg:linear'  
silent: 1  
subsample: 0.7
```

<sup>7</sup><https://huggingface.co/transformers/perplexity.html>

<sup>8</sup><https://xgboost.readthedocs.io/en/latest/>

## B.2 MT-DNN

MT-DNN uses `yaml` as its config file format. Below are the contents of our task config file:

```
data_format: PremiseAndOneHypothesis
enable_san: false
metric_meta:
- Pearson
- Spearman
n_class: 1
loss: MseCriterion
kd_loss: MseCriterion
adv_loss: MseCriterion
task_type: Regression
```

## B.3 Ensemble

Threshold above which a sample is assigned its *reduced* prediction (ie. `XGBoostreduced` prediction) instead of its *full* prediction (ie. `XGBoostfull` prediction): 0.59. Note that this threshold is used to compute our `XGBoostfull+reduced` prediction.

Weighted average ensemble (single word subtask):

- Weight for `XGBoostfull+reduced` prediction: 0.5
- Weight for MT-DNN prediction: 0.5

Weighted average ensemble (MWE subtask):

- Weight for `XGBoostfull+reduced(head)`: 0.28
- Weight for `XGBoostfull+reduced(tail)`: 0.17
- Weight for MT-DNN prediction: 0.55

# cs60075\_team2 at SemEval-2021 Task 1 : Lexical Complexity Prediction using Transformer-based Language Models pre-trained on various text corpora

Abhilash Nandy    Sayantan Adak    Tanurima Halder    Sai Mahesh Pokala

Indian Institute of Technology, Kharagpur, India

## Abstract

This paper describes the performance of the team cs60075\_team2 at SemEval 2021 Task 1 - Lexical Complexity Prediction. The main contribution of this paper is to fine-tune transformer-based language models pre-trained on several text corpora, some being general (E.g., Wikipedia, BooksCorpus), some being the corpora from which the CompLex Dataset was extracted, and others being from other specific domains such as Finance, Law, etc. We perform ablation studies on selecting the transformer models and how their individual complexity scores are aggregated to get the resulting complexity scores. Our method<sup>1</sup> achieves a best Pearson Correlation of 0.784 in sub-task 1 (single word) and 0.836 in sub-task 2 (multiple word expressions).

## 1 Introduction

Complex words hinder the readability of a text, as discussed in (William, 2004). To mitigate this problem, there is a necessity of lexical simplification (Leroy et al., 2013), and predicting the complexity of words is an integral part of this process.

Language Models learn the probability of co-occurrence of words in a corpus. They have been used for various sentence completion and text-based classification tasks. The first language models were n-gram Markov Models (Rabiner and Juang, 1986), which performed well for tasks that did not require very long-range dependencies. Then came RNNs (Cho et al., 2014a), LSTMs (Hochreiter and Schmidhuber, 1997) and GRUs (Cho et al., 2014b), which were able to understand longer contexts, but struggled with long paragraphs due to the vanishing gradient problem. Transformers (Vaswani et al., 2017) were a task-agnostic solution that performed better due

<sup>1</sup>The code is available at <https://github.com/abhilnandy2/CS60075-Team-2-Task-1>

to the presence of Attention Layers between hidden layers of the neural network, which helped the layers of the neural network to look at the entire input at once. Transformers can perform very well on a broad suite of tasks by fine-tuning on a small number of task-specific samples. The intuition behind using such transformer-based language models for Lexical Complexity Prediction (LCP) was - transformer models pre-trained on different corpora would mimic annotators (of the CompLex Dataset (com)) having different backgrounds. Since the final score is an aggregation of the annotation scores given by annotators, we aggregate the various scores that are given as outputs by the transformer-based models fine-tuned on the CompLex Dataset.

The rest of the paper is organized as follows. Section 2 gives an overview of our solution approach, Section 3 talks about the corpora used for pre-training and the dataset used for fine-tuning for the LCP task, Section 4 discusses the experimental settings, baselines used, and a comparison and analysis of the results and Section 5 gives a conclusion.

## 2 Solution Overview

### 2.1 Model Architecture

We use several transformer models. The general block diagram of such a model is shown in Fig. 1. The input to a model is the tokenized form of a sentence, and the tokenized form of the word/multi-word expression whose complexity score is to be predicted (separated by special tokens), and the target output is the complexity score. Each model consists of a transformer encoder, having the architecture of either BERT (Devlin et al., 2018) or RoBERTa (Liu et al., 2019), followed by a linear layer and a sigmoid activation layer so that the output is squashed in the range (0, 1). Sigmoid Ac-

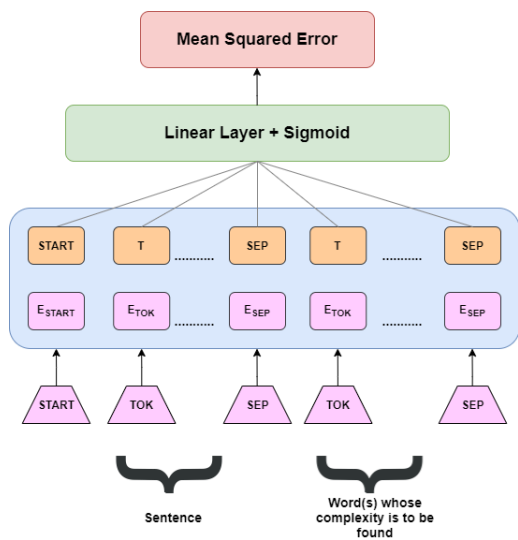

Figure 1: General Block Diagram of the Transformer

tivation Function is applied, as the target complexity score is a value between 0 and 1. To compute loss for backpropagation, the mean squared error loss function is used, as the problem is, as such, a regression problem.

## 2.2 Pre-training the transformer on text corpora

In order to initialize the weights and the embeddings of the transformer encoder, it is pre-trained on large text corpora so that it has syntactic, lexical and semantic knowledge before fine-tuning on the task-specific data. This is done for two reasons - (1) To increase the rate of convergence towards the lexical complexity prediction task (2) To mimic an annotator from a particular background.

In order to pre-train a transformer, specific pre-training tasks are performed. If the transformer being used is RoBERTa, Masked Language Modelling (MLM) is performed, where 15% of all the tokens are randomly replaced by a  $\langle MASK \rangle$  token. Such a masked sentence is provided as input to the transformer language model, and a Softmax Layer activation Function is applied for the output corresponding to the masked token to find out the probabilities of various tokens in the vocabulary being in the place of the  $\langle MASK \rangle$  in the original, unmasked sentence. The target is the actual token that was masked. A cross-entropy loss function is used to calculate the loss that is backpropagated. In the case of the BERT Transformer, in addition to the MLM pre-training task, Next Sentence Prediction (NSP) Task is also performed. Two sentences are taken from the corpus, where either one sen-

tence follows the other, or the two sentences are far apart. The output is either 1 corresponding to the sentences being adjacent to each other, and 0 being the case when they are far apart. Both the cases have the same number of samples while training. The output corresponding to the *START* (here,  $\langle CLS \rangle$ ) token is passed through a linear layer to get a 2x1 shaped vector, which is then followed by a Softmax Layer, thus giving probabilities of whether the second sentence comes after the first one or not.

## 3 Data

### 3.1 Data used for pre-training

Since we require several transformer language models pre-trained on a wide variety of corpora, we make it a point that we have transformers pre-trained on text corpora from which the CompLex Dataset has been extracted. These corpora are - (1) World English Bible Translation (Christodouloupoulos and Steedman, 2015) (We used the data found in this link <sup>2</sup>) (2) English part of the European Parliament Proceedings from europarl (Koehn, 2005) (3) CRAFT corpus (Bada et al., 2012) of bio-medical domain. We pre-train three RoBERTa language models on these three corpora (initialized by weights from (Liu et al., 2019)) using the MLM pre-training task.

### 3.2 Data used for fine-tuning

For fine-tuning, we do not use any external data other than the datasets that have been provided for both the sub-tasks <sup>3</sup>.

## 4 Experiments and Results

### 4.1 Transformer Language Models used

We use the predictions from 9 transformer-based language models, 4 of which have a RoBERTa encoder, and the other 5 have a BERT-based encoder. 2 models are pre-trained on general domain corpora like Wikipedia and BooksCorpus, 2 models on biomedical and clinical data, 2 models on Europarl data, 1 on Bible, 1 on Financial data, and 1 on scientific papers. Also, 6 of the pre-trained transformer models were publicly available in the HuggingFace Models Catalog <sup>4</sup>, while the other 3 were pre-trained by us on the three datasets from

<sup>2</sup><https://www.kaggle.com/oswinrh/bible>

which CompLex Dataset is extracted, as mentioned in Section 3.1.

## 4.2 Training, validation and Test Sets

For each sub-task, the training and the test sets are the same as those provided for the competition. The trial data given for each sub-task is taken to be the validation data.

## 4.3 Hyperparameters

For pre-training, the RoBERTa transformer language model, a batch size of 16 is used and is trained up to 1 epoch. The rest of the parameters are the same as in (Liu et al., 2019).

When fine-tuning, irrespective of whether the model has a RoBERTa or a BERT Transformer encoder, the input sequence length is set to 256, with padding or truncation, as is the case. A learning rate of  $2 \times 10^{-5}$  is used with a batch size of 32, and a Weighted Adam Optimizer is used. The network is fine-tuned for 4 epochs. The Pearson Correlation on the validation data is calculated for every epoch, and the checkpoint giving the best Pearson Correlation is regarded as the best checkpoint, which would later be used for predicting outputs on the test data.

## 4.4 Methods of Aggregation used

In order to aggregate the complexity scores of a particular combination of models, we use the following two strategies - sample-wise average and sample-wise maximum across all transformer models. We then do the same across all permutations,

see which combination gives the best test results and report it as the final result.

## 4.5 Baselines

We use XGBoost (Chen and Guestrin, 2016) to perform a boosting-based regression model, with an objective of squared error and other default parameters and hyperparameters over a set of features. The different baselines use different feature sets, which are as follows -

1. **xgb-A** - word length (sum of word lengths in the case of MWE), number of syllables and word frequency (from various text sources) (Speer et al., 2018) (average of word frequencies in the case of MWE) of the word/expression whose complexity is to be found, and the type of corpus of the sentence (either Bible, Europarl, or Biomedical).
2. **xgb-B** - Concatenation of features of xgb-A and the 50 and 100-dimensional GloVe (Pennington et al., 2014) word vectors of the word/expression whose complexity is to be found. For the expression, the sum of the GloVe Vectors of the individual words would be taken.
3. **xgb-C** - Concatenation of features of xgb-B and the probabilities of the word/expression whose complexity is to be found given the sentence with that word/expression that is masked, where the probabilities are predicted by different transformer-based masked language models pre-trained on different corpora.

**Note:** The probability of the word/token given the masked sentence is approximated as the product of the probabilities of predicting each token, given other tokens of the sentence are masked. E.g., Given a sentence  $S$  - "I just love mowing the lawn with a lawn mower." Let's say one is required to find out the complexity of the expression - "lawn mower". First, 'lawn' is masked in  $S$ , and the probability to predict 'lawn' using the transformer model  $M$  is found, denoted by  $P1$ . Similarly, 'mower' is masked in  $S$ , and the probability to predict 'mower' using  $M$  is found, denoted by  $P2$ . Resultant feature value =  $P1 * P2$

#### 4.6 Results and Discussion

Table 1 compares the Pearson Correlations (higher the better) and mean squared errors (lower the better) of our best (according to Pearson Correlation) aggregate results (for both average as well as maximum aggregation), some ablations, and the baselines for both the sub-tasks.

Based on the results, we can infer the following

1. **xgb-B** performs better than **xgb-A**, suggesting that, GloVe Word Vector features perform a vital role in complexity prediction, as they contain some contextual information regarding the word.
2. **xgb-C** performs the best among the baselines, as it also considers the probabilities of predicting the masked tokens whose complexity is found, adding to the contextual information.
3. Fine-tuning **BERT-BASE-UNCASED** transformer model for the LCP task performs better than the best baseline in case of sub-task 1, which could be attributed to the reason that, fine-tuning attention-based transformer models captures even more contextual information than the baselines.
4. Fine-tuning and aggregating RoBERTa Transformer models pre-trained on the three corpora from which the CompLex Dataset was extracted (**BIBLE+EUROPARL+BIOMED**), still gives better results than the baselines (except for **xgb-B** and **xgb-C** in case of sub-task 2), but performs inferior as compared to **BERT-BASE-UNCASED** model for single

word sub-task, while performing almost similar in case of Multi-Word Expressions sub-task. Also, the average aggregation performs better than the maximum aggregation.

5. The combination of transformer models that gives the best results upon aggregation (**BEST COMBINATION**), consists of 3-4 different transformer models fine-tuned on the dataset, suggesting that, **transformer models pre-trained on domains related as well as unrelated to the dataset (such as Financial Data, Legal Data), are able to best mimic annotators coming from various backgrounds**. Even in this case, average aggregation performs better than maximum aggregation.
6. If we consider the evaluation metrics of Pearson Correlation (PC) and Mean Squared Error (MSE), it can be seen (especially in the single-word sub-task) that they are negatively correlated, as is expected.

## 5 Conclusion

We show that aggregating the results of various fine-tuned transformer models pre-trained on various corpora from different domains gives high Pearson Correlation and low mean squared errors compared to individual transformers and regression models using attributes such as hand-crafted features, word embeddings, transformer-based language model prediction probabilities, etc. This shows that transformer-based language models, each pre-trained on a different text corpus, can better imitate annotators of the dataset, who come from diverse backgrounds and prior knowledge.

## Abstract

We present our approach to predicting lexical complexity of words in specific contexts, as entered LCP Shared Task 1 at SemEval 2021. The approach consists of separating sentences into smaller chunks, embedding them with Sent2Vec, and reducing the embeddings into a simpler vector used as input to a neural network, the latter for predicting the complexity of words and expressions. Results show that the pre-trained sentence embeddings are not able to capture lexical complexity from the language when applied in cross-domain applications.

## 1 Introduction

Lexical complexity plays a crucial role in reading comprehension. Predicting lexical complexity of words within sentences in specific textual context can enable systems to better perform certain NLP tasks, such as simplifying texts, and favoring less fortunate readers in a giving target language. The SemEval 2021 proposes a Lexical Complexity Prediction (LCP) shared task (Task 1) (Shardlow et al., 2021) based on a new annotated English dataset with a Likert scale (Shardlow et al., 2020).

Word embeddings (Mikolov et al., 2013; Devlin et al., 2019) are very important resources that support several NLP tasks by providing a semantic latent representation that heuristically captures relationships in language that are very difficult to observe otherwise. Furthermore, such semantic representation can be used to embed language structures other than just words.

Sent2Vec (Pagliardini et al., 2018) is an unsupervised model designed to compose sentence embeddings using word vectors along with n-gram embeddings, simultaneously training composition and the embedding vectors themselves. Sent2Vec has been used in several NLP tasks, such as analysing semantic properties of sentences (Zhu et al., 2018),

classification of sentences in the biomedical domain (Agibetov et al., 2018), automatic detection of incoherent speech (Iter et al., 2018), and measuring sentence similarity (Quan et al., 2019),

In this work, we aim to test the ability of Sent2Vec to detect the complexity of English words and expressions in specific contexts. We evaluate in what extent the semantic information captured when learning the embedding representation is able to incorporate word complexity.

Our approach uses pretrained Sent2Vec models and aims to validate in what extent such models are able to predict complexity of words. Results show strong evidence that pretrained sentence embeddings do not capture complexity features from language, specially when applied in cross-domain applications.

## 2 Method

The proposed shared task consists of determining the complexity of token words in the context of given input sentences (Lexical Complexity Prediction-LCP). Training input sentences annotated with a Likert scale corresponding to the complexity score of target words are given. Sub-task 1 focus on predicting the complexity score of single words. Meanwhile, Sub-task 2 targets multi-word expressions.

Our overall strategy consists on generating chunks of the sentence, embed those chunks with Sent2Vec and then reduce those embeddings into a simpler vector, which would then finally be used as the neural network's input.

Our approach uses pretrained Sent2Vec models to obtain embedding representation of multiple parts of the input sentence split by the target token words. For a given input sentence  $S$ , we obtain embeddings for: a)  $S$ : the full sentence; b)  $S_0$ : the amount of text from the beginning of the sentence

up to the target token(s) (except the latter); c)  $T$ : the target word token(s), and d)  $S_1$ : the amount of text from the target token(s) up to the end of the sentence (except the former). When target tokens are in the beginning or in the end of a sentence,  $S_0$  or  $S_1$  are represented by a zero-value vector.

We reduce the vector representation of each sentence constituent into distance-based arrays that are fed into a neural network estimator. The reduction itself consisted of simplifying the text (using Spacy) and then feeding different chunks into Sent2Vec. Finally, an array of the distances between the chunks' embeddings to the token word's embeddings was used as input to a neural network coming from the Scikit-Learn package.

We use the context given by the two splits of the input sentence ( $S_0$  or  $S_1$ ) to measure the complexity of the token word(s) ( $T$ ). Thus, our pipeline consists of four major steps: *text preprocessing*, *chunking*, *context embedding* and *estimator training*. The chosen estimator was a Multi-Layer Perceptron (MLP).

Figure 1 illustrates this pipeline for an example sentence and token word.

## 2.1 Text Preprocessing

We use a simple preprocessing step based on off-the-shelf components from Spacy Python package (Honnibal et al., 2020)<sup>1</sup> that apply the following filters in the raw input sentence:

- Turning it into only lowercase characters;
- Removing all punctuation;
- Removing all words recognized by Spacy as stop words (unless the stop word was part of the target token  $T$ ).

The reformatted sentences are then split into parts  $S$ ,  $S_0$ ,  $S_1$  and  $T$  to be fed into the next step of the pipeline.

## 2.2 Context Embedding

We embed the four elements of a sentence resulted from the previous preprocessing step using a pretrained Sent2Vec model (torontobooks\_unigrams model has been chosen).<sup>2</sup> As a setback, the token word was often embedded as a null vector (consisting only

<sup>1</sup><https://spacy.io>

<sup>2</sup><https://github.com/epfml/sent2vec#downloading-sent2vec-pre-trained-models>

of zeroes), as expected that such target words from specific domains would be off the pretrained vocabulary.

Instead of concatenating the four resulting embeddings into a single vector to be used as input by our estimator, we perform a reduction that aims to represent how close (distance) to its context a token word is. Thus, our estimator input comprises: a) three norm distances (NumPy's `linalg.norm` method (Harris et al., 2020)) between each sentence embedding ( $S$ ,  $S_0$ , and  $S_1$ ) and the token word's embedding ( $T$ ), and b) a boolean value in the set  $\{0, 1\}$  indicating whether the token word's embedding was a null vector.

## 2.3 Estimator Training

Finally, we use the obtained embedding reductions from the previous step to train a MLP from the Scikit-Learn Python package (`neural_network.MLPRegressor`) (Pedregosa et al., 2011). The MLP was instantiated with the `max_iter` and `random_state` arguments set to 500 and 1, respectively. The estimator was fitted to the input with its `fit` method, with the `X` and `y` parameters being vectors of the reduced embeddings ( $X$ ) and corresponding given token word complexities ( $y$ ).

Our estimator is designed to predict the complexity value for a given token word in context. However, token words can be a misuse of given information, since the complexity of a word varies with context. Our goal with reducing embeddings from fractions of the original sentence into a small vector that served as input to the estimator was similar to the Input Hypothesis, an approach to language learning that grows in popularity.

The Input Hypothesis, also referred to as “+1 method” and surveyed in Wang (2017), discusses a process for acquiring languages by being exposed to content that is slightly above the learner's current level. This is argued to work because the learner is then able to understand the whole sentence (i) and consequently annex a new word or construction (+1) to their vocabulary because of intelligible context.

Reducing embeddings from chunks of the original sentence into a vector of distances from the token word can be expressed as an attempt to symbolize the size (complexity) of this “+1” (the token word) - that is, the neural network input is an observation of how obtainable from its context a given

Figure 1: Illustrated pipeline for our approach

token word is.

We then validate the trained model using `model_selection.train_test_split` method (Scikit-Learn), setting `random_state` parameter set to 1. This method divides the dataset into training and testing subsets. With the MLP fitted with the training subset, the efficiency with which it would handle foreign inputs is measured with a call to its `score` function (using the testing sets as arguments). This function returns the coefficient of determination  $R^2$  of a prediction.

## 2.4 Development Environment

Our solution is made available in a Google Colab file<sup>3</sup>. In order to execute the code, it's necessary to duplicate the file and change the environment variables related to file access (the Sent2Vec models and input files). More information on this process can be found on the file itself.

Since the Google Colab platform permits by default the use of up to a little over 12.5GB RAM, the options of Sent2Vec pretrained models to use are limited: the model we used for this task has only 2GB.

## 3 Results

The task is divided between two subtasks: single- and multi-word tokens. Both have the same format: each line of the input has an ID, a sentence, a corpus to which it belongs, and a token. For training data, each line also includes a complexity value. The difference between the first and second subtasks is that the first limits a token to one single

<sup>3</sup>[https://colab.research.google.com/drive/1MCNfDzM-BW9Zopxs9qFFT8sDLb6FrAM\\_?usp=sharing](https://colab.research.google.com/drive/1MCNfDzM-BW9Zopxs9qFFT8sDLb6FrAM_?usp=sharing)

word, while the second doesn't.

Tables 1 and 2 present the final results of the competition for the two subtasks, respectively. Participant's performance is ranked in each subtask separately. For the submissions without a team name - that is, the submissions made by users not linked to teams -, the user name is available inside brackets. The tables also show each participant's scores for individual corpora. Our approach is identified as C3SL.

We believe the flaws in our approach can be explained in two-fold: a) pretrained embeddings are sensitive to the domain or context used during training, and the way semantic information is captured in a latent representation is not reflected the in the same way in cross-domain applications; and b) even if a latent representation of text would able to capture semantic complexity of certain expression in context, the same is not reflected by the norm or cosine distances between multiple chunks and the target expressions.

## 4 Related Work

Some of the previous work show that Sent2Vec is not the best alternative to consistently achieve high accuracy in subsequent NLP and NLU tasks based on embedding representation of sentences, except when training Sent2Vec with domain-specific corpora.

Miftahutdinov et al. (2019) attempt to use the Twitter unigram pretrained model from Sent2Vec in order to improve their approach when performing extraction of adverse drug reactions from Tweets. However, results show that utilizing Sent2Vec as tweet representations did not improve classification quality.

Cho et al. (2019) use SentVec embeddings to propose a language scheme that generates candidate utterances using paraphrasing and methods from semi-supervised learning.

An empirical study of sentence embeddings (Krasnowska-Kieraś and Wróblewska, 2019) aims to analyse in what extent linguistic information is retained in vector representations of sentences by comparing ten embeddings approaches. Results show that Sent2Vec was only able to outperform other approaches in only 1 out of 11 tasks (word classification task).

Lo et al. (2018) use Sent2Vec trained on the WMT18 news translation task parallel training data (Koehn et al., 2018) to calculate distance of sentence vectors aiming to improve their semantic textual similarity approach when filtering a noisy web crawled parallel corpus.

Iter et al. (2018) aim to automatically extract linguistic features for detecting symptoms of schizophrenia. They compare a number of sentence embeddings and show that, although Sent2Vec outperforms the mean vector sentence embedding (used as a baseline model within the experiments), all other models perform better when measuring coherence using concept overlap and ambiguous pronoun usage.

Zhu et al. (2018) evaluate semantic properties of sentence embeddings models in five tasks: negation detection, negation variants, clause relatedness, argument sensitivity, and fixed point reorder. Results show that Sent2Vec is only able to outperform other embedding models in the clause relatedness task,

which explores whether the similarity between a sentence and its embedded clause is higher than between a sentence and its negation. The resulting accuracy is in the 30-35% range.

## 5 Conclusions

We presented an approach for the LCP Shared Task 1 at SemEval 2021 for predicting the lexical complexities of words in context. We used pretrained Sent2Vec models using a vector formed from embedded chunks of sentences as input for a neural network to perform as the final complexity estimator. Implemented and executed on the Google Colab platform, our approach used little resources.

The results show that pretrained Sent2Vec models alone cannot capture a semantic representation that reflects a word’s or expression’s complexity within cross-domain contexts. As a way of extending our experiments, we plan to perform further analysis in subsequent classification tasks in the biomedical domain using reinforcement strategies to enrich the semantic information captured by embedding representation of sentences.

## Abstract

This paper presents our system for the single- and multi-word lexical complexity prediction tasks of SemEval Task 1: Lexical Complexity Prediction. Text comprehension depends on the reader’s ability to understand the words present in it; evaluating the lexical complexity of such texts can enable readers to find an appropriate text and systems to tailor a text to an audience’s needs. We present our model pipeline, which applies a combination of embedding-based and manual features to predict lexical complexity on the CompLex English dataset using various tree-based and linear models. Our method is ranked 27 / 54 on single-word prediction and 14 / 37 on multi-word prediction.

## 1 Introduction

The rapid expansion of social media and other online channels has made readable information available at an astounding rate. However, the accessibility of this information is often limited by the complexity of this information, especially among readers with low literacy levels in the language of the text and those with reading disabilities. Furthermore, even to the average reader, specialized jargon found in governmental documents and scientific fields is often difficult to decipher.

Systems to guide these users may redirect readers to more easily comprehensible sources, convert the text to simpler wording, or provide additional information about what difficult words mean. The development of such systems is benefited by the ability to evaluate the complexity of sections of the text. While there is currently a large amount of available text data, very little of it is labeled with word complexity; automating the labelling process would make much more data available to aid the

development of NLP systems in tasks such as text simplification.

Multiple features of a word can affect lexical complexity. In addition to a word’s frequency, length and syllable count, the context in which a word is found is likely to affect its understandability. The additional factor of the reader’s proficiency in a language makes this task complex as many words have a highly variable complexity.

In this paper, we describe our model that predicts single- and multi-word lexical complexity scores.

## 2 Background

### 2.1 Task Overview

All data was provided through SemEval Task 1 (Shardlow et al., 2021). Our dataset consists of an augmented version of the CompLex Corpus (Shardlow et al., 2020), which contains English sentences from three genres of corpora: the Bible, Europarl, and biomedical writing. From each sentence, both single- and multi-word tokens were selected and annotated by approximately 7 annotators. Each token was annotated on complexity from a scale of 1-5, though for this competition, complexity was normalized to a continuous scale between 0 and 1.

Token complexity can differ based on the complexity of the token both with and without context. For example, for one instance, the token *river* was rated to have a complexity of 0.0, while *jurisprudence* had a complexity of around 0.672 for another instance. However, token complexities can also change based on the context from which it came from. For example, the token *wisdom* was given a complexity of 0.125 when it was associated in the sentence “*The rod of correction gives wisdom, but a child left to himself causes shame to his mother.*” However, the same token was given a significantly higher complexity score of 0.368 when associated with the sentence “*For in much wisdom is much*

\*Co-first authors.

†Co-senior authors.

*grief; and he who increases knowledge increases sorrow.”*

Given that GloVe embeddings (Pennington et al., 2014) store semantic meaning of single words, we chose to use GloVe embeddings to represent both tokens and sentences. With this approach, we determine that despite contextual variation, inherent properties of the token itself are sufficient to explain much of the variance in lexical complexity.

## 2.2 Traditional Text Complexity Metrics

Many traditional metrics for calculating the complexity of text predict with syllable to word count ratios. For example, the Flesch-Kincaid Grade Level Formula <sup>1</sup> (Kincaid et al., 1975) calculates the complexity of a text with the formula

$$GL = 0.39 \frac{\text{words}}{\text{sentence}} + 11.8 \frac{\text{syllables}}{\text{word}} - 15.59.$$

Other models based on the grade level of a text, such as the Automated Readability Index and the SMOG Index (Kincaid et al., 1975), also exist. Our original hypothesis inferred that these indexes would be good indicators to predict the complexity of a token. However, through empirical analysis, we found that these indicators provided no marginal benefit compared to GloVe sentence embeddings and simpler handcrafted features. As seen in Table 1, we found that the correlation coefficients of traditional complexity metrics to dataset complexity values were low. To test this, we initially included these traditional metrics in our feature space for the following models. Our model reported an R score of 0.63 with the Flesch-Kincaid Grade and SMOG Index as additional features. We removed these features after observing little benefit or worse loss scores (in comparison to Table 2). This suggests that word complexity in context may be embedded in a deeper semantic level than simple word and syllable lengths.

Model	Pearson
Flesch-Kincaid Grade	0.07
Automated Readability Index	0.07
SMOG Index	0.03

## 3 System Overview

### 3.1 Single Word Complexity Score

#### 3.1.1 Data Representation and Features

This system uses a combination of GloVe (Pennington et al., 2014) word embeddings and hand-crafted features as final features to predict complexity on. Pre-trained GloVe embeddings with a dimension of 300 for both the single-word token and each word in the context sentence were used. For the single-word embeddings, PCA with a final dimension of 100 was applied. Since the context sentences contained a variable number of words, we calculated the component-wise mean of all the word-vector representations in the context sentence. We found that sentence features had low mutual information, hence we decided to use a limited number of 10 PCA features to calculate the mean of the sentence features. This mean representation is concatenated with the GloVe embedding of the single-word token.

In other words, let  $\mathbf{t}$  be the GloVe embedding of the single-word token, and  $\mathbf{w}_i$  be the GloVe embedding for word  $i$  in the context sentence, with  $n$  words. We calculate the sentence representation  $\mathbf{s}$  to be

$$\mathbf{s} = \frac{\sum_i^n \mathbf{w}_i}{n},$$

leading to features  $\mathbf{r} = [\mathbf{t}, \mathbf{s}]$  with a dimensionality of 110 features.

On top of this representation, we include hand-crafted features. Through manual tuning, we created a set of manual features:

- **NUMLETTERS**: the number of letters in the token
- **NUMCAPITALS**: the number of capital letters in the token
- **NUMSYLLABLES**: the number of syllables in the token
- **NUMDIGITS**: the number of digits in the token
- **ISFIRSTCAPITAL**: whether or not the first letter is capitalized (implying it is a subject or technical term)
- **NUMSENTWORDS**: the number of words in the context sentence
- **CORPUSTYPE**: the type of corpus the sentence is taken from

- **POS**: the part of speech of the token
- **ISINNER**: whether or not the token is in a named entity

The "POS" and "IsInNER" features are obtained from the Stanza NLP package (Qi et al., 2020).

Instead of relying on the frequencies of words in the text we were analyzing, we found that a more representative frequency metric could be obtained by counting word occurrences in all Wikipedia articles. Hence we decided to use frequencies of word as they appear in the English Wikipedia articles as of February 2019.<sup>2</sup> This feature was concatenated with all of the other handcrafted features and GloVe embeddings, leading to a final feature dimensionality of 126.

### 3.1.2 Learning Models<sup>3</sup>

Because the system primarily treats the input datapoints as sets of vectors and other numerical features, most of the models used were regressors made for data. As the baseline, we used linear regression with the GloVe embeddings for only the single-word token and obtained a baseline R of 0.7888 on the train set.

We explored the following machine learning models:

- **Ridge regression** is a linear least squares model with L2 regularization to reduce overfitting and variance. We use  $\alpha = 0.00001$  as the regularization coefficient to prevent overfitting.
- **Support Vector Regression** is a Support Vector Machine for a regression task that tolerates errors within a certain degree  $\epsilon$ . We use  $\epsilon = 0.02$  as the distance within which no penalty is associated, and  $C = 0.2$  as a regularization parameter to reduce overfitting.
- **Decision Tree Regression** creates a model as a series of decision rules. As a baseline, we created a decision tree with `max_depth = 6`, though other models use varying depths.
- **AdaBoost Regression** (Freund and Schapire, 1996) sequentially applies decision trees, with each tree placing more weight on data that

<sup>2</sup><https://github.com/IlyaSemenov/wikipedia-word-frequency>

<sup>3</sup>All models were implemented using SKLearn (Pedregosa et al., 2012) unless otherwise mentioned.

previous trees did not fit well to. We use DecisionTreeRegressors with `max_depth= 10` as the base estimator, with a total of  $n_{estimators} = 20$  decision trees.

- **XGBoost Regressor** overcomes the inefficiency in gradient boosting of creating a single decision tree at a time by parallelizing tree building. We used `max_depth= 4` and  $\lambda = 2000$  as a regularization parameter. As  $\lambda$  is responsible for L2 regularization of weights, using a higher value would make the model more conservative by encouraging smaller weights.
- **LightGBM Regressor**<sup>4</sup> (Ke et al., 2017) is a framework that uses tree based learning algorithms for gradient boosting. Our model uses gain-based feature importance, with  $\lambda = 50$  and  $n_{leaves} = 40$  and a minimum of 100 datapoints per leaf. To avoid overfitting, we regularize with path smoothing of 1, set a maximum tree depth of 15, and trained using DART boosting.
- **Stacking** We also tested a stack of estimators with a final Ridge regressor to get an ensemble of predictions and reduce overfitting. We stacked five AdaBoost Regressors with  $n_{estimators} = 50, 100$  estimators respectively, each with a base estimator of a Decision Tree Regressor with `max_depth` varying between 5, 7, and 9. On top of this, we stacked two Support Vector Regressors with  $\epsilon = 0.01, 0.001$  and  $C = 0.1, 0.01$  respectively. Finally, we stacked three LightGBM Regressors, each with 100, 50, and 10 leaves respectively. This method was used with the theory that combining multiple models would result in better predictive power than one model alone.
- **Bagging** is an ensemble method involving training copies of a base model on independent random samples of the full dataset. We used an LGBM with  $n_{leaves} = 40$ , `reg_lambda = 100`, `path_smooth = 1`, `max_depth = 12`, and `feature_fraction = 0.75` as our base model. We set  $n_{estimators} = 10$ , `max_samples = 0.8`, and `max_features = 0.75` in order to reduce variance of the decision tree.

<sup>4</sup><https://github.com/microsoft/LightGBM>

- **BERT** We also explore context-dependent deep learning architectures: in particular, we fine-tune the pre-trained BERT model (Devlin et al., 2019). We leverage the pre-trained BERT neural network<sup>5</sup> by tokenizing each sentence, and providing the target word to the model as a second sentence. With 2-3 fully connected layers added on top of the pre-trained model, we fine-tuned this model to generate a numerical complexity prediction, by optimizing on the L2 Loss. All experiments were implemented using SKLearn (Pedregosa et al., 2012) and HuggingFace<sup>6</sup>.

## 3.2 Multi-word Complexity Score

### 3.2.1 Data Representation and Features

Our multi-word data representation closely mirrored our single-word token representation. All hand-crafted features were crafted in the same way as the single word counterparts, except for the POS and NER features which were not included. For example, the feature **NumLetters** includes the number of letters from both words. The context sentence embeddings were calculated with the same methodology of applying PCA with dimension of 10 to the mean of the GloVe embeddings.

The key difference between the two models lies in the representation of the multi-word tokens themselves. The data provided was consistent in that each multi-word token consisted of two words. Therefore, to represent these tokens, we concatenated the GloVe representation of each word in the token, as well as the difference between both GloVe vectors. From there, we applied PCA of dimension 150 to this embedding, which was determined through experimentation, and concatenated this with the other hand-crafted and context sentence features mentioned previously.

More concretely, let  $\mathbf{t}_1, \mathbf{t}_2$  be the GloVe embeddings of each word in the multi-word token. We found the new representation of a multi-word token  $\mathbf{m}$  to be

$$\mathbf{m} = [\mathbf{t}_1, \mathbf{t}_2, \mathbf{t}_1 - \mathbf{t}_2].$$

This was concatenated with sentence representation  $\mathbf{s}$  and handcrafted features for a final dimensionality of 174 features.

<sup>5</sup>We use tokenizers and pre-trained models from the HuggingFace transformers library: [https://huggingface.co/transformers/model\\_doc/bert.html](https://huggingface.co/transformers/model_doc/bert.html)

<sup>6</sup><https://huggingface.com>

### 3.2.2 Learning Models

Given the similarity of the multi-word representations versus the single-word representations (the only difference being the addition of a second token's GloVe embedding), we used the LightGBM Regressor outlined in section 3.1.2, as this model performed the best in the single word token setting. This proved to be an effective way to predict multi-word complexity.

## 4 Experimental Setup

The train and validation dataset splits provided were used in our experimental setup. In addition, we used K-fold validation to reduce overfitting. Using K-fold, we split the training set into  $k$  smaller sets arbitrarily, train using  $k - 1$  folds, and cross-validate with the remaining fold in the train set. This reduces leakage from the validation set into the model so that we can accurately validate our methods.

Task predictions were evaluated using Pearson correlation, though Spearman correlation, mean absolute error, mean squared error, and R-squared were also reported. We compared the performance of our own models using Pearson correlation to keep one consistent evaluation metric.

## 5 Results

### 5.1 Single Word Results

From Table 2, LGBMRegressor performs the best in terms of the Pearson metric. Therefore, we chose this model as our final model for submission.

We found that transforming the word frequencies to a logarithmic scale did not improve results across the models we tested. This is expected because tree-based regressors (Adaboost, LGBM, XGB) are invariant to monotonic scaling. Our results on the task evaluation metrics are shown in Table ??.

We suspect Ensemble Stacking overgeneralized and did not perform effectively as a result, though other stacking methods could perform better. Surprisingly, the contextual deep learning approach of BERT did not perform well on the task, only approaching similar performance to the baseline linear regression on GloVe embeddings.

Though we scored 27th place out of 54 teams overall in the Pearson metric for single-words, the top score was only 0.03 points higher than our own evaluation score. We suspect that different methods of stacking regressors and using complex decision

Model	Pearson
Linear Regression	0.7888
BERT	0.7892
Ridge	0.7829
SVR	0.7945
DecisionTreeRegressor	0.7083

Pearson	0.7533	(27)
Spearman	0.7044	(34)
MAE	0.0653	(25)
MSE	0.0071	(29)
R2	0.5615	(26)

Table 3: Evaluation results (single-word)

trees would have created a model that predicts well with the CompLex dataset. However, whether this type of model will generalize to future datasets is a subject of investigation.

## 5.2 Multi-word Expressions Results

We note that our multi-word expression Pearson metric, as shown in Table ??, performs better than our single word Pearson, and ranks 14th out of 37 teams. This is most likely because averaging the GloVe representations of the two tokens allows for more data points to be represented in the decision tree model.

## 6 Conclusion

In this paper we describe tree-based modelling of words in context to predict lexical complexity. We find that lexical complexity is already embedded in

Metric	Score	Ranking
Pearson	0.8280	(14)
Spearman	0.8124	(18)
MAE	0.0711	(24)
MSE	0.0080	(24)
R2	0.6671	(14)

Table 4: Evaluation results (multi-word)

GloVe representations of words and that complex architectures provide some increase in predictive performance.

For future work, we suggest taking additional contextual features into account, such as the proximity of each neighboring word. We also suggest looking into newer transformer models to represent contextual embeddings.

As larger bodies of text become widely available to wide audiences for public consumption, we are hopeful that such systems will help readers identify suitable texts for their reading level and help build systems that can tailor text to varied reading levels, allowing for greater accessibility.

## Acknowledgments

This research effort would not have been possible without the support of Stanford ACMLab. The authors thank Matthew Shardlow, Richard Evans, Gustavo Henrique Paetzold and Marcos Zampieri for organizing SemEval 2021 Task 1: Lexical Complexity Prediction. We also thank Yasmine Mitchell for helpful discussions.

## Abstract

Evaluating the complexity of a target word in a sentential context is the aim of the Lexical Complexity Prediction task at SemEval-2021. This paper presents the system created to assess single words lexical complexity, combining linguistic and psycholinguistic variables in a set of experiments involving random forest and XGboost regressors.

Beyond encoding out-of-context information about the lemma, we implemented features based on pre-trained language models to model the target word's in-context complexity.

## 1 Introduction

Lexical complexity prediction is the task aiming at evaluating the complexity of a word in context, modeling a crucial aspect of reading comprehension. Complex words can slow down the reading process; there is a well-known correlation between a word's difficulty and the time spent looking at it, as emerging from eye-tracking experiments (Mousikou et al., 2021).

Assessing the complexity of a specific word in context is a crucial prerequisite for NLP systems aiming to evaluate a text's readability and produce a simplified version of it. It is a prerequisite for text simplification systems based on lexical substitutions and can be the starting point to tailor a text to the user's needs. It is a topic worthy of investigation from multiple points of view. In the past, datasets containing crowdsourced evaluations of lexical items' complexity (Paetzold and Specia, 2016b; Štajner et al., 2018) have been used in evaluation campaigns.

In this paper, we introduce the system used to assess single English words lexical complexity at SemEval-2021 Lexical Complexity Prediction task (Shardlow et al., 2021). Based on previous approaches to this issue, we combine linguistic and

psycholinguistic variables, using a random forest regressor and an XGboost regressor. The majority of the variables encode information about the word out-of-context (e.g., frequency, number of letters, age of acquisition) without considering the sentential context and how it can affect an item's complexity.

To approximate in-context complexity, we consider the cloze probability of a word as its probability to complete a particular sentence frame. We experiment with different language models in a masked word prediction framework, taking into account the first ten most probable words occurring in that context.

## 2 Related works

A wide range of approaches has been used for lexical complexity prediction in past evaluation campaigns. However, previous tasks focused on classification since the proposed datasets labeled words in context as easy or difficult.

Including more classes makes the task more difficult. (Garí Soler et al., 2018) investigate the role of word embeddings in lexical complexity prediction for French words, using as training sets two French lexical resources that encode the distribution of words across different levels of difficulty. According to the authors, the task is influenced by the context of use of the words. Word embeddings, encoding contextual information, can be helpful to determine the lexical complexity of target words. The authors experimented with different neural network settings (with and without hidden layers), using as features the number of characters, the number of phonemes, and the log frequency in a corpus of film subtitles plus word embeddings trained on Wikipedia with fastText. However, the combination of word embeddings with such features does not improve the results compared with other sets

of features that always contain frequency, a crucial indicator of lexical complexity.

In past evaluation campaigns, there have been occasional attempts at incorporating word embeddings models in the automatic evaluation process, with the assumption that lexical complexity should be evaluated as a contextual variable. However, better results have been obtained considering just static, out-of-context properties of lemmas.

More recently, the trend to use embeddings from language models to predict psycholinguistic variables can provide insights about how to incorporate them in experiments aiming at understanding the complexity of human comprehension (Hao et al., 2020).

However, if we frame lexical complexity as a measure strongly dependent on words' psycholinguistic properties, we should recognize that past computational efforts for predicting word norms did not take into account the role of context (Russo, 2020; Charbonnier and Wartena, 2019). Static word embeddings such as word2vec have been used to predict values of psycholinguistic norms usually assessed in experimental settings (Ljubešić et al., 2018; Rothe and Schütze, 2016). More recent Transformed-based language models that consistently incorporate contextual knowledge have not yet been considered for this task.

### 3 The Dataset

The Lexical Complexity Prediction shared task at SemEval-2021 (LCP-2021) (Shardlow et al., 2021) is based on an English dataset with a 5-point Likert scale annotation. The complexity score is similar to that included in another dataset (Shardlow et al., 2020). It ranges from very easy for very familiar words to very difficult (unclear words that an annotator had never seen before). Annotators are explicitly invited to evaluate the role of the sentence in inferring the meaning of the word. The task is structured into two sub-tasks:

- Sub-task 1: predicting the complexity score of single words;
- Sub-task 2: predicting the complexity score of multi-word expressions.

The task is inspired by two previous competitions (CWI 2016 and CWI 2018) about boolean complex word identification, aiming at identifying which words are likely to be considered complex or

domain	mean	std dev
bible	0.296	0.132
europarl	0.287	0.109
biomed	0.325	0.152

Table 1: Mean complexity and standard deviation for each domain in the LCP-2021 training dataset.

not by a given target population. However, in LCP-2021 lexical complexity is a continuous property, and the task consists of predicting the complexity score for each target word in context.

7,662 sentences and 3,298 unique tokens compose the LCP-2021 training dataset for single words evaluation: each token appears in more than one sentence, making the impact of context crucial especially for subsets of sentences with highly variable values. For example, the word *livers* occurs 2 times in the dataset, with different complexity scores:

- *The activity of BCKDH in livers of homozygous knockout mouse pups was undetectable, accounting for the accumulation of unmetabolized BCAA.* (complexity score = 0.0499)
- *The comparison of gene expression in livers of mock- or cadmium-treated Mtf1Mx-cre and Mtf1loxP mice revealed several MTF-1 target gene candidates.* (complexity score = 0.323)

Sentences are extracted from three domains: the Bible, the English part of the European Parliament proceedings, and a biomedical corpus composed of scientific papers. Table 1 reports the mean complexity and the standard deviation for each domain. Target words extracted from the biomedical corpus are the most complex. Due to the variability in complexity for the same target word, the biomedical corpus is also the domain that poses significant challenges.

We propose a system for sub-task 1, encoding for each target word numerical values concerning a set of variables described in Section 4. We do not propose a system for sub-task 2.

### 4 Out-of-Context and In-Context Lexical Complexity

The lexical complexity of a word can be represented as an out-of-context property of a lemma or an in-context property of a word.

Following the first approach, the same lemma

has a fixed lexical complexity value, depending on features such as the number of characters or senses in WordNet (see the list of out-of-context features below).

When considering the word in context, its disambiguation could affect its complexity rating because a sense could be more complex than the others (for example, when a word is used in its specialized sense). However, because of the lack of methodologies for assessing senses' complexity and the unsatisfactory performance of word sense disambiguation systems, the role of senses' complexity for lexical complexity prediction can not be investigated. Several systems participating at CWI2018 took into account the role of context, focusing on the whole sentence where target items occur. However, quite interestingly, one of the best models (Gooding and Kochmar, 2018) does not consider the influence of the textual context for determining the target word's complexity. We provide the list of out-of-context features used in our system:

- Length: length of each target word (number of characters);
- Syllables: number of syllables of each target word<sup>1</sup>;
- length sentence: length of each sentence (number of tokens);
- Word freq: frequency of the target word in the Exquisite Corpus<sup>2</sup>;
- AoA Kup: age of acquisition (AoA) of the target word in (Kuperman et al., 2012) dataset. The age of acquisition of a word is a psycholinguistic variable concerning the age at which a word is typically learned. We assume that easy words are learned at a younger age;
- Children freq: the natural logarithm of the frequency of lemmas in children movies subtitles included in a corpus of subtitles (Paetzold and Specia, 2016a). We expect that difficult words will be less frequent in this corpus;
- Visual Genome (VG) freq: the natural logarithm of the lemmas' frequency in the Visual Genome descriptions corpus. The Visual Genome dataset (Krishna et al., 2017)

<sup>1</sup>The values are obtained using syllables 0.1.0 <https://pypi.org/project/syllables/>

<sup>2</sup>The values are obtained using wordfreq 2.3.2 <https://pypi.org/project/wordfreq/>

is the largest dataset of image descriptions for English. It is composed of dense annotations of objects, attributes, and relationships between objects for 108K images. As a pre-processing step, the descriptions have been annotated with TreeTagger (Schmid, 1994) and the list of lemmas has been ordered by frequency;

- ImageNet: the presence of the target word in ImageNet (boolean feature). Only concrete nouns can be included as pictures in this resource. We assume that easy words tend to be more frequently concrete (Russakovsky et al., 2015);
- Uppercase: this variable takes into account the relative number of uppercase letters in the target words, and it is used to detect acronyms. We notice that acronyms are generally rated as difficult word;
- Scrabble: for each target word, its value according to Scrabble's rules. In this word game, each letter's number of points is based on the letter's frequency in standard English. We expect that complex words will have higher ratings;
- Senses: number of senses of the target word in WordNet (Fellbaum, 1998);
- Bible/europarl/biomed: boolean feature encoding if the sentence belongs to one of these domains.

A word  $x$  is difficult in a sentential context if the reader has never encountered it. The relative frequency should be sufficient to explain the perceived complexity of  $x$ ). A word can also be difficult if its meaning in that specific context is not the most common one, i.e when a specialized sense is accessed or a metaphorical meaning is created. If we know a word by the company it keeps, we do not know a word when its company is somewhat eccentric.

Lexical complexity as an in-context property can be modeled considering the influence of the surrounding text. There are two ways to model the textual context's influence on the lexical complexity of a target word: local context (a window span surrounding the target word) and global context (the whole sentence). In the first case, words surrounding the target word can increase the overall

complexity in that text span. In the second case, the probability of a word in a masked word prediction task that concerns the whole sentence can be a good approximation of the intuition that words semantically difficult to generate are more complex than the simpler ones. We implemented two types of variables as in-context features to address in-context lexical complexity:

- Position [Language Model]: The target word’s position among the first ten most probable words completing the sentence in a masked context for five language models. The language models tested are BERT, XLNet large, BART, ELECTRA, and RoBERTa. We used pre-trained models made available by HuggingFace;
- Out-of-context complexity of the previous tokens: the value is obtained by selecting the five content words (nouns, adjectives, or verbs) preceding the target word and averaging their complexity values resulting from a random forest regressor that includes just out-of-context variables.

The Pearson correlations among each feature and target word’s lexical complexity reveal that word frequencies are the most relevant features, especially frequencies extracted from children movies’ subtitles (see Figure 1). The age of acquisition of words is another variable strongly correlated with the complexity of the target words ( $r=0.55$ ).

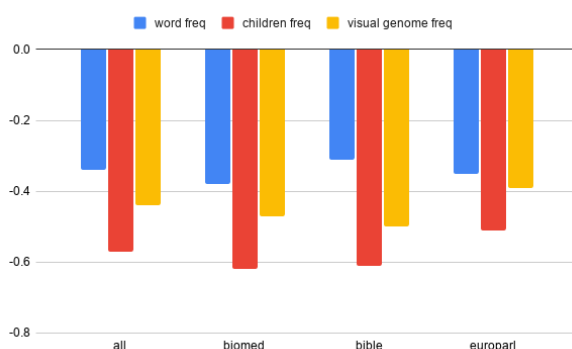

Figure 1: Pearson correlations between lexical complexity and word frequencies from different corpora, reported for each LCP-2021 domain.

## 5 Experiments

The set of features described in Section 4 has been implemented for the training set, tested on trial set,

Domain	MAE	R
bible	0.075	0.69
europarl	0.054	0.76
biomed	0.066	0.86
all_out_of_context	0.063	0.817
all_in_context	0.095	0.415
all	0.065	0.80

Table 2: Random forest regression results on trial set.

features	MAE	R
all_out_of_context	0.063	0.793
all	0.062	0.799

Table 3: Average random forest regression results on five training-trial splits.

and - to avoid overfitting - on multiple training-test splits with test sets mimicking the trial set’s composition. We experimented with a system based on a random forest regressor (RF), and a system based on an XGboost regressor (Chen and Guestrin, 2016), both implemented in sklearn. For the RF regressor, we choose to measure the quality of a split with mean absolute error. We also normalized the features with the standard scaler function (scaling each feature between 0 and 1). We obtained comparable results, with random forest regressor performing slightly better for several training-trial splits. For this reason, Table 2 summarises RF results. We report the mean absolute error (MAE) and Pearson correlation (R), used to rank the systems at LCP-2021 task.

In-context features emerge as useless from these results; however, testing with different trial sets, we infer that this set of features could improve the performance (see Table 3) and, as a consequence, we included all the features for the processing of the test set released by LCP-2021 organisers. Concerning the role of word frequencies, that are negatively correlated with lexical complexity (see Section 4), frequencies from a general corpus used together with frequencies from children movies subtitles guarantee a good performance of the RF regressor in terms of MAE and Pearson correlation (see Table 4). Our system ranked 22 out of 54 for the single word complexity prediction task. The best result on the test set was obtained using all the features and the random forest regressor (see Table 5).

features	MAE	R
Word freq + children freq	0.069	0.74
Word freq + VG freq	0.068	0.752

Table 4: Average random forest regression results on five training-trial splits for frequency features.

all features	
Pearson	0.7561
MAE	0.0641
Spearman	0.7067
MSE	0.0069
R2	0.5707

Table 5: Best random forest regression results on test set (official results).

## 6 Conclusions

This paper briefly reports the system created to predict single words’ complexity score for the Lexical Complexity Prediction shared task at SemEval-2021 (LCP-2021).

Our system ranked 22 out of 54 for this sub-task, with slightly inferior results to the ones obtained on trial sets. The significative role of frequencies extracted from different corpora paves the way to further investigations in this direction.

Encoding in-context complexity as a variable related to pre-trained language models’ predictions had no significant impact on the results. However, in-context complexity could be modeled in different ways. Experimenting with how in-context target word’s complexity changes depending on the frequencies of the surrounding words is a future analysis topic.

## Abstract

This paper describes systems submitted to SemEval 2021 Task 1: Lexical Complexity Prediction (LCP). We compare a linear and a non-linear regression models trained to work for both tracks of the task. We show that both systems are able to generalize better when supplied with information about complexities of single word and multi-word expression (MWE) targets simultaneously. This approach proved to be the most beneficial for multi-word expression targets. We also demonstrate that some hand-crafted features differ in their importance for the target types.

## 1 Introduction

SemEval-2021 Task 1 is the task of Lexical Complexity Prediction (LCP) (Shardlow et al., 2021). The goal of the task is to assign a target in a context a continuous value ranging between 0 and 1, where 1 indicates complete unintelligibility and 0 signals perfect familiarity as perceived by a native speaker. The task has two tracks: predicting the complexity score of single words and predicting the complexity score of multi-word expressions (MWE). Such a task can be useful in applications like text simplification or automatic language proficiency evaluation.

The CompLex dataset (Shardlow et al., 2020) used in this task is the first English dataset for the task of LCP. The dataset contains single words and MWEs annotated with their lexical complexity score in a specific context. The annotations were provided by native speakers of English. The targets and their contexts were obtained from texts of different domains: the Bible, Europarl, and biomedical texts. The dataset opens several avenues for research. For instance, how does the perceived complexity of single words and MWEs differ? How does context affect the lexical difficulty of a target?

How does text genre affect comprehensibility of words?

We were interested if there is a difference in performance when using the same representation methods for single words and MWEs. It was decided to approach both tracks as the same problem. We did not distinguish between MWEs and single words and they both were treated as one lexical unit. The same array of features was extracted to represent the targets and linear and non-linear regressors were trained using both subcorpora. This strategy showed performance gains for both single targets and MWEs.<sup>1</sup>

In addition, we wanted to investigate how much the classic hand-crafted features like frequency and length together with subword information and contextualized embeddings (not employed previously for LCP) contribute to complexity estimation of both single words and MWEs. We present the analysis of feature importance rankings in Section 6.

## 2 Related Work

Complex Word Identification (CWI) is the task of determining how difficult a lexical unit is to a target audience (Shardlow, 2013). The knowledge about the lexical unit complexity can benefit several NLP tasks such as text simplification (TS) or applications related to second-language (L2) acquisition.

The goal of TS is to adapt a text to make information, for example, news, more accessible for readers. The TS target group can be language learners (Petersen and Ostendorf, 2007), people with cognitive disabilities (Yaneva et al., 2016) or people with low literacy skills (Aluisio et al., 2010). One of the strategies of TS is lexical simplification (LS). LS is the task of substituting complex words with simpler ones without changing the original mean-

<sup>1</sup>The code and notes are available at <https://github.com/katildakat/COMPLEX>

ing. To perform the LS one should first identify the units that might pose a difficulty (Shardlow, 2013).

In the area of L2 acquisition, lexical complexity information can be used both for generating study materials appropriate for a learner’s level (Alfter and Volodina, 2018) and for evaluating how proficient a student is (del Río, 2019).

To understand what makes a word complex for a target audience, one needs to obtain data with complexity annotated. The first manually labelled resource for CWI (CWI 2016) was introduced in SemEval-2016 Task 11 (Paetzold and Specia, 2016). It contained sentences with words marked by non-native speakers of English as either difficult or easy to understand. A word was labelled as complex if at least one annotator marked it as such. Thus, words were classified in a binary fashion without addressing the proficiency levels or native languages of the annotators.

Another CWI dataset (CWI 2018) was presented for BEA workshop 2018 (Yimam et al., 2018). It contains CWIG3G2 datasets (Yimam et al., 2017) expanded further with the French subcorpus. This is a multilingual dataset with words and MWEs marked as complex or simple within a given context. There is no standard form for MWEs. The annotators were free to label any sequence of words as a difficult MWE. The complexity judgments were collected from native and non-native speakers. In addition to the binary labels, the words were also assigned an aggregated complexity score. The score was computed as the proportion of annotators that found a word complex.

In summary, in both CWI 2016 and CWI 2018 the annotators were not asked to provide a degree of difficulty. The MWEs in CWI 2018 were not clearly defined making the nature of their complexity hard to investigate. The CompLex dataset used in SemEval-2021 Task 1 was constructed to amend the aforementioned faults of CWI 2016 and CWI 2018. First, it treats complexity as a continuous value. Second, it bounds MWEs to only pairs of adjective-noun or noun-noun phrases allowing for more targeted research. We believe that models trained using CompLex have more flexibility in their application. For example, one could set a threshold of complexity to account for different language proficiency levels for both TS and L2 acquisition-related applications.

One of the goals of CWI is to establish what makes a word complex. The reports for CWI 2016

(Paetzold and Specia, 2016) and CWI 2018 (Yimam et al., 2018) as well as the investigation of CWI 2016 results (Paetzold and Specia, 2016) show that such features as frequency and length are the most predictive for establishing word complexity. Moreover, according to the baselines provided by SemEval-2016 Task 11 organizers (Paetzold and Specia, 2016), the degree of polysemy of a word was also quite successful. In addition to hand-crafted features, the teams in both competitions made use of different static word embeddings but they didn’t outperform the frequency-based features.

### 3 System overview

A linear and a non-linear models were compared. We have trained a linear regression and a multilayer perceptron using the same array of features. The features can be divided into two categories: embeddings and hand-crafted features for both target and context.

#### 3.1 BERT Embeddings

For embeddings, it was decided to represent targets and their context using BERT model (Devlin et al., 2018). First, BERT is able to provide a target with a representation dependent on the context. Second, because of its next sentence prediction objective during training, it is also able to produce a separate representation for the whole sentence in the same vector space as a target. We were interested to see if target representation would benefit from combination with this additional context information.

When a single word target is present in the BERT’s token vocabulary, it is represented simply as a vector assigned to it by the model. In the case when a target is absent from the BERT’s vocabulary, it is represented as an average vector of its subword embeddings. MWE targets were always represented as an average representation for their BERT tokens. Contexts were assigned with [CLS] token embeddings. Finally, target and context embeddings were combined into a mean vector of 768 dimensions. When used as features to represent the training dataset in the linear regression model, mean embeddings demonstrated a slightly better performance on the trial data than concatenated vectors. For this reason, we have opted for the average embeddings of targets and contexts instead of the concatenation.

### 3.2 Hand-crafted features

In addition to contextualized embeddings, we were also interested to explore other features. We were especially interested to study how the target’s subword information can be used to explain its complexity value. The final set of features was as follows:

1. The number of BERT vocabulary tokens (an average number for MWE) in a target. This feature was chosen because it implicitly contains frequency information about a target. BERT uses WordPiece tokenizer (Wu et al., 2016). WordPiece is a frequency-based word segmentation algorithm. It learns to unite substrings into new vocabulary items to increase the likelihood of its training data. This means the targets that were tokenized into several BERT tokens were infrequent in the tokenizer’s training data.
2. A BERT score for a masked target. This feature was intended to convey information about how easy it is to predict a target in a given context. This approach however has a downside for our specific BERT implementation: BERT base model was trained to predict a randomly masked WordPiece token not a whole word token. It was decided that all single word targets are to be replaced with one MASK token. An average log probability to appear in place of a mask for every target subtoken was collected. MWE targets were substituted with two MASK tokens. An average log probability for subtokens of both words is collected, summed and divided by two.
3. A number of subwords a target is divided into (an average number for MWE) by a Morfessor segmentation model (Virpioja, 2013). This feature was expected to be a better complexity predictor than a target length in characters since it might be able to indicate a number of word parts connected to semantic or grammatical meaning.
4. An average frequency of subwords a target contains. This feature was expected to reflect how easy it would be to derive a meaning from word subparts. The frequencies were estimated using the segmentation model. In CWI 2018 the character n-gram frequency information employed by (Alfter and Pilán, 2018) achieved high results. The success of this approach might be supported by the evidence that morphological awareness affects how both native and non-native speakers process words (Kimppa et al., 2019) (Deacon et al., 2014). This feature was chosen to investigate if frequency of morpheme-like subwords is also a good lexical complexity predictor.
5. A number of WordNet synsets (Fellbaum, 1998) that a target is present in. This feature was used to provide the information on the target’s degree of polysemy. For the MWEs, we counted both synsets for the whole expression as well as synsets where either of the parts is present.
6. The length of a target in characters (an average length for MWEs).
7. Finally, we have chosen to include word frequency (an average frequency for MWEs). Frequency information is known to be a good predictor for complexity, so it was reasonable to use it as a baseline to compare other features to.

For the submitted system, the embedding features were concatenated with hand-crafted features into 775 dimensional vector. This vector was used as an input to both regressor types.

We have also investigated if the described setup would benefit from feature selection. We decided to half the original feature vector’s size in half by leaving only 400 most informative dimensions. For the linear model, the dimensions were ranked by their F-score. The mutual information was used to chose the dimensions for the neural model.

## 4 Experimental setup

### 4.1 Data

During the system development phase, models were trained only with the train subsets of the data, and then their performance was evaluated on trial subsets. For the final submission, both linear and non-linear models were trained with all the data available (single target train and trial, MWE target train and trial).

	LR all	NN all	LR 400	NN 400
Singles	0.666	<b>0.712</b>	0.688	0.707
MWEs	0.783	0.785	<b>0.796</b>	0.774

Table 1: Joint System Results

## 4.2 Parameters and Tools

Both linear regression and neural network models were trained with scikit-learn 0.24.0<sup>2</sup>. It was also used for the feature selection process. The neural network model is a simple Multilayer Perceptron regressor with one ReLu layer of 20 neurons and alpha parameter set to 0.9. Using 8-fold cross validation procedure on all labelled data, we noticed that smaller layer sizes and larger alpha parameters produced better results. However, we feel it is important to note that the hyperparameters were not tuned with proper care, and we believe that better configurations might be possible.

We used BERT base model (cased) to get contextualized embeddings. The cased model was chosen because in CompLex dataset case plays an important role when distinguishing a target from other words in context. The model was used through the 4.0.0 version of transformers library (Wolf et al., 2020).

The Morfessor segmentation model was trained with Morfessor 2.0<sup>3</sup> using logarithmic frequency dampening for words in the data, and with the corpus weight parameter  $\alpha = 0.1$ . The text used for the segmentation model comes from samples of all subcorpora in The Corpus of Contemporary American English (COCA) but for the Academic texts<sup>4</sup>.

The WordNet was used via NLTK 3.4<sup>5</sup>. The word frequencies were obtained using the Zipf frequency estimates in the 'best' wordlist of wordfreq library<sup>6</sup> (Speer et al., 2018).

## 5 Results

The results of the systems trained jointly with single and MWE targets are presented in Table 1. The results for the systems trained with each subcorpus separately are reported in Table 2. The results in both tables are given using Pearson correlation co-

efficients for the test data indicated by row names. LR stands for the linear regression model, and NN stands for the neural regressor. Captions 'all' and '400' distinguish between models trained using all 775 dimensions or 400 with the best scores.

For the single word track, the CodaLab system for some reason accepted only the linear scores, and for the MWE track CodaLab, conversely, accepted only non-linear model predictions. Moreover, the top score for the linear model in the single word track was reported without using Morfessor features.

## 6 Discussion

As can be seen from the results tables, two trends are obvious: MWE targets always benefit from being trained together with single word targets, and the non-linear model tends to slightly outperform the linear one. This can be contributed both to the nature of MWE and to the smaller size of the MWE subcorpus. Although the linear system trained with only single word targets showed better results than the joint one, the non-linear model has also gained from the information about both types of targets when predicting single word complexity. Finally, the feature selection procedure was able to improve the performance of the linear model.

We were interested to find what features for MWEs and single words signal lexical complexity in a similar manner and what features differ in their usefulness. For this purpose, we collected F-scores and mutual information values for the hand-crafted features evaluated for the joint dataset as well as

for the target type subcorpora.

The ranks of hand-crafted features according to their F-scores and mutual information values can be found in Table 3. The features are listed in the same order as they were presented in Section 3.2. The names of the columns reflect the content of the dataset divisions that were explored: S stands for the single targets part of the data, MWE stands for the examples with only MWE targets, and S+MWE marks the results for the joint dataset. The mutual information ranks can be found in 'm' columns and F-scores are given in 'f' columns. The ranks are reported for the features evaluated with the train and the trial parts of the corpus simultaneously.

The information collected in Table 3 shows some differences in feature importance for predicting single word targets and MWE targets, as well as, differences in how suitable some features are for linear and non-linear models. Moreover, the consistency of how high most of the hand-crafted features rank indicates that they remain relevant for LCP and CWI tasks even in presence of such modern approaches as contextualized embeddings.

All hand-crafted features were present in the top 20 highest scored dimensions with mutual information for the joint data and for the single target data. For the MWE targets, information about morph frequency played a less important role placed at only 110 place. Moreover, with the F-score rankings, morph frequency was absent in the top 20 dimensions from all the data configurations.

Target length in characters has not appeared in the top 20 most correlated features for the joint dataset and for the single targets, but it was still relevant for MWEs. Word frequency was rated as the highest correlated feature in all setups, it was followed by the BERT token number feature. These two features were followed by morph number and by the probability of a masked target. Surprisingly, the subword frequency feature was not as successful. The reason for this can be the small amount of data it was estimated on.

## 7 Conclusion

This paper presents the results of two systems submitted to SemEval 2021 Task 1: Lexical Complexity Prediction (LCP). We show that training a system jointly with single word targets and MWE targets benefits the predictability of both target types, especially the MWEs. We also show that the frequency of subwords feature is more predictive for

single targets, while length of a target in characters is more useful for MWE complexity estimation. Finally, we show that classic frequency feature is still the most predictive one, even when used together with new contextualized embeddings.

For the future work, we would like to explore if the underwhelming results of the subword frequency feature can be amended by collecting statistics from a larger resource. Another thing we would like to research is what makes the joint training with single and MWE targets successful. Is it the smaller amount of data available for MWEs? Or is it the nature of noun-noun and adjective-noun MWE expressions? Does the second word of the pair contribute more to the MWE complexity and thus compares better to single word targets?

## 8 Acknowledgments

I would like to express my gratitude to the anonymous reviewer for their insightful and helpful comments. I also want to thank Ragheb Al-Ghezi for proofreading and Mikko Kurimo for his comments on an earlier draft of the paper. Lastly, I want to say thank you to Science-IT team for providing computational environment used in the experiments. This work is a part of DigiTala project which is funded by the Academy of Finland (grant number 322625).

# GX at SemEval-2021 Task 2: BERT with Lemma Information for MCL-WiC Task

Wanying Xie

Beijing Language and Culture University, China

xiewanying07@gmail.com

## Abstract

This paper presents the GX system for the Multilingual and Cross-lingual Word-in-Context Disambiguation (MCL-WiC) task. The purpose of the MCL-WiC task is to tackle the challenge of capturing the polysemous nature of words without relying on a fixed sense inventory in a multilingual and cross-lingual setting. To solve the problems, we use context-specific word embeddings from BERT to eliminate the ambiguity between words in different contexts. For languages without an available training corpus, such as Chinese, we use neural machine translation model to translate the English data released by the organizers to obtain available pseudo-data. In this paper, we apply our system to the English and Chinese multilingual setting and the experimental results show that our method has certain advantages.<sup>1</sup>

## 1 Introduction

In recent years, contextual embeddings have drawn much attention. The approaches of calculating contextual embeddings include multi-prototype embeddings, sense-based and contextualized embeddings (Camacho-Collados and Pilehvar, 2018). However, it is not easy to evaluate such multiple embedding methods in one framework. Pilehvar and Camacho-Collados (2019) present a large-scale word in context dataset to focus on the dynamic semantics of words. Following and expanding them, the MCL-WiC task (Martelli et al., 2021) performs a binary classification task that indicates whether the target word is used with the same or different meanings in the same language (multilingual data set) or across different languages (cross-lingual data set). Besides, it is the first SemEval task for Word-in-Context disambiguation (Martelli et al., 2021).

<sup>1</sup>Reproducible code: <https://github.com/yingwaner/bert4wic>

A typical solution to the problems is obtaining context-specific word embeddings, such as Context2vec (Melamud et al., 2016) and Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019). BERT is designed to pre-train deep bidirectional representation in unlabeled texts by jointly conditioning in the left and right contexts of all layers. Due to its powerful capabilities and easy deployment, we use BERT as our major system and fine-tune on the training data released by the organizer to get the context-specific word embeddings.

In this paper, we participate in the sub-task of multilingual settings in English and Chinese. The organizer only provides English training data, and we fine-tune the pre-trained English BERT model based on this data. For Chinese tasks where no training set is available, we train a satisfactory neural machine translation (NMT) model to translate the English training set into Chinese and then fine-tune the Chinese BERT model based on the pseudo-data. The experimental results show that our method achieves 82.7% in English multilingual setting and 76.7% in Chinese multilingual setting.

## 2 Background

In this section, we will briefly introduce the word-in-context task and the structure of BERT for the sentence pair classification task.

### 2.1 Word-in-Context

The MCL-WiC task (Martelli et al., 2021) expands the Word-in-Context (WiC) (Pilehvar and Camacho-Collados, 2019) task to be multilingual and cross-lingual settings. For WiC, each instance has a target word *lemma*, which provides it with two contexts. Each context triggers the specific meaning of the word *lemma*. The task is to identify whether *lemma* in two contexts corresponds to

Figure 1: Overall fine-tuning procedures for our system. The token Lemma is the target word that require the system to judge whether it has the same meaning in two sentences.

the same meaning, which has been widely investigated in recent years. Wiedemann et al. (2019) perform word sense disambiguation models with contextualised representations. Hu et al. (2019) prove that the supervised derivation of time-specific sense representation is useful. Giulianelli et al. (2020) present an unsupervised approach to lexical-semantic change that makes use of contextualized word representations. Loureiro and Jorge (2019) compute sense embeddings and the relations in a lexical knowledge base. Scarlini et al. (2020) drop the need for sense-annotated corpora so as to collect contextual information for the senses in WordNet.

## 2.2 BERT

Neural contextualized lexical representation has been widely used in natural language processing, which benefits from deep learning model in optimizing tasks while learning usage dependent representations, such as ULMFiT (Howard and Ruder, 2018), ELMo (Peters et al., 2018), GPT (Radford et al., 2018, 2019), and BERT (Devlin et al., 2019). BERT is pre-trained by two unsupervised tasks: masked LM task, which is simply masking some percentage of the input tokens at random, and then predicting those masked tokens; and next sentence prediction task, which is whether the next sentence in the sentence pair is the true next sentence. In the fine-tuning phase, task-specific inputs and outputs are plugged into the BERT and all parameters are fine-tuned end-to-end.

The architecture of BERT is a multi-layer bidirectional Transformer encoder based on the original implementation described in Vaswani et al.

(2017). There are several encoder layers in the BERT model. For a single layer in Transformer encoder, it consists of a multi-head self-attention and a position-wise feed-forward network. Specifically, there are specialized input and output formats for different downstream tasks. For language pair classification task, the input format is [CLS] + Sentence 1 + [SEP] + Sentence 2 + [SEP]. At output layer, the [CLS] representation is fed into an output layer for the classification task, such as entailment, sentiment analysis, and the word-in-context disambiguation task.

## 3 System Overview

Systems proposed for both English and Chinese multilingual settings were based on BERT model (Devlin et al., 2019) with task-specific input modifications. We participate in the multilingual setting and divide the system into two parts according to the language: English setting and Chinese setting.

### 3.1 English Setting

Following Devlin et al. (2019), we initialize our model with the well pre-trained model, which has been trained on the large-scale data set and obtained the general knowledge. Then we fine-tune the model on the English parallel sentences released by the organizers.

**Model Architecture** The model architecture in the fine-tuning stage is shown in Figure 1. On the basis of the original BERT input, *lemma* token is added, which is the target word that needs the system to judge whether it has the same meaning

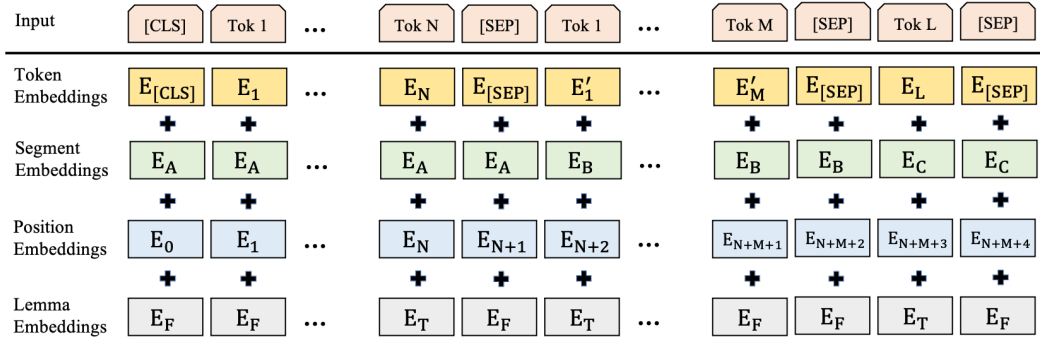

Figure 2: Our system input representation. The input embeddings are the sum of the token embeddings, the segment embeddings, the position embeddings, and the lemma embeddings. It is only at the position of the lemma tokens that the lemma embedding is  $E_T$ . In this example, we assume that Tok N in sentence 1 and Tok 1 in sentence 2 are also lemma tokens.

in the sentence pair. For instance, given the sentence pairs 'They opposite to the policies designed to tackle inflation.' and 'I tackled him about his heresies.', the standard input format is:

[CLS] They opposite to the policies designed to tackle inflation . [SEP] I tackled him about his heresies . [SEP] tackle [SEP] where *tackle* is the lemma token, which is also the word that needs to be judged by the system whether it has the same meaning in two sentences. In this way, we emphasize the target word so that the output  $T_{[CLS]}$  of the output layer can express whether the lemma token is synonymous in the two sentences.

**Input Representation** In addition, we also made some modifications for the input representation, which is made up of the sum of the corresponding token, segment, and position embeddings according to Devlin et al. (2019). The input representation of our system is shown in Figure 2. We adjust the segment embeddings of the lemma token to further emphasize the importance of the target word in the whole sentence pair, which is represented as  $E_C$ . Moreover, we introduce lemma embeddings in the input representation. Lemma embeddings are similar to segment embeddings, but segment embeddings are to distinguish between sentence 1 and sentence 2, while lemma embeddings are to distinguish between the position of lemma tokens and the position of other tokens. Only the lemmas in sentence 1 and sentence 2 and the final lemma Tok L will be marked  $E_T$ , and the other positions will be marked  $E_F$ , that is, for a training example, there will be three lemma markers  $E_T$  in lemma embeddings. In this way, we enhance the relationship of lemma tokens to make them

more closely connected, and at the same time highlight and emphasize the position and importance of lemma tokens, so that the final output can obtain enough lemma token information.

### 3.2 Chinese Setting

The multilingual setting in Chinese is more difficult because there is no available training data in Chinese, so it is not possible to fine-tune the pre-trained BERT model. In order to solve this problem, we introduce neural machine translation method.

**Neural Machine Translation** Due to the superior performance of Transformer, we use it as our neural machine translation model. We first train an English-to-Chinese translation model on an open-source dataset and evaluate its performance to ensure that it has sufficient translation quality. Then, we use this translation model to translate sentence 1 and sentence 2 from the English training set released by the organizer into Chinese, respectively, and regard the generated sentences as the training data of Chinese MCL-WiC task. Finally, we use the pre-trained Chinese BERT model to fine-tune this generated data set to get our final model.

**Model Architecture** The system in Chinese setting is somewhat different from the system in English setting in that there is no lemma token. We use machine translation to translate English training data into Chinese, because every token in a sentence has a context, so sentence to sentence translation does not change the meaning of the whole sentence much. However, a lemma token has no context, so it is difficult for translation model to choose which token to translate into the target

	English				Chinese			
	Valid	$\Delta$	Test	$\Delta$	Valid	$\Delta$	Test	$\Delta$
Fine-tuning	81.2	-	81.6	-	67.9	-	76.7	-
+Lemma Token	81.8	0.6	82.1	0.5	67.1	-0.8	76.0	-0.7
+Segment $E_C$	82.2	0.4	82.4	0.3	67.3	0.2	76.3	0.3
+Lemma Embeddings	82.5	0.3	82.7	0.3	-	-	-	-

Table 1: Main results on English and Chinese tasks. The measure is accuracy (%). The '+' in systems represent an increase in modules of the system in the previous row.  $\Delta$  represents the difference between the result of the current system and that of the previous row.

language, because it may correspond to multiple meanings. Therefore, the final submitted system to the task has no lemma token, no segment embedding  $E_C$  and no lemma embeddings. However, in order to analyze the role of lemma tokens in this multilingual setting, we will report the results with lemma token and segment embedding in Table 1 and Section 5.1. In this case, the lemma token will be translated to the most common Chinese word.

## 4 Experimental Setup

In this section, we will describe the experimental settings for English and Chinese in detail.

### 4.1 English Setting

Take one pre-trained English cased BERT *base* model<sup>2</sup> with 12 layer, 768 hidden, 12 heads, and 110M parameters, and fine-tune on the English training data in 5 epochs with batch size is 16 and max sequence length is 128. The dropout rate is 0.2 and other settings are followed Devlin et al. (2019).

### 4.2 Chinese Setting

The fine-tuning setups are the same as the English ones, except that the pre-training model is a Chinese BERT *base*<sup>3</sup> with a layer of 12, hidden size of 768, heads of 12, and parameters of 110M.

For machine translation model, we implement Transformer *base* model (Vaswani et al., 2017) using the open-source toolkit *Fairseq-py* (Ott et al., 2019). The training data of English-Chinese is from UNPC v1.0 and MultiUN v1 in WMT17<sup>4</sup>, which are total 30.4M sentences. We trained the model with dropout = 0.1 and using Adam optimizer (Kingma and Ba, 2015) with  $\beta_1 = 0.9$ ,

<sup>2</sup>[https://storage.googleapis.com/bert\\_models/2018\\_10\\_18/cased\\_L-12\\_H-768\\_A-12.zip](https://storage.googleapis.com/bert_models/2018_10_18/cased_L-12_H-768_A-12.zip)

<sup>3</sup>[https://storage.googleapis.com/bert\\_models/2018\\_11\\_03/chinese\\_L-12\\_H-768\\_A-12.zip](https://storage.googleapis.com/bert_models/2018_11_03/chinese_L-12_H-768_A-12.zip)

<sup>4</sup><http://www.statmt.org/wmt17/translation-task.html>

$\beta_2 = 0.98$ , and  $\epsilon = 10^{-9}$ . The translation is detokenized and then the quality is 35.0, which is evaluated using the 4-gram case-sensitive BLEU (Papineni et al., 2002) with the *SacreBLEU* tool (Post, 2018).<sup>5</sup> This translation model achieves satisfactory results, which shows that the method of translating English training set into Chinese has theoretical basis and feasibility.

## 5 Results

In this section, we will first report the main results of English and Chinese multilingual setting and analyze the importance of all the factors in the system. Then, we explore the probability of error for each part of speech.

### 5.1 Main Results

We conduct our experiments based on BERT frame<sup>6</sup>. The specific meanings of each system in the main experiment are as follows:

**Fine-tuning** Following the standard fine-tuning format of Devlin et al. (2019), sentences 1 and 2 are connected by [SEP].

**+Lemma Token** Lemma token is added on the basis of the previous system, and the training input at this time is '[CLS] + Sentence 1 + [SEP] + Sentence 2 + [SEP] + Lemma + [SEP]'.

**+Segment  $E_C$**  Based on the previous system, the segment embedding of the final lemma token is set to  $E_C$ .

**+Lemma Embeddings** Lemma embedding will be added on the basis of the previous system, and the input representation at this time consists of four parts: token, segment, position, and lemma embeddings.

The main results are shown in Table 1, and the specific analysis is as follows:

<sup>5</sup>BBLEU+case.mixed+lang.en-zh+numrefs.1+smooth.exp+test.wmt17+tok.zh+version.1.4.4

<sup>6</sup><https://github.com/google-research/bert>

	English		Chinese	
	Num	Acc	Num	Acc
NOUN	528	83.14	554	78.70
VERB	298	83.22	364	75.82
ADJ	144	81.94	62	69.35
ADV	30	73.33	20	60.00
Overall	1000	82.70	1000	76.70

Table 2: Error analysis on the test set. Num represents the number of examples of this part of speech in the test set, and Acc represents the accuracy (%) of the current part of speech.

**English** Fine-tuning alone can obtain relatively good performance, and the performance has been further improved with the introduction of the three new modules. Here we conduct experiments to check their influence on our method by adding them one by one. With the addition of +Lemma Token, our system has a significant improvement, while the improvement brought by the other two modules is slightly lower, indicating that the presence or absence of lemma token has a greater impact.

**Chinese** Fine-tuning achieves the best performance in this task. After the introduction of +Lemma Token, the result shows that the effect is greatly reduced, which may be because the translated lemma token is not necessarily the appropriate translation result. Because fine-grained translations of individual tokens have no context, they often fail to translate properly, as mentioned in Section 3.2. However, after the introduction of +Segment  $E_C$ , the effect has been slightly improved, which proves that our idea is effective. Because it is difficult to get the exact position of the lemma word after translation, there is no result of +Lemma Embeddings. Based on the above results, we use Fine-tuning as the final system for the Chinese task. In other words, our final model has no lemma token, no segment embedding  $E_C$  and no lemma embeddings.

## 5.2 Error Analysis

Lemma tokens have different parts of speech, so we think about the relationship between the accuracy of system prediction and the parts of speech of lemma tokens. Based on this, we reported the accuracy of each part of speech in the test set, as shown in Figure 2.

There are similar findings of error analysis for English and Chinese tasks. The order of the data

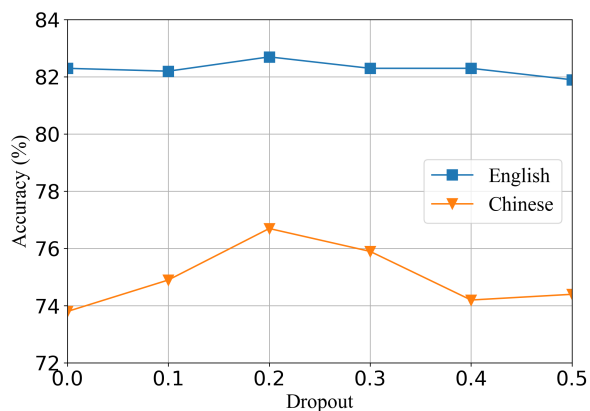

Figure 3: The performance of different dropouts on test set in English and Chinese tasks.

volume on the test set is NOUN, VERB, ADJ, and ADV. The distribution of these data types is consistent with the training set, and each part of speech in the training set is 4123, 2269, 1429, and 175, which is also in descending order and occupies roughly the same proportion of each part of speech. Therefore, the parts of speech with more data in the training set often get better performance on the test set, which indicates the importance of data size. More data can enable the model to learn more classification knowledge and behavior, which affects the prediction results.

## 5.3 Impact of Dropout

To analyze the importance of dropout, we conducted experiments by using different dropouts on both English and Chinese test sets, and the results are shown in Figure 3. As we can see, the performance of the two tasks increases with the increment of dropout rate and reach the best performance when dropout rate equals 0.2. As dropout rate continues to increase, the performance deteriorates, which indicates that too many lost parameters may make the model difficult to converge.

Besides, Dropout performs differently in terms of data quality. In general, real corpus (English) should be of better quality than pseudo corpus (Chinese). On this basis, the performance of different dropout models on high-quality real corpus is relatively stable, with a gap of less than 1%, while the performance of pseudo corpus fluctuates greatly, with a gap of 3%.

## 6 Conclusion

In this paper, we describe the GX system participating in the MCL-WiC task. In order to obtain the

general basic knowledge, we use the pre-trained BERT model and then fine-tune it on the data released by the organizer. In order to further emphasize the relationship between sentence pairs and the importance of lemma, we introduce three new factors: lemma token, lemma segment embedding, and lemma embedding, and finally get better results. Our system reaches 82.7% in English multilingual setting and 76.7% in Chinese multilingual setting.

## Abstract

This paper presents the PALI team’s winning system for SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation. We fine-tune XLM-RoBERTa model to solve the task of word in context disambiguation, i.e., to determine whether the target word in the two contexts contains the same meaning or not. In implementation, we first specifically design an input tag to emphasize the target word in the contexts. Second, we construct a new vector on the fine-tuned embeddings from XLM-RoBERTa and feed it to a fully-connected network to output the probability of whether the target word in the context has the same meaning or not. The new vector is attained by concatenating the embedding of the [CLS] token and the embeddings of the target word in the contexts. In training, we explore several tricks, such as the Ranger optimizer, data augmentation, and adversarial training, to improve the model prediction. Consequently, we attain the first place in all four cross-lingual tasks.

## 1 Introduction

This year, the SemEval-2021 task 2, multilingual and cross-lingual word-in-context (WIC) disambiguation (Martelli et al., 2021), defines the task of identifying the polysemous nature of words without relying on a fixed sense inventory in a multilingual and cross-lingual setting. The task aims to perform a binary classification task to determine whether the target word contains the same meaning or not in two given contexts under both the same language (multilingual) setting and the different languages (cross-lingual) setting. In the multilingual setting, the tasks consist of English-English (En-En), Arabic-Arabic (Ar-Ar), French-French (Fr-Fr), Chinese-Chinese (Zh-Zh) and Russian-Russian (Ru-Ru) while in the cross-lingual setting, the tasks consist of English-Chinese (En-Zh),

English-French (En-Fr), English-Russian (En-Ru), and English-Arabic (En-Ar).

The tasks contain the following challenges:

- The same word may deliver different meanings in different context (Lei et al., 2021).
- The training data is scarce. For example, in the multilingual tasks, there is only training data in En-En, while in the cross-lingual tasks, there is no training data.

To overcome these challenges, we explore the uniqueness of the tasks and implement several key technologies:

- First, we follow (Botha et al., 2020) to specially design an input tag for the multilingual pre-training XLM-RoBERTa model to emphasize the target word in the contexts. That is, the target word is encompassed by the special symbols of `<t>` and `</t>`. Meanwhile, the given two contexts are concatenated by the `<SEP>` token.
- Second, we apply data augmentation and add external data from WordNet to enrich the training data. It is noted that we only expand the data in the task of En-En and do not consider other techniques, e.g., back-translation, for the cross-lingual tasks. Adversarial training is also applied to learn more robust embeddings for target words. The Ranger optimizer with the look-ahead mechanism in the AdamW optimizer is adopted to speed up the convergence of training.
- Finally, we construct a new vector on the fine-tuned embeddings, i.e., concatenating the embedding of the [CLS] token and the learned embeddings of the target words’ in both contexts. The new vector is then fed into a fully-connected network to produce the binary classification prediction. Cross-validation and model ensemble are also applied to attain a robust output.

The rest of this paper is organized as follows: In Sec. 2, we briefly introduce related work. In Sec. 3, we detail our proposed system. In Sec. 4, we present the experimental setup, procedure, and the results. Finally, we conclude our work in Sec. 5.

## 2 Related Work

The SemEval-2021 task 2 aims to handling the tasks of multilingual and cross-lingual word-in-context disambiguation (Martelli et al., 2021), i.e., to determine whether the target word contains the same meaning in both given contexts. In the following, we will elaborate several related work.

Some recent effort, e.g., (Pilehvar and Camacho-Collados, 2018), has been conducted to curate and release datasets to solve the task of WiC disambiguation. Though it can be narrowed down to binary classification, some techniques have to be implemented to enhance the model performance. For example, the trick of input highlighting mechanism (Botha et al., 2020) can be facilitated to promote the importance of the target word. The idea of unifying entity linking and word sense disambiguation (Moro et al., 2014) can be borrowed to solve the task. The idea of freezing the trained model for other languages (Artetxe et al., 2020) can be explored to relieve the issue of no training data in the cross-lingual tasks.

Recently, due to the superior performance in tackling NLP tasks (Yang et al., 2021; Yang and Shen, 2021; Wang et al., 2021), pre-trained language models, such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), start to dominate the way of word representations than static word embedding methods, e.g., Word2Vec (Mikolov et al., 2013) and FastText (Joulin et al., 2017). Especially, the XLM-RoBERTa (Conneau et al., 2020) model is a newly released large cross-lingual language model based on RoBERTa and is trained on 2.5TB filtered CommonCrawl data in 100 languages. Different from other XLM models, XLM-RoBERTa does not require the language token to understand which language is used and can determine the correct language from the input ids. It is a powerful tool for understanding multilingual languages and is very helpful for solving the WiC disambiguation task under the cross-lingual setting. Hence, we choose XLM-RoBERTa in our system.

A critical issue of the task is lack of training data. Though existing methods, e.g., lexical substitution (Zhang et al., 2015), back translation (Xie

et al., 2020), and data augmentation (Fadaee et al., 2017), can be applied to enrich the data, we mainly explore the usage of WordNet (Fellbaum, 1998) and the technique of pseudo labelling (Wu and Prasad, 2018) because WordNet contains rich synonyms while pseudo labelling is effective to utilize the abundant unlabeled data via their pseudo labels.

Adversarial training (Tramèr et al., 2018) is an effective method to regularize parameters by introducing noise and to improve model robustness and generalization. We also explore its possibility in fine-tuning XLM-RoBERTa to increase the robustness of the learned the word embeddings.

## 3 Overview

In the following, we present the task definition, data preprocessing, and our proposed system design.

### 3.1 Task Definition

The task of WiC disambiguation is framed by a binary classification task. Each instance in WiC has a target word  $w$ , whose part-of-speech is in {NOUN, VERB, ADJ, ADV}, with two given contexts,  $c_1$  and  $c_2$ . Each of these contexts triggers a specific meaning of  $w$ . The task is to identify if the occurrences of  $w$  in  $c_1$  and  $c_2$  correspond to the same meaning or not. Figure 1 illustrates an example from the dataset.

```
{
  "target word": "play",
  "sentence1": "In that
    context of coordination
    and integration, Bolivia
    holds a key play in any
    process of infrastructure
    development.",
  "sentence2": "In schools,
    when water is needed, it
    is girls who are sent to
    fetch it, taking time away
    from their studies and
    play."
}
```

Figure 1: An example from the WiC disambiguation task.

### 3.2 Data Preprocessing

The training dataset consists of two files in the JSON format: the .data file and the .gold file. The .data file contains the following information:

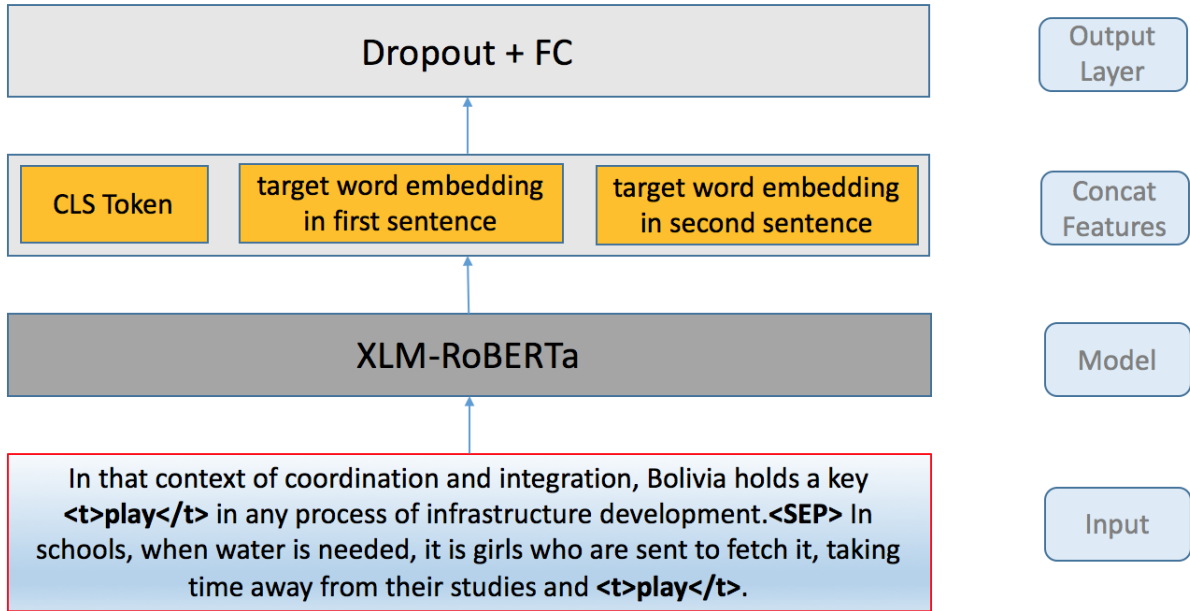

Figure 2: Fine-tuned XLM-RoBERTa model architecture.

	Training	Test
No. of target words	3,726	491
No. of pairs	8,000	1,000
Min. tokens	6	5
Avg. tokens (original)	24	26
Max. tokens (original)	88	116
Max. tokens (post-proc.)	81	81

Table 1: Statistics of the data

unique id of the pair, target lemma, part-of-speech in {NOUN, VERB, ADJ, ADV}, the first sentence, the second sentence, the start and the end indices (zero-based numbering) of the target word in the first and the second context, respectively. The .gold file contains unique id of the pair and the label, which is represented by T or F.

For the training dataset, we clean up the text by completing word abbreviation, removing special punctuation, and segmenting the sentences into subword lists by Byte-Pair Encoding (BPE) (Sennrich et al., 2015). Since it is difficult to capture the meaning of the target word in the context for long sentences (Pan et al., 2019; Zhu et al., 2021), we limit the length of each sentence with maximum 40 words before and after the target word.

We include additional resource, WordNet, to augment our training data because WordNet is a large lexical database of English. Nouns, verbs, adjectives and adverbs are grouped into sets of cognitive

synonyms (synsets), each expressing a distinct concepts. Here, we randomly select example sentences of target word in WordNet to expand our training corpus, which increases around 30% of training data. By such preprocessing, we obtain the dataset and report the statistics in Table 1.

### 3.3 Model Design

Figure 2 outlines our model architecture, which consists of four modules, i.e., input design, model learning, final feature construction, and the classifier. The whole framework is based on fine-tuning the pre-trained XLM-RoBERTa model to conduct binary classification on two given contexts. Different from the inputs for XLM-RoBERTa, the input of our system contains of the following modifications: first, in order to highlight the target word in the contexts, we borrow the setting in (Lei et al., 2017; Botha et al., 2020) by adding special symbols <t> and </t> to embrace the target word in the contexts. Given the example presented in Fig. 1, the target word of “play” is then embraced by the additional symbols, <t> and </t> in the contexts. Second, we concatenate the given two contexts by <SEP>. Figure 2 illustrates the result in the input module. Moreover, in the experiment, we exchange the order of the contexts to get more training data.

After learning the tokens’ representations by XLM-RoBERTa, we construct a new vector by concatenating the [CLS] token’s representation in the last layer of XLM-RoBERTa and the representa-

tions of the target word in both sentences. As BPE tokenization may separate a target word into several subwords, we compute its representation by averaging the corresponding representations. Next, the newly constructed feature is fed into a fully-connected network to compute the final binary prediction probability.

During training, we conduct the following techniques to increase the model convergence and robustness:

- **Optimizer.** We adopt the Ranger (Yong et al., 2020) optimizer to replace the AdamW because it is a more synergistic optimizer combining rectified Adam and the look-ahead mechanism with gradient centralization in one optimizer.
- **Adversarial training.** We apply the fast gradient method (Miyato et al., 2017) in the training to obtain more stable word representations.
- **Cross validation.** We also apply stratified  $K$ -fold cross validation on the training set and the development set. For each fold, we hold the group as a local test set and set the remaining groups as the training set. We then average the model prediction on each fold as the final prediction to obtain more robust results.
- **Pseudo labelling.** Pseudo labelling (Wu and Prasad, 2018) is an effective semi-supervised learning method to utilize the abundant unlabeled data via their pseudo labels. In this work, we first train our model on the training set. Next, we apply the trained model to predict the En-En multi-lingual test set and use the predicted labels as our pseudo labels. Finally, both the training set and the En-En pseudo labels are included to train a final model. Especially, we observe that by this trick, this final model can improve the prediction performance on cross-lingual tasks slightly.

It is noted that in the cross-lingual tasks, we do not back-translate the subwords to English but apply the same model trained from the En-En dataset because it allows us to maintain the target word in the corresponding languages seamlessly. This is similar to the procedure in (Artetxe et al., 2020).

## 4 Experiments

In the following, we detail our experimental setup and present the results with analysis.

### 4.1 Setup

Our code is written in Pytorch based on the Huggingface Transformer library<sup>1</sup> for XLM-RoBERTa. Other hyperparameters are set based on our hand-on experience. For example, the seed for the random generator is set to 3,999. The batch size is set to 10 and the hidden feature size is 1,024. The maximum length limit of a context is 240 though it is unreachable because we have conducted trimming in the data preprocessing procedure. The dropout rate is tested from {0.2, 0.3, 0.25, 0.28} and finally fixed to 0.28.  $K$  in the stratified cross validation is set to 5. The two special tokens,  $\langle t \rangle$  and  $\langle /t \rangle$ , are included into the word dictionary for learning.

The training data consists of the official En-En multilingual training corpus and the contexts from WordNet. At the beginning, we choose XLM-RoBERTa<sub>Base</sub> as the backbone of our system to explore the possibility of our implementation tricks. After identifying the effectiveness of the designed input in Sec. 3.2, we apply XLM-RoBERTa<sub>Large</sub> to tune the corresponding hyperparameters, such as changing the learning rate, the batch size, the dropout rate, and the early stop mechanism. Furthermore, we observe that long contexts may ignore the importance of the target word in the contexts. Hence, we center on the target words to cut off the contexts at both ends with a certain length. To further strengthen the influence of the target word in a context, we concatenate the embedding of the [CLS] token with the embeddings of the target word in the contexts as the final input for the logit fully-connected network. From our experiment, this strategy can significantly boost the model performance while improving the convergence.

### 4.2 Results

Table 2 reports the results of different implementation strategies on the tasks. From the results, we observe that

- By replacing XLM-RoBERTa<sub>Base</sub> with XLM-RoBERTa<sub>Large</sub>, we can gain at least 3% improvement on all tasks.
- By applying Ranger optimizer, we attain the results in Large+RO, which gain an average increase of 0.2% per task. We conjecture the improvement comes from the fact that the model converges to a more optimal solution.
- In Large+RO+LRA, we vary the learning rate

<sup>1</sup><https://github.com/huggingface/transformers>

Strategy	Avg	En-En	Fr-Fr	Ru-Ru	Zh-Zh	Ar-Ar	En-Ru	En-Zh	En-Fr	En-Ar
Base	80.8	85.5	80.7	78.7	80.9	79.1	81.0	81.9	79.1	80.4
Large	85.1	88.2	84.2	84.3	87.0	82.6	84.6	85.7	85.6	83.9

Large + RO + LRA	85.4	89.2	84.9	85.1	86.8	83.2	84.8	85.6	85.2	84.1
Large + RO + LRA + ES	85.5	89.0	84.8	85.5	86.9	83.1	85.2	85.2	85.4	84.1
Large + RO + CTWE	86.3	90.0	85.8	85.9	87.1	83.9	86.0	86.1	85.4	86.2
Large + RO + CTWE + HC	86.3	89.9	85.7	85.9	87.2	84.2	85.6	86.7	85.0	86.3
Large + RO + CTWE + HC + WordNet	86.5	91.6	85.8	85.7	87.1	84.0	85.3	87.1	85.6	86.0
Large + RO + CTWE + HC + WordNet + AT	87.0	91.1	86.3	85.9	87.9	85.1	86.3	87.2	86.3	86.9
Large + RO + CTWE + HC + WordNet + AT + PL	<b>88.1</b>	<b>91.7</b>	<b>86.9</b>	<b>86.5</b>	<b>89.2</b>	<b>86.5</b>	<b>88.0</b>	<b>87.9</b>	<b>88.6</b>	<b>87.2</b>

Table 2: Results of fine-tuning XLM-RoBERTa under different strategies. The abbreviation is defined as follows: Base: XLM-RoBERTa<sub>Base</sub>; Large: XLM-RoBERTa<sub>Large</sub>; RO: Ranger Optimizer; LRA: learning rate adjustment; ES: early stop; CTWE: concatenating target words’ embeddings; HC: the best parameters for LRA and ES; AT: adversarial training; PL: pseudo labels.

from  $1.5e-5$ ,  $1.3e-5$ ,  $1.2e-5$ , to  $1.21e-5$  progressively and finally find that when the learning rate is  $1.2e-5$ , we attain the best performance. We then search the optimal epoch for the early stop by setting the maximum number of epoch to 10. In Large+RO+LRA+ES, we observe the optimal epoch for early stop (the patience value) is 3. These parameters are then fixed for HC. From the results, we notice that tuning the learning rate and adopting the early stop mechanism can improve the model performance accordingly.

- By concatenating target the word embedding, we obtain the results in Large+RO+CTWE, and actually, our model can be trained with fewer epochs and attain around 1.1% improvement on average.
- By adding more training data from WordNet, we get another 0.2% average improvement in Large+RO+CTWE+HC+WordNet. We conjecture the improvement mainly comes from the increase of the training data.
- By adding the Pseudo label data, we can gain another 0.8% average improvement. The score of EN-EN test dataset is generally higher than other test dataset. We discover that the first 462 pieces of English test dataset have the same target word as test dataset in other tasks. Therefore, adding EN-EN pseudo label helps predict other tasks.

In sum, we conclude that by applying XLM-

RoBERTa<sub>Large</sub> on the Ranger optimizer, the target word embedding concatenation mechanism, more external training data, and pseudo labels, we can improve the model performance accordingly.

Finally, our system attains the champion on the En-Ar, En-Fr, En-Ru, and En-Zh cross-lingual tasks. In multilingual tasks, we also sit at eighth place, seventh place, sixth place, seventh place, and fifth place for the En-En, Ar-Ar, Fr-Fr, Ru-Ru, Zh-Zh tasks, respectively.

## 5 Conclusion

In this paper, we present our system to tackle the word-in-context disambiguation task. We fine-tune the XLM-RoBERTa model to solve both multilingual and cross-lingual word-in-context disambiguation tasks. We specifically design the input format to emphasize the target word in two contexts and promote the importance of the target word by concatenating the embeddings in the corresponding context with the [CLS] token to output the classification probability. We apply several training tricks to improve the robustness of model and attain improvement during this procedure. The competition results demonstrate the effectiveness of our implementation. In the future, we plan to explore more model architecture to boost the performance for multilingual tasks.

former Encoder (Vaswani et al., 2017) achieved the best results in many NLP tasks.

We participated in SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation (MCL-WiC) English task. This task is to predict whether a word with the same part of speech has the same meaning in a sentence pair (Martelli et al., 2021). We are inspired by the work of Chen, Weilong and others on the task of predicting the influence of context on word similarity (Chen et al., 2020), and use methods based on RoBERTa (Liu et al., 2019) and Tf-Idf (Ramos et al., 2003) to complete the task. At the same time, we also tried to combine ALBERT (Lan et al., 2020) with BERT (Devlin et al., 2019) and Tf-Idf to observe their performance on the English data set. We introduce our methods and experiments in detail in Sections 2 and 3. Our model code can provide reference <sup>1</sup>.

## 2 Data and Methods

In this section, we will introduce the data we use in the task and the models and methods we use.

### 2.1 Data Description

The task organizer team provides each team with training data sets, validation data sets, and test data sets related to the "Multilingual and Cross-lingual Word-in-Context Disambiguation" task. Because we only successfully submitted the test set prediction results of the English task, we only discuss the English data set here. The training data set and the validation data set are composed of two parts. The first part contains the ID, the lemma of the target word, the part of speech of the target word, the sentence pair data, and the position index of the target word in the sentence pair. The target word is usually only one word, and they have the same part

<sup>1</sup><https://github.com/Hub-Lucas/hub-at-task2>

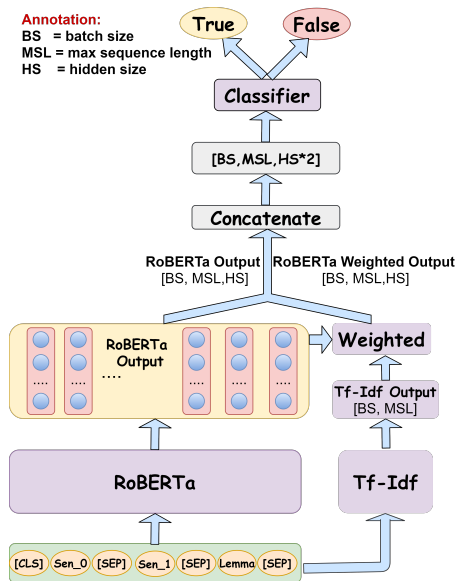

Figure 3: The model structure and data flow we used in the task.

of speech in the sentence pair. The second part is whether the target words appearing in the sentence pair are tags with the same meaning.

If two words have the same meaning, it is "True", otherwise it is "False". The sentence lengths in the sentence pairs are not the same. Compared with the training data set and the validation data set, the test set only contains the first part mentioned above. We need to use our method to predict whether the same words appearing in sentence pairs in the test set have the same meaning. Table 1 shows a sample of sentence pair data we used in the task.

There are 8000 and 1000 data in the training set and validation set respectively. The proportions of the "True" label and the "False" label in the training set and the validation set are the same, both are 50% and 50%. There are 1000 pieces of data in the test set. Information about word frequency

ID	Lemma	Part of Speech	Sentence	Start	End
151	excess	NOUN	We want to rebuild our country, which was dismantled by the <b>excesses</b> of Mobutu	60	68
151	excess	NOUN	More often than not, words per page are well in <b>excess</b> of that standard.	48	54

Table 1: The sample data of a pair of sentence pairs we use in the task.

$$[Tf - Idf\_Output]_i \times [RoBERTa\_Output]_i = [Weighted]_i \quad (1)$$

$$[Tf - Idf\_Output]_i^T \times [Weighted]_i = [RoBERTa\_Weighted\_Output]_i \quad (2)$$

$$0 \leq i < batch\_size \quad (3)$$

will be involved in our method. We use word cloud graphs to visualize the text data in the training set and the text data in the test set. The word cloud image clearly shows us the characteristics of word frequency distribution in the text data set. Figure 1 and Figure 2 show the word frequency information in the training set, validation set, and test set.

## 2.2 Methods

Combined with the analysis and understanding of task description and task data set, we chose to develop a system based on RoBERTa and Tf-Idf. Besides, we also tried to use the combination of ALBERT (Lan et al., 2020), BERT (Devlin et al., 2019) and Tf-Idf to verify their effect on the verification set. Due to the addition of the attention mechanism, Transformer has achieved good results in multi-tasking in the field of natural language. The three models of BERT, ALBERT, and RoBERTa are all based on the improvement of the transformer architecture. Compared with BERT, ALBERT not only has fewer parameters, but also has the characteristics of parameter sharing between different layers (Lan et al., 2020; Devlin et al., 2019). Therefore, ALBERT is better than BERT in terms of memory space and training time. Compared with ALBERT (Lan et al., 2020), RoBERTa (Liu et al., 2019) does not perform the task of predicting the next sentence during the pre-training process, and also uses a new dynamic masking mechanism. At the same time, the pre-training time of the RoBERTa model is longer, using a larger batch size, and the corpus data used for pre-training is also larger (Liu et al., 2019).

In our system, the first step is to use the pre-

processed data as the input data of RoBERTa and Tf-Idf. In the second step, we get the output result of the last layer of RoBERTa (RoBERTa Output) and the output result of Tf-Idf (Tf-Idf Output). In the third step, we use the output result of Tf-Idf to weight the output result of RoBERTa. We can get a weighted result, we call it RoBERTa weighted output. In the fourth step, we connect the RoBERTa output result and the RoBERTa weighted output result together. In the fifth step, we use the result of the previous step as the input of the classifier. Use the classifier to output the prediction results of the model. In the final step, the results of the model prediction are processed into the format required by the task organizer team.

Among them, the shape of RoBERTa output [batch\_size, max\_sequence\_length, hidden\_size]. The shape of Tf-Idf output is [batch\_size, max\_sequence\_length]. Equation 1-3 is the process of weighting operation.

In equation 1,  $[Tf - Idf\_Output]_i$  is the result of the  $i - th$  batch of Tf-Idf output.  $[RoBERTa\_Output]_i$  is the result of the  $i - th$  batch of RoBERTa output. The result of multiplying these two matrices is  $[Weighted]_i$ .

In equation 2,  $[Tf - Idf\_Output]_i^T$  is the transpose of  $[Tf - Idf\_Output]_i$  matrix. The result of multiplying  $[Tf - Idf\_Output]_i^T$  and  $[Weighted]_i$  is  $[RoBERTa\_Weighted\_Output]_i$ .

In equation 3, The value range of  $i$  is an integer between 0 and batch\_size. Calculate the value of each  $[RoBERTa\_Weighted\_Output]_i$  to get  $[RoBERTa\_Weighted\_Output]$ . Its shape is the same as RoBERTa output.

Figure 3 shows the model structure and data flow

Method	F1 Score
ALBERT+Tf-Idf	82.53
BERT+Tf-Idf	82.04
RoBERTa	83.41
RoBERTa+Tf-Idf	84.81

of RoBERTa combined with Tf-Idf.

### 3 Experiment and Results

In this section, we will introduce the data preprocessing methods and experimental settings we used in the task and the final results.

#### 3.1 Data Preprocessing

Combined with our analysis in the data description section, we remove the stop words of sentence pairs in the data. For the stop word list, we use the stopwords package provided by NLTK. To use the Tf-Idf algorithm to obtain the weighted output, and to ensure that the shape of the text encoding processed by the Tf-Idf algorithm is consistent with the output shape of RoBERTa, we have deleted the part of the text encoding that exceeds the maximum sentence length. For those less than the maximum sentence length for text encoding, we perform zero-padding operations. The encoding of Tf-Idf is obtained using the toolkit provided by gsim (Řehůřek and Sojka, 2010)<sup>2</sup>.

In the data input, we use the [SEP] symbol to separate the sentence pairs together. Then use the [SEP] symbol to concatenate Lemma that appears in each sentence in the sentence pair. It should be noted that the three models we used in the experiment, BERT, ALBERT, and RoBERTa, are different in the division of symbols. Here, we use [CLS] and [SEP] uniformly for the convenience of description.

#### 3.2 Experiment setting

As we introduced in the previous section, on the data set for this task, we use 4 different models to experiment with the result scores on the validation set. We adjust the parameters as much as possible to achieve the optimal results of each different model, so different models use different parameter combination settings.

<sup>2</sup><https://github.com/RaRe-Technologies/gensim>

Team	F1 Score	Rank
jaymundra	93.30	1
rohangpt	93.30	1
oyx	93.30	1
rohangpt	93.20	2
dipakam	92.80	3
LucasHub(our team 'hub')	84.60	49

Table 3: In the result list released by the task organizer team, the top 3 submitted test set prediction results scores and our submitted test set prediction results scores. There are a total of 175 results on the leaderboard of the English task. There are a total of 87 places from the first to the last.

- ALBERT+Tf-Idf: The epoch, batch size, maximum sequence length, and learning rate for the model are 6, 32, 150, and 3e-5, respectively.
- BERT+Tf-Idf: The epoch, batch size, maximum sequence length, and learning rate for the model are 4, 32, 150, and 4e-5, respectively.
- RoBERTa+Tf-Idf: The epoch, batch size, maximum sequence length, and learning rate for the model are 5, 32, 150, and 3e-5, respectively.
- RoBERTa: The epoch, batch size, maximum sequence length, and learning rate for the model are 5, 32, 150, and 3e-5, respectively.

## 4 Results

The final result score evaluation index uses the F1 score. Therefore, the effects of the different models we used in the experimental phase are all using F1 scores to determine which model is better.

We use the same validation set data to evaluate the performance of different models. Comparing the result score obtained by the combination of ALBERT, BERT and Tf-Idf with the score obtained by the combination of RoBERTa and Tf-Idf, it can be seen that the combination strategy of RoBERTa can get a better F1 score. Compared with the F1 score obtained by using RoBERTa alone, the F1 score obtained by RoBERTa+Tf-Idf is better. This also verifies the feasibility and effectiveness of our method. We sort the results according to Table 2.

The prediction result of the English test set we finally submitted is predicted by RoBERTa+Tf-Idf.

Compared with the F1 scores obtained by the top three teams in the English data, there is still a certain gap. Our F1 score ranks middle among all result scores. Our final ranking is 49th. We sort the results according to Table 3.

## 5 Conclusion

This paper proposes a model that combines RoBERTa and Tf-Idf to calculate whether the target words in English sentence pairs are similar. We introduced our analysis of the data, the methods used in the experiment, and the results of the experiment in Sections 3 and 4. We compared the effects of different models of ALBERT, BERT, RoBERTa and the combination of Tf-Idf. The experimental results also prove that RoBERTa+Tf-Idf can get better results in our method. In future work, we will improve our methods to get better results. For example, other types of word embedding vectors can be introduced into our model, and the method of weighting and vector fusion can also be improved.

## Abstract

In this paper, we describe our proposed methods for the multilingual word-in-Context disambiguation task in SemEval-2021. In this task, systems should determine whether a word that occurs in two different sentences is used with the same meaning or not. We proposed several methods using a pre-trained BERT model. In two of them, we paraphrased sentences and add them as input to the BERT, and in one of them, we used WordNet to add some extra lexical information. We evaluated our proposed methods on test data in SemEval-2021 task 2.

## 1 Introduction

Measuring semantic similarity is a task that is important in many applications such as summarization, plagiarism detection, etc. To measure the semantic similarity between two words or sentences, the words' meaning in their contexts should be understood. In "Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation" of SemEval 2021 (Martelli et al., 2021), systems should determine whether a word that occurs in two different sentences is used with the same meaning or not. The considered languages in the Word-in-Context Disambiguation task of the evaluation are Arabic, Chinese, English, French, and Russian (Martelli et al., 2021). Due to our internal limitation, we only evaluated the proposed methods on the English dataset.

In most cases, humans can understand the correct meaning of each word by paying attention to the context of that word. This was the main reason for proposing the attention mechanism for machine translation (Vaswani et al., 2017). Because attention plays an important role in BERT topology (Devlin et al., 2019), we believe it should work for the WSD task. However, in some cases, the two sentences may be about the same subject, while

the target word has a different meaning. In these cases, find out that whether the target word has the same meaning in both sentences or not is difficult. To overcome this challenge, we need to add some extra information about the contexts to the input of the BERT.

We proposed four main methods for this task. In the first method, we use the BERT model as a language representation model in which the inputs are the two sentences that come in a row and are separated by a "[SEP]" token. Furthermore, the target word is surrounded by a "[TGT]" token in both sentences. Then, the first output of the last layer is used as a classifier to determine whether the word has the same meaning in the two sentences or not. In the second one, we added some information about the target word from the WordNet<sup>1</sup> to the end of each input and used the same strategy as the first method. In the third and fourth methods, we used the paraphrases of sentences as additional inputs to the BERT.

The remainder of the paper is organized as follows: In section 2, we provide a short literature review of the WSD task and mention some related works that used BERT for this task. After that, in section 3, we introduce our methods in consequent sections: the first method that only uses the BERT model is explained in Section 3.1. The second method that uses the BERT model and some additional information from WordNet is explained in Section 3.2. The third and fourth methods that use the BERT model and add paraphrased sentences as an additional input to the model are explained in Section 3.3. Then in Section 4, the used datasets in our experiments are specified. Finally, the results and discussion are presented in Section 5.

## 2 Background

### 2.1 Task Setup

The dataset provided by MCL-WiC<sup>2</sup> addresses both multilingual and cross-lingual aspects, covers all part-of-speeches, and also a high number of domains and genres. The task of the challenge is a binary classification where systems should specify whether the target word has the same meaning in both sentences (T for true) or different meaning (F for false). The sentences can be from the same language (multilingual dataset) or across different languages (cross-lingual dataset) (Martelli et al., 2021).

In the following you can find an example of sentence pair in English from the multilingual dataset<sup>3</sup>:

- In that context of coordination and integration, Bolivia holds a key play in any process of infrastructure development.
- A musical play on the same subject was also staged in Kathmandu for three days.

In this example, the target word “play” should be tagged as F (False) since it is used in two distinct meanings.

We evaluated our methods on the English part of the multilingual dataset. We used the MCL-WiC training set, containing 8000 sentence pairs in English as the training data, and the MCL-WiC development set containing 1000 sentence pairs in English as the validation set for our system.

### 2.2 Related works

There are several published works that used BERT for WSD task (Wiedemann et al., 2019; Du et al., 2019; Yap et al., 2020; Guo et al., 2020) and also some other papers that combined BERT and WordNet for this task (Levine et al., 2020; Peters et al., 2019).

For example, (Levine et al., 2020) proposed a method named SenseBERT in which the model is pre-trained to predict the masked words and their WordNet super-senses. They proposed a mechanism in which they pay attention to the words at the sense level. Therefore, they achieved a lexical-semantic level language model. SenseBERT achieved 72.1 % accuracy on the “Word in

Context” task which is a state-of-the-art result on this task.

(Peters et al., 2019) proposed a general method in which multiple knowledge bases are embedded into large-scale models. By doing that and using structured knowledge, they enhanced their representations. First, they use an entity linker to retrieve relevant entity embeddings for each knowledge base (KB). After that, they use word-to-entity attention to update contextual word representations. They trained entity linkers and self-supervised language modeling together in an end-to-end multi-task setting in which a large amount of raw text is combined with a small amount of entity linking supervision. By merging WordNet and a subset of Wikipedia into BERT, KnowBert shows improvement in several tasks such as word sense disambiguation. This method achieved a good result on the “Word in Context” task with 70.9 % accuracy.

“GlossBERT” is another work that was proposed in (Huang et al., 2019). The contexts and glosses of the target words were put together and considered as inputs to the BERT. Three BERT-based models were proposed for WSD. The SemCor3.0 training corpus was used to fine-tune the pre-trained BERT model and finally, the models were evaluated on several English WSD benchmark datasets. The experimental results show that the proposed method achieved new state-of-the-art results on the WSD task.

## 3 System Overview

In this section, we explain our proposed methods. The first method that relies only on the BERT model is explained in Section 3.1. This method is further improved in 3.2 by adding some extra information extracted from the WordNet to the BERT’s input. Finally, in section 3.3 we explain an augmentation method by generating the paraphrases of both sentences and add them as an extra input to the BERT.

### 3.1 BERT Method

In this method, we fine-tune a BERT model using the TensorFlow-models PIP package as explained in [fine-tuning-BERT Tutorial](#). To do this, we use the pre-trained BERT encoder (large-uncased-BERT) from [TensorFlow Hub](#). As mentioned in the tutorial, to fine-tune a pre-trained model, exactly the same tokenization, vocabulary, and index mapping with the model should be used. So we

<sup>2</sup>Multilingual and Cross-lingual Word-in-Context Disambiguation task

<sup>3</sup>[https://github.com/SapienzaNLP/mcl-wic/blob/master/SemEval-2021\\_MCL-WiC\\_all-datasets.zip](https://github.com/SapienzaNLP/mcl-wic/blob/master/SemEval-2021_MCL-WiC_all-datasets.zip)

rebuild and use the tokenizer that was used by the base model.

Next, we preprocess the provided data and prepare it as the input of the BERT model. For every pair of sentences first, we add a “[TGT]” token before and after the target word in both sentences. After that, we add a “[SEP]” (Separator) token at the end of both sentences. Then we encode them separately by the tokenizer. The tokenizer itself changes all words to lowercase and separates the unknown words. We also encode and add a “[CLS]” token at the first position of each example to be able to do a classification task. Examples are constructed by concatenation of two sentences. Note that we had to add “[TGT]” as a token into the tokenizer vocabulary. Here is an example of a pair of sentences:

```
[CLS] In that context of coordination and
integration, Bolivia holds a key [TGT]
play [TGT] in any process of infras-
tructure development. [SEP] A musical
[TGT] play [TGT] on the same subject
was also staged in Kathmandu for three
days.[SEP]
```

The output of the tokenization process is named input word ids. For the above example, we will have:

```
[ 101 1999 2008 6123 1997 12016 1998
8346 1010 11645 4324 1037 3145 1
2377 1 1999 2151 2832 1997 6502 2458
1012 102 1037 3315 1 2377 1 2006 1996
2168 3395 2001 2036 9813 1999 28045
2005 2093 2420 1012 102 ]
```

Note that input word ids vectors should be padded with zero token ids to make them equal length.

We also add two vectors as extra inputs to the BERT model. One of them is called input mask, in which, for every non-padding token, we put “1”, and for every padding token, we put “0”. Another one is called input type ids in which, for each token of the first sentence, second sentence, and padding tokens, we put “1”, “2”, and “0” respectively. Thus, the input vectors equivalent to the above sentence pairs (without padding tokens) are as follows:

```
input_word_ids: [101 1999 2008 6123
1997 12016 1998 8346 1010 11645 4324
1037 3145 1 2377 1 1999 2151 2832
```

```
1997 6502 2458 1012 102 1037 3315 1
2377 1 2006 1996 2168 3395 2001 2036
9813 1999 28045 2005 2093 2420 1012
102 ]
```

```
input_mask: [1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1
1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1
1 1 1 1 1 1 1 ]
```

```
input_type_ids: [0 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1
1 1 1 1 1 1 1 1 1 1 2 2 2 2 2 2 2 2 2 2 2 2
2 2 2 2 2 2 2 ]
```

After preparing the input, we define the BERT classifier with the following configuration:

```
'attention_probs_dropout_prob': 0.1,
'hidden_act': 'gelu',
'hidden_dropout_prob': 0.1,
'hidden_size': 768,
'initializer_range': 0.02,
'intermediate_size': 3072,
'max_position_embeddings': 512,
'num_attention_heads': 12,
'num_hidden_layers': 12,
'type_vocab_size': 2,
'vocab_size': 30522
```

As mentioned in [fine-tuning-BERT Tutorial](#) : “BERT adopts the Adam optimizer with weight decay. It uses a learning rate that firstly warms up from 0 and then decreases to 0.” We choose the batch size= 32 and train the BERT classifier with maximum epochs=10. We also use an early stopping call back, which is based on the validation set loss, and make the training process stopped, when the validation loss increase in two steps.

### 3.2 BERT plus WordNet method

As mentioned before, in some WSD cases using just the target word context can not be helpful, so we proposed a new method in which some information from the WordNet is added to the end of each sentence.

In this method, for every synset of the target word, we define a score that indicates how much that synset is related to the target word in this context. To calculate this score, we used the following equation:

$$path\_dist = \sum_{w \in context} \frac{1}{position\_dist(w, target\_w) \times \min_{syn_2 \in syns(w)} (spd(syn_1, syn_2))} \quad (1)$$

where *position\_dist* indicates how much the target word is far from the word “*w*” in the context. So, the farther the word is, the effect of that to calculate the path dist is less. “*syns(w)*” are all synsets of the word “*w*” in the context. “*syn<sub>1</sub>*” is the synset of the target word that we want to calculate its path distance. Note that, before calculating the score, we remove all stop words, punctuations, and numbers from the context of the target word. *spd* is a function that is already implemented in NLTK package<sup>4</sup>. It returns the distance of the shortest path linking the two synsets (if one exists). For each synset, all the ancestor nodes and their distances are recorded and compared. The ancestor node common to both synsets that can be reached with the minimum number of traversals is used. If no ancestor nodes are common, -1 is returned. If a node is compared with itself, 0 is returned<sup>5</sup>.

As can be seen, if the *path\_dist* increases, the synset is less related to the target word in this context. Therefore, we sort the synsets based on how relevant they are to the target word and use their Lexname<sup>6</sup> (which is called supersense in (Levine et al., 2020)) to represent them. After that, we add all the sorted Lexnames at the end of each sentence separated by a “[LX]” token.

Here is an example for a pair of sentences:

**sentence1:** in that context of coordination and integration , bolivia holds a key [TGT] play [TGT] in any process of infrastructure development .[LX] time [LX] state [LX] act [LX] communication [LX] event [LX] attribute [SEP]

**sentence2:** a musical [TGT] play [TGT] on the same subject was also staged in kathmandu for three days .[LX] time [LX] communication [LX] act [LX] state [LX] attribute [SEP]

Finally, we define *input\_word\_ids*, *input\_mask*, and *input\_type\_ids* same as in Section 3.1 and train the model defined in that section.

<sup>6</sup>More information about Lexname can be found at <https://wordnet.princeton.edu/documentation/lexnames5wn>

### 3.3 BERT plus Paraphrase Method

As paraphrasing changes the structure and some words of a sentence while the meaning remains the same, it can be helpful to add some extra information as input to the BERT encoder. By adding this information, we help the model to see other meanings of the context words.

We used Machine Translation to generate paraphrases of the sentences. To do that, we use Microsoft Translator Text API<sup>7</sup> to translate all of the sentences from English to Spanish and then translate them back from Spanish to English. As this API has reliable results on translating from and to the Spanish language, we choose it as the intermediate language. However, other languages such as French and Germany can be used as well.

Based on this idea, two methods are proposed in this section:

#### 3.3.1 Using generated paraphrases

In the first method, we add the paraphrased sentences word ids, mask, and type\_ids as additional inputs to the BERT encoder. Thus, the input to the BERT encoder is constructed from 6 parts instead of 3 parts defined in Section 3.1. Normally, three input vectors are used for the BERT. In this case, we add three additional input vectors which are made with the paraphrase of sentences instead of sentences themselves. In our opinion, the best way of combining this new data is to concatenate paraphrases to the main sentences, but in this work, due to our internal limitations, we could not do this, and instead, we extended the three inputs to six. In practice, the input is the sum of the embedded vectors of the six vectors. We do not use the “[TGT]” token before and after the target word in the generated paraphrase because it may be changed.

#### 3.3.2 Using just the different words

As the generated paraphrases are not very different from the original sentences most of the time, we propose another method in which we just find the words that are changed in the generated paraphrase and then concatenate them with the original words in the original sentence with a “[S]” token. To do that, we should find the original word of each newly generated word by finding the most similar word from the main sentence to the generated word. We used the *fastText*<sup>8</sup> pre-trained model in English to

<sup>7</sup><https://www.microsoft.com/en-us/translator/business/translator-api/>

Table 1: Results of the proposed methods in 5 different runs. Std in the last column indicate *Standard Deviation*.

find the most similar word, and then consider it as the paraphrased word.

## 4 Experimental Setup

As mentioned before, we used the MCL-WiC training set, containing 8000 pair sentences in English as the training data, and the MCL-WiC development set containing 1000 pair sentences in English as the validation data for our system. Similarly, the MCL-WiC test set containing 1000 pair sentences in English was used as the test data. The results displayed in Table 1 are based on the test set. We use the validation set only for finding the best number of fine-tuning iterations. It is worth mentioning that in test phase of the third method, we first paraphrase the sentences of the test set and make them ready for the model input as we did for the training and validation sets. All reported results are based on accuracy that is the main criteria for the challenge.

## 5 Results

Due to the random initialization of classifier layer weights, different results were achieved from different runs. So, we decided to run each experiment 5 times and report the average and standard deviation of model accuracy.

Table 1 shows the obtained results from different methods based on the accuracy percentage. It is obvious that adding generated sentence level paraphrases proposed in Section 3.3.1 improves the average accuracy compared to the BERT method. However, we got only a marginal improvement by adding paraphrased words proposed in Section 3.3.2. We guess the reason for this has two folds: first, we had some difficulties in finding the original word of the changed word, and using only the fastText may not be helpful. For example, the word “play” changed to “work” in the generated paraphrase, while using the fastText, the system found another word instead of “work”. The second reason can be eliminating not-changed words that cause a

discontinuity in the word context.

On the other hand, adding more information from WordNet proposed in Section 3.2 is not very helpful, and the accuracy is not changed compared to the base method proposed in Section 3.1. This has happened because of the used way for adding this information to the input and the shape of information. For example, adding only the two first synsets or adding lemmas or glosses of synsets instead of their lexnames may cause better results.

It is clear that there is a variation in the results of each method for different runs. The last column of the table shows the standard deviation of the five obtained results for each method. The second and third methods have smaller STD that means these methods are robust to random initialization classifier’s weights, and we can trust more to the results.

In summary, adding generated paraphrases from sentences increase the performance of the model. However, using a better method for generating paraphrases can lead to better results.

## 5.1 Conclusion

In this work, we proposed four BERT-based methods for the WSD task. To handle some issues such as the same contexts for different word meanings, we proposed to add some extra information from WordNet or generate paraphrases of sentences. We trained and evaluated our proposed methods on the MCL-WiC training and testing sets, respectively. The results show that adding generated paraphrases as an additional input to the BERT can be helpful. Although, the performance of the paraphrase generation method plays an important role. So, for future works, using different methods of generating paraphrases can be considered. Besides, as mentioned before, adding only the two first synsets or adding lemmas or glosses of synsets instead of their lexnames from WordNet can be investigated. Due to lack of time, we could not spend too much effort on this challenge, and we leave it for the future.

## Abstract

This paper describes the system of the Cambridge team submitted to the SemEval-2021 shared task on Multilingual and Cross-lingual Word-in-Context Disambiguation. Building on top of a pre-trained masked language model, our system is first pre-trained on out-of-domain data, and then fine-tuned on in-domain data. We demonstrate the effectiveness of the proposed two-step training strategy and the benefits of data augmentation from both existing examples and new resources. We further investigate different representations and show that the addition of distance-based features is helpful in the word-in-context disambiguation task. Our system yields highly competitive results in the cross-lingual track without training on any cross-lingual data; and achieves state-of-the-art results in the multilingual track, ranking first in two languages (Arabic and Russian) and second in French out of 171 submitted systems.

## 1 Introduction

Polysemy still poses a great challenge to natural language processing (NLP) applications. Depending on its context, an ambiguous word can refer to multiple, potentially unrelated, meanings. Recently, as an application of Word Sense Disambiguation (WSD) (Navigli, 2009, 2012), Word-in-Context (WiC) disambiguation has been framed as a binary classification task to identify if the occurrences of a target word in two contexts correspond to the same meaning or not. The release of the WiC dataset (Pilehvar and Camacho-Collados, 2019), followed by the Multilingual Word-in-Context (XL-WiC) dataset (Raganato et al., 2020), has helped provide a common ground for evaluating and comparing systems while encouraging research in WSD and context-sensitive word embeddings.

In this paper, we describe our submission to the SemEval-2021 shared task on Multilingual and Cross-lingual Word-in-Context (MCL-WiC) Disambiguation (Martelli et al., 2021), which involves determining whether a word shared by two sentences in the same language (multilingual track) or across different languages (cross-lingual track) has the same meaning in both contexts. Compared to previous WiC and XL-WiC benchmarks, two new languages are introduced as well as a cross-lingual track where systems are evaluated under a ‘zero-shot’ setting.

The MCL-WiC task directly classifies pairs of sentences with regard to the meaning of the shared word. By turning WSD into a binary comparison task, MCL-WiC avoids the need for sense tags of previous WSD shared tasks (Manandhar et al., 2010; Navigli et al., 2013; Moro and Navigli, 2015). It also resembles the Word Sense Alignment (WSA) task (Ahmadi et al., 2020) more closely, in which definitions from different dictionaries have to be aligned. Contextualised word embeddings and pre-trained Transformer-based (Vaswani et al., 2017) language models have been increasingly applied to these tasks and state-of-the-art results have been reported (Hadiwinoto et al., 2019; Vial et al., 2019; Levine et al., 2020; Raganato et al., 2020; Pais et al., 2020; Manna et al., 2020; Lenka and Seung-Bin, 2020).

In line with previous research, we develop a neural system based on pre-trained multilingual masked language model XLM-R (Conneau et al., 2020). Additionally, we introduce three distance-based features to be used together with the widely used sequence and token representations for MCL-WiC disambiguation. To further improve system performance, we apply automatic data augmentation and extract examples from multiple external resources. A two-step training strategy is then employed to make use of both in-domain and out-of-

domain<sup>1</sup> data.

In the remainder of the paper, we present the MCL-WiC disambiguation shared task in Section 2 and our approach in Section 3. In Section 4, we describe the experiments and present results on the development set. Section 5 summarises the official evaluation results. Finally, we provide an analysis of our system in Section 6 and conclude in Section 7.

## 2 Task Description

The MCL-WiC dataset used in the shared task consists of sentence pairs sharing the same target word in the same language or across different languages. The task considers five languages: Arabic (AR), Chinese (ZH), English (EN), French (FR) and Russian (RU); and contains five multilingual (EN-EN, AR-AR, FR-FR, RU-RU, ZH-ZH)<sup>2</sup> and four cross-lingual (EN-AR, EN-FR, EN-RU, EN-ZH) sub-tracks. Training data is available for the multilingual EN-EN sub-track only, and development data is available for all five multilingual sub-tracks. No cross-lingual training or development data is provided. Statistics of the MCL-WiC dataset are

<sup>1</sup>In this paper, we use the term ‘out-of-domain’ to refer to data from additional resources (i.e. not provided by the shared task organisers) - see Section 4.1 for more details.

<sup>2</sup>[language of sentence #1]-[language of sentence #2]

presented in Table 1.

Results are computed using the accuracy measure, i.e. the ratio of correctly predicted instances (true positives or true negatives) to the total number of instances.

## 3 Approach

### 3.1 Data augmentation

Each instance in the (\*)WiC datasets (i.e. WiC, XL-WiC and MCL-WiC) is composed of a target word and two sentences in which the target word occurs. We notice that there are cases where the same sentence appears in multiple instances. As shown in Table 2, two existing instances, which share the same target word, contain the same first sentence, but different second sentences. Therefore, we construct new instances by pairing the second sentences from these existing instances and assign labels based on the original labels:

- If both existing instances are positive (‘T’, i.e. the target word is used in the same meaning), the resulting instance should be positive (‘T’) as well - see Example (a) in Table 2:

$$M(w_{s_1}) = M(w_{s_2}), M(w_{s_1}) = M(w_{s_3}) \\ \Rightarrow M(w_{s_2}) = M(w_{s_3})$$

where  $M(w_{s_n})$  indicates the meaning of the target word ( $w$ ) used in sentence  $n$  ( $s_n$ ).

- If one of them is positive (‘T’) and the other is negative (‘F’, i.e. the target word is used in a different meaning), the new instance should then be negative (‘F’) - see Example (b) in Table 2:

$$M(w_{s_1}) = M(w_{s_2}), M(w_{s_1}) \neq M(w_{s_3}) \\ \Rightarrow M(w_{s_2}) \neq M(w_{s_3})$$

### 3.2 Model

Following Raganato et al. (2020), we use pre-trained XLM-R as the underlying language model, which is a Transformer-based multilingual masked language model that has been trained on one hundred languages (Conneau et al., 2020). Unlike previous WiC and XL-WiC models employing a logistic regression classifier (Wang et al., 2019; Raganato et al., 2020), we add two additional layers on top of the Transformer-based model to perform classification: a linear layer with *tanh* activation, followed by another linear layer with *sigmoid* activation.

The model takes as input the two sentences in each instance. For the representation to be fed into the linear layers, we concatenate the representation corresponding to the first special token ( $[s]$ ) of the input sequence,<sup>3</sup> the vector representations of the target word in the first ( $[w_{s_1}]$ ) and second sentences ( $[w_{s_2}]$ ), as well as the element-wise absolute difference, cosine similarity (*cos*) and Euclidean distance (*dist*) between these two vectors:

$$[s; w_{s_1}; w_{s_2}; |w_{s_1} - w_{s_2}|; \cos; \text{dist}] \quad (1)$$

For those cases where the target word is split into multiple sub-tokens, we take the averaged representation rather than the representation of its first sub-token, which has been used in previous work (Wang et al., 2019; Raganato et al., 2020).<sup>4</sup>

### 3.3 Training strategy

Inspired by the success of multi-stage training for tasks like grammatical error correction (Kiyono et al., 2019; Omelianchuk et al., 2020; Yuan and Bryant, 2021) and machine translation (Zhang et al., 2018), we employ a two-step training strategy: 1) pre-training on out-of-domain data; and 2) fine-tuning with in-domain MCL-WiC data.

<sup>3</sup>The  $[s]$  token in XLM-R is equivalent to the  $[CLS]$  token in BERT (Devlin et al., 2019).

<sup>4</sup>Our preliminary experiments show that using the averaged representation is more effective than that of the first sub-token.

<b>Sentence #1</b>	I went outside to get some fresh <b>air</b> .	(A2)
<b>Sentence #2</b>	He has an <b>air</b> of authority.	(C2)
<b>Label</b>	F	

Table 3: A sentence-pair example extracted from CALD. The target words are marked in bold. A2: elementary English, C2: proficiency English.

## 4 Experiments

### 4.1 Data

In addition to the MCL-WiC dataset provided by the shared task organisers, we introduce two types of out-of-domain data: 1) (\*)WiC datasets: WiC and XL-WiC; and 2) sentence pairs constructed with examples extracted from datasets that have been annotated with both complexity and sense information: the Cambridge Advanced Learner’s Dictionary (CALD)<sup>5</sup> and SeCoDa (Strohmaier et al., 2020).

**WiC** The English WiC dataset was created using example sentences from WordNet (Fellbaum, 1998), VerbNet (Kipper-Schuler, 2005), and Wiktionary. We extract 6,066 labelled instances (by removing those without gold labels) and use them for the shared task.

**XL-WiC** The XL-WiC dataset extends the WiC dataset to 12 more languages from two resources: multilingual WordNet for ZH, Bulgarian (BG), Croatian (HR), Danish (DA), Dutch (NL), Estonian (ET), Farsi (FA), Japanese (JA) and Korean (KO); and multilingual Wiktionary for FR, German (DE), Italian (IT). In total, the XL-WiC dataset contains 112,430 labelled non-English sentence pairs, including 3,046 ZH-ZH instances and 48,106 FR-FR ones.<sup>6</sup> In contrast to the MCL-WiC task, the XL-WiC dataset does not include any cross-lingual sentence pairs.

**CALD** The CALD contains information about which words and which meanings of those words are known and used by learners at each Common European Framework of Reference (CEFR) level from A1 (beginner) to C2 (proficiency English). Only example sentences sharing the same target word, that is used in a different meaning as well as at a different CEFR level, are paired. In this

<sup>5</sup><https://www.englishprofile.org/wordlists/evp>

<sup>6</sup>In the XL-WiC dataset, the number of instances varies considerably by language - see Raganato et al. (2020) for more details.

Dataset	Language	#instances (w/o aug.)	#instances (with aug.)	Training stage
WiC	EN-EN	6,066	8,276	pre-training
XL-WiC(FR)	FR-FR	48,016	54,771	pre-training
XL-WiC(ZH)	ZH-ZH	3,046	3,370	pre-training
XL-WiC	All*	112,430	127,765	pre-training
CALD	EN-EN	34,205	-	pre-training
SeCoDa	EN-EN	10,712	-	pre-training
MCL-WiC-train	EN-EN	8,000	10,798	fine-tuning
MCL-WiC-dev(EN)	EN-EN	1,000	-	development

Table 4: Summary of datasets used in our experiments. All\*: FR-FR, ZH-ZH, BG-BG, HR-HR, DA-DA, NL-NL, ET-ET, FA-FA, JA-JA, KO-KO, DE-DE, and IT-IT; w/o aug.: without data augmentation; with aug.: with data augmentation.

#	Pre-training data	EN-EN	AR-AR	FR-FR	RU-RU	ZH-ZH	Avg.

way, sentence pairs are encoded with additional word complexity information. In total, we generate 34,205 negative EN-EN instances.<sup>7</sup> An example is given in Table 3.

**SeCoDa** is an English language corpus of words annotated with both complexity and word senses. The original data comes from three sources: professional News, WikiNews and Wikipedia articles. The senses are drawn from the CALD and come at two levels of granularity. To use this dataset for the MCL-WiC task, sentences sharing an annotated word are paired: if the word shares a sense, the pair of sentences is labelled as ‘T’; otherwise, it is labelled as ‘F’. We use the finer level of granularity for this assignment. Overall, we extract 10,712 labelled pairs (9,015 positive and 1,697 negative).

All the data introduced in this section is regarded as out-of-domain data and therefore used in the pre-training stage, and the in-domain MCL-WiC training data is used in the fine-tuning stage. For development, we use only the EN-EN MCL-WiC development set (**MCL-WiC-dev(EN)**) - see Table 4). A single model is developed to target all multilingual and cross-lingual tracks. It is worth noting that neither the multilingual AR-AR and RU-RU data nor the cross-lingual data is used for

<sup>7</sup>Due to time limitations, we have not used any positive instances from CALD and leave it for future work.

training, i.e. zero-shot.

The data augmentation method proposed in Section 3.1 is applied to the (\*)WiC datasets, but not to CALD or SeCoDa. Detailed statistics of the corpora used in our experiments are presented in Table 4.

## 4.2 Training details

In our experiments, models are trained by minimising the binary cross-entropy loss between their prediction and the gold label. We use the AdamW optimiser (Loshchilov and Hutter, 2019) with a fixed learning rate of 1e-5 for all models.<sup>8</sup> We use a dropout layer with a dropout probability of 0.2. The input texts are processed in batches of 8 and are padded or truncated to a length of 182.<sup>9</sup> We select the model with the best validation accuracy on **MCL-WiC-dev(EN)**. Each model is trained on one NVIDIA Tesla P100 GPU.

## 4.3 Results

We construct three pre-training sets using different combinations of the out-of-domain data and

<sup>8</sup>We use the pre-trained xlm-roberta-large model provided by Hugging Face (<https://huggingface.co/>) transformers library (Wolf et al., 2020).

<sup>9</sup>We use a maximum sequence length of 182, which is the length of the longest input sequence in the MCL-WiC training set.

System	EN-EN		AR-AR		FR-FR		RU-RU		ZH-ZH	
	Acc.	Rank	Acc.	Rank	Acc.	Rank	Acc.	Rank	Acc.	Rank
#4	92.50	6	84.80	1	86.50	2	87.40	1	85.80	13

Table 6: Official results of our best submitted system on the MCL-WiC test set (multilingual track). Acc.: accuracy.

System	EN-AR		EN-FR		EN-RU		EN-ZH	
	Acc.	Rank	Acc.	Rank	Acc.	Rank	Acc.	Rank
#1	86.50	6	85.70	10	86.80	9	88.80	5

Table 7: Official results of our best submitted system on the MCL-WiC test set (cross-lingual track).

train three systems. All these systems are fine-tuned with the augmented version of the MCL-WiC training set (**MCL-WiC-train<sub>aug.</sub>** - see Table 4). Results on the MCL-WiC multilingual development set are presented in Table 5, where **WiC<sub>aug.</sub>** is the augmented version of the WiC dataset, **XL-WiC<sub>aug.</sub>** is the augmented version of the full XL-WiC dataset for all 12 languages, and **XL-WiC(FR&ZH)<sub>aug.</sub>** is a subset of **XL-WiC<sub>aug.</sub>**, containing only examples in FR and ZH (i.e. the only two languages shared by MCL-WiC and XL-WiC).

We can see that adding pre-training examples in other languages from the XL-WiC dataset improves the results for all languages except for EN-EN, where the accuracy slightly drops from 89.90 to 89.60 (Table 5 #2). Interestingly, Raganato et al. (2020) also reported performance gains in all languages after adding multilingual data. Examples from different languages can still help models better generalise across languages. The addition of English data from CALD and SeCoDa is also beneficial, yielding further improvements in all languages except for ZH-ZH (#3). Finally, the predictions from all three systems are used in an ensemble model. For each final prediction, the majority vote (MV) of these predictions is taken, i.e. the prediction with the most votes is chosen as final prediction. The ensemble model yields the highest averaged score, as well as in EN-EN and ZH-ZH sub-tracks (#4), suggesting that all three systems (#1, #2 and #3) are complementary.

## 5 Official evaluation results

We submit our systems to all multilingual and cross-lingual tracks. The official results of our best submission for each track are reported in Table 6 and Table 7. Our ensemble system (**System #4**) achieves state of the art in the multilingual track,

ranking first in both AR-AR and RU-RU sub-tracks without any AR or RU training data, and second in FR-FR out of 171 submitted systems. For the cross-lingual track, our ‘zero-shot’ system (**System #1**) is consistently within the top ten ranks out of 171 total submissions.<sup>10</sup>

## 6 Analysis

### 6.1 Effect of two-step training

We propose a two-step training strategy to make use of both in-domain and out-of-domain data. To investigate the effectiveness of both training steps, we undertake an ablation study, in which we remove one training step at a time. Table 8 presents the ablation test results of the system pre-trained on **WiC<sub>aug.</sub> + XL-WiC(FR&ZH)<sub>aug.</sub>**, and fine-tuned on **MCL-WiC-train<sub>aug.</sub>** (i.e. **System #1** in Table 5).

The results of the ablation study demonstrate the effectiveness of the two-step training strategy, and show that it is crucial to have both pre-training and fine-tuning stages. Performance drops in all multilingual sub-tracks when removing either step, except for removing the pre-training step in FR-FR (+0.70). This is interesting as the model is pre-trained on data for only three sub-tracks, where FR-FR is one of them. For the other two languages, we observe the biggest performance decrease: ZH-ZH (-2.80) and EN-EN (-2.30). Overall, the fine-tuning stage seems more effective than the pre-training stage, though more data is used in the latter (10,798 for fine-tuning vs. 66,417 for pre-training), demonstrating the importance of having high-quality in-domain data.

<sup>10</sup>It is to be noted that the calculation of the rank counts every submission, even if they were made by the same team.

Ablated stage	EN-EN		AR-AR		FR-FR		RU-RU		ZH-ZH		Avg.	
	Acc.	$\Delta$	Acc.	$\Delta$	Acc.	$\Delta$	Acc.	$\Delta$	Acc.	$\Delta$	Acc.	$\Delta$

Representation	EN-EN	AR-AR	FR-FR	RU-RU	ZH-ZH	Avg.
$[s; w_{s_1}; w_{s_2}]$	84.70	<b>77.30</b>	80.10	<b>83.80</b>	67.30	78.64
$[s; w_{s_1}; w_{s_2};  w_{s_1} - w_{s_2} ]$	85.40	77.00	80.60	81.50	70.30	78.96
$[s; w_{s_1}; w_{s_2};  w_{s_1} - w_{s_2} ; \cos; \text{dist}]$	<b>87.60</b>	77.10	<b>80.80</b>	82.70	<b>75.40</b>	<b>80.72</b>

Table 9: Results of models using different representations. Systems are trained on MCL-WiC-train<sub>aug</sub> and evaluated on MCL-WiC-dev (multilingual track). The best results in each sub-track are marked in bold. *cos*: cosine similarity, *dist*: Euclidean distance.

## 6.2 Comparison of representations

In our system, the representation pooled out from the underlying pre-trained language model is a combination of three vector representations (of the first token and target word in both sentences), and three distance-based features: the element-wise absolute difference, cosine similarity and Euclidean distance between the target word in both sentences (see Section 3.2). We further experiment with different representations and present our results in Table 9. We can see that our proposed representation yields the overall best performance across different languages, suggesting that the addition of all three distance-based features is indeed helpful.

## 7 Conclusion

In this paper, we presented the contribution of the Cambridge University team to the SemEval 2021 shared task on MCL-WiC Disambiguation. Using XLM-R, a pre-trained multilingual Transformer-based language model, as a starting point, we investigated automatic data augmentation, the use of multiple external datasets, multi-stage training strategies, and the representation of tokens and their distance. Our detailed analysis demonstrated the effectiveness of the two-step training strategy for making use of both in-domain and out-of-domain data, as well as the benefits of adding distance-based features to the representation for WiC disambiguation. Our best system yields highly competitive results in the cross-lingual track and achieves state-of-the-art results in the multilingual track, ranking first in two languages (AR and RU) and second in FR out of 171 total submissions.

## Acknowledgments

We would like to thank Mariano Felice and Shiva Taslimipoor for their valuable comments and suggestions. This paper reports on research supported by Cambridge Assessment, University of Cambridge. This work was performed using resources provided by the Cambridge Service for Data Driven Discovery operated by the University of Cambridge Research Computing Service, provided by Dell EMC and Intel using Tier-2 funding from the Engineering and Physical Sciences Research Council (capital grant EP/P020259/1), and DiRAC funding from the Science and Technology Facilities Council. ## Abstract

This paper describes our submission to SemEval 2021 Task 2. We compare XLM-RoBERTa Base and Large in the few-shot and zero-shot settings and additionally test the effectiveness of using a k-nearest neighbors classifier in the few-shot setting instead of the more traditional multi-layered perceptron. Our experiments on both the multi-lingual and cross-lingual data show that XLM-RoBERTa Large, unlike the Base version, seems to be able to more effectively transfer learning in a few-shot setting and that the k-nearest neighbors classifier is indeed a more powerful classifier than a multi-layered perceptron when used in few-shot learning.

## 1 Introduction and Motivation

Word Sense Disambiguation (WSD) is the task of disambiguating semantic meaning at the word level and is an important part of Natural Language Processing (NLP) with applications in several downstream tasks (Wang et al., 2020b). In recent years, Few Shot Learning (FSL) has been successful in several domains (Wang et al., 2020a) including in NLP (Yan et al., 2018). Modern deep neural networks require a significant amount of training data that might not always be available. FSL is a solution to this problem, wherein training data from a related domain or language can be used to augment training on the target domain/language with significantly less data. FSL can be characterised as n-way k-shot classification.

We participate in SemEval Task 2 Multilingual and Cross-lingual Word in Context Disambiguation (Martelli et al., 2021), which provides 8,000 training examples in English but only 32 in the other target languages. In addition the tasks requires disambiguation of word pairs in the cross lingual setting between EN-AR, EN-FR, EN-RU,

and EN-ZH, where only 8 examples each are available. This sparsity in training data led us to explore the use of FSL for this task.

We hypothesise that:

1. “Large” models, which have been shown to have a lot more linguistic information and high-level generalisability, are more likely to be able to generalise their learning in the few-shot setting, and
2. that the use of a k-nearest neighbors (KNN) classifier is likely to be more effective in the few-shot setting. This hypothesis is based on our exploration of related work (Section 2).

Our experiments on both the multi-lingual and cross-lingual data show that these hypotheses are in fact correct. We show that XLM-RoBERTa Large, unlike the Base version, seems to be able to more effectively transfer knowledge in a few-shot setting, and that the KNN classifier is indeed a more powerful classifier than a multi-layered perceptron (MLP) when used in few-shot learning. To ensure reproducibility and so other researchers can build on this work, we release the program code, hyperparameters and experiments associated with this work<sup>1</sup>.

## 2 Related work

The first effective method that implemented Few Shot Learning in NLP was that by Koch et al. (2015), who introduced the application of the siamese network in one-shot learning. The siamese network is typically used to calculate semantic similarity between sentences and was shown to be powerful in the FSL setting.

A recent use of zero-shot learning in WSD was work by Kumar et al. (2019), who proposed the

<sup>1</sup><https://github.com/weilk/SemEval-2021-Task-2>

extension of WSD systems by incorporating Sense embeddings (EWISE). These sense embeddings are derived from a knowledge graph, namely WordNet (Miller, 1998), and graph embeddings. EWISE predicts over an embedding space instead of the discrete label space and allow generalized zero-shot learning capability. Instead of using annotated data, it uses definitions from WordNet.

Pelevina et al. (2017) proposed a simple and effective method which uses clustering in ego-networks. Egocentric networks are local networks with one central node, known as the “ego”. This method allows labeling of words in the context with learned sense vectors thus providing a new approach to unsupervised WSD.

Our use of the K Nearest Neighbours (KNN) classifier is motivated by the work by Snell et al. (2017), who proposed a very straightforward network, similar to the nearest class mean approach (Mensink et al., 2013), that makes use of the classes of “prototypical” examples to classify new examples based on their distances. We extend this method by use of pre-trained models and a KNN classifier (Section 3).

### 3 Methodology

In this section, we describe the different models used for the task. Our models are built on top of XLM-RoBERTa, but because cross-lingual data is limited, we used FSL during training. We also perform data preprocessing, especially in the case of Chinese and Arabic where tokenisation is inexact.

#### 3.1 Data Preprocessing

We only use data available from the official data set provided<sup>2</sup> for all our experiments. We performed additional preprocessing in the case of Chinese and Arabic as it is often difficult to locate the target word in these cases. This is because Conneau et al. (2020) use the SentencePiece algorithm as the basis of XLMRobertaTokenizer, which tends to output the largest granularity words by meaning in both Chinese and Arabic. Due to this, it is possible that the target word may either be included in the hypernym’s word-piece or be cut and included in a different hypernym’s word-piece.

For example, XLM-RoBERTa tokeniser was used to tokenise a Chinese sentence, and the output is shown in Figure 1. The target word is “事情”.

<sup>2</sup><https://github.com/SapienzaNLP/mcl-wic>

However, the tokeniser includes the target word in the larger word “这件事情”. To get around this and to ensure correct word tokenisation, we add a comma (“,”) around the target word in both Chinese and Arabic sentences as in: “中国报告这件事情,”.

```
In [22]: tokenizer.tokenize("中国报告这件事情")
Out[22]: ['_中国', '报告', '这件事情']
```

Figure 1: Tokenise Chinese sentence

### 3.2 System Architecture

In order to find the most effective model architecture, we experiment with different variations: The cosine similarity between contextual word representations obtained from XLM-RoBERTa (Conneau et al., 2020) using multiple thresholds, classification of pre-generated XLM-RoBERTa embeddings using a multi-layer perceptron, and finally an end to end model with a softmax layer for classification. Our experiments showed the end to end model to be most effective, which we use for all downstream experimentation.

#### 3.2.1 The Base End-to-end Model

Models used in this work are variations of the base end-to-end model detailed in Figure 2. The model takes as input the two sentences and the positions of the target words. Each of the input sentences are transformed into the contextual word embeddings using XLM-RoBERTa and from the resultant embeddings the contextual embeddings associated with the target word are selected. These vectors,  $v_1$  and  $v_2$  are further augmented with their difference and concatenated into a single vector  $v_1, v_2, v_1 - v_2, v_2 - v_1$ . We note that although adding the vectors  $v_1 - v_2$  and  $v_2 - v_1$  does not provide the model with any additional information, our initial experiments showed that this boosted performance.

This combined vector is then passed through a transformer layer and a mean pool layer splits the output of the transformer layer into two different vectors which are compared using cosine similarity. The cosine similarity of these vectors is used to build a vector  $(cos, 1 - cos)$  which is then passed through either an MLP or a KNN classifier. This output is finally passed through a softmax layer to classify the word in the two sentences as belonging to the same meaning or not.

Figure 2: The architecture of the model used for sense disambiguation.

### 3.2.2 Zero-Shot Models

The zero-shot methods we use are variations of the base model, one which uses the Base version of XLM-RoBERTa, and the other which uses the Large version of XLM-RoBERTa. In this setting we use an MLP classifier instead of the KNN classifier. These models are trained on the English training data and tested on the multi-lingual and cross-lingual settings.

### 3.2.3 Few-Shot Models

The models that we use in the few-shot setting are modifications of the zero-shot model and we use the zero-shot model as a baseline. In all cases we start with the model trained on the English training data. The first variation replaces the multi-layered perceptron with a KNN classifier (with  $k = 2$ ), and the second variation replaces XLM-RoBERTa Base with XLM-RoBERTa Large. These variations are further detailed in Section 4 and are trained on the minimal data available in the target language pairs.

## 4 Experiments Design

We design several experiments to find the best performing model. All the experiments are performed

on the same platform<sup>3</sup>. We also use warmup in all the experiments and further hyperparameters are detailed in the documentation associated with the program code released with this work. For each experiment, five different random seed are tested and we choose the best performing model.

We use the English training data to train our baseline and zero-shot models. The development data provided consisted of 1000 examples for each language in the multi-lingual setting (en-en, ar-ar, zh-zh, fr-fr, and ru-ru). We divide this into a Dev-Train subset consisting of 600 examples, a Dev-Validation and Dev-Test subsets consisting of 200 examples each. In the cross-lingual setting, where we have only 8 examples from each language pair, we use the trial data for few shot training and do not use a validation or test set due to data sparsity. Finally, due to data sparsity in the target languages we freeze the transformer layers of XLM-RoBERTa during the few shot training phase.

Based on the results of these experiments, we select the best five models to submit to the official websites. These models were:

<sup>3</sup>System: Ubuntu 16.04.6 LTS. CPU:Intel(R) Xeon(R) CPU E5-2680 v3 @ 2.50GHz. 4 cores,8 threads. GPU:GeForce RTX 3090 24GB. Pytorch+cuda:1.7.1+cu110. Python 3.7.4

	EN-AR	EN-FR	EN-RU	EN-ZH
XLM-RoBERTa Base + MLP, Zero-Shot	74.30 (46)	80.00 (39)	81.60 (35)	76.30 (43)
XLM-RoBERTa Large + MLP, Zero-Shot	76.70 (41)	<b>84.00 (19)</b>	82.90 (28)	81.00 (37)
XLM-RoBERTa Base + MLP, Few-shot	73.00 (49)	76.50 (50)	80.10 (40)	75.50 (44)
XLM-RoBERTa Large + MLP, Few-shot	80.40 (34)	81.40 (34)	80.70 (38)	81.80 (33)
XLM-RoBERTa Large + KNN, Few-shot	<b>81.90 (30)</b>	83.90 (20)	<b>83.30 (24)</b>	<b>83.60 (29)</b>

Table 1: Accuracy on the final cross-lingual test set with the rank achieved by that submission in brackets. The highest score for each language pair is highlighted in bold. Rows 1, 3 and 2, 4 are comparable results between zero-shot and few-shot settings.

	EN-EN	AR-AR	FR-FR	RU-RU	ZH-ZH
XLM-RoBERTa Base + MLP, Zero-Shot	84.50 (50)	78.20 (40)	78.60 (44)	78.10 (34)	81.40 (32)

XLM-RoBERTa Large + MLP, Few-shot	87.10 (38)	<b>81.00 (27)</b>	83.40 (22)	82.00 (24)	82.00 (28)
XLM-RoBERTa Large + KNN, Few-shot	<b>88.50 (33)</b>	78.40 (38)	83.60 (21)	81.90 (25)	<b>82.10 (27)</b>

Table 2: Accuracy on the final multi-lingual test set with the rank achieved by that submission in brackets. The highest score for each language pair is highlighted in bold. Rows 1, 3 and 2, 4 are comparable results between Zero-Shot and few shot settings. The variation in en-en is a result of random initialisation.

1. XLM-RoBERTa Base with a multi-layered perceptron as the **baseline** zero-shot model.
2. XLM-RoBERTa Large with a multi-layered perceptron as a second zero-shot model.
3. XLM-RoBERTa Base with a multi-layered perceptron, additionally trained on available target language data as a few-shot model.
4. XLM-RoBERTa Large with a multi-layered perceptron, additionally trained on available target language data as a second few-shot model.
5. XLM-RoBERTa Large with a K-Nearest Neighbour classifier, additionally trained on available target language data as a third few-shot model.

## 5 Results and Analysis

The final results in the cross-lingual and multi-lingual settings are displayed in Tables 1 and 2 respectively. Each table displays the accuracy on the corresponding test set with the rank achieved by that submission in brackets (out of a total of 87 teams).

In each of the two tables, rows 1, 3 and 2, 4 provide a comparison between the zero-shot and few shot settings. It is interesting to note that few shot learning is *not* effective when using the base

version of XLM-RoBERTa. Across both the cross-lingual and multi-lingual settings, the minimal additional data does little to boost performance and in some cases actually reduces performance.

XLM-RoBERTa Large on the other hand, seems to be able to transfer knowledge extracted from training in English to the other languages and *gains the most when those languages are significantly different from English, the language in which the majority of the training data is available in*. The impact of few shot learning is the largest when the difference between the original training data (in this case English) and the target languages is largest. As can be seen from Table 1, the increase on the English-Arabic test set between the zero-shot and few shot settings is *nearly 5 percentage points* despite the few-shot model having been trained on only 8 examples. This same trend can be observed on the English-Chinese dataset albeit to a smaller extent.

The use of a KNN classifier, in place of an MLP, improves performance across the board providing the best results in a lot of the cases and comparable results in the rest. These results seem to validate the results obtained by Snell et al. (2017), who show that the use of a KNN to classify examples related to prototypical examples is an effective method in few-shot learning (Section 2).

## 6 Conclusions and Future work

This paper described our submission to SemEval 2021 Task2, multi-lingual and cross-lingual word in context disambiguation. Given the nature of the task, wherein we are provided with training data in English and very limited training data in the other target languages, we use zero-shot and few-shot learning.

We hypothesised (Section 1) that two methods will significantly boost performance in the few-shot learning setting: a) The use of “Large” pre-trained models which have been shown to have access to a lot more linguistic information and so generalisability, and b) the use of a KNN classifier instead of a multi-layered perceptron.

Our experiments, described in Section 5, confirm that this is indeed the case. We find that XML-RoBERTa Large is able to significantly increase performance in the few-shot setting, especially when the target languages are dissimilar to English, which is the language the majority of the training data is available in. We additionally find that the use of a KNN classifier boosts performance in the few-shot setting.

We additionally show that when using pre-trained models, tokenisers might split words in ways that are not conducive to the task at hand, especially in languages such as Chinese, where word delimitation is inexact. We handle this limitation by using a comma to delimit words in ways that are specific to the problem, which is both effective and easy to implement.

In future, we intend to explore the use of these methods on other datasets and problems beyond word sense disambiguation.

## Abstract

We experiment with XLM RoBERTa for Word in Context Disambiguation in the Multi Lingual and Cross Lingual setting so as to develop a single model having knowledge about both settings. We solve the problem as a binary classification problem and also experiment with data augmentation and adversarial training techniques. In addition, we also experiment with a 2-stage training technique. Our approaches prove to be beneficial for better performance and robustness.

## 1 Introduction

Language is complex even for human beings, let alone for computers. The same word serves different purposes in different scenarios, thus increasing the complexity of the Word Sense Disambiguation (WSD). For example in English, the word “bank” can refer to a financial institution or the land alongside a river. Many works revolving around WSD have been done with the help of explicit word sense inventories like WordNet<sup>1</sup> and BabelNet<sup>2</sup>. With the advent of advanced deep learning models, it is desirable to develop systems that have a good understanding of languages without such gold standards of word sense. This unsupervised learning can help the model learn better latent representations of words in different contexts.

In this paper, we aim to develop a single system that has knowledge of both multilingual and cross-lingual word sense disambiguation by training models with the combined data for both settings. We present our approaches for WSD in the multilingual and cross-lingual domain. The task is treated as a binary-classification problem: whether words have the same sense in the two given pairs of sentences. We experiment with XLM-RoBERTa

(Conneau et al., 2019), which is based on the Transformer architecture (Vaswani et al., 2017), as the backbone of our architectures in both the settings. In addition, we also leverage external data and different training techniques and data augmentation.

The rest of the paper is organized as follows : various related works have been discussed in section 2, followed by a brief description of the shared task dataset in section 3. The system overview and experimental settings are covered in sections 4 and 5. Sections 6 contain the results. Section 7 concludes the paper and also includes scope of future work.

## 2 Related Work

Silberer and Ponzetto (2010) make use of graph algorithms for the word sense disambiguation task. They build a multilingual co-occurrence graph in which the multilingual nodes are connected with translation edges and labelled with the target word’s translations as obtained from the corresponding contexts.

Authors in Banea and Mihalcea (2011), use multilingual vector space which is obtained by expanding monolingual features engineered from more than one language, in order to generate a more effective, robust and utilitarian vector representation. These engineered features are then used for WSD.

Languages like Arabic do not have as many resources in the available dataset as compared to more common languages like English. To tackle this issue for the Persian language, Lefever and Hoste (2011) follow a two phase approach - in the first phase, they utilize an English Word sense disambiguation system to assign “sense tags” to words appearing in English sentences and then in the following phase, they transfer the senses obtained in the previous phase to corresponding Persian words.

In the Semeval-2013 WSD task (Navigli et al.,

<sup>1</sup><https://wordnet.princeton.edu/>

<sup>2</sup><https://babelnet.org/>

2013), Rudnick et al. (2013) take a classification-based approach to the Cross-Lingual WSD task. They build the HLTDI system in which they perform word alignment on the Europarl corpus. This helps them find samples in the training data which have ambiguous focus words. The paper describes three variants of the classifier - one is trained over local features, the second is trained over the data with translation of the focus word in the four target languages added to the feature vector and the final variant builds a Markov network of the first classifier in order to find the best translation.

A few works have also been submitted as a part of SemDeep-5 workshop (Espinosa-Anke et al., 2019). Ansell et al. (2019) make use of contextualised ELMo word embeddings. A Bidirectional Long Short Term Memory(LSTM) cell is used to extract better representation of the given sentences. To disambiguate the words, they optimise the cosine distance between the concatenated hidden representations of words, preceding and following the target word. Soler et al. (2019) augment the dataset by automatically substituting target words using contextual similarity. They then experiment with different contextual word embeddings and train a logistic regression classifier on top of that.

### 3 Dataset

The dataset (Martelli et al., 2021)<sup>3</sup> provided by the shared task organizers consists of both multilingual and cross-lingual data in English (EN), Arabic (AR), French (FR), Russian (RU) and Chinese (ZH). The dataset consists of two sentences and the words in corresponding sentences (which need disambiguation) and the corresponding label.

### 4 System Overview

Our experiments revolve around Facebook’s XLM RoBERTa model, which was an update to their XLM-100 Language Model. XLM RoBERTa is based on the transformer architecture consisting of multi-attention heads which apply a sequence-to-sequence transformation on the input text sequence. The training procedure is inspired from RoBERTa (Liu et al., 2019) i.e. only the Masked Language Model objective is used. XLM RoBERTa is scaled up to 100 languages, thus becoming a good choice for multi-lingual datasets.

Another motivation to experiment with XLM RoBERTa comes from the facility of “Cross Lin-

gual Transfer”, which can help with unbalanced data of different languages. Knowledge is transferred for all languages if the model is trained for a particular task using data of only one language. Thus, this feature saves effort of gathering more data to make the data distribution balanced.

#### 4.1 Problem Formulation

We perform experiments keeping the model architecture constant across all experiments. The model accepts both the sentences concatenated together. The input to the model is formulated as :  $word_1 + \langle /s \rangle + sentence_1 + \langle /s \rangle + word_2 + \langle /s \rangle + sentence_2$ , where  $\langle /s \rangle$  is the separator token in XLM RoBERTa vocabulary.

Dropout is applied on the pooled encoding output from the model. The dropout probability is set to 0.3. The dropout applied output is then passed through a linear layer which provides us with the logits corresponding to the 2 classes.

#### 4.2 Data Augmentation

Data augmentations are considered an important technique to avoid overfitting of neural networks thus making them more generalised. Since our model architecture accepts both the sentences together, there is room to apply a simple data augmentation during training. Consider  $t_1$  and  $t_2$  are the 2 sentences for a particular data instance. The training data is augmented as  $t_1 \oplus t_2$  and  $t_2 \oplus t_1$ , where  $\oplus$  represents concatenation. We apply the augmentation taking care that no data leakage takes place in the validation data.

#### 4.3 Two Stage Training

To leverage the property of Cross Lingual Transfer, we first train the model on the WiC dataset (Pilehvar and Camacho-Collados, 2018), which consists only of English data. Then we train the same model (trained on WiC) on the MCL WiC dataset. This technique instills some knowledge via cross lingual transfer, about WSD in the first stage and then builds on the knowledge using the shared task dataset.

#### 4.4 Adversarial Training (AT)

Adversarial training is another technique that is used to increase the robustness of models, which also helps in better generalisation. Adversarial training in Computer Vision is done by directly perturbing the input images. However, text data

<sup>3</sup><https://github.com/SapienzaNLP/mcl-wic>

Model	EN-AR	EN-FR	EN-RU	EN-ZH
2 stage + Train Aug	75.3	78.2	78.7	75.2
2 stage + Train Aug + TTA	74.6	78.0	<b>78.9</b>	<b>75.3</b>
2 stage + Train Aug + AT	76.8	78.1	76.9	74.6
2 stage + Train Aug + AT + TTA	<b>76.9</b>	<b>79.5</b>	78.0	74.6
Best performance	89.1	89.1	89.4	91.2

Table 2: Test Scores for Cross Lingual Setting

being discrete in nature, the perturbations are added to the word embeddings.

Many approaches for adversarial training in NLP have been developed. We experiment using Miyato et al. (2016) approach with little modification. In their approach, the word embeddings are normalized first. Required perturbations are created using the gradients obtained via backpropagation. Let the sequence of (normalized) word embedding vectors of a text be  $t$ . The model parameters are represented by  $\theta$ . The probability of the text belonging to class  $y$  is given by  $p(y|t; \theta)$ . The adversarial perturbations  $z_{adv}$  are computed as follows:

$$g = \nabla_t \log p(y|t; \theta)$$

$$z_{adv} = -\epsilon g / \|g\|_2$$

where  $\epsilon$  is a hyper-parameter controlling the size of the perturbations. The adversarial loss is defined as :

$$L_{adv}(\theta) = -\frac{1}{N} \sum_{n=1}^N \log p(y_n | t_n + z_{adv,n}; \theta)$$

By using the gradients calculated from the above loss, the weights of the model are updated (the non-perturbed word embeddings of the model are updated). Our experiments deviate from the above method in the part that we do not normalize our pre-trained word embedding of the model, since doing so might change the semantic meaning of the pre-trained word embeddings. We perform adversarial training XLM RoBERTa model using  $\epsilon = 1$ .

Model	CV
W/O extra techniques	73.68
Train Aug	74.68
2 stage + Train Aug	75.64
2 stage + Train Aug + AT	<b>77.07</b>

Table 1: Cross Validation Scores

#### 4.5 Test Time Augmentation (TTA)

The usage of the training data augmentation can be extended to test time as well. For a given data instance  $t_1$  and  $t_2$ , the model predictions for  $t_1 \oplus t_2$  and  $t_2 \oplus t_1$  are combined using simple averaging of probabilities. Thus, this simple augmentation can help boost the performance of the model.

## 5 Experimental Setup

We make use of combined training and validation data provided by the shared task organizers. We perform a stratified 5 fold cross validation using the combined data. In all our experiments, we fine tune the entire model. Each fold is trained for 20 epochs using early stopping with patience of 6 and tolerance of  $1e-3$ . The models are optimised using AdamW (Loshchilov and Hutter, 2017) with a learning rate of  $5e-6$  and a batch size of  $16^4$ . Inputs of maximum sequence length 172 are used in the model. The models have been implemented using Pytorch (Paszke et al., 2019) and Huggingface’s Transformers (Wolf et al., 2019) library.

## 6 Results

Accuracy score is the official evaluation metric for the shared task. The test predictions are obtained by combining the predictions of all the 5 fold models (by averaging the predictions from all models). Table 1 lists down the cross validation accuracy scores of all the experiments. The test scores are categorised as cross-lingual and multilingual and are presented in tables 2 and 3 respectively. For bench marking purpose, we also mention the best performances achieved by participants of the shared task.

A few observations can be made by looking at the results:

<sup>4</sup>It is important to note that XLM RoBERTa requires a much smaller learning rate as compared to BERT and other models, for training; XLM RoBERTa is incapable of learning if trained using high learning rates like  $2e-5$

Model	EN-EN	AR-AR	FR-FR	RU-RU	ZH-ZH
2 stage + Train Aug	84.5	79.7	78.8	77.4	79.6
2 stage + Train Aug + TTA	<b>85.4</b>	<b>80.2</b>	79.0	<b>77.7</b>	<b>80.4</b>
2 stage + Train Aug + AT	85.2	79.0	80.2	76.9	79.2
2 stage + Train Aug + AT + TTA	85.1	80.0	<b>80.5</b>	77.6	79.7
Best performance	93.3	84.8	87.5	87.4	91.0

Table 3: Test Scores for Multilingual Setting

1. Test Time Augmentation helps in boosting the scores.
2. In the cross lingual setting, models trained with and without adversarial training are competent to the same extent. On the other hand, in the multilingual setting, models trained without adversarial training seem to have the upper hand.

## 7 Conclusion and Future Work

We explore the performance of XLM RoBERTa at Word In Context Disambiguation both in the multilingual and cross lingual setting. We also explore different training techniques such as two-stage training and adversarial training along with some simple augmentations to make our models robust and more generalized. Test Time Augmentations, based on training augmentation turn out to be useful. For future work, we can explore the performance of ensembling different kinds of models trained with and without adversarial training together, so as to produce more robust results. It will also be interesting to experiment with larger backbone models in the current architecture.

## Abstract

This paper presents a set of experiments to evaluate and compare between the performance of using CBOV Word2Vec and Lemma2Vec models for Arabic Word-in-Context (WiC) disambiguation without using sense inventories or sense embeddings. As part of the SemEval-2021 Shared Task 2 on WiC disambiguation, we used the `dev.ar-ar` dataset (2k sentence pairs) to decide whether two words in a given sentence pair carry the same meaning. We used two Word2Vec models: Wiki-CBOV, a pre-trained model on Arabic Wikipedia, and another model we trained on large Arabic corpora of about 3 billion tokens. Two Lemma2Vec models was also constructed based on the two Word2Vec models. Each of the four models was then used in the WiC disambiguation task, and then evaluated on the SemEval-2021 `test.ar-ar` dataset. At the end, we reported the performance of different models and compared between using lemma-based and word-based models.

## 1 Introduction

As a word may denote multiple meanings (*i.e.*, senses) in different contexts, disambiguating them is important for many NLP applications, such as information retrieval, machine translation, summarization, among others. For example, the word “table” in sentences like “I am cleaning the table”, “I am serving the table”, “I am emailing the table”, refer to “furniture”, “people”, and “data” respectively. Disambiguating the sense that a word denotes in a given sentence is important for understanding the semantics of this sentence.

To automatically disambiguate word senses in a given context, many approaches have been proposed based on supervised, semi-supervised, or unsupervised learning models. Supervised and semi-supervised methods rely on full, or partial, labeling of the word senses in the training corpus

to construct a model (Lee and Ng, 2002; Klein et al., 2002). On the other hand, unsupervised approaches induce senses from unannotated raw corpora and do not use lexical resources. The problem in such approaches, is that unsupervised learning of word embeddings produces a single vector for each word in all contexts, and thus ignoring its polysemy. Such approaches are called static Word Embeddings. To overcome the problem, two types of approaches are suggested (Pilehvar and Camacho-Collados, 2018): multi-prototype embeddings, and contextualized word embeddings. The latter suggests to model context embeddings as a dynamic contextualized word representation in order to represent complex characteristics of word use. Proposed architectures such as ELMo (Peters et al., 2018), ULMFiT (Howard and Ruder, 2018), GPT (Radford et al., 2018), T5 (Raffel et al., 2019), and BERT (Devlin et al., 2018), achieved breakthrough performance on a wide range of natural language processing tasks. In multi-prototype embeddings, a set of embedding vectors are computed for each word, representing its senses. In (Pelevina et al., 2017), multi-prototype embeddings are produced based on the embeddings of a word. As such, a graph of similar words is constructed, then similar words are grouped into multiple clusters, each cluster representing a sense. As for Mancini et al. (2016), multi-prototype embeddings are produced by learning word and sense embeddings jointly from both, a corpus and a semantic network. In this paper we aim at using static word embeddings for WiC disambiguation.

Works on Arabic Word Sense Disambiguation (WSD) are limited, and the proposed approaches are lacking a decent or common evaluation framework. Additionally, there are some specificities of the Arabic language that might not be known in other languages. Although polysemy and disambiguating are challenging issues in all languages,

they might be more challenging in the case of Arabic (Jarrar et al., 2018; Jarrar, 2021) and this for many reasons. For example, the word *šāhd* (شاهد) could be *šāhid* (شاهد) which means a *witness*, or *šāhada* (شاهد) which means *watch*. As such, disambiguating words senses in Arabic, is similar to disambiguating senses of English words written without vowels. Second, Arabic is a highly inflected and derivational language. As such, thousands of different word forms could be inflected and derived from the same stem. Therefore, words in word embeddings models will be considered as different, which may affect the accuracy and the utility of their representation vectors, as the same meaning could be incarnated in distributed word forms in corpora, which has led some researchers to think that using lemma-based models might be better than using word-based embeddings in Arabic (Salama et al., 2018; Shapiro and Duh, 2018). This idea will be discussed later in sections 5 and 6.

Alkhatlan et al. (2018) suggested an Arabic WSD approach based on Stem2Vec and Sense2Vec. The Stem2Vec is produced by training word embeddings after stemming a corpus, whereas the Sense2Vec is produced based on the Arabic WordNet sense inventory, such that each synset is represented by a vector. To determine the sense of a given word in a sentence, the sentence vector is compared with every sense vector, then the sense with maximum similarity is selected.

Laatar et al. (2017) did not use either stemming or lemmatization. Instead, they proposed to determine the sense of a word in context by comparing the context vector with a set of sense vectors, then the vector with the maximum similarity is selected. The context vector is computed as the sum of vectors of all words in a given context, which are learnt from a corpus of historical Arabic. On the other hand, sense vectors are produced based on dictionary glosses. Each sense vector is computed as the sum of vectors (learnt from the historical Arabic corpus) of all words in the gloss of a word.

Other approaches to Arabic WSD (Elayeb, 2019) employ other techniques in machine learning and knowledge-based methods (Bouhriz et al., 2016; Bousmaha et al., 2013; Soudani et al., 2014; Merhbene et al., 2014; Al-Maghasbeh and Bin Hamzah, 2015; Bounhas et al., 2015).

In this paper, we present a set of experiments to evaluate the performance of using Lemma2Vec vs CBOV Word2Vec in Arabic WiC disambiguation.

The paper is structured as follows: Section 2 presents the background of this work. Section 3 overviews the WiC disambiguation system. Section 4 and Section 5, respectively, present the Word2Vec and Lemma2Vec models. In Section 6 we present the experiments and the results; and in section 7 we summarize our conclusions and future work.

## 2 Background

Experiments presented in this paper are part of the SemEval shared task for Word-in-Context disambiguation (Martelli et al., 2021).

The task aims at capturing the polysemous nature of words without relying on a fixed sense inventory. A common evaluation dataset is provided to participants in five languages, including Arabic, our target language in this paper. The dataset was carefully designed to include all parts of speeches and to cover many domains and genres. The Arabic dataset (called multilingual *ar-ar*) consists of two sets: a train set of 1000 sentence pairs for which tags (TRUE or FALSE) are revealed, and a test set of 1000 sentence pairs for which tags were kept hidden during the competition. Figure 1 gives two examples of sentence pairs in the *dev.ar-ar* dataset. Each sentence pair has a word in common for which start and end positions in sentences are provided. Participants in the shared task were asked to infer whether the target word carries the same meaning (TRUE) or not (FALSE) in the two sentences.

### 3 System Overview

This section describes our method to Arabic WiC disambiguation based on two types of embeddings: CBOV Word2Vec and Lemma2Vec.

Given two sentences,  $s_1$  and  $s_2$ , and two words,  $v_i$  from  $s_1$  and  $w_j$  from  $s_2$ , the objective is to check whether  $v_i$  and  $w_j$  have the same meaning. To this end, our system extracts contexts of  $v_i$  and  $w_j$  from the sentence pair, represents them in two vectors and finally compares the two resulting vectors using the cosine similarity. The context of a word  $w$  of size  $n$  (denoted by  $context(w, n)$ ) is composed of the words that surround the word  $w$ , with  $n$  words on the left and  $n$  words on the right ( $n$  varying between 1 and 10 in conducted experiments). To represent  $context(w, n)$  in a vector space, two methods are proposed: first one is based on CBOV Word2Vec embeddings vectors (Mikolov et al., 2013) of the words appearing in the context, whereas the second is based on the Lemma2Vec of lemmas of words appearing in the context. To select the best way to represent the  $context(w, n)$  by a vector, classification experiments were conducted using (i) different pooling operations, *min*, *max*, *mean*, and *std* to combine words/lemmas vectors of the context, (ii) different threshold values (between 0.55 and 0.85) and (iii) the removal of functional words (also called stop words). The later are used to express grammatical relationships among other words, they are characterized by they high frequency in the corpus which might affect the WiC disambiguation accuracy. The cosine similarity is then used to compare vectors of  $context(v_i, n)$  and  $context(w_j, n)$ . Figure 2 illustrates how the cosine similarity is calculated from  $context(v_i, 3)$  and  $context(w_j, 3)$ .

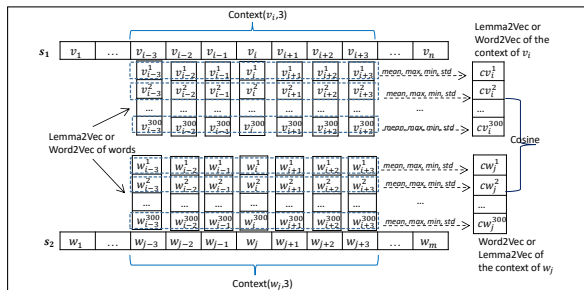

Figure 2: Calculation of  $context(v_i, 3)$  and  $context(w_j, 3)$  vectors and the cosine similarity between.

Classification experiments on SemEval-2021 ar-ar datasets were conducted using the following

two CBOV Word2Vec models and two corresponding Lemma2Vec models: (i) Wiki-CBOV, a pre-trained Word2Vec model from the set of AraVec models (Soliman et al., 2017), (ii) our CBOV Word2Vec model that we trained ourselves, (iii) Lemma2Vec model that we constructed based on the Wiki-CBOV model, and (iv) Lemma2Vec that we constructed based on our CBOV Word2Vec model. Based on these four models, four experiments were conducted to tune the following parameters: context size (*context\_size*), *threshold*, pooling operation (*pooling*) and removing of functional words (*stop\_words*).

### 4 Corpus and trained Word Embeddings

Two CBOV Word2Vec models were used in our experiments. The Wiki-CBOV (Soliman et al., 2017), which consists of 234,173 vocabulary size, and another model we trained our self which consists of 334,161 vocabulary size. The Wiki-CBOV model was learnt from a corpus of Arabic Wikipedia articles of about 78 million words, the principal hyperparameters are: 5 for minimum word count and 5 for window size.

Our CBOV Word2Vec model was trained on Modern Standard Arabic corpora, such as (El-Khair, 2017; Abbas and Smaili, 2005; Abdelali et al., 2014) of about 3 billion words; it was fit using 300-dimensional word vectors, 100 the minimum count of words, training epochs of 5 and window size of 5.

Before training the Word2Vec model, several normalization and preprocessing steps were performed. First, all diacritics, punctuations, Madda character, digits (Hindi and Arabic), Latin characters (including accented letters) were removed. Second, some special Arabic letters are unified. Third, sequences of repeated characters with length larger than 2 were reduced to one character; repeated spaces were also replaced by one space. Fourth, different forms of Alifs (ا | آ | إ) are replaced with (ا). Spaces followed by a period character and new lines were considered to be end of sentence marks. The split method in Python is used in tokenization. The vocabulary size of the resulted model is 334,161.

### 5 Constructing the Lemma2Vec models

Two Lemma2Vec models were produced, based on both: the Wiki-CBOV Word2Vec model, and our CBOV Word2Vec model. Each vocabulary in

each of the Word2Vec models was lemmatized first. Then a vector for each lemma (*i.e.*, Lemma2Vec) is calculated as following: first all word forms belonging to this lemma are fetched, then their Word2Vec vectors are combined through a *mean* pooling operation. The lemmatization process was performed using in-house tools and lexicographic databases <sup>1</sup> belonging to Birzeit University (Jarrar, 2021; Jarrar and Amayreh, 2019; Jarrar et al., 2019). In case of a word cannot be lemmatized due to misspelling, incorrect tokenization or in case of foreign word (not included in our database), then the corresponding Lemma2Vec is considered to be its Word2Vec vector.

Table 1 summarizes the lemmatization results that we performed on both, the Wiki-CBOW model and our CBOW Word2Vec model. The lemmatized words of SemEval-2021 all *ar-ar* dataset, as well as the Word2Vec and Lemma2Vec of *ar-ar* datasets words’s vectors used in this paper are available on-line <sup>2</sup>.

	Wiki-CBOW	Our Word2Vec

Unique lemmas	100,040	54,788
Words not lemmatized	22,054	28,098

Table 1: Lemmatization results for both models.

## 6 Experiments Results and Discussion

Given our Arabic WiC disambiguation method described in Section 3, and given the SemEval multilingual *dev.ar-ar* dataset provided by SemEval-2021 (Martelli et al., 2021), four classification experiments were conducted using the cosine similarity and based on the two Word2Vec models and the two Lemma2Vec models. The objective is to tune the following parameters for each model: *context\_size* (ranging from 1 to 10), *threshold* (we determined empirically the range from 0.55 to 0.85 with 0.1 step size), *pooling* (*min*, *max*, *mean* and *std*), and *stop\_words* (*yes*, *no*). Then the values of parameters corresponding to the high F1-scores for TRUE (T) and FALSE (F) classes are selected in order to classify sentence pairs in the *test.ar-ar* dataset. For each model we did

	Exp1	Exp2	Exp3	Exp4
<b>Model</b>	Word2Vec Wiki-CBOW	Lemma2Vec Wiki-CBOW	Word2Vec our model	Lemma2Vec our model
<i>context_size</i>	4	1	4	1
<i>pooling</i>	<i>min</i>	<i>min</i>	<i>min</i>	<i>mean</i>
<i>threshold</i>	0.66	0.56	0.83	0.58
<i>stop_words</i>	<i>yes</i>	<i>yes</i>	<i>no</i>	<i>yes</i>
<b>Dataset</b>	<i>dev.ar-ar</i>			
<b>Tag</b>	T	F	T	F
Precision	52	52	57	58
Recall	54	51	61	53
F1-score	53	52	59	56
<b>Dataset</b>	<i>test.ar-ar</i>			
Accuracy	57	59	59	<b>60</b>

Table 2: Best F1-score, precision and recall values of the four experiments on *dev.ar-ar* dataset with the values of tuned parameters. Below are accuracies on *test.ar-ar* dataset.

the following to find the high F1-scores for T and F: For each *context\_size* (between 1 and 10) and for each value of the *stop\_words* (*yes* or *no*) we plotted 8 line plots (4 for T and 4 for F) for each of the four pooling operations (*mean*, *max*, *min* and *std*) and for *threshold* ranging from 0.55 to 0.85 (*i.e.*, 20 plots for each model, resulting 80 plots).

Figures 3a, 3b, 3c and 3d show the best 4 F1-scores line plots for each of the four models, and Table 2 shows the effective F1-scores values for T and F classes as well as precision and recall values (best results marked in bold). The values of parameters corresponding to the best result were then used in classifying the *test.ar-ar* dataset. The accuracies are reported in Table 2 as well.

As shown in Figure 3, the Lemma2Vec models have the tendency to perform better with shorter context sizes compared with the Word2Vec models. A possible reason may be that, in case of Lemma2Vec, the narrow meaning of words is affected due to the increase number of words involved in Lemma2Vec vector calculation. The impact of Lemma2Vec on the narrow meaning of words is discussed in the next subsection.

The results with *yes* for *stop\_words* are slightly better but not significant. Additionally, the *min* pooling was generally the best operation to combine the context vectors, and the results of both *min* and *max* pooling were close to each other.

## 6.1 Lemma2Vec-Word2Vec Error Analyses

This subsection discusses the performance of using lemma-based vs. word-based models in the WiC disambiguation task, which we summarize in Table 3 and Table 4.

	TRUE	FALSE	Total
Correct L2V - Correct W2V	225	145	370
<b>Correct L2V - Wrong W2V</b>	118	98	216
<b>Wrong L2V - Correct W2V</b>	66	116	182
Wrong L2V - Wrong W2V	91	141	232
Total	500	500	1000

Table 3: Wiki-CBOW Lemma2Vec vs. Word2Vec

Table 3 presents the results of experiments 1 and 2 (using Word2Vec and Lemma2Vec of Wiki-CBOW) whereas Table 4 presents the results of experiments 3 and 4 (using Word2Vec and Lemma2Vec of our CBOW model). In each table, we compare between cases that were correctly or wrongly classified by both models. For example, the second row in Table 3 shows that 216 sentence pairs (118 TRUE class + 98 FALSE

	TRUE	FALSE	Total
Correct L2V - Correct W2V	124	241	365
<b>Correct L2V - Wrong W2V</b>	188	45	233
<b>Wrong L2V - Correct W2V</b>	58	178	236
Wrong L2V - Wrong W2V	130	36	166
Total	500	500	1000

Table 4: Our Lemma2Vec vs. our Word2Vec

class) were correctly classified using the Wiki-CBOW’s Lemma2Vec model but wrongly classified using the Word2Vec. Similarly, 182 sentence pairs in the third row were correctly classified using the Word2Vec but wrongly classified using the Lemma2Vec.

As shown in both tables’ second and third rows, the Lemma2Vec did not significantly improve the overall results; but notably, the Lemma2Vec shows a significant improvement over Word2Vec for TRUE class whereas Word2Vec is better for FALSE class.

This conclusion is valid for all models, whatever are the corpora content, size and *min\_count*

test.ar-ar.342	(Correct with Lemma2Vec – Wrong with Word2Vec)
والنظام الحالي للدورات يسمح بمراعاة مختلف مواقف الوفود، ويتمتع بصوتة معينة..... sentence1: ..... عن الميزانية وسرعة برامج المنظمة <b>ومرونتها</b> من محدودية الموارد المتاحة في الميزانية العادية..... sentence2: ..... Class: TRUE	
test.ar-ar.994	(Wrong with Lemma2Vec – Correct with Word2Vec)
يتميز بقلة أو عدم وجود تخييلات جنسية والرغبة في ممارسة الجنس لفترة من الزمن. sentence1: ..... الذي يميز الرواية عن باقي الأجناس الأدبية الثرية الأخرى، وإنما توجد مقومات فنية أخرى... sentence2: ..... Class: FALSE	

Figure 4: Example of errors.

hyperparameter.

To understand the gain and loss by the lemma-based models, we manually analyzed most cases. Figure 4 illustrates such cases. The first sentence pair in Figure 4 was correctly classified by the Lemma2Vec (in **Exp4**) and wrongly by the Word2Vec (in **Exp3**). This illustrates that the lemma vector as a generalized model for its inflections (*i.e.*, a mean of word forms' vectors) was better in deciding that both contexts are similar and that the two word forms have the same meaning. However, the second example in Figure 4 illustrates the other way. The Lemma2Vec was too general, and the Word2Vec was specific enough, to decide that the two word forms, in the two contexts, are different. The word from al-ğins (الجنس) could mean both *genus* and *sex*; however the other word form al-ʾağnās (الأجناس), is semantically distinctive by its own morphology - as it can only be plural of *genus*, and cannot be plural of *sex*.

To conclude, although Lemma2Vec outperforms Word2Vec in some cases (mostly in the TRUE sentence pairs class), it underperforms Word2Vec in others cases (mostly in the FALSE sentence pairs class). Since the distribution of TRUE and FALSE is equal in the datasets, the overall performance of both models is close to each other. Nevertheless, in case of an application scenario where a large proportion of sentence pairs is expected to be TRUE, we recommend the use of Lemma2Vec, otherwise the Word2Vec.

## 7 Conclusions and Further Work

We presented a set of experiments to evaluate the performance of using Word2Vec and Lemma2Vec models in Arabic WiC disambiguation, without using external resources or any context/sense embedding model. Different models were constructed based on two different corpora, and different types of parameters were tuned. The final results demonstrated that Lemma2Vec models are slightly better than Word2Vec models for Arabic WiC disambiguation. More specifically, we found that

Lemma2Vec outperforms Word2Vec for TRUE sentence pairs, but underperforms it for FALSE sentence pairs.

We plan to extend our work to use our Lemma2Vec model to build a multi-prototype embeddings using the large lexicographic database available at Birzeit University. We plan also to fine tune the recently released Arabic BERT models, such as (Safaya et al., 2020; Antoun et al., 2020; Abdelali et al., 2021; Inoue et al., 2021), using the same database.

## Acknowledgments

We would like to thank the shared task organizers and the reviewers for their valuable comments and efforts towards improving our manuscript. We would like to also thank Taymaa Hammouda for her technical support.

## Abstract

Consulting a dictionary or a glossary is a familiar way for many humans to figure out what does a word in a particular context mean. We hypothesize that a system that can select a proper definition for a particular word occurrence can also naturally solve tasks related to word senses. To verify this hypothesis we developed a solution for the Multilingual and Cross-lingual Word-in-Context (MCL-WiC) task, that does not use any of the shared task data or other WiC data for training. Instead, it is trained to embed word definitions from English WordNet and word occurrences in English texts into the same vector space following an approach previously proposed by Blevins and Zettlemoyer (2020) for Word Sense Disambiguation (WSD). To estimate the similarity in meaning of two word occurrences, we compared different metrics in this shared vector space and found that L1-distance between normalized contextualized word embeddings outperforms traditionally employed cosine similarity and several other metrics. To solve the task for languages other than English, we rely on zero-shot cross-lingual transfer capabilities of the multilingual XLM-R masked language model. Despite not using MCL-WiC training data, in the shared task our approach achieves an accuracy of 89.5% on the English test set, which is only 4% less than the best system. In the multilingual subtask zero-shot cross-lingual transfer shows competitive results, that are within 2% from the best systems for Russian, French, and Arabic. In the cross-lingual subtask are within 2-4% from the best systems.

## 1 Introduction

SemEval-2021 Task 2 is a multilingual and cross-lingual word-in-context disambiguation task (MCL-WiC) for five different languages (Martelli et al.,

2021).<sup>1</sup> Each example in the multilingual subtask consists of two sentences in English, Russian, French, Arabic, or Chinese language containing occurrences of the same target word. In the cross-lingual subtask each example consists of two sentences in different languages containing occurrences of two different target words. The participants were asked to detect whether those occurrences corresponded to the same or different meanings. These tasks are formalized as binary classification tasks. The datasets contain the same number of examples for each class. Accuracy is utilized as the main performance metric.

Recent SOTA approaches to the WiC task mainly include fine-tuning large universally pre-trained masked language models (Raffel et al., 2020; Liu et al., 2019) on labeled WiC datasets. Instead, we decided to train a system that selects the most appropriate definition for each word occurrence following an approach proposed by Blevins and Zettlemoyer (2020) for Word Sense Disambiguation (WSD) and experimented with different ways of adapting such system to the MCL-WiC task. During the evaluation period, we experimented with distances between probability distributions over word definitions but did not manage to achieve good results. But through the post-evaluation period, we switched to distances between the contextualized word embeddings of our gloss-informed language model and improved our results significantly achieving comparable results with the 2nd best system for French and 6th best system for Arabic in the multilingual subtask.

Our main interest was whether the word-in-context systems can benefit from using gloss information, provided for each possible sense of the word.

<sup>1</sup><https://competitions.codalab.org/competitions/27054>

## 2 Background

Here we summarize prior work linking word occurrences and word definitions. One of the first approaches in this field (Lesk, 1986) calculated the lexical overlap between the context of a particular word occurrence and all possible definitions of this word. This approach did not take into account word synonymy or other lexical relations. The following work tried to combine state-of-the-art language models with glosses from some dictionaries.

One of such methods has been proposed by Kumar et al. (2019). Their EWISE system used a pre-training procedure for a gloss encoder, that learned knowledge graph embeddings from WordNet (Miller, 1995). After this pre-training, the authors froze the gloss encoder and started to train a context encoder with labeled WSD data. While the method of Kumar et al. (2019) requires relational information from a knowledge graph, the method proposed by Huang et al. (2019) relies fully on gloss information. The developed system jointly encodes the context with all possible glosses of the target word. The authors used a pre-trained BERT (Devlin et al., 2019) model as initialization for their encoder.

A similar approach has been proposed by Blevins and Zettlemoyer (2020), who trained two separate Transformer-based encoders for word occurrences (Context encoder) and word definitions (Gloss encoder), both initialized with BERT weights (Devlin et al., 2019). To represent a word occurrence, the outputs of the Context encoder for all of its subwords were averaged. To represent a definition, the output of the Gloss encoder from [CLS] token was taken. Finally, for a word occurrence and all of its definitions, the dot products between those outputs were calculated and the softmax function was applied to them, resulting in a probability distribution over possible word senses. The whole model was trained using cross-entropy loss to select the correct word sense on WSD data.

## 3 System overview

In order to learn sense-dependent representations of words, we pre-train our system on the Word Sense Disambiguation task. Following the BEM model (Blevins and Zettlemoyer, 2020), our system consists of two separate encoders: Context Encoder and Gloss Encoder.

**Context encoder ( $T_c$ )** takes a sentence  $c = c_0, \dots, c_{i-1}, w_c, c_{i+1}, \dots, c_n$  containing a target word  $w_c$  to be disambiguated, where  $w_c$  is the  $i^{th}$  word in the sentence. The encoder then produces the target word representation:

$$r_{w_c} = T_c(c)[i]$$

For target words that are tokenized into multiple subword units, we average representations of these subwords.

**Gloss encoder ( $T_g$ )** takes as input a gloss  $g_s$  that defines a word sense  $s$  and encodes it as:

$$r_s = T_g(g_s)[0]$$

Taking the output from the first input token, which should be [CLS] for BERT or <s> for XLM-R.

We can score each of the possible senses  $s \in S_w$ , for a target word  $w_c$  by taking the dot product of  $r_{w_c}$  against every  $r_s$  for  $s \in S_w$ :

$$\phi(w_c, s) = r_{w_c}^T r_s$$

Both encoders were initialized with BERT or XLM-R weights. Then the whole system was pre-trained on English WSD data (Miller et al., 1994) with cross-entropy loss. We denote this pre-training procedure as Gloss Language Modeling (GLM) and compare it with pure Masked Language Modeling (MLM) pre-training. In both cases, the models were not fine-tuned on any MCL-WiC data.

### 3.1 Adaptation to the MCL-WiC task

As EWISE (Kumar et al., 2019) and BEM (Blevins and Zettlemoyer, 2020) systems work only with English data, we extend the proposed approach to the multilingual setting by replacing BERT with XLM-R model (Conneau et al., 2019). In the result section, we discuss how this affects the resulting performance.

Here we present two approaches to the final MCL-WiC task, one using distributions over possible word definitions and another exploiting different similarity measures between contextualized target word embeddings from the Context Encoder. The latter is also applicable to the contextualized word embeddings obtained from MLM pre-trained XLM-R, which we consider as a baseline.

#### 3.1.1 Probability distribution over glosses

Here we exploit probability distributions  $P(\text{sense}|w_{c_1})$  and  $P(\text{sense}|w_{c_2})$  produced by

Sentence	gloss #1	gloss #2	gloss #3
dev.en-en.1, Meanings are the same			
No clause in a contract shall be interpreted as evading the responsibility of <b>superiors</b> under international law	one of greater rank or station or quality (0.82)	the head of a religious community (0.12)	a combatant who is able to defeat rivals (0.06)
In Senegal too, the customs officer and his <b>superiors</b> receive a premium in case of detecting and preventing smuggling	one of greater rank or station or quality (0.58)	the head of a religious community (0.3)	a combatant who is able to defeat rivals (0.09)
dev.en-en.16, Meanings are different			
During the fight both of them <b>tripped</b> , the author falling on the victim and stabbing him with the knife by accident	miss a step and fall or nearly fall (0.998)	cause to stumble (0.0009)	put in motion or move to act (0.0004)
The father of the child also cannot take the child to <b>trip</b> during the fostering duration, without permission of fosterer	make a trip for pleasure (0.9)	miss a step and fall or nearly fall (0.06)	get high, stoned, or drugged (0.02)

Table 1: Examples from the MCL-WiC development set with 3 most probable glosses of the target word predicted by our system. Word in **bold** is the target word. The rounded probabilities for each of the meanings are given in parentheses.

our WSD system for words  $w_{c_1}$  and  $w_{c_2}$  in their contexts  $c_1$  and  $c_2$ .  $w_{c_1}$  and  $w_{c_2}$  have the same lemma and consequently have the same set of possible meanings  $S_w$  from the vocabulary.

**Gloss match prob:** The probability that two word occurrences,  $w_{c_1}$  and  $w_{c_2}$ , have the same meaning (positive class) is calculated as:

$$P(1|w_{c_1}, w_{c_2}) = \sum_{s_i \in S_w} P(s_i|w_{c_1}) \cdot P(s_i|w_{c_2})$$

**Gloss JSD:** As an alternative measure of word similarity in context, we compute Jensen–Shannon divergence between two distributions  $P(\text{sense}|w_{c_1})$  and  $P(\text{sense}|w_{c_2})$ .

Because these methods rely on gloss information, we need a vocabulary to find them. As for English, we can easily use WordNet (Miller, 1995), it becomes problematic to find definitions for other languages. To counteract this obstacle during the competition we used the following procedure. First, we translated all samples from other languages to English via machine translation<sup>2</sup>. Then we generated all possible translations of the target word with Yandex Translation API<sup>3</sup> and word2word library<sup>4</sup>. Finally, we tried to find one of the possible target word translations in the translated sentence. If there was no match for both sentences, we predicted True, if a match was only for one, we predicted False. In case of more than one match in the translated sentence, we took the first one. In the end, we had two

<sup>2</sup>[https://huggingface.co/transformers/model\\_doc/marian.html](https://huggingface.co/transformers/model_doc/marian.html)

<sup>3</sup><https://yandex.com/dev/dictionary/>

<sup>4</sup><https://github.com/kakaobrain/word2word>

occurrences of possibly different translations of the target word into English and could use previous metrics. But unlike the original English method where we need to disambiguate between meanings of the same word, here we build the distribution over all possible glosses of all possible translations of the target word.

### 3.1.2 Similarity between contextualized word embeddings

In this subsection, we propose methods that fully rely on the Context encoder and thus do not require any additional vocabulary or glosses. We achieve such generalization by using only outputs from the trained Context encoder.

**Cosine:** Cosine similarity between outputs of the encoder.

**Euclidian+norm:** Euclidian distance between L2 normalized outputs of the encoder.

**Manhattan+norm:** Manhattan distance between L1 normalized outputs of the encoder.

## 3.2 Threshold selection

As MCL-WiC is a binary classification problem, we need to transform our continuous similarity measures into binary predictions. We select the best threshold with grid search on one of the following datasets.

1. (**xx dev**) The threshold is selected on the development set of the target language.
2. (**en dev**) The threshold for all languages is selected on the English development set.

Figure 1: Comparison of pre-training methods and similarity measures on the English MCL-WiC test set.

Figure 2: Comparison of pre-training methods and similarity measures on MCL-WiC test sets.

3. (**semcor**) Instead of utilizing MCL-WiC development data, we tried estimating the optimal threshold on the training SemCor dataset. Based on sense annotations, we constructed 30K sentence pairs in WiC format. This resulted in a nearly-balanced WiC dataset, which was used for grid search.
4. (**cl trials**) The threshold for the cross-lingual subtask is selected on the concatenated cross-lingual MCL-WiC trial sets.

## 4 Experimental setup

Besides choosing the best final predictor for MCL-WiC, we also experimented on encoder initialization. In the result section, we compare the performance of the models, initialized with BERT base (Devlin et al., 2019), XLM-R base, and XLM-R large (Conneau et al., 2019). We trained our models on the English SemCor dataset (Miller et al., 1994) with glosses from the WordNet 3.0 (Miller, 1995). Systems based on the XLM-R base and XLM-R large (Conneau et al., 2019) were trained 20 and 10 epochs respectively. Following standard practices, we used SemEval-2007 (Pradhan et al., 2007) as our development set for early stopping. For the

system with BERT-base, we used the originally provided checkpoint by Blevis and Zettlemoyer (2020).

## 5 Results

### 5.1 Similarity measures

The results of the experiments with different similarity measures for English and non-English languages are given in Figure 1 and Figure 2 respectively. Figure 1 shows that approaches based on GLM context outputs strongly outperform methods based on distributions over senses from the vocabulary.

Figures 1, 2 also provide an observation, that almost for any language and model Manhattan+norm distance shows the best results. The only exception is the MLM BERT base model, where Euclidean+norm performs slightly better.

### 5.2 GLM vs MLM

Figure 4 shows the gap between GLM and pure MLM pre-training. Experiments show that models trained with GLM procedure strongly outperform their MLM counterparts in every language and with any base model.

Model	en	ru	fr	ar	zh
our post-evaluation results					
GLM XLM-R base - Manhattan+norm	85.1	80.1	80.5	79.2	79.1
MLM XLM-R base - Manhattan+norm	78.8	63.6	69.6	67.1	72.1
GLM XLM-R large - Manhattan+norm (en dev)	<b>89.5</b>	<b>85.7</b>	<b>86.5</b>	<b>84.2</b>	<b>83.5</b>

best submissions					
Best for each lang.	<b>93.3</b>	<b>87.4</b>	<b>87.5</b>	<b>84.8</b>	<b>91</b>

Table 2: Best test score for each of the proposed systems. (*MT*) states for the Machine Translation technique, described in Section 3.1. The threshold for binary classification was calculated either on the English dev set (*en dev*), or on a part of SemCor dataset (*semcor*), or on the dev set, corresponding to the target language (all others). *Best for each lang.* stands for the best results of the competition for each of the languages.

Surprisingly, the XLM-R base model outperforms the large one when pre-trained with MLM objective only. However, after GLM pre-training the large model performs significantly better than the base model. We suspect that this is due to the strong grammatical bias of contextualized word embeddings after MLM pre-training also observed by Laicher et al. (2021). It is easier to correctly predict the grammatical form of a masked word in a particular context than the exact lemma of that word. Thus, the model is much more confident in the grammatical form resulting in distant embeddings for the same word in the same sense but in different grammatical forms. Since the large model shall better optimize the MLM objective, its embeddings likely contain stronger grammatical component hiding the sense component relevant for the MCL-WiC task. Since word definitions correspond to word senses and not word forms, the GLM objective helps eliminating the irrelevant grammatical component from contextualized embeddings.

### 5.3 Correlation between WSD and MCL-WiC performance

We also suspected that during pre-training on the English WSD data, GLM models can overfit to English texts and partially lose their cross-lingual transferability. Thus, the best epoch checkpoint based on WSD development set may not be the best in terms of MCL-WiC. In Figure 3 we show how MCL-WiC accuracy for each language and WSD F1 score for English change during training. Multilingual WiC performance for epoch 0 stands for the MLM model without any GLM training.

Figure 3: Test MCL-WiC score and SemEval07 dev F1 score for the XLM-R large model depending on the epoch.

The results show that choosing the best checkpoint by WSD F1 score, we get nearly optimal results on MCL-WiC for each language, except for French.

### 5.4 Interpreting system predictions

As our system embeds word definitions from WordNet (Miller, 1995) and word occurrences into the same vector space, we can search for the nearest definitions for each occurrence of the target word. In Table 1 we show some examples from the development set with top3 senses (glosses) predicted by our system for each occurrence. We used GLM XLM-R large as a backbone for this purpose.

### 5.5 Overall multilingual results

Table 2 shows overall results on the competition’s test set. The submission *GLM BERT base - Gloss JSD* sent during the competition employed English BERT base (Devlin et al., 2019) backbone in the

Figure 4: Test score for the best GLM and MLM models for each language.

WSD model, which was applicable to English data only. The submission *GLM BERT base (MT) - Gloss JSD* exploits the same basic idea but extends the first approach to other languages with the translation technique, described in Section 3.1. For both submissions, due to a mistake, we used the GLM model trained for only one epoch on SemCor (Miller et al., 1994).

As we can see from the table 2, our best system on every language is GLM pre-trained XLM-R large model with Manhattan+norm distance and the threshold selected on the English MCL-WiC development set. This system shows rather strong results achieving the performance of the 2nd best system for French and the 6th best system for Arabic. Since this system does not use any non-English resources for training, we suspect that it will work for a variety of other languages on which XLM-R was initially pre-trained, though the performance may vary.

## 5.6 Cross-lingual results

Table 3 shows our post-evaluation results on the cross-lingual subtask of MCL-WiC. The threshold selected on the English dev set does not transfer to the cross-lingual test sets, unlike multilingual test sets. This is due to larger distances between contextualized embeddings returned by XLM-R for word occurrences in different languages. Selecting threshold on the concatenation of cross-lingual trial sets works much better. However, since there are only 32 cross-lingual examples, there is a wide interval of optimal thresholds giving the same accuracy on trial. Our implementation selected the smallest one, however, some larger thresholds resulted in a significant decrease in performance.

Model	en-ar	en-fr	en-ru	en-zh
our post-evaluation results				
(en dev)	77.6	81.5	81.8	78.9
(cl trials)	<b>85.2</b>	<b>85.5</b>	<b>87.2</b>	<b>89.2</b>
best submissions				
Best for each pair	<b>89.1</b>	<b>89.1</b>	<b>89.4</b>	<b>91.2</b>

Table 3: Post-evaluation test scores for the cross-lingual subtask. For each of our systems, we used GLM XLM-R large model and Manhattan+norm distance. *Best for each pair* stands for the best results of the competition for each pair of languages individually.

Thus, a larger cross-lingual development set is required for robust selection of the threshold.

## 6 Conclusion

In this paper, we presented Gloss Language Modeling (GLM) procedure as a pre-training strategy for MCL-WiC systems. We have shown that this procedure improves multilingual WiC performance on all languages for both XLM-R and BERT backbones.

Apart from that, we proposed an interpretable zero-shot multilingual WiC algorithm which does not require any labeled data for the multilingual WiC task except for the threshold selection, which can be performed using only English development data without loss of accuracy for other languages. We also found that L1-distance between normalized contextualized word embeddings outperforms traditionally employed cosine distance.

## Abstract

We describe the University of Alberta systems for the SemEval-2021 Multilingual and Cross-lingual Word-in-Context (MCL-WiC) disambiguation task. We explore the use of translation information for deciding whether two different tokens of the same word correspond to the same sense of the word. Our focus is on developing principled theoretical approaches which are grounded in linguistic phenomena, leading to more explainable models. We show that translations from multiple languages can be leveraged to improve the accuracy on the WiC task.

## 1 Introduction

This paper describes the University of Alberta systems for SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation (Martelli et al., 2021). We focus on the monolingual (English) variant of the task, which is the same as the original WiC task (Pilehvar and Camacho-Collados, 2018). An instance of the WiC task consists of two sentences that share a *focus word* in common; the word may be inflected differently in each sentence (e.g. “they had searched his flat a few days before” and “the production of lithium from salt flats”) but will share the same lemma and part of speech. A WiC task system must decide, given such a pair of sentences, whether the *focus tokens* have the same meaning in both sentences. Systems are compared in terms of their accuracy, the percentage of test instances correctly identified as TRUE (same meaning) or FALSE (different meaning). The dataset includes training, development, and testing splits; as our methods are unsupervised, we do not use the training data.

The goal of this paper is an exploration of the use of translation information for the WiC task. The intuition underlying our work is that distinctions in meaning tend to be reflected in distinctions in

translation. We have previously presented methods leveraging translation information to improve word sense disambiguation (Luan et al., 2020), and most frequent sense detection (Hauer et al., 2019), and have demonstrated that word senses which share translations are, in general, semantically related (Hauer and Kondrak, 2020a). We have also presented theoretical formalizations of lexico-semantic phenomena which view synonymy and translation as two aspects of semantic equivalence (Hauer and Kondrak, 2020b). Our team additionally presented a method based on translation information (Hauer et al., 2020) for the SemEval-2020 Task 2 on Predicting Multilingual and Cross-Lingual Lexical Entailment (Glavaš et al., 2020). In this task, we investigate whether translation can be used to detect semantic equivalence in context, just as in the aforementioned prior task we investigated whether translation can be used to detect lexical entailment between word types. Our focus is on developing principled theoretical approaches which are grounded in linguistic phenomena, leading to more explainable models.

Our more complex methods depend upon a mapping between word senses and translations, as different senses of a word often translate differently. We obtain such a mapping from BabelNet (Navigli and Ponzetto, 2012), which combines information from Princeton WordNet (Fellbaum, 1998), multilingual lexical resources, and translations produced by MT models. WordNet is comprised of synonym sets, or *synsets*, which BabelNet enriches with translations. Each of the resulting multi-lingual synsets, or *multi-synsets*, contain lexicalizations of a single concept in various languages, allowing the translations of a given sense of a word to be identified. We treat BabelNet as an imperfect implementation of a universal multi-wordnet with the theoretical properties described by Hauer and Kondrak (2020b).

Figure 1: An example of the “translation criss-cross” described in Section 3.2.

Our results can be interpreted as a proof-of-concept for the use of contextual translations as indicators of semantic similarity. We show that the methods that we develop for the WiC task can leverage translations to improve over baselines, especially when multiple target languages are considered. While it is not our objective to compete with state-of-the-art supervised methods, we consider this to be a positive result, and a strong lead for future work on contextual semantic analysis.

This paper is structured as follows: Section 2 provides an overview of relevant prior literature. Section 3 discusses the theoretical model underlying our work. Section 4 outlines our methods. Section 5 describes our experiments and results.

## 2 Related Work

Methods for WiC task can be roughly divided into two paradigms: contextualized-embedding-based systems, and word sense disambiguation-based systems. Pilehvar and Camacho-Collados (2018) introduce the WiC dataset as a benchmark for evaluating context sensitive word representations. Soler et al. (2019) achieve improvements by combining similarity scores from different types of contextual word and sentence embeddings. Liu et al. (2020) propose a method to enhance contextual representations by leveraging other pre-trained contextual or static embeddings.

Another approach to WiC task is to employ a word sense disambiguation (WSD) system to tag the target words with senses from a pre-defined sense inventory and subsequently make a decision based on the predicted synsets of the target words. Loureiro and Jorge (2019b) use the LMMS sense embeddings (Loureiro and Jorge, 2019a) to disambiguate the target words. A simple approach of checking if the disambiguated senses are equal lead to competitive performance in the SemDeep-5 WiC challenge (Anke et al., 2019). SENSEMBERT (Scarlini et al., 2020a) and ARES (Scarlini et al., 2020b) embeddings, when used as features in a

BERT-based model, also achieve competitive results on the WiC task.

Our methods combine elements of both paradigms. We employ contextual embeddings in our proposed translation-based methods. However, we take the embeddings of the translations of the target words instead of the target words themselves. Similarly to WSD based approaches, our methods also analyze the common synsets of the focus tokens and their translations, with the goal of identifying a probable shared synset. The most similar prior work to our approach is that of Pesutto et al. (2020) at the graded word similarity task (Armendariz et al., 2020) of SemEval 2020, who propose a translation-based approach to evaluate the contextual similarity of a pair of words. They hypothesize that leveraging similarity information from more languages would allow greater accuracy. We follow a similar intuition in our work.

## 3 Theoretical Solution

We first present a theoretical solution, which provides the foundation for the development of our actual methods described in Section 4. We assume that the two source sentences  $S_1$  and  $S_2$  in each instance of the WiC task can be translated into any natural language as sentences  $T_1$  and  $T_2$ . Furthermore, we assume that the literal lexical translations  $t_1$  and  $t_2$  of the focus word  $s$  can be identified in  $T_1$  and  $T_2$ , respectively. For example, in Figure 1, the focus word  $s$  in the English sentences  $S_1$  and  $S_2$  is the noun *differential*, and word alignment identifies *écart* and *différentiel* as  $t_1$  and  $t_2$ . Note that the two translations may have the same POS and lemma, a scenario we denote as  $t_1 = t_2$ .

### 3.1 Substitution Test

Our theoretical solution is based on the notion of the linguistic *substitution test* for verifying the synonymy of senses (Hauer and Kondrak, 2020b), which takes as input two sentences *which differ only in a single word*, and returns TRUE if and

only if the two sentences have the same meaning. In other words, it decides whether the substitution of one word with another changes the meaning of the sentence. Note that this substitution test is not sufficient to decide the WiC task, as the input sentences for this task *share* a single word, rather than *differ* in a single word. The substitution test can be implemented by consulting a native speaker, or approximated by a computer program. In Section 4, we discuss an implementation based on contextual embeddings.

An example of a valid input to the substitution test would be the sentences *I work at the plant* and *I work at the factory*. For this input, the substitution test would return TRUE, since the word substitution does not change the meaning of the sentence. The sentences *I work at the plant* and *I work at the flower* would likewise constitute a valid input; however, given these sentences, the substitution test would return FALSE, since the sentences differ semantically.

### 3.2 Translation Criss-Cross

In order to apply the substitution test to an instance of the WiC task, we first translate the two source input sentences  $S_1$  and  $S_2$  into a target language, producing two target sentences  $T_1$  and  $T_2$ . We identify the two lexical translations  $t_1$  and  $t_2$  of the focus word  $s$  in  $T_1$  and  $T_2$ . Assuming that the translations are correct and literal, the senses of  $s$  in  $S_1$  and  $t_1$  in  $T_1$  will be synonymous, as well as the senses of  $s$  in  $S_2$  and  $t_2$  in  $T_2$ . If  $t_1$  and  $t_2$  have the same POS but different lemmas, we can replace  $t_1$  with  $t_2$  in  $T_1$  to produce a sentence  $T_1'$  which differs from  $T_1$  in a single word. The application of the substitution test to  $(T_1, T_1')$  returns TRUE if and only if the sense of  $t_2$  in  $T_1'$  is synonymous with the sense of  $s$  in  $S_1$ , which implies that, in addition to  $s$  and  $t_1$ , the multi-synset containing the sense of  $s$  in  $S_1$  must also include  $t_2$ .

Using our running example in Figure 1,  $T_1'$  would be created by replacing *écarts* with *différentiel* in  $T_1$ . This produces *les différentiel de taux d'intérêt croissant*, which, while not necessarily grammatical, can still be evaluated by the substitution test to decide whether the substitution alters the semantic content of the sentence. (Or, equivalently, whether *écart* and *différentiel* are synonymous in this particular context.)

We repeat the process with the roles of  $T_1$  and  $T_2$  reversed. That is, we construct  $T_2'$  by replacing

$t_2$  with  $t_1$  in  $T_2$  in order to verify whether the sense of  $t_1$  in  $T_2'$  is synonymous with the sense of  $s$  in  $S_2$ . If the substitution test returns FALSE for either of the two target sentence pairs, we can conclude that the two multi-synsets that correspond to the senses of  $s$  in  $S_1$  and  $S_2$  must be different. Therefore, this instance of the WiC task is resolved as FALSE. However, if the substitution test returns TRUE for both pairs of sentences, we cannot immediately resolve the instance of the WiC task, because there could exist two (or more) multi-synsets that all contain  $s$ ,  $t_1$ , and  $t_2$ . To complicate matters, this partial solution to the WiC task can only be applied if  $t_1$  and  $t_2$  have the same POS but different lemmas.

A complete theoretical solution can be obtained by considering translations in multiple languages. If the focus word  $s$  is not used in the same sense in  $S_1$  and  $S_2$ , we would expect that in *some* language, the translations  $t_1$  and  $t_2$  will be different *and* not mutually replaceable in both sentences. This expectation is consistent with the speculation of Palmer et al. (2007) that translation into a sufficiently large set of language will eventually lexicalize every sense distinction. It is also supported by the findings of Bao et al. (2021) who found no evidence for the existence of universal colexifications, that is, pairs of concepts that are expressed by the same word in every natural language.

### 3.3 Multi-Synset Intersection

For each language  $F_i$  in the set of all natural languages  $\mathcal{L}$ , let  $t_1^i$  and  $t_2^i$  be the lexical translations of the focus word  $s$  in the first and second input sentences, respectively. Let  $T$  be the set consisting of the focus word, and all its lexical translations; that is  $W = \{s\} \cup_{F_i} \{t_1^i, t_2^i\}$ . Assuming access to a perfect universal multi-wordnet, we define the set  $C$  to be the set of multi-synsets that contain all words in  $T$ .

The size of  $C$  provides clues to the resolution of the WiC task. We need to consider three cases:  $|C| = 0$ ,  $|C| = 1$ , and  $|C| \geq 2$ . With some caveats, these three cases roughly imply the following answers to the WiC task: FALSE, TRUE, and UNKNOWN, respectively. We discuss these three cases in turn.

If  $|C| = 0$ , then no single concept can be expressed by  $s$  and all its translations in  $T$ , according to the multi-wordnet. That is, there exist two translations of the focus word which cannot express the same concept, assuming the completeness of

the multi-wordnet. Therefore, the two focus tokens must correspond to distinct multi-synsets, implying FALSE.

If  $|C| = 1$ , there exists exactly one multi-synset that contains the focus word and all its translations. Therefore, it is possible, albeit not guaranteed, that the focus word in both source sentences is used in the sense that corresponds to that unique multi-synset. In order to be sure, we could apply the criss-cross method described in Section 3.2.

$|C| \geq 2$  would imply that there exist two concepts which are colexified (expressed by a single word) in all languages. Following Bao et al. (2021), we assume that universal collocations are at best extremely rare. Even if they exist at all, we could still apply the solution described in Section 3.2 to decide the WiC task. Of course, if we are considering translations into only a small number of languages, the possibility of  $|C| \geq 2$  is much more likely. In fact, we observe  $|C| = 3$  in our running example, because three different BabelNet multi-synsets contain the English focus word and its two French translations.

## 4 Methods

In this section we describe four methods based on the theoretical ideas in Section 3. All four methods rely on identifying lexical translations of the focus word in both source sentences. If the lexical translations cannot be recovered from the translated sentences for any of the target languages, all methods use the same backoff approach, which is to return FALSE for that test instance.

### 4.1 IDENT and CVAL

Our two simplest methods are IDENT and CVAL. IDENT is a baseline method which returns TRUE **iff** the lexical translations  $t_1$  and  $t_2$  have the same lemma and POS in all applicable target languages. CVAL is a method directly based on the cardinality of the set  $C$  as defined in Section 3.3. CVAL returns TRUE **iff** the translations of the focus word are identical in each language **and**  $|C| > 0$ .

### 4.2 Synonymy Check

We implement the substitution test as a heuristic *synonymy check* using dense contextualized embeddings. Such embeddings allow us to construct, for any word token in a given sentence, a vector in a continuous semantic space. The objective in designing such embeddings is that semantically

similar tokens should have similar vectors, commonly measured by cosine similarity. Additional technical details of the embeddings are provided in Section 5.

Given a pair of sentences which differ only in the substitution of single word, we obtain dense contextualized embeddings of the distinguishing word in each sentence. We then calculate the cosine similarity between the two embeddings. If the similarity is greater than a threshold tuned on a development set, this is taken as an indication that replacing one of the distinguishing words with the other does not alter the meaning of the sentence, as the replacement word has the same meaning as the original word. This implementation of the substitution test is used as a subroutine by our remaining two methods.

### 4.3 SUB and CSUB

The SUB method attempts to apply the synonymy check to each pair of translated sentences  $T_1$  and  $T_2$  in each target language, without referring to the  $|C|$  value. If the translations of the focus word in  $T_1$  and  $T_2$  differ, we create the sentences  $T'_1$  and  $T'_2$ , as described in Section 3.2, and apply the synonymy check to  $(T_1, T'_1)$  and  $(T_2, T'_2)$ . SUB returns TRUE if the synonymy check succeeds for all target languages for which the translations  $t_1$  and  $t_2$  can be identified. The synonymy check trivially succeeds if  $t_1$  and  $t_2$  have the same POS and lemma; intuitively, tokens which translate the same way are likely to have similar meanings. If either application of the synonymy check fails, SUB returns FALSE. In summary, this method is similar to the IDENT method, except that the synonymy check is applied if the translations differ.

CSUB combines CVAL with SUB. The only difference with the SUB method is that the synonymy check is not applied when  $|C| = 0$ . This is because the lack of any common multi-synset in a complete perfect multi-wordnet is theoretically sufficient to exclude the possibility of the two source focus tokens having the same sense.

## 5 Experiments

In this section, we describe the application of our methods to the English development and test sets. We begin by specifying various implementation details. Next, we describe our development experiments, including results and error analysis. Finally, we present our results on the test set. While our

method is, in theory, applicable to any language, and even to cross-lingual subtasks, we focus exclusively on the English monolingual subtask due to time and resource constraints.

### 5.1 Translation and Lemmatization

We use BabelNet (Navigli and Ponzetto, 2010, 2012) as our multi-wordnet; in particular, we make use of the BabelNet multi-synsets which are linked to Princeton Wordnet synsets. This allows us to exclude synsets that refer to named entities, rather than lexicalized concepts, to limit the impact of noise in BabelNet.

For translation, we use Google Translate, as it is fast and publicly available. In our analysis, we found the lexical translations obtained using Google Translate to be of generally high quality, which is important given our method’s dependence on machine translation. We use French, Italian, and Russian as our languages of translation. The choice of the translation languages is based on the languages selected for the shared task, and also on the BabelNet coverage. French and Russian are two of the languages covered by the shared task. On the other hand, Italian seems to have the best BabelNet coverage among the non-English languages.

For lemmatization, we use TreeTagger (Schmid, 1999, 2013), with pre-trained lemmatization models for the source and all target languages. We lemmatize the bitexts to improve the quality of the word alignment.

### 5.2 Word Alignment

Following lemmatization, we align each input sentence with its translation in each target language. To improve the quality of our unsupervised alignment, we obtain a large sentence-aligned parallel corpus (*bitext*) in the source and target languages. We then append to the bitext all of the lemmatized input sentences, and all of their lemmatized language translations. Finally, we apply an unsupervised knowledge-based alignment algorithm to the augmented bitext, and, for each sentence, identify the word or phrase in the translated sentence corresponding to the source focus word. Once each input sentence is aligned with its translation, we extract the lemmas aligned with each focus word token. These are the lexical translations of the focus word for this language.

To carry out the alignment, we use BabAlign (Luan et al., 2020), a state-of-the-art knowledge-based aligner. BabAlign leverages translation infor-

mation from BabelNet to create synthetic training data and post-process the alignment produced using a base unsupervised alignment method. Specifically, we use FastAlign (Dyer et al., 2013) as the base aligner. When aligning input sentences with translations, we concatenate the sentences and their translations with the OpenSubtitles bitext (Lison and Tiedemann, 2016) for the corresponding language pair. For each language pair, we use the first 1M sentences of the OpenSubtitles bitext.

### 5.3 Contextual Embeddings

To obtain contextual representations for the purposes of deciding the substitution check, we use BERT (Devlin et al., 2019), a deep neural architecture trained with the masked language model. We chose BERT because it has been proven to capture the semantics of a word in context (Coenen et al., 2019). The context is the sentence containing the focus word. Specifically, we use cased multilingual BERT to generate contextualized embedding of focus words by summing up the last four hidden layers of the BERT model. This choice was based on the results achieved by Devlin et al. (2019) in the named entity recognition task, and by Soler et al. (2019) in the SemDeep-5 WiC shared task.<sup>1</sup>

We use cased multilingual BERT embeddings with 768 dimensions, 12 layers, 12 attention heads, and 179M parameters. To implement the substitution check, we generate contextualized embeddings of the translations of the focus tokens, and their substitutes, by summing the last four hidden layers of the BERT model. Since BERT uses sub-tokens to generate embeddings, we analyzed the impact of two different sub-token selection techniques for predicting word similarity: using only the first sub-token, and using the mean over all the sub-tokens. In our development experiments, we found that the former yielded better results. Therefore, only the first sub-token is used to create contextualized embeddings for the substitution method.

### 5.4 Development Results

Table 1 shows the results of our development experiments. The baseline translation identity method IDENT does surprisingly well, outperforming both methods based on intersecting sets of multi-synsets, CVAL and CSUB. Indeed, these methods tend to suffer accuracy degradation as more languages of translation are added. We speculate that this is due

<sup>1</sup><https://www.dfki.de/declerck/semdeep-5/challenge.html>

Lang.	FR	IT	RU	ALL
IDENT	<b>59.6</b>	<b>58.1</b>	<b>57.1</b>	59.7
CVAL	58.9	57.6	54.3	55.5
SUB	59.3	58.0	55.6	<b>60.8</b>
CSUB	59.2	57.8	54.3	54.1

Table 1: MCL-WiC accuracy (%) on the En-En dev set with different methods and languages of translation.

to these methods being more vulnerable to noise (errors or omissions) in the multi-wordnet and in the extraction of lexical translations. However, the best performing method is SUB, which also shows improvement when combining all three languages of translation. Thus, it also shows the most promise for further improvement by adding additional languages.

Our error analysis suggests that there are three principal causes of errors. First, translation may be non-literal. For example, in one instance, the adverb “unevenly” is translated into French as the adjective “inégalé” (“unequal”), leading to a false negative. Second, distinct but synonymous translations may lead to false positives. In one instance, the focus word “stain” is translated as “souillé” in one sentence and “tachée” in the other. The focus tokens have distinct meanings, reflected in their distinct translations, “stain on a reputation” versus “stain on a surface”. However, the translations pass the BERT-based synonymy check, since they can be synonymous in some contexts. Finally, in some cases, distinct senses of a word may nevertheless translate the same way. For example, in one instance, the focus word “superior” was used in two distinct meanings. Both these meanings can be expressed by the French word “supérieur”, and indeed, “superior” was translated as “supérieur” in both sentences, resulting in a false positive.

### 5.5 Test Results and Discussion

Table 2 shows our results on the test data. Consistent with our development experiments, the SUB method achieves the best performance with the combination of all three languages. The IDENT method once again performs surprisingly well despite its simplicity, outperforming the more complex CVAL and CSUB methods. Different from the development experiments, when only one language of translation is used, Russian yields substantially better performance compared to French or Italian across all four methods, and Italian likewise yields

Lang.	FR	IT	RU	ALL
IDENT	55.8	<b>58.9</b>	<b>61.0</b>	61.1
CVAL	54.8	55.6	56.0	55.2
SUB	<b>56.1</b>	57.6	60.6	<b>63.2</b>
CSUB	55.2	55.2	55.8	55.7

Table 2: MCL-WiC accuracy (%) on the En-En test set with different methods and languages of translation.

better performance than French.

Table 3 gives additional details for the results of the SUB method. For each of the three languages, and the combination of all three, we provide the number of true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN), as well as the accuracy. We observe that using multiple languages of translation results in a substantial reduction in false positives, at the possible expense of an increase in false negatives, while maintaining an overall higher accuracy.

Lang.	TP	TN	FP	FN	Accuracy
FR	369	192	308	131	56.1
IT	376	200	300	124	57.6
RU	327	279	221	173	60.6
ALL	339	293	207	161	63.2

Table 3: Detailed breakdown of the results of our best performing method, SUB.

## 6 Conclusion

Overall, our results provide a solid proof-of-concept for the utility of multilingual translation for the WiC task. While not competitive with state-of-the-art supervised methods, our results empirically verify the hypothesis that translations convey semantic information, and that this phenomenon has applications in lexical semantics. The IDENT and SUB methods consistently benefit from translation into multiple languages, and this result generalizes to unseen test data.

## Abstract

Identifying whether a word carries the same meaning or different meaning in two contexts is an important research area in natural language processing which plays a significant role in many applications such as question answering, document summarisation, information retrieval and information extraction. Most of the previous work in this area rely on language-specific resources making it difficult to generalise across languages. Considering this limitation, our approach to SemEval-2021 Task 2 is based only on pretrained transformer models and does not use any language-specific processing and resources. Despite that, our best model achieves 0.90 accuracy for English-English subtask which is very compatible compared to the best result of the subtask; 0.93 accuracy. Our approach also achieves satisfactory results in other monolingual and cross-lingual language pairs as well.

## 1 Introduction

Words' semantics have a dynamic nature which depends on the surrounding context (Pilehvar and Camacho-Collados, 2019). Therefore, the majority of words tends to be polysemous (i.e. have multiple senses). For few examples, words such as "cell", "bank" and "report" can be mentioned. Due to this nature in natural language, it is important to focus on word-in-context sense while extracting the meaning of a word which appeared in a text segment. Also, this is a critical requirement to many applications such as question answering, document summarisation, information retrieval and information extraction.

Word Sense Disambiguation (WSD)-based approaches were widely used by previous research to tackle this problem (Loureiro and Jorge, 2019; Scarlini et al., 2020). WSD associates the word in a text with its correct meaning from a predefined sense inventory (Navigli, 2009). As such

inventories, WordNet (Miller, 1995) and BabelNet (Navigli and Ponzetto, 2012) were commonly used. However, these approaches fail to generalise into different languages as these inventories are often limited to high resource languages. Targeting this gap, SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation is designed to capture the word sense without relying on fixed sense inventories in both monolingual and cross-lingual setting. In summary, this task is designed as a binary classification problem which predicts whether the target word has the same meaning or different meaning in different contexts of the same language (monolingual setting) or different languages (cross-lingual setting).

This paper describes our submission to SemEval-2021 Task 2 (Martelli et al., 2021). Our approach is mainly focused on transformer-based models with different text pair classification architectures. We remodel the default text pair classification architecture and introduce several strategies that outperform the default text pair classification architecture for this task. For effortless generalisation across the languages, we do not use any language-specific processing and resources. In the subtasks where only a few training instances were available, we use few-shot learning and in the subtasks where there were no training instances were available, we use zero-shot learning taking advantage of the cross-lingual nature of the multilingual transformer models.

The remainder of this paper is organised as follows. Section 2 describes the related work done in the field of word-in-context disambiguation. Details of the task data sets are provided in Section 3. Section 4 describes the proposed architecture and Section 5 provides the experimental setup details. Following them, Section 6 demonstrates the obtained results and Section 7 concludes the paper with final remarks and future research directions.

## 2 Related Work

**Unsupervised systems** Majority of the unsupervised WSD systems use external knowledge bases like WordNet (Miller, 1995) and BabelNet (Navigli and Ponzetto, 2012). For each input word, its correct meaning according to the context can be found using graph-based techniques from those external knowledge bases. However, these approaches are only limited to the languages supported by used knowledge bases. More recent works like Hettiarachchi and Ranasinghe (2020a); Ranasinghe et al. (2019a) propose to use stacked word embeddings (Akbik et al., 2018) obtained by general purpose pretrained contextualised word embedding models such as BERT (Devlin et al., 2019) and Flair (Akbik et al., 2019) for unsupervised WSD. Despite their ability to scale over different languages, unsupervised approaches fall behind supervised systems in terms of accuracy.

**Supervised systems** Supervised systems rely on semantically-annotated corpora for training (Raganato et al., 2017; Bevilacqua and Navigli, 2019). Early approaches were based on traditional machine learning algorithms like support vector machines (Iacobacci et al., 2016). With the word embedding-based approaches getting popular in natural language processing tasks, more recent approaches on WSD were based on neural network architectures (Melamud et al., 2016; Raganato et al., 2017). However, they rely on large manually-curated training data to train the machine learning models which in turn hinders the ability of these approaches to scale over unseen words and new languages. More recently, contextual representations of words have been used in WSD where the contextual representations have been employed for the creation of sense embeddings (Peters et al., 2018). However, they also rely on sense-annotated corpora to gather contextual information for each sense, and hence are limited to languages for which gold annotations are available. A very recent approach SensEmBERT (Scarlini et al., 2020) provide WSD by leveraging the mapping between senses and Wikipedia pages, the relations among BabelNet synsets and the expressiveness of contextualised embeddings, getting rid of manual annotations. However, SensEmBERT (Scarlini et al., 2020) only supports five languages making it difficult to use with other languages.

Considering the limitations of the above meth-

ods, in this paper we propose an approach which is based on general purpose transformer models and does not rely on external knowledge bases. Also, our approach shows strong few-shot/zero-shot learning performance removing the hurdle of having manually-curated training data for each language pair.

## 3 Data

The data set used for SemEval-2021 Task 2 is designed targeting a binary classification problem following Pilehvar and Camacho-Collados (2019). To preserve the multilinguality and cross-linguality of the task, five different languages: English, Arabic, French, Russian and Chinese have been considered for data set preparation. In the monolingual setting, per instance, a sentence pair written in the same language is provided with a targeted lemma to predict whether it has the same meaning (True) or different meanings (False) in both sentences. In the cross-lingual setting, each sentence pair is written in two different languages with the same prediction requirement. Few samples from the monolingual and cross-lingual data sets are shown in Table 1.

The monolingual data set covers the language pairs: en-en, ar-ar, fr-fr, ru-ru and zh-zh. For each language, 8-instance trial data sets with labels were provided to give an insight into the task. As training data, 8,000 labelled instances were provided only for the English language and as dev data, 1,000 labelled instances were provided per each language. To use with final evaluation, for each language, 1,000-instance test data sets were provided.

The cross-lingual data set covers the language pairs: en-ar, en-fr, en-ru and en-zh. Similar to the monolingual data set, 8-instance trial data sets with labels were provided for each language pair. However, no training or dev data sets were provided for the cross-lingual setting. To use with the final evaluation, 1,000-instance test data sets were provided per each language pair.

## 4 TransWiC Architecture

The main motivation behind the TransWiC architecture is the success transformer-based architectures had in various natural language processing tasks like offensive language identification (Ranasinghe and Hettiarachchi, 2020; Ranasinghe et al., 2019c; Pitenis et al., 2020), offensive spans identification (Ranasinghe and Zampieri, 2021a; Ranasinghe et al., 2021), language detection (Jauhiainen et al.,

	Lang.	Sentence 1	Sentence 2	Label
ML	fr-fr	la <b>souris</b> mange le fromage	le chat court après la <b>souris</b>	T
	en-en	In the private <b>sector</b> , activities are guided by the motive to earn money.	The volume V of the <b>sector</b> is related to the area A of the cap.	F
CL	en-fr	click the right <b>mouse</b> button	le chat court après la <b>souris</b>	F

Table 1: Monolingual (ML) and cross-lingual (CL) sentence pair samples with targeted lemma (highlighted in red colour) and label (T:True, F:False). Lang. column represent the languages which are indicated using ISO 639-1 codes<sup>1</sup>

Figure 1: Default sentence pair classification architecture - ([CLS] Strategy).  $W_T$  is the target word.

2021) question answering (Yang et al., 2019) etc. Apart from providing strong results compared to RNN based architectures (Hettiarachchi and Ranasinghe, 2019; Ranasinghe et al., 2019c), transformer models like BERT (Devlin et al., 2019), XLM-R (Conneau et al., 2020) provide pretrained language models that support more than 100 languages. This is a huge benefit when compared to the models like SensEmBERT (Scarlini et al., 2020) which supports only five languages. Furthermore, multilingual and cross-lingual models like multilingual BERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) have shown strong transfer learning performance across scarce-resourced languages which can be useful in non-English monolingual subtasks where there are fewer training examples and cross-lingual subtasks where there are no training examples available (Ranasinghe and Zampieri, 2020, 2021b; Ranasinghe et al., 2020a). There-

fore we took the general purpose transformers like BERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020), reworked their sentence pair classification architecture with so called *strategies* described below to perform well in word-in-context disambiguation task.

**Preprocessing** As a preprocessing step we add two tokens to the transformer model’s vocabulary:  $\langle B \rangle$  and  $\langle E \rangle$ . We place them around the target word in both sentences. For example, the sentence "la souris mange le fromage" with the target word "souris" will be changed to "la  $\langle B \rangle$  souris  $\langle E \rangle$  mange le fromage".

- i [CLS] Strategy - This is the default sentence pair classification architecture with transformers (Devlin et al., 2019) where the two sentences are concatenated with a [SEP] token and passed through a transformer model. Then the

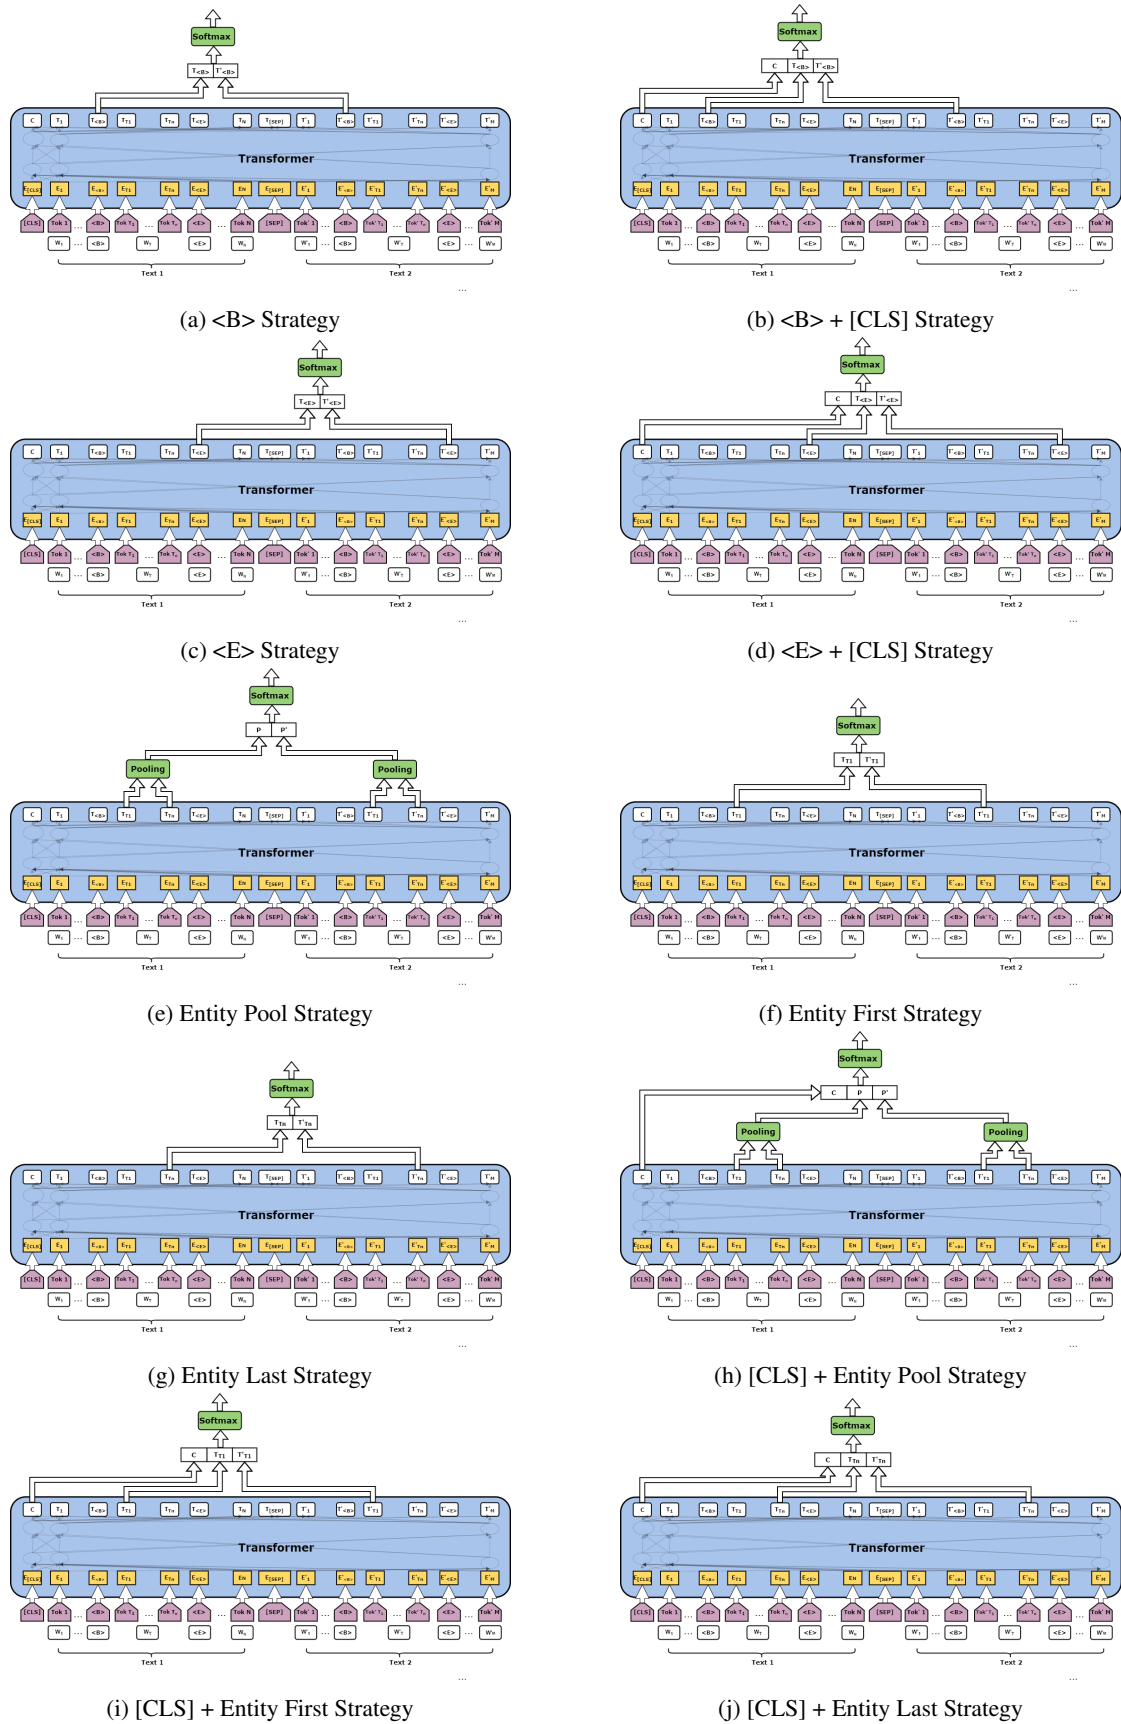

Figure 2: Strategies in the TransWiC Framework.  $W_T$  is the target word.

output of the [CLS] token is fed into a softmax layer to predict the labels (Figure 1).

- ii **<B> Strategy** - We concatenate the output of two <B> tokens of the two sentences and feed it into a softmax layer to predict the labels (Figure 2a).
- iii **<B> + [CLS] Strategy** - We concatenate the output of two <B> tokens of the two sentences with the [CLS] token and feed it into a softmax layer to predict the labels (Figure 2b).
- iv **<E> Strategy** - Output of the two <E> tokens of the two sentences are concatenated and feed into a softmax layer to predict the labels (Figure 2c).
- v **<E> + [CLS] Strategy** - We concatenate the output of two <E> tokens of the two sentences with the [CLS] token and feed it into a softmax layer to predict the labels (Figure 2d).
- vi **Entity Pool Strategy** - To effectively deal with rare words, transformer models use sub-word units or WordPiece tokens as the input to build the models (Devlin et al., 2019). Therefore, there is a possibility that one target word can be separated into several sub-words. In this strategy, we generate separate fixed-length embeddings for each target word by passing its sub-word outputs through a pooling layer. The pooled outputs are concatenated and fed into a softmax layer to predict the labels (Figure 2e).
- vii **Entity First Strategy** - Similar to the previous strategy, instead of using all the sub-words of the target word, we only use the output of the first sub-word in this strategy. We feed the concatenation of these outputs into a softmax layer to predict the labels (Figure 2f).
- viii **Entity Last Strategy** - Similar to the *Entity First Strategy* instead of the first sub-word, we use the last sub-word to represent the target word. We feed their concatenation into a softmax layer to predict the labels (Figure 2g).
- ix **[CLS] + Entity Pool Strategy** - We concatenate the pooled outputs generated by *Entity Pool Strategy* with the [CLS] token and feed it into a softmax layer to predict the labels (Figure 2h).

- x **[CLS] + Entity First Strategy** - Similar to the *[CLS] + Entity Pool Strategy*, instead of the pooled outputs, we concatenate the first sub-word output of the target words with [CLS] token and feed it into a softmax layer to predict the labels (Figure 2i).

- xi **[CLS] + Entity Last Strategy** - In this strategy, we concatenate the last sub-word output of the target words with [CLS] token and feed it into a softmax layer to predict the labels (Figure 2j).

## 5 Experimental Setup

This section describes the training data and hyperparameter configurations used during the experiments.

### 5.1 Training Configurations

**English-English** For the English-English sub-task, we performed training on the English-English training data for each strategy mentioned above. During the training process, the parameters of the transformer model, as well as the parameters of the subsequent layers, were updated. We used the saved model from a particular strategy to get predictions for the English-English test set for that particular strategy.

**Other Monolingual** Since there were less training data available for non-English monolingual datasets, we followed a *few-shot* learning approach mentioned in Ranasinghe et al. (2020c,b). When we are starting the training for non-English monolingual language pairs, rather than training a model from scratch, we initialised the weights saved from the English-English experiment. Then we performed training on the dev data for each language pair separately. Similar to English-English experiments, during the training process, the parameters of the transformer model, as well as the parameters of the subsequent layers, were updated.

**Crosslingual** Since there were no training data available for cross-lingual datasets, we followed a *zero-shot* approach for them. Multilingual and cross-lingual transformer models like multilingual BERT and XLM-R show strong cross-lingual transfer learning performance. They can be trained on one language; typically a resource-rich language and can be used to perform inference on another language. The cross-lingual nature of the transformer models has provided the ability to do this

(Ranasinghe et al., 2020c). Therefore, we used the models trained on the English-English dataset to get predictions for cross-lingual datasets.

## 5.2 Hyperparameter Configurations

We used a Nvidia Tesla K80 GPU to train the models. We divided the input dataset into a training set and a validation set using 0.8:0.2 split. We predominantly fine-tuned the learning rate and the number of epochs of the classification model manually to obtain the best results for the validation set. We obtained  $1e^{-5}$  as the best value for the learning rate and 3 as the best value for the number of epochs. We performed *early stopping* if the validation loss did not improve over 10 evaluation steps. The rest of the hyperparameters which we kept as constants are mentioned in the Appendix. When performing training, we trained five models with different random seeds and considered the majority-class self ensemble mentioned in Hettiarachchi and Ranasinghe (2020b) to get the final predictions.

## 6 Results and Evaluation

Organisers used the accuracy as the evaluation metric as shown in Equation 1 where TP is True Positive, TN is True Negative, FP is False Positive and FN is False Negative.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (1)$$

Since there were less or no training data available for other monolingual and cross-lingual settings, we trained and evaluated models for each of our strategies using English-English training and dev sets. Then the best models are picked to use with few-shot and zero-shot learning approaches. We report the results obtained by English-English evaluation in Table 2. In the BERT column, we report the results of the bert-large-cased model while in the XLM-R column, we report the results of the xlm-r-large model.

As shown in Table 2, some strategies outperformed the default sentence pair classification architecture. Among all experimented strategies <B> + [CLS] strategy performed best. Usually, multilingual transformer models like XLM-R do not outperform the language-specific transformer models. Surprisingly, in this task XLM-R models outperform bert-large models. We selected three best performing models for the submission; XLM-R

Strategy	BERT	XLM-R
CLS	0.8350	0.7860
<B>	0.8450	0.8750 <sup>‡</sup>
<B> + CLS	0.8590	<b>0.8810<sup>‡</sup></b>
<E>	0.6672	0.5590
<E> + CLS	0.6982	0.5630
Entity Pool	0.8420	0.8521
Entity First	0.8390	0.8462
Entity Last	0.8550	0.8660
CLS + Entity Pool	0.8570	0.8700 <sup>‡</sup>
CLS + Entity First	0.8540	0.8580
CLS + Entity Last	0.8568	0.8610

Table 2: TransWiC accuracy in English-English dev set for each strategy. Best is in Bold. Submitted systems are marked with ‡

<B> + [CLS], XLM-R <B> and XLM-R [CLS] + Entity Pool.

Since multilingual models provided the best results for the English-English dataset, it provided an additional advantage as they can be used directly in other language pairs too as mentioned in Section 5. For other language pairs, we did not perform any evaluation due to the lack of data availability. We trusted the cross-lingual performance of XLM-R and used the best three models of the English-English experiment. For the rest of the monolingual pairs, we used the few-shot learning approach using the given dev sets and for the cross-lingual pairs, we used the zero-shot learning approach mentioned in Section 5.

We report the results we got for the test set in Table 3. According to the results, <B> + [CLS] strategy performs best in all the language pairs except Ar-Ar, where <B> strategy outperforms <B> + [CLS] strategy. When compared to the best models submitted to each language pair, our approach shows very competitive results in the majority of the monolingual language pairs. However, we believe that the cross-lingual performance of our methodology should be improved. Nonetheless, we believe that as a methodology that did not use any language-specific resources and did not see any language-specific data, the results are at a satisfactory level.

## 7 Conclusions

In this paper, we presented our approach for tackling the SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation. We use the pretrained transformer models and re-

Strategy	Monolingual					Crosslingual				
	en-en	ar-ar	fr-fr	ru-ru	zh-zh	en-ar	en-fr	en-ru	en-zh	
I	<B> + [CLS]	<b>0.9040</b>	0.7800	<b>0.7970</b>	<b>0.7610</b>	<b>0.6210</b>	<b>0.6690</b>	<b>0.5860</b>	<b>0.6900</b>	<b>0.7640</b>
	<B>	0.8980	<b>0.7980</b>	0.7760	0.7160	0.6090	0.6260	0.5850	0.6770	0.7280
	[CLS] + Entity Pool	0.8400	0.7621	0.7321	0.6954	0.5880	0.5921	0.5572	0.6561	0.7002
II	Best System	0.9330	0.8480	0.8750	0.8740	0.9100	0.8910	0.8910	0.8940	0.9120

Table 3: Row I shows the accuracy scores for the test set with strategies submitted. Best results for each language pair with our strategies are in bold. Row II shows the accuracy scores for the test set with the best system submitted for each language pair.

model the sentence pair classification architecture for this task with several strategies. Our best strategies outperform the default sentence pair classification setting for English-English. For other monolingual language pairs, we use the few-shot learning approach while for cross-lingual language pairs we use the zero-shot approach. Our results are compatible with the best systems submitted for each language pair and are at a satisfactory level given the fact that we did not use any language-specific processing nor resources.

As future work, we would be looking to improve our results more with new strategies. We would like to experiment with whether adding language-specific processing and resources would improve the results. We are keen to add different neural network architectures like Siamese transformer networks (Reimers and Gurevych, 2019) that perform well in sentence pair classification tasks (Ranasinghe et al., 2019b; Mueller and Thyagarajan, 2016) to the TransWiC framework. Furthermore, we are hoping to work in a multi-task environment and experiment whether transfer learning from a similar task like semantic textual similarity (Cer et al., 2017) would improve the results for this task.

## Abstract

This paper presents our approaches to SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation task. The first approach attempted to reformulate the task as a question answering problem, while the second one framed it as a binary classification problem. Our best system, which is an ensemble of XLM-R based binary classifiers trained with data augmentation, is among the 3 best-performing systems for Russian, French and Arabic in the multilingual subtask. In the post-evaluation period, we experimented with batch normalization, subword pooling and target word occurrence aggregation methods, resulting in further performance improvements.

## 1 Introduction

In the Semeval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation task, the participants were asked to classify whether the target word, occurring in two sentences (sentence1 and sentence2), is used in the same or in a different meaning. The two sentences could be in the same language or different languages. There were two subtasks:

- **Multilingual Word-in-Context Disambiguation**, where both sentences were in the same language, either Arabic, Chinese, English, French or Russian
- **Cross-lingual Word-in-Context Disambiguation**, where the first sentence was in

English and the second one was either in Arabic, Chinese, French, or Russian.

More detailed information regarding the task is provided by [Martelli et al. \(2021\)](#).

We participated in both tracks and experimented with two approaches<sup>1</sup>. The first approach fine-tunes XLM-R ([Conneau et al., 2020a](#)) as a question answering system searching in the second sentence for a word with the same meaning as the target word in the first sentence. The second approach fine-tunes XLM-R as a binary classifier, and ensembles several such classifiers. Also, we used data augmentation to double the number of training examples. This second approach took the 2nd place for the monolingual subtask in Arabic and the 3rd place for the monolingual subtask in French and Russian. In the cross-lingual subtask, the system ranked 6th for French and Arabic. The same system was applied to all subtasks and languages.

During the post-evaluation period, we performed thorough experiments with our system. We compared different subword pooling methods, including mean, max, first pooling and their combinations, and found that combinations do not help and mean pooling is overall the best choice. Unlike pooling, instead of a simple concatenation of contextualized embeddings for the target word occurrences, it is helpful to combine their difference and normalized component-wise product. Finally, we found it beneficial to add a batch normalization

<sup>1</sup><https://github.com/davletov-aa/mcl-wic>

layer before feeding those vectors into the classification head.

## 2 Related Work

Word Sense Disambiguation (WSD) is the task of associating the occurrence of a word in a text with its correct meaning from a predefined inventory of senses (Navigli, 2009; Scarlini et al., 2020a). Word-in-Context Disambiguation is a new declination of WSD aiming to evaluate the ability of modern language models to accurately represent context-sensitive words (Pilehvar and Camacho-Collados, 2019; Scarlini et al., 2020b). Its advantage is that it does not rely on pre-defined sense inventories. Because Word Sense Disambiguation relies on world knowledge for successful solving (Navigli, 2009), modern large pre-trained models show promising results in solving this task.

Among such works, we can mention ARES (Scarlini et al., 2020b). ARES is a semi-supervised approach for creating sense embeddings. The authors use BERT and UKB (Agirre et al., 2014) to find contexts that are similar to each other and link them to meanings in WordNet (Miller et al., 1990). Then, they enrich synset contexts with collocational information from SyntagNet (Maru et al., 2019). Finally, they enrich SemCor (Miller et al., 1993) contexts and WordNet glosses to create sense-level representations. ARES performs better than models with a comparable number of parameters such as BERT or RoBERTa (Liu et al., 2019).

However, there has been substantial progress in the field of language modelling since BERT first appeared. Many researchers have noticed that BERT is undertrained and that training it longer and on more data, increases the model performance. Among such new models, we may name XLM-RoBERTa (XLM-R) (Conneau et al., 2020a). XLM-R, as well as BERT, is based on a Transformer model (Vaswani et al., 2017). XLM-R uses masked language modelling objective (Devlin et al., 2018; Lample and Conneau, 2019) for model training, where some tokens are replaced with a special "[MASK]" token and the model is to restore the masked tokens. XLM-R was trained on a cleaned two-terabyte CommonCrawl Corpus in 100 languages.

A new promising approach to language task modelling is treating any natural language task as a question answering problem. Among such works, we can mention (Cohen et al., 2020) where the au-

Set	Pos	Neg

thors restructured relation classification as a Question Answering (QA) like span prediction problem. It allowed them to get state-of-the-art results for TACRED and SemEval 2010 task 8 datasets. We decided to adopt a similar approach to the task of word sense disambiguation.

## 3 Submitted Systems Description

Our systems are based on XLM-RoBERTa (XLM-R) model Conneau et al. (2020b). We used XLM-R large model as a backbone in all our submissions but switched to XLM-R base for some of the post-evaluation experiments. Two model training scenarios have been tested. In the first case (AG), due to the symmetric nature of the dataset, we decided to augment the dataset and flip the first and the second sentences. In the second case (MTL), multi-task learning was applied. More detailed descriptions are provided in the following sections. We used transformers library (Wolf et al., 2019).

### 3.1 Data

In all our experiments we used only the datasets provided in the shared task. For training, we employed the whole English train set, 70% of the development sets for other languages and all the trial data. The remaining data were used to select hyperparameters and do early stopping. We employed a lexical split resulting in different target words for training and validation. Table 1 presents detailed statistics. Optionally, in systems with **AG** suffix, train and test time data augmentation was performed by swapping sentences in each example to double the amount of data. If the predictions for symmetric examples were conflicting with each other we assumed the prediction is negative.

Figure 1: QA-based model architecture

### 3.2 QA Systems

Inspired by the work of Cohen et al. (2020), in our preliminary experiments we tried to solve MCLWIC in Question Answering (QA) task manner, where we predict the start and end positions (the span) of the answer in a given text.

Given the target word  $w$  and a pair of tokenized sentences  $[s_1 \dots w \dots s_n]$  and  $[k_1 \dots w \dots k_n]$ , we form the following input to XLM-R model with marked by  $\bullet$  and  $/$  symbols target word in the first sentence:

$[CLS]$  Find the same sense of the marked word  $[EOS]$   $s_1 \dots \bullet w \dots s_n [EOS]$   $k_1 \dots w \dots k_n [EOS]$ . We tokenize target word in context and its left and right contexts for both sentences separately.

The architecture of our QA system could be seen in Figure 1. We predict the span  $A$  (answer) of the target word in the second sentence if it is used in the same meaning as in the first sentence and the span of the  $[CLS]$  token otherwise. Also, we additionally predict the span of  $Q$  (question) of the target word in the first sentence. We use a dropout layer followed by a linear layer over XLM-R output  $o_i$  from the last layer at timesteps  $i$  to predict the probability that  $o_i$  is the start or the end of the spans  $Q$  and  $A$ .

As for each target word we had its part of speech label (PoS), we decided to predict it using a linear layer over the output corresponding to  $[CLS]$  token from the last layer of XLM-R.

During the training process, we optimize the weighted sum of cross-entropy losses of  $A$  span,  $Q$  span, and PoS predictions. And as the corresponding weights, we take the softmax over the learnable weights' vector  $V \in R^3$ .

We fine-tuned the models in the settings from Table 2. Four times per training epoch we were validating our models and saving the best one. During the inference we assumed the positive answer if the model predicted possible span  $A$  that satisfied conditions  $A_{start} < A_{end}$  and  $A_{start} > PrefixQuestion$ . We did not try to train QA sys-

tems with symmetric data augmentation.

Further, we will be referring to the model validated on the English development set as the MTL-EN model. And as MTL-XX we will be referring to the models validated on one of the remaining development sets for the Russian, Arabic, French and Chinese languages.

### 3.3 BC Systems

Along with QA models, we tried a more traditional and straightforward approach of fine-tuning XLM-R as a binary classifier (BC).

So, given the target word  $w$  and a pair of tokenized sentences  $[s_1 \dots w \dots s_n]$  and  $[k_1 \dots w \dots k_n]$  we formed the following input example to XLM-R model:

$[CLS]$   $s_1 \dots w \dots s_n [EOS]$   $k_1 \dots w \dots k_n [EOS]$ . The sentences were tokenized the same way as in QA models.

We feed it to XLM-R and pool outputs  $o_s$  and  $o_k$  from the last layer from the subwords corresponding to the target word in two sentences. In our submissions we either took the output from the **first** subword, or used **max** pooling. In the post-evaluation, we also tried **mean** pooling and found, that it consistently provides the best results. Then we tried concatenating it with first (**mf**) or max (**mm**) pooled vectors, as well as both of them (**mmf**). Finally, we tried concatenating min, max and mean pooled outputs (**mmm**).

After obtaining fixed-sized representations of the first and the second target word occurrence, we concatenate them and feed them to the binary classifier, which is the sequence of dropout, linear, tanh, dropout and linear layers. The architecture of the model is depicted in Figure 2.

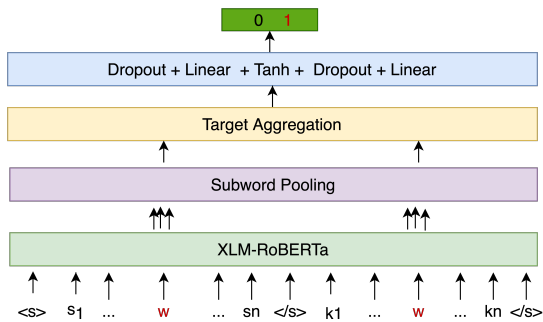

Figure 2: BC-based model architecture

In the post-evaluation period we tried replacing concatenation (**concat**) with alternative aggregation techniques. First, we tried using component-wise difference (**diff**) or multiplication (**mul**) with an optional normalization of word occurrence vectors (**mulnorm**). Then we tried combining representations obtained with different aggregation techniques by concatenating them. We denote those combinations by letter sequences, where **c** stands for the concatenation of the first and the second vector, **d** for their difference and **m** for their component-wise product. The inputs to each of those operations can be optionally normalized, which is denoted by **n** after the corresponding operation. For instance, **dmn** means that we concatenate the difference of non-normalized and the product of normalized vectors. Also in the post-evaluation, we found it beneficial to apply batch normalization before feeding aggregated representations into the classification head.

During training, we applied 2-class softmax and optimized the cross-entropy loss. We fine-tuned BC models using almost the same settings as for QA models. Here, we used the constant learning rate of  $1e-5$  with linear warmup during the first 10% of training steps. During post-evaluation, we added linear learning rate decay.

Our submitted BC systems are ensembles of these three models: first, first-AG and max-AG differing by subwords pooling strategy and by use of data augmentation. We would be referring to the ensemble of these models validated on the English dev set as ENS-EN and as ENS-XX for an ensemble of models validated on corresponding dev sets.

## 4 Experiments and Results

As our submissions showed us that BC models perform much better than QA models, in our post-

Figure 3: Data augmentation effect on xlmr.large performance

Figure 4: Comparison of target aggregation methods for xlmr.base (mean pooling, no batchnorm)

Figure 5: Comparison of subword pooling methods for xlmr.base (dmn agg. with batchnorm)

evaluation experiments we focused on them. In the following experiments, we report the best accuracy obtained during training on the English development set (*best dev.en-en*) and the best average accuracy on all non-English development sets (*best dev.nen-nen*) from our own split. For those epochs where the best dev set accuracy is achieved,

we report accuracy on the official English test set (*test.en-en*) and averaged over official non-English test sets (*test.nen-nen*). Due to space limitations, we report the results on all test sets only for our best models in Table 3.

In the first experiment, we trained the submitted models with and without data augmentation. Figure 3 shows that the augmentation never decreases performance, at least if the learning rate is selected properly. Thus, we always performed data augmentation in the following experiments.

Figure 4 compares target aggregation techniques. The concatenation of the difference of non-normalized vectors and component-wise product of normalized vectors (**dmn**) proved to outperform all other methods by a large margin, especially when the learning rate is properly selected. Thus, we used this technique for the following experiments. A simple concatenation of target embeddings, which was used in our submissions, is more than 3% worse and is often outperformed by the difference or component-wise product.

Since concatenating normalized and non-normalized vectors can make training difficult, we decided to apply batch normalization before feeding those vectors into the classification head. Figure 6 shows that batch normalization does not improve results for English much, but considerably improves the average performance on other languages. This is probably due to the fact, that the overwhelming majority of training examples are in English.

Also, from figure 6 we notice that for English different poolings give similar performance. For other languages, first pooling is a bad option. We hypothesise that this results from non-English words being split into sub-word tokens more frequently. Mean pooling consistently outperforms other poolings. Figure 5 additionally compares combinations of different subword poolings. However, those combinations did not improve results compared to single mean pooling.

Finally, we estimated how much the additional multilingual training data help compared to using only English training examples and counting on cross-lingual zero-shot transfer. In table 3 we denote xlmr.base models fine-tuned only on English train and trial data as **enonly**. We see that including non-English examples into the training set improves the results by 1.5-3% for multilingual and even more for cross-lingual scenarios. Surprisingly,

it also gives some improvement for English.

Table 3 summarizes the results of our submitted systems and the following post-evaluation experiments. During the evaluation period, we made a total of 4 submission attempts, two for the Question Answering based approach and two for the binary classifier approach. During training the best checkpoint was selected either individually for each language using corresponding dev set accuracy (XX), or by English dev set accuracy (EN). We see that the first approach to the task (MTL-EN, MTL-XX) shows much worse results compared to the second one (ENS-EN, ENS-XX). For the second approach, we submitted two ensembles consisting of three models shown in the same Table 3. As expected, ensembling the models helped to improve the results greatly.

As we figured out that **dmn** target aggregation and **mean** subword pooling performs significantly better compared to other variants for XLMR.base model, we trained XLMR.large version with hyperparameters from the best XLMR.base model. The results of the models validated either by score on English dev set (EN), or by the average score for non-English dev sets (nEN), or by scores on each dev set individually (XX), are shown in the third group of results in the Table3. We see that these models outperform any single model from the evaluation phase for all multilingual subtask’s test sets and test.en-ar set from cross-lingual subtask.

And lastly, we report the results for an ensemble of three XLMR.large models: two mean-dmn models trained with learning rates  $1e-5$  and  $2e-5$  and one mean-cnmm model trained with learning rate equal to  $1e-5$ . We see that using ensemble of models with new subword pooling and target aggregation techniques helps us to improve our official results from competition. We improved our results for test.ru-ru (3 → 2), test.fr-fr (2 → 1), test.en-en (15 → 12), test.zh-zh (21 → 17), test.en-ar (6 → 4) and test.en-zh (17 → 12) sets.

## 5 Conclusion

In this paper, we have described our approach to SemEval-2021 Task 2. We tried treating Word-in-Context Disambiguation as question answering and binary classification problems. In our case, binary classification turned out to be a more promising approach. Also, we found that mean pooling over subwords is the best option, batch normalization helps when added before classification head, and concate-

## Abstract

This paper presents a word-in-context disambiguation system. The task focuses on capturing the polysemous nature of words in a multilingual and cross-lingual setting, without considering a strict inventory of word meanings. The system applies Natural Language Processing algorithms on datasets from SemEval 2021 Task 2, being able to identify the meaning of words for the languages Arabic, Chinese, English, French and Russian, without making use of any additional mono- or multilingual resources.

## 1 Introduction

The computational task of disambiguating a word in the context of its sentence is still a very challenging topic facing natural language processing (NLP). In this study, we refer to word meaning that requires a multidisciplinary approach for its detection. From sense-based and contextualized embeddings, all tries are aimed at providing an understanding of words in context. We notice that evaluating such approaches is not easy. For instance, traditional Word Sense Disambiguation (WSD) fails to test latent representations unless these are linked to explicit sense inventories such as WordNet (Matuskevych, 2016) or BabelNet (Navigli and Pozetto, 2012; Luan *et al.*, 2020). To resolve the problem of disambiguation for both lingual dimensions, we tried to use a combination of well-known algorithms to provide an optimal system.

The legitimate research questions this paper intend to answer: *Is Word-in-Context Disambiguation a barrier for NLP techniques?*

The approach we propose in this paper investigates two models of cross-lingual word embeddings, comparing them to the shared-translation effect and the cross-lingual coactivation effects of false and true friends (cognates) found in human language. We find that the similarity structure of the cross-lingual word embeddings space yields the same effects as the human bilingual lexica (Merlo and Rodriguex, 2019). Research on bilingual lexica has uncovered fascinating interactions between the L1 (native language) and L2 (second language) lexica showing that both production and comprehension coactivate lexical items in both languages, indicating that bilinguals store lexical representations from their native and their second language in the same space.

The rest of the paper is organized as follows: section 2 describes the literature related to sense disambiguation, section 3 presents the dataset and method of this study, section 4 resumes the results of the conducted experiments, followed by section 5 with the conclusions and discussions about how to increase the accuracy.

## 2 Background

This topic has attracted significant attention in recent years, evidenced by increasing number of workshops (e.g., SemEval-2013 Task 10: Cross-lingual word Sense Disambiguation - CLWSD). Participating in such competitions is especially attractive since teams have thus access to labeled data.

For binary tasks, as the case of this competition, there are many computational models to be used in detecting the right word sense.

The recent advancements in corpus linguistics technologies, as well as the availability of more and more textual data, encourage many researchers to take advantage of comparable and parallel corpora to address different NLP tasks. Work on this topic is however highly subjective and biased. In general, the methods are based on Bag of Words features, usually normalized with  $tf*idf$  or character n-grams features for stylistic purposes.

Most approaches are supervised methods which can be classified into different methods:

(1) *regression*, based on the embeddings in one language using a leastsquares objective (Dinu et al., 2015; Artexe et al., 2018);

(2) *orthogonal*, based on the embeddings in one or both languages under the constraint of the transformation (Zhang et al., 2016; Smith et al., 2017);

(3) *canonical*, based on the embeddings in both languages to a shared space, using canonical link extension of it (Lu et al., 2015).

Also, several systems use an approach similar to ours' in considering Sent2vec the main algorithm (Pagliardini et al., 2018). Other systems used a *maxent* classifier trained over local context or even a KNN (*K-Nearest Neighbors*) classifier to solve the CLWSD (*Cross-Lingual Word Sense Disambiguation*) task. One of the interesting approaches was using machine translation (Baker et al., 1993). Although the winning systems for the CLWSD task used different approaches (statistical machine translation and classification algorithms), they also only used a parallel corpus to extract disambiguating information, while not using external resources such as WordNet. As a consequence, their system is very flexible and language-independent.

The topic of multilingual and cross-lingual disambiguation has attracted significant attention in recent years (Akyürek et al., 2020), with approaches ranging from learning effective vector representations (Loureiro and Jorge 2019, Scarlini et al., 2020) to infusing neural networks with knowledge graph information (Bevilacqua and Navigli 2020).

Our approach is more focused on recent research on the bilingual lexicon, which uncovered fascinating interactions between the lexica of the native language and that of the second language in bilingual speakers. Thus, it has been found that the lexicon of the underlying native language affects the organization of the second language (Riley et

al., 2020). In that spirit, our system includes distributed representations to disambiguate words in context.

### 3 Datasets and Methods

The dataset for the SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation is detailed in the task description paper (Martelli et al., 2021).

Language	Total words	Training words	Testing words
Arabic	20000	15000	5000
Chinese	16000	12000	4000
English	24500	16500	8000
French	22000	15500	6500
Russian	20000	14500	5500

Table 1: Corpus statistics

#### 3.1 Dataset

The dataset (Table 1), released in JSON format and divided into .data and .gold files, had the following composition: training, development and test subsets for multilingual and cross-lingual settings.

The data files contain the following information:

- (1) unique id of the pair;
- (2) target lemma;
- (3) part of speech;
- (4) first sentence;
- (5) second sentence;
- (6) start and end indices of the target word occurring in the first and second sentence.

The training data set contains 8000 entries for each multilingual language and 8000 entries for cross-lingual language combinations, and in the test dataset there are 1000 entries for each. The .gold files contain the following information, as exemplified below:

- unique id of the pair
- tag (binary, either T/F)

```
{
  "id": "training.en-en.0",
  "tag": "F"
},
```

We used NLTK to tokenize the sentences and removed the stop words, only keeping the lemmas in sentence1 and sentence2 respectively, and the

gold tag. After the transformation, the data in the training files look as exemplified below:

```
{
  "sentence1": "context
coordination integration Bolivia hold
key play process infrastructure
development ",
  "sentence2": "school water needed
girl sent fetch taking time away study
play ",
  "lemma": "play",
  "tag": "F"
},.
```

### 3.2 Methods

We considered that our system will first solve the multilingual part, followed by the cross-lingual part. Therefore, we propose the specific architecture presented in Figure 1.

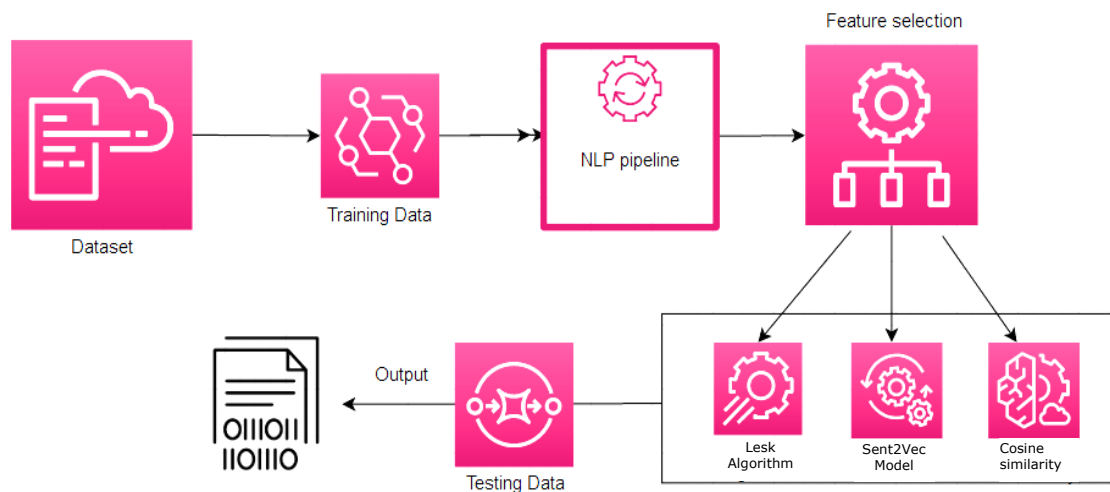

Figure 1. The System Architecture

Sent2Vec presents a simple but efficient unsupervised method to train distributed representations of sentences. It can be thought of as an extension of FastText and Word2vec (CBOW) to sentences. The sentence embedding is defined as the average of the source word embeddings of its constituent words. This model is furthermore augmented by learning source embeddings for both unigrams and various n-grams of words occurring in sentences and averaging the n-gram embeddings along with the words (Pagliardini et al., 2018). Thus, in our output, we have the initial tag from the labelled data, along with the score obtained through Sent2Vec.

As baseline, we used the Lesk algorithm. Thus, we extracted the definition of the queried target word from the first and the second sentence,

respectively. Finally, we compared the definitions of the target word in the two contexts, thus reaching the *True* or *False* tag. Lesk output before comparing definitions is presented below. Using NLTK-WORDNET, we extracted all synonyms for a target word.

Sentence 1: In that context of coordination and integration, Bolivia holds a key play in any process of infrastructure development.

```
-Sense:Synset('play.v.02')
-Definition:act or have an effect in
a specified way or with a specific
effect or outcome
```

Sentence 2: A musical play on the same subject was also staged in Kathmandu for three days.

```
-Sense:Synset('play.v.28')
-Definition:discharge or direct or
be discharged or directed as if in a
continuous stream
```

Our final approach was to combine the Lesk algorithm, along with Sent2Vec and vector cosine (Bojanowski et al., 2017). The cosine similarity is computed for each pair of sentences in our input. The pipeline used cross-lingually aligned versions of *fasttext* word vectors.

After running all modules, we obtained two scores, given by the cosine similarity and Sent2Vec

respectively, and a tag ( $T$  or  $F$ ) provided by the Lesk algorithm. In order to apply an integrative approach, we transformed the tags from the Lesk algorithm into a 3rd score: if the tag is  $T$  the Lesk score became 0.9, while if the tag is  $F$ , the score became 0.3. These values were determined empirically, after several tests with different weights. Below are the scores obtained for the pair of sentences discussed above.

```
sent2vec score: 0.0912621021270752
lesk score: 0.3
cosine score: 0.14142135623730948
gold tag: F
```

In order to establish a ranking on the three scores and their influence on the final tag, we tested and analyzed several combinations of weights, as follows:

```
Score1 - 30%sent2vec*10 + 30%lesk +
40%cosine*10: 0.9294717313304636
Score2 - 30%sent2vec*10 + 20%lesk +
50%cosine*10: 1.0408930875677729
Score3 - 30%sent2vec*10 + 40%lesk +
30%cosine*10: 0.818050375093154
Score4 - 40%sent2vec*10 + 20%lesk
+ 40%cosine*10: 0.9907338334575388
```

After a detailed error analysis in which we compared the gold tags from the development corpus with those issued in each of our combinations, we decided that the final tags be assigned according to the score brought by the formula (1):

```
(1) FiiCros_formula = 20%*Lesk + 30%
* Sent2Vec*10 + 50% Cosine *10
```

## 4 Results

The results for each individual task (Precision, Recall and F1-score) using the specific test dataset are presented: for multilingual test dataset (Table 2) and for crosslingual dataset (Table 3). The baseline identified 4483 correct tags out of 8000 inputs. After fine tuning the weights of the combination of our algorithms with the final formula discussed above our system reached 5760 correct tags out of 8000 inputs.

Model	Precision	Recall	F1-score
Lesk Baseline EN-EN	56%	65%	60,17%
Lesk + Sent2Vec + Cosine Vectorial EN-EN	72%	68%	69,94%
Lesk Baseline FR-FR	52%	61%	56,14%
Lesk + Sent2Vec + Cosine Vectorial FR-FR	70%	66%	67,94%
Lesk Baseline AR-AR	50%	59%	54,13%
Lesk + Sent2Vec + Cosine Vectorial AR-AR	68%	64%	65,94%
Lesk Baseline ZH-ZH	51%	60%	55,14%
Lesk + Sent2Vec + Cosine Vectorial ZH-ZH	69%	65%	66,94%
Lesk Baseline RU-RU	53%	62%	57,15%
Lesk + Sent2Vec + Cosine Vectorial RU-RU	71%	67%	68,94%

Table 2. Experimental Results for multilingual test dataset

Model	Precision	Recall	F1-score
Lesk Baseline EN-AR	53%	61%	56,71%
Lesk + Sent2Vec + Cosine Vectorial EN-AR	70%	66%	67,94%
Lesk Baseline EN-FR	49%	58%	53,12%
Lesk + Sent2Vec + Cosine Vectorial EN-FR	67%	64%	65,46%
Lesk Baseline EN-ZH	44%	55%	48,88%
Lesk + Sent2Vec + Cosine Vectorial EN-ZH	64%	60%	61,93%
Lesk Baseline EN-RU	47%	57%	51,51%
Lesk + Sent2Vec + Cosine Vectorial EN-RU	65%	61%	62,93%

Tables 3. Experimental Results for crosslingual dataset

We noticed to have lower scores when using the baseline (Lesk algorithm) than the combination of the three algorithms (Lesk, Sent2Vec and Cosine Vectorial).

Although it might have seemed to have similar results with the simple Word2Vec version, we considered Sent2Vec to be more reliable because it did not depend on the number of words in the vocabulary, and this was an advantage since the sizes of the vocabularies were diverse across languages.

## 5 Conclusion and Discussions

This paper presents a system participating at SemEval 2021 Task 2. Our solution indicates a good start for solving word sense disambiguation.

The main challenge behind word sense disambiguation is to make ample use of the available technologies since ambiguities in any language provide great difficulty in the use of information technology. The major difficulty lays in the fact that words in human language can be interpreted in more than one way, depending on the context (Tan, 2013).

Since we performed a detailed investigation of monolingual and bilingual disambiguation, our experimental results showed that Sent2vec and Lesk approaches are remarkably efficient for both tasks. The overall results are satisfactory and exceed the baseline; however, there is still room for improvement.

A larger and well-annotated dataset would provide more opportunities for exploring the issue of disambiguation. Additionally, building a dataset sufficient in size and diversity will allow experiments with deep learning methods. The biggest challenge in this project was working in different languages at the same time while some tools were available to English only.

From our research, we noticed that the average scores are around 75% when applying separately Lesk and Sent2Vec (or even Word2Vec), and it seems to be similar when combining the two.

## Abstract

This paper presents our submitted system to SemEval 2021 Task 4: *Reading Comprehension of Abstract Meaning*. Our system uses a large pre-trained language model as the encoder and an additional dual multi-head co-attention layer to strengthen the relationship between passages and question-answer pairs, following the current state-of-the-art model DUMA. The main difference is that we stack the passage-question and question-passage attention modules instead of calculating parallelly to simulate re-considering process. We also add a layer normalization module to improve the performance of our model. Furthermore, to incorporate our known knowledge about abstract concepts, we retrieve the definitions of candidate answers from WordNet and feed them to the model as extra inputs. Our system, called WordNet-enhanced DUAL Multi-head Co-Attention (WN-DUMA), achieves 86.67% and 89.99% accuracy on the official blind test set of subtask 1 and subtask 2 respectively.

## 1 Introduction

Recently, there has been an increasing interest on Machine Reading Comprehension (MRC). While most MRC studies such as CNN/Daily Mail (Hermann et al., 2015) focus on concrete concepts, SemEval 2021 Task 4, *Reading Comprehension on Abstract Meaning* (ReCAM), targets abstract concept understanding, including *imperceptibility* in subtask 1 and *nonspecificity* in subtask 2. The former, *imperceptibility*, highlights the abstract words that refer to ideas and concepts that do not correspond directly to human perception. The latter is for hypernyms and abstract concepts such as the class of vertebrate which includes whales as a concrete subclass (Changizi, 2008).

\*Equal contribution.

Passage

The 29-year-old Belgium international, whose old deal ran until 2018, has made 179 appearances for the Premier League club since his 2012 move from Ajax. "It's a big relief. The future looks great so I'm very happy to be a part of it," he said. "This is an unbelievable group of talent. There's a great buzz around Tottenham." Vertonghen's new deal comes a day after striker Harry Kane signed a contract until 2022.

Question

Tottenham Hotspur defender Jan Vertonghen has signed a new contract, @placeholder him to the club until 2019.

Figure 1: An example of ReCAM subtask 1.

In this task, given news fragments and incomplete abstracts, the machine needs to select the most suitable abstract words from candidate answers. Figure 1 shows one example of ReCAM subtask 1. Passage is the news sections and Question is a human written summary in which abstract words have been removed. Machines are requested to choose abstract words from five candidates for replacing @placeholder.

For this shared task, we regard both subtasks as multi-choice MRC tasks. Various deep neural networks and attention mechanisms (e.g. (Dhingra et al., 2017; Wang et al., 2018; Zhang et al., 2020a,b; Jin et al., 2020)) have been proposed to address these tasks. In our work, following the state-of-the-art model DUMA (Zhu et al., 2020), we adopt a Pre-trained Language Model (PrLM) as encoder and extend with an additional dual multi-head co-attention layer to strengthen the relationship between passages and question-answer pairs. For the dual multi-head attention layer, while DUMA builds passage-question and question-passage attention modules in a parallel way to simulate the transposition thinking process,

our model stacks two attention modules in order to simulate the process of re-considering for a deeper understanding of the passage. More details on our attention calculation process can be found in Section 2. Furthermore, we add an additional layer normalization module immediately after the attention module. From our experiments, we found that this additional normalization module definitely improves our model’s performance.

Our most significant design decision is to use WordNet (Miller, 1995) to expand on the abstract concepts in the candidate answers. Intuitively, expanding an abstract concept according to its definition in a dictionary should help as it helps relate the abstract concept with others that may occur in the text. A key conclusion that we can draw from our experiments is that this is indeed the case. One problem that we encountered when implementing this idea was that most English words have multiple entries in WordNet. For example, *bank* in WordNet can have Noun definitions as well as Verb definitions. We addressed this problem by using some heuristics and some additional information such as part-of-speech labels. Because of the significant role played by WordNet, we call our system **WordNet-enhanced DUal Multi-head Co-Attention (WN-DUMA)**.

We remark that our system did not use any additional training data for the tasks. In the final evaluation, our model is ranked 10 out of 23 and 9 out of 28 on the official subtask 1 and subtask 2 blind test set with 86.67% and 89.99% accuracy, respectively. The code for our model is publicly available<sup>1</sup>.

The rest of the paper is organized as follows. Section 2 gives the details of our system. Section 3 describes our experimental setup including the datasets and hyper parameters used for training. Section 4 presents experimental results. Section 5 concludes this paper with some final remarks.

## 2 System Description

In this section, We describe the framework of our end-to-end model WN-DUMA. Figure 2 depicts the detailed architecture of our approach, with inputs at the bottom and outputs at the top.

**WordNet-enhanced Encoder** We regard both subtask 1 and 2 as multi-choice MRC problems. Such a problem includes a passage, a question with

<sup>1</sup><https://github.com/zzshou/RCAM>

Figure 2: The overall model architecture.

a *@placeholder*, and 5 candidate answers to choose from. First, we replace *@placeholder* in the question with the given 5 candidate answers to form 5 options. In the tasks, the candidate answers are all single words with abstract meanings, so we decided to add some extra knowledge from WordNet (Miller, 1995) to help the system better understanding the abstract meanings. More specifically, for a single candidate answer, we find its part-of-speech tag based on the option it’s located in, and extract its definitions under this part-of-speech tag. After tokenization, every instance is cast into the input form: [CLS] *passage* [SEP] *option + answer definition* [SEP]. To encode input tokens into representations, we feed them through a PrLM based on Transformer to obtain sequence embeddings, which draws a global relationship between the passage and the option-definition.

**Dual Multi-head Co-Attention Layer** Based on the above process, we further separate the output representations from transformer encoder to acquire the passage context embeddings  $E^P \in \mathbb{R}^{d_{model} \times l_p}$  and the context embeddings of option-

definition  $E^{OD} \in \mathbb{R}^{d_{model} \times l_{od}}$ , where  $l_p, l_{od}$  denote the maximum length of passage and option-definition respectively. Then based on the bi-directional matching network of DUMA which is quite similar to the multi-head self-attention module in vanilla transformer block (Vaswani et al., 2017), we first take  $E^{OD}$  as Query,  $E^P$  as Key and Value to calculate one of the co-attention representations, which simulates the process of human re-reading the passage with impression of option and definition. The formulas are listed as follows:

$$Q_i = E^{OD}W_i^Q \quad (1)$$

$$K_i = E^P W_i^K \quad (2)$$

$$V_i = E^P W_i^V \quad (3)$$

$$head_i = softmax(\frac{Q_i K_i^T}{\sqrt{d_k}}) V_i \quad (4)$$

$$MHA = Concat(head_1, \dots, head_h) W^O \quad (5)$$

$$REP_1 = Normalize(E^{OD} + MHA) \quad (6)$$

where  $W_i^Q \in \mathbb{R}^{d_{model} \times d_q}$ ,  $W_i^K \in \mathbb{R}^{d_{model} \times d_k}$ ,  $W_i^V \in \mathbb{R}^{d_{model} \times d_v}$ ,  $W_i^O \in \mathbb{R}^{h d_v \times d_{model}}$  are linear transformations with learnable parameters,  $d_q, d_k, d_v$  denote the dimension of *Query*, *Key* and *Value*,  $h$  denotes the number of heads. Different from the structure of DUMA, here we make two changes: 1) apply "Add and Normalize" after getting the multi-head attention representation, which could result in more stable training. 2) compute another co-attention representation by stacking rather than paralleling: take the acquired  $REP_1$  as *Key* and *Value*,  $E^P$  as *Query*, which simulates the process of re-considering the option-definition with deeper understanding of the passage. Finally, we obtain  $REP_1$  and  $REP_2$ , which have the same dimension as  $E^{OD}$  and  $E^P$ , respectively. As a result, we can stack the co-attention module for  $k$  layers.

**Classifier** Here the co-attention representations  $REP_1$  and  $REP_2$  are merged and used for final classification:

$$I_1 = AvgPool(REP_1) \quad (7)$$

$$I_2 = AvgPool(REP_2) \quad (8)$$

$$M = Concat(I_1, I_2) \quad (9)$$

$$logits = MW_M \quad (10)$$

where  $I_1, I_2 \in \mathbb{R}^{d_{model}}$ ,  $M \in \mathbb{R}^{2d_{model}}$ ,  $W_M \in \mathbb{R}^{d_{model} \times n_{class}}$  denotes the one-layer fully-connected neural network,  $n_{class}$  denotes the number of candidate answers. Consequently, for a single instance, we could get as many logits as the

	Task 1	Task 2

Answer vocabulary size	4,333	4,775

Table 1: Basic statistics of subtask 1 and subtask 2 dataset.

candidate answers, which are used to compute the cross-entropy loss by softmax.

### 3 Experimental Setup

**Data and Metric** We used the official datasets (Zheng et al., 2021) provided by SemEval 2021 Task 4 competition. They were collected from BBC News in English language. Some basic statistics are listed in Table 1. According to the requirement of the organizers, participants could only use the corresponding dataset for a specific subtask to build models to ensure fairness. For better performance, technics like multi-task learning (Wan, 2020) are recommended for MRC tasks. In both subtask 1 and subtask 2, we utilize accuracy as the metric to evaluate our model performance.

**Hyper Parameters** All of our codes are written based on PyTorch<sup>2</sup>. To extract the word definition of candidate answers, we use NLTK toolkit (Bird et al., 2009). The transformer encoder we used is pretrained ALBERT-xxlarge-v2 model<sup>3</sup>. Since the code of DUMA is not open-source, we reimplement it by only using one co-attention layer where the attention heads are 64 and the dimension of *Query*, *Key* and *Value* are all 64, because it is pointed that more co-attention layers do not improve the performance (Zhu et al., 2020). The setting is also applied to our WN-DUMA for fair comparison.

Due to limited resources, the maximum sequence length of input tokens is set to 150 for both subtask 1 and subtask 2. In fact, we found that sequence length longer than 150 can only slightly improve the model performance. We choose mini-batch size equal to 2, and the AdamW optimizer

<sup>2</sup><https://pytorch.org/>

<sup>3</sup><https://github.com/huggingface/transformers>

(Loshchilov and Hutter, 2018) with an initial learning rate of  $5e-06$ . We use some strategies for more stable training: 1) clip the gradient norm to 10; 2) adopt a linear scheduler with warm up of the first 10% training steps. To avoid overfitting, we apply 0.1 dropout (Srivastava et al., 2014) rate to the co-attention layer. We trained all the models for 3 epochs, evaluate on the dev set at every 200 training steps and save the model with the best dev accuracy. For each single model, we run experiments for 5 times with different random seeds and use the average as the ultimate performance.

## 4 Results

### 4.1 Quantitative Analysis

Table 2 summarizes the experimental results. The first three models only have encoder (without enhancement of WordNet) and classifier part. It is clearly seen that ALBERT is much more efficient as encoder for abstract meaning understanding. It is worth noting that by only using the question and answer as input, the ALBERT model can also get pretty good results, as table 2 shows. Intuitively, it may be because the model could utilize syntax and semantics of the question sentence to choose the correct answer without looking through the passage.

Compared to ALBERT<sub>xxlarge</sub>, adding DUMA layer obtains around 0.2% improvement in subtask 1, and more than 3% improvement in subtask 2. Besides, our WN-DUMA single model achieves further improvements based on DUMA on both subtasks, +0.83% and +1.3% respectively, without increasing the number of parameters. Using a majority vote scheme, we ensemble our WN-DUMA model with different parameters for more stable predictions. Eventually, our ensemble models which get 87.57% on subtask 1 dev set and 90.01% on subtask 2 dev set acquire the best performance on test sets (86.67% and 89.99%, respectively) among our submissions.

Figure 3 and Figure 4 illustrate the dev accuracy of different models on subtask 1 and subtask 2 as the number of training steps increases. It is interesting to observe that models with co-attention layer (DUMA and WN-DUMA) could get over 70% accuracy with only 10% of training examples. While ALBERT model has to be trained with the full dataset to get relatively high accuracy. Consequently, our WN-DUMA model may be useful when there only exists a small amount of training

Figure 3: Subtask 1 dev accuracy over number of training steps.

Figure 4: Subtask 2 dev accuracy over number of training steps.

data.

### 4.2 Error Analysis

In order to further improve our model performance in the future, we analyze some incorrect predictions made by WN-DUMA, and classify them into two categories:

- Candidate answers with similar meanings. In some failure cases, the similarities between candidate answers are too high to distinguish. For example, outstanding and extraordinary, challenge and attempt, etc.
- Lack of commonsense and relying too much on the information of the passage. Due to the fact that the question is the summary of the passage, the machine need to choose the most appropriate answer from a global perspective with some commonsense. However, our model make decisions by only capturing the local information in some cases. A spe-

Model	Task 1 dev	Task 1 test	Task 2 dev	Task 2 test

Table 2: Model comparison on subtask 1 and subtask 2 dataset.

Passage

Joe Wincott of The Sandon School in Chelmsford, Essex said an extra £1.3bn promised by the government was too late to help it in the next academic year. The head teacher said cutting lessons from 26 to 25 hours a week would allow him to balance the school budget. Education Secretary Justine Greening said per pupil funding was set to go up from £4,100 to £4,800 in 2018. Mr Wincott said the school budget had been cut by £450,000 since 2011 and he had reduced the costs of "everything from power supplies, examination and photocopying". He said: "We were down to the situation where we were unable to balance our budget for 2017-2018, so we took the decision... to drop to 25 hours, which is what most schools deliver." Parents at the mixed comprehensive school, which has 1,270 pupils aged 11 to 18 and was rated good in its last Ofsted inspection, had been "remarkably understanding". But the head teacher added a "significant number of pupils" were entering the school system, and pay, pension and National Insurance contributions were all due to increase. As a result, he believes the promised extra pupil funding in 2018 will "probably put us where we are now, but without having to make cuts to staff".

Question

A @placeholder school will cut an hour of teaching a week from the autumn in a bid to save £ 100,000.

Candidate Answers

secondary    temporary    troubled    new    third

✓    predicted

Figure 5: An failure example made by WN-DUMA. The ground true is the answer with a correct mark at the bottom. While the prediction is the answer with "predicted" at its bottom.

cific example can be seen in Figure 5. We can see that the model predicts that the answer is "troubled", most likely because the passage mentions "the school was trapped into financial difficulties".

## 5 Conclusion

In this paper, we describe our submitted system in SemEval 2021 Task 4 ReCAM. Unlike previous MRC datasets, ReCAM focus more on machine's ability in understanding and representing abstract concepts. In order to provide more knowledge of abstract word, we extract WordNet definitions for each candidate answer based on part-of-speech tags. In addition, our proposed WN-DUMA model consists of a PrLM as the encoder and a dual multi-head co-attention layer to enhance the relationship

between passage and question-answer pairs as human's re-considering process. Our WN-DUMA model improves the performance of our baseline model DUMA on these datasets.

There are some limitations in our experiments. Firstly, training data size of this task is limited compared to other MRC tasks, with less than 3400 training pairs in both subtasks. This is understandable as collecting labeled data in many natural language processing tasks is expensive. Secondly, using ALBERT<sub>xxlarge</sub> PrLM, we only set 150 as the maximum text length in our experiments due to device limitation. Important sentences in the passage that are highly relevant to the summary are sometimes not covered. For PrLMs, their performance always improve as the number of their parameters increase. The use of large pre-trained models sometimes requires the sacrifice of context. For our future work, we plan to explore ways to train models more efficiently with limited amount of labeled data, and to design more cost-effective models to deal with long input texts.

t.markchom@pgr.reading.ac.uk, huizhi.liang@reading.ac.uk

## Abstract

Most question answering tasks usually focus on predicting concrete answers, e.g., named entities. These tasks can be normally achieved by understanding the contexts without additional information required. In Reading Comprehension of Abstract Meaning (ReCAM) task, the abstract answers are introduced. To understand abstract meanings in the context, additional knowledge is essential. In this paper, we propose an approach that leverages the pre-trained BERT Token embeddings as a prior knowledge resource. According to the results, our approach using the pre-trained BERT outperformed the baselines. It shows that the pre-trained BERT token embeddings can be used as additional knowledge for understanding abstract meanings in question answering.

## 1 Introduction

Question answering (QA) is one of the machine reading comprehension tasks. The goal is to find an answer of a given question based on a given context. In most QA tasks (Chen et al., 2016; Lai et al., 2017), the answers are commonly concrete words appearing in the contexts. Abstract words, on the other hand, have usually been ignored in such tasks. Unlike concrete words, these abstract words are difficult to understand since they cannot be perceived directly with human senses. To study machine comprehension of abstract meaning, a task called Reading Comprehension of Abstract Meaning (ReCAM) (Zheng et al., 2021) was proposed. Unlike other QA tasks, the answers in ReCAM are abstract words that used to summarise the information in the contexts.

ReCAM is divided into three subtasks. For subtask 1, the abstract answers are in the form of imperceptible words such as ‘objective’, ‘chance’, and ‘prospective’. Subtask 2 is about nonspecificity. The answers in this subtask are abstract words that

represent nonspecific or general concepts such as ‘vertebrate’. Subtask 3 focuses on generality of the models developed in the first two subtasks. In this subtask, the model in subtask 1 must be evaluated on subtask 2 data and vice versa. Based on these abstract answers, a machine has to understand the abstract meaning of certain words. This requires an additional knowledge to fulfill the lack of abstract concept information (Bi et al., 2019). For example, given a context which is a passage and a question shown in Table 1. In the example of Table 1, the context contains a passage and a question. The answer ‘neglected’ does not appear anywhere in the given passage. However, the sentence, ‘it gradually fell into disrepair in the late 1980s’, provides a clue to answer the question. If the model has a prior knowledge that the word ‘disrepair’ have a connection with ‘neglect’, then the correct answer will be chosen.

In this work, we propose to use a pre-trained word/token embedding model to provide external knowledge for abstract meaning understanding. The pre-trained BERT token embedding is chosen in this work due to its good performance in various natural language processing tasks. In our approach, the token embeddings are firstly extracted by the pre-trained BERT model. Presumably, these embeddings are enriched with additional information for understanding the abstract meanings. These embeddings are used as inputs in our approach to predict answers. In this way, the prior knowledge from the pre-trained model can be leveraged in the task of abstract answer prediction.

## 2 Related Work

A QA task usually requires a machine to understand a context to answer a question. Typically, a context is a passage and an answer usually appear somewhere in a given passage. Several ap-

proaches have been proposed to compute a combined passage-question representation and then use it to find an answer. The DeepLSTM Reader (Hermann et al., 2015) uses a deep long-term short-term memory (LSTM) encoder to find a representation of a concatenated passage-question text. The Attentive Reader (Hermann et al., 2015) attentively aggregates words to compute a passage representation based on a question. The Attentive Reader was modified in (Chen et al., 2016) where a deep LSTM module with the dot product attention function were replaced by a shallow bi-directional LSTM module with the bi-linear attention function. Recently, Dhingra et al. (2017) proposed a model called Gated-Attention (GA) Reader. It combines a multi-hop architecture and a novel attention mechanism to learn the representations. These models have shown good performances in question answering when answers are concrete words. However, in ReCAM task, the answers are abstract. Only the given contexts may not suffice to answer the questions.

Recently, word/token embeddings from pre-trained models have been popularly used in many applications. They are capable of providing additional knowledge from the resources they were pre-trained. Several pre-trained models have been proposed in the past few years such as GloVe (Pennington et al., 2014) and ELMo (Peters et al., 2018). Many models have also been developed from the transformer architecture (Vaswani et al., 2017), e.g., BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and DistilBERT (Sanh et al., 2020). They have been highly successful in pre-training token embeddings for various downstream tasks including QA. However, there has been no work where such models are applied in a QA task that focuses on imperceptibility and nonspecificity abstractness.

### 3 Using pre-trained token embeddings for a QA task

Each sample in the dataset of both subtasks consists of three components: passage, question and options. Each passage is a long text that is used to provide context for answering a question. Each question is a passage-summarized text containing one special token, *@placeholder*. This token is a representative of a word (an answer) that should be filled to complete the text. The correct answer must be selected from five possible options provided in each sample. Table 1 shows one exam-

ple in subtask 1. In the table, the first row is the passage providing a context for this sample. The second row is the question, which is a sentence that summarises the given passage. It contains one placeholder indicated by *@placeholder* token. This placeholder should be replaced by an abstract word corresponding to the passage. The third row is the list of options that can be selected to replace the placeholder in the question. The correct options is marked in bold which is 'neglected' in this case. The last row is the label indicates the answer of this example ranging from 0 (the first option) to 4 (the last option).

Given a context (a passage and a question containing a placeholder token), a placeholder embedding extracted from the pre-trained BERT model should be able to guide an answer. Due to the fact that the BERT model considers token contexts to learn token embeddings, a placeholder embedding should comprise information of its context. That means any word or token with a similar embedding should also be in the same context as a placeholder as well. Thus, to find the correct answer from a list of options, every option embedding extracted from the pre-trained BERT model is compared with a placeholder embedding. Then, any option with the most similar embedding compared to a placeholder embedding should be an answer. Accordingly, we propose an approach that considers similarity between placeholder and option embeddings to predict answers. Several metrics such as dot product, cosine similarity and euclidean distance can be considered to measure the similarity. The selected metric in this work is described in Section 4.

To extract placeholder and option embeddings in each sample, a question and a passage are firstly concatenated in the following form:

[CLS] + Question + [SEP] + Passage + [SEP]

This form is conventional in BERT framework. Normally, a '[CLS]' token is added for a classification purpose. It is usually represented a sentence level embedding. However, it is not utilized in our approach since we utilized embeddings in a token level. Two '[SEP]' tokens in the form are used to separate a question and a passage. Similarly, for every option in each sample, both '[CLS]' and '[SEP]' tokens are added as follows:

[CLS] + Option + [SEP]

Then, the pre-trained BERT model is used to extract embeddings from these prepared inputs.

<b>Passage</b>	The Trainspotting author has agreed to become patron of The Leith Theatre and launch a new fundraising drive. The Leith Theatre Trust took over the lease of the art deco venue from City of Edinburgh Council last year ... However, it gradually fell into disrepair in the late 1980s and eventually had to be closed down by the council ...
<b>Question</b>	Irvine Welsh is to spearhead a campaign aimed at reviving a @placeholder theatre in Leith 30 years after its last show.
<b>Options</b>	(A) <b>neglected</b> , (B) renewed, (C) lavish, (D) revised, (E) proposed
<b>Label</b>	0

Table 1: An example of a passage, a question, and five options. The task is to select the correct answer (bold) for replacing @placeholder

The placeholder embedding is extracted from the question-passage concatenated input and each option embedding is extracted from each option input. These embeddings are used as inputs of the proposed approach. As for targets, all labels given are converted to one-hot vectors. With the placeholder and options embeddings as inputs and the one-hot vectors as targets, our proposed approach learn how to predict the probabilities that each option is an answer for each sample. Figure 1 shows the input and target generated from an example shown in Table 1. The pre-trained BERT model is used to extract embeddings of the placeholder and option tokens in the prepared format. The embeddings are the hidden weights of the given tokens from the last hidden layer of the pre-trained BERT model. The label 0 is converted to a one-hot vector  $[1, 0, 0, 0, 0]$ . These embeddings are then passed through the prediction model. This prediction model consists of six learning modules for learning placeholder and five option embeddings in each sample. These modules consist of a dense layer with an output size 768 and a tanh activation function. They take a 768-dimensional pre-trained BERT token embedding and outputs the fine-tuned embedding with the same size. For each placeholder embedding, the fine-tuned embedding is produced by the placeholder embedding module. Similarly, for each option embedding, the fine-tuned option embedding is also obtained from the corresponding option learning module. However, using separate option learning module for each option may cause a bias in selecting some options at the end. We therefore propose to use shared-weight modules for learning all fine-tuned option embeddings simultaneously. In other words, all options in each sample are learned by the modules that share the same weights. After that, for

each option, the similarity between the fine-tuned placeholder and the fine-tuned option embedding is computed. All of the similarities from all options are then concatenated to form a vector with the size 5. A softmax activation function is applied on the concatenated vector to produce the final output with the same size. This output vector represent the probabilities that each option is an answer of a given sample. The entire proposed approach is illustrated in Figure 2. In the figure,  $p$  denotes the fine-tuned placeholder embedding while  $o_0, o_1$  and  $o_4$  denote the first, the second and the last option embedding respectively.  $s$  denotes a similarity function.  $s(p, o_i)$  is the similarity between  $p$  and any  $o_i$ .

## 4 Experimental setup

The pre-trained BERT model used in this work is BERT-Base-Uncased<sup>1</sup> (Turc et al., 2019). All inputs were converted to lower case and tokenized by BERT-Uncased tokenizer. The prediction model was trained using RMSprop optimizer for 100 epochs with the learning rate set to 0.001. A categorical cross entropy was used as a loss function. To avoid over-fitting, both L1 and L2 regularizers were added at the dense layer in both placeholder and option learning modules. The regularization factors were set to 0.001. To select the similarity metric, we examined three functions, i.e., dot product ( $s_d$ ), cosine similarity ( $s_c$ ) and euclidean-distance-based similarity ( $s_e$ ) computed by

$$s_d(p, o) = p \cdot o \quad (1)$$

$$s_c(p, o) = \frac{p \cdot o}{\|p\| \|o\|} \quad (2)$$

$$s_e(p, o) = \frac{1}{1 + \|p - o\|} \quad (3)$$

<sup>1</sup><https://github.com/google-research/bert>

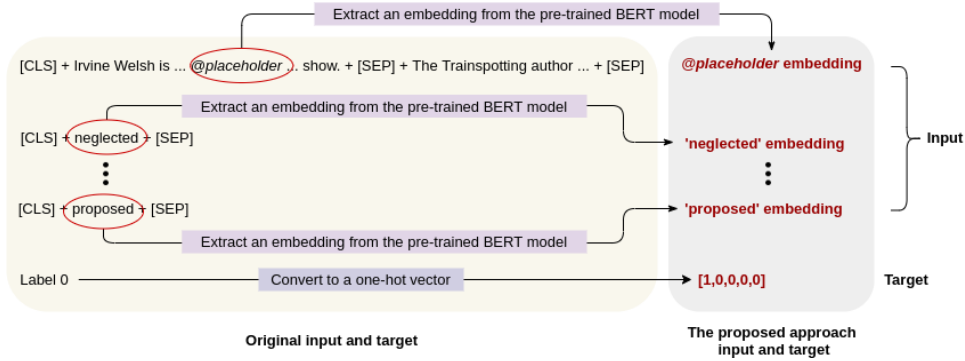

Figure 1: The input and target generated from an example shown in Table 1

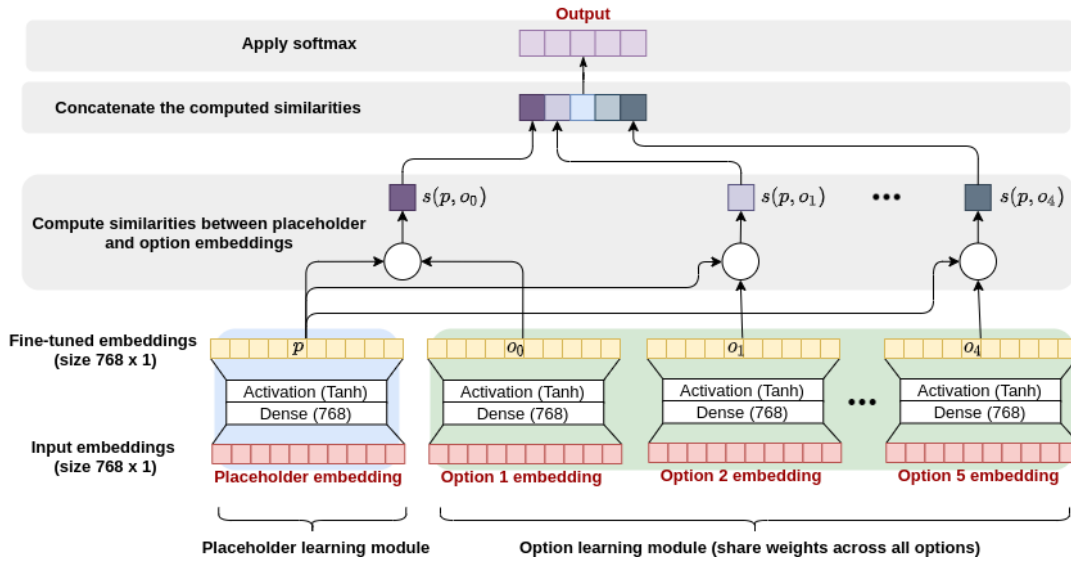

Figure 2: The proposed approach framework

where  $p$  denotes a placeholder embedding and  $o$  denotes an option embedding. We applied these metrics in the proposed approach and performed experiments on the development sets provided. The results are shown in Table 2. As in the table, the proposed approach using a dot product performed best compared to the others. Hence, a dot product was used in the proposed approach when it was applied on the trial and test sets

Similarity metric	Accuracy	
	Subtask 1	Subtask 2
$s_d$	0.48	0.46
$s_c$	0.34	0.31
$s_e$	0.33	0.31

Table 2: Evaluation results of the proposed approach using different similarity metrics on the development sets

#### 4.1 baselines

We compared the proposed approach named as **BERT-S** with other three baselines as follows:

- **MLP**: a multilayer perceptron (MLP) binary classifier. It consists of two hidden layers with the size 512 and 128 with a rectified linear unit (ReLU) activation function. The output is produced by an output layer with the size 1 and a sigmoid activation function. Each input is a concatenated placeholder-option embedding and its label is 1 if the option is an answer and 0 otherwise. For every sample, an answer is chosen from the concatenated placeholder-option embedding that gives the highest prediction value. A binary cross entropy was used as a loss function. The model was trained by RMSprop optimizer for 100 epochs with the learning rate 0.01.
- **GA**: the GA Reader proposed in (Dhingra et al., 2017). It uses a novel multiplicative

Dataset	Method	Accuracy			
		Subtask 1	Subtask 2	Subtask 3-1	Subtask 3-2
Trial	MLP	0.44	0.28	0.20	0.19
	GA	0.32	0.25	0.24	0.25
	BERT-C	0.26	0.14	0.21	0.21
	BERT-S	<b>0.50</b>	<b>0.30</b>	<b>0.29</b>	<b>0.27</b>
Test	MLP	0.47	0.46	0.27	0.25
	GA	0.19	0.21	0.20	0.19
	BERT-C	0.38	0.34	0.24	0.25
	BERT-S	<b>0.50</b>	<b>0.49</b>	<b>0.34</b>	<b>0.39</b>

Table 3: Evaluation results on the trial and test sets of all subtasks

gating mechanism, combined with a multi-hop architecture to learn token embeddings based on the given question. The GA Reader obtains state-of-the-art results on three QA benchmarks. However, those benchmarks only focuses on concrete concept answering.

- **BERT-C**: a modified version of the proposed approach. Instead of using similarities between the fine-tuned placeholder and option embeddings, scalar outputs from an MLP are used. After the fine-tuned placeholder and option embeddings are obtained, each fine-tuned option embedding is concatenated to the fine-tuned placeholder embedding. Then, the concatenated embedding is fed to a MLP module. This MLP module consists of three dense layers with the output size 512, 128 and 1 respectively. The scalar outputs from all options are then concatenated and proceeded as in **BERT-S**. The other settings were also set as same as the settings in **BERT-S**.

## 5 Results

The proposed approach was evaluated on the trial and test sets of all three subtasks. The evaluation metric is accuracy. The results of subtask 1 and 2 are shown in Table 3. There are two results of subtask 3 shown as subtask 3-1 and subtask 3-2. Subtask 3-1 is the proposed approach trained on subtask 1 but evaluated on subtask 2. Similarly, subtask 3-2 is the proposed approach trained on subtask 2 but evaluated on subtask 1. As shown in the table, the proposed approach performed better in subtask 1 compared to subtask 2. It means that the pre-trained BERT model applied in this work is capable of understanding imperceptible words. In contrast, it is not suitable for nonspecific

abstract words as it performed poorer in subtask 2. For subtask 3, the proposed approach is not generalized across imperceptible and nonspecific concepts. This can be implied by the significant drop in accuracy in both subtask 3-1 and 3-2. However, compared with the baselines, the proposed approach performed better in all subtasks.

## 6 Conclusion

In this work, we propose to use the pre-trained BERT token embeddings for QA of abstract meaning. These embeddings are additional information that help understanding abstract meanings in the tasks. According to the results, our approach outperformed the baselines in every subtask. It means that the pre-trained BERT model is effective in QA of abstract meaning that focus on imperceptibility and nonspecificity. For the future work, it is worth to fine-tune the embeddings from the pre-trained model in an end-to-end manner. Other resources, e.g., semantic graphs, are also worth considering to provide more information for machine comprehension of abstract meanings.

## Abstract

This paper presents the system developed by our team for Semeval 2021 Task 4: Reading Comprehension of Abstract Meaning. The aim of the task was to benchmark the NLP techniques in understanding the abstract concepts present in a passage, and then predict the missing word in a human written summary of the passage. We trained a Roberta-Large model trained with a masked language modeling objective. In cases where this model failed to predict one of the available options, another Roberta-Large model trained as a binary classifier was used to predict correct and incorrect options. We used passage summary generated by Pegasus model and question as inputs. Our best solution was an ensemble of these 2 systems. We achieved an accuracy of 86.22% on subtask 1 and 87.10% on subtask 2.

## 1 Introduction

There has been a lot of research in evaluating the performance of machine learning models to identify concrete concepts present in text and answer questions based on it (Hermann et al., 2015a). The organizers of ReCAM task at Semeval 2021 have provided a dataset to benchmark the models' performance on understanding the abstract concepts in the text in English language. The models are required to predict the missing words in a human written summary of the passage. This can help assess if the models can accurately capture the important concepts and meaning in the text.

The paper is organized as follows: In Section 2, we give a background on the problem and method that has been used, in Section 3, we present the proposed system architecture, in Section 4, we present the hyperparameters analysis done on the system, in Section 5, we present the results of the proposed architecture along with other approaches taken, and in Section 6, we conclude the paper.

## 2 Background

### 2.1 Dataset

The organizers provide two different datasets (Zheng et al., 2021) for two subtasks exploring two different definitions of abstractness (Spreen and Schulz, 1966; Changizi, 2008), *imperceptibility* and *nonspecificity*. Anything which can't be perceived is described as an *Imperceptible* concept (Example: culture, economy etc.) (Spreen and Schulz, 1966; Coltheart, 1981; Turney et al., 2011). *Nonspecificity*, as described by (Changizi, 2008), rather than looking at concrete things, focuses on generalizing the text (Example: hypernyms of words; vertebrate for whale). Subtask 3 explores the relationship between the two definitions.

### 2.2 Masked Language Modelling

Masked Language Models have played an important role in BERT (Devlin et al., 2019) and subsequent transformer models' success on different datasets. Masked Language Modelling is based on *Cloze* task (Taylor, 1953), which is described as filling the blanks in sentence using the surrounding context. Consider a Sequence  $\mathbf{S}$  containing  $n$  tokens ( $\mathbf{w}_1, \mathbf{w}_2, \mathbf{w}_3, \dots, \mathbf{w}_n$ ). In Masked Language Models, a token  $\mathbf{w}_t$  is replaced with a special token [MASK] and all the other tokens ( $\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_{t-1}, \mathbf{w}_{t+1}, \dots, \mathbf{w}_n$ ) are used to predict this token.

In our model, we use Roberta-Large's (Liu et al., 2019) Language Model (LMs), RobertaForMaskedLM, which randomly replaces 15% of tokens in a sequence and then tries to predict the masked word. Masked LMs perform better than left-to-right, right-to-left LMs, and concatenation of both. In a multi-layer Bidirectional LM, each word can indirectly see itself (from 2nd layer onwards) after the first layer, making the process redundant.

Recently, Pegasus model, pretrained on C4(Raffel et al., 2020) and HugeNews dataset, (Zhang et al., 2020) has shown state-of-the-art results for abstractive summarization on many summarization tasks (Narayan et al., 2018; Hermann et al., 2015b; Koupae and Wang, 2018). It has a transformer-based encoder-decoder architecture but has been trained with a novel self-supervised objective. It masks entire sentences in a corpus which are then generated later as one sequence capturing the abstractive summary.

### 3 System Overview

The key components in our proposed system are abstractive summarization of context using Pegasus, Roberta for Masked Language Modelling and Roberta for sequence classification. Algorithm 1 presents our system’s algorithm for predicting the option using the given context and masked question.

---

#### Algorithm 1 MLM + Sequence Classification

26:    end if
27:  end for
28:  return answer
29: end function

```

---

**Abstractive Summarization** We use pretrained Pegasus-XSum (Zhang et al., 2020; Narayan et al.,

2018) to capture the abstractive summary from context which relates closely to the task at hand. We also experimented by finetuning it for the given task, by giving the corpus as input and passing the text, obtained from question after replacing @placeholder with the correct option, as output. We further experimented with extracting three line summaries by splitting context into three parts and extracting summary for each.

**RobertaForMaskedLM** The task at hand can be converted into predicting the masked token by replacing the @placeholder in question with the [MASK] token. We use RobertaForMaskedLM to predict the masked token. To help the model get the context in question, we prepend the summary from Pegasus-XSum to the masked question text. To finetune the model, we train it by passing concatenation of summary and masked question as input and providing concatenation of summary and filling the question with correct blank as output. Once the model is trained, we use Huggingface’s (Wolf et al., 2020) pipeline to predict the top 5 words for filling the masked token. Out of five predictions, word which has the highest probability of filling the blank and which is present in the given options is selected as the answer.

**Roberta For Sequence Classification** In some of the cases, we observed that the predicted words weren’t present in the options. For handling such cases, we use Roberta for Sequence Classification. We convert the task into a binary classification task by filling the masked question with correct option and treating it as one class and by filling the mask with wrong options as another class. This leads to a class-imbalanced dataset (1:4 ratio). To handle this, we randomly selected equal number of wrong-option class. On the test set, option which achieves the highest softmax score out of all the given options, is selected as the answer.

### 4 Experimental Setup

All the experiments were conducted in a Google Colab system with 12GB RAM and T4-Nvidia GPU. We experimented with different settings in three components in our system: summary extraction, Masked Language Model (MLM) and handling cases when word predicted by MLM is not present in the options.

[CLS] Super ##league leaders Manchester Thunder maintained their 100 % start to the season with victory over Surrey Storm . Hertfordshire Ma ##ver ##icks suffered only their second Super ##league [MASK] of the season after Team Bath beat them 55 - 54 in a thrill ##ing round 13 match . [SEP]

Visualizing the top 10 most important words.

Figure 1: Saliency map

**Summary Extraction** To identify the role of summary in the task, we experimented with three settings: no summary for prediction, extracting a one line summary from Pegasus-XSum and extracting a three line summary from Pegasus-XSum. To get a three line summary, we broke the context into three equal parts and fed into the summary model. Extracting one-line summary performed best for both the subtasks.

**Finetuning RobertaForMaskedLM** For Masked Language Model (MLM) to work, its very important for the model to identify and understand the context. Using the entire context meant that for some cases, the input size would exceed the limit (512 tokens) for model. So, we experimented with two settings, one line summary prepended to question, and using context when number of tokens wouldn't exceed the limit and one line summary when it did. For an untrained MLM, the latter setting performed better. Also, by training the MLM, a further improvement of 4-5% was observed. The MLM is trained with a batch size of 2 using the Adam (Kingma and Ba, 2017) optimizer with a learning rate of 1e-5.

**Handling missing cases for Masked Language Modelling** In few of the cases it was observed that the top 5 predictions made by MLM were not found in options. For such cases, we experimented with two settings: to find a pair of prediction and option which has the highest cosine similarity using Spacy embeddings (Honnibal et al., 2020), or to predict options using Sequence Classification (correct option as class 0, incorrect options as class 1). Input for Sequence classification was concatenating one line summary with question in which @placeholder is replaced with the options. If the option used to replace @placeholder is correct, output class is 0 else 1. Using Sequence Classification worked better than cosine similarity. Also, Roberta-Large outperformed other transformer models for

sequence classification on this dataset. The sequence classification model is trained with a batch size of 8, sequence length of 128 and using the Adam (Kingma and Ba, 2017) optimizer with a learning rate of 1e-5.

## 5 Results

We have mentioned the accuracy of all the systems developed by us for subtasks 1 and 2 in Table 1 and 2. We have also plotted a saliency map in Fig. 1 (with AllenNLP(Gardner et al., 2017) demo tool) to visualize the importance of each token in the prediction of the masked word. The example input from training set is: "Superleague leaders Manchester Thunder maintained their 100% start to the season with victory over Surrey Storm. Hertfordshire Mavericks [MASK] only their second Superleague loss of the season after Team Bath beat them 55 - 54 in a thrilling round 13 match." The top 5 predictions by the transformer model for the masked token are: "suffered", "recorded", "experienced", "sustained", "had". The correct option is "suffered". This demonstrates the effectiveness of using summary as context and formulating the problem as masked language modeling task.

### 5.1 Error Analysis

Across the 2 subtasks, masked language model made predictions which were present as part of options for 87% of the data. We present error analysis of the MLM over here:

#### a. Capturing more than one meaning

**Context: (truncated)** ... said he was too young to swim and should have still been in his mother's care ..... mother failed to show ... It tends to be when there's quite stormy weather the pups will get into trouble and they do get very tired, very hungry and very dehydrated and they just wouldn't survive without assistance. ....

**Question:** A @placeholder baby grey seal who was rescued from the rocks at Corbiere in Jersey will be flown to the UK on Friday .

System Description	Subtask 1	Subtask 2
Roberta-Large as binary classifier with summary and question as input	72.69	73.20
T5 large with passage, question, options concatenated	57.20	57.85
Untrained Roberta Large with MLM objective	72.64	73.36
Untrained Roberta Large with MLM objective and cosine similarity of word embeddings in failed cases	77.76	77.95
Trained Roberta Large with MLM objective	81.30	82.23
Trained Roberta Large with MLM objective and cosine similarity of word embeddings for failed cases	85.10	86.03
<b>Trained Roberta Large with MLM objective and Roberta binary classifier for failed cases</b>	<b>87.25</b>	<b>88.40</b>

Table 1: +-Accuracy of experimental setups on validation set

System Description	Trained On	Evaluated On	
		Subtask-1	Subtask-2
Trained Roberta Large with MLM objective and cosine similarity of word embeddings for failed cases	Subtask-1 Subtask-2	83.20 73.92	77.24 85.37
<b>Trained Roberta Large with MLM objective and Roberta binary classifier for failed cases</b>	Subtask-1 Subtask-2	<b>86.22</b> 78.56	82.44 <b>87.10</b>

Table 2: Accuracy of experimental setups on Test set

**Correct Option:** lone

**Predicted Options:** rare, stranded, distressed, tiny

For this particular example, the number of tokens didn't exceed 512 and entire context was used. As suggested by the context, its a rare event that a pup would be found without mother, stranded since mother didn't show or couldn't find the pup and is distressed as well.

#### b. Failure to capture information in one line summary

**Context: (truncated)** ... "I am very saddened by this, but what matters most now is the well-being of our kids," he told People magazine. "I kindly ask the press to give them the space they deserve during this challenging time." Jolie, 41, filed for divorce from Pitt, 52, citing irreconcilable differences on Monday. Her lawyer, Robert Offer, said the decision had been made "for the health of the family". .....

**Summary:** Actor Brad Pitt has said he is "very saddened" after his wife Angelina Jolie filed for divorce.

**Question:** Actor Brad Pitt has said he is " very saddened " that his wife Angelina Jolie has filed for divorce and has asked for @placeholder on their children 's behalf.

**Correct Option:** privacy

**Predicted Options:** support, custody, forgiveness, protection, counseling

For this particular example, 1-line summary was used and as evident no information pertaining to children could be located in it. Our best guess for these predictions are based on the data on which model is trained and is pretty much commonsense seeing the presence of "custody" and "support".

#### c. More than one correct answer

**Context:** . A lunar eclipse is when the Moon is fully covered by the Earth's shadow. It is the second one this year. The Moon's surface showed up coppery orange or red because the light from all the Earth's sunsets and sunrises were reflected on to it during the eclipse. In this timelapse, the Moon can be seen re-appearing as the shadow moves away.

**Question:** A total lunar eclipse has been visible across much of the Americas and Asia , resulting in a @placeholder " Blood Moon " .

**All Options:** bizarre, special, dramatic, lunar, visible

**Correct Option:** dramatic

**Predicted Options:** rare, special, spectacular, unique, partial

With a context being concise and straightforward, it can also be termed as special or rare other than dramatic. As per our algorithm, our system predicted special.

## 6 Conclusion

We have described the systems developed by us to solve the Reading Comprehension challenge at SemEval 2021. In our best performing submission, we framed the problem as a masked language modeling task. We used the predictions from a separately trained binary classifier when the above system failed to generate words which were not part of the options. Our models were able to achieve high accuracy with a relatively simple setup. We were ranked 11th out of 23 participants in subtask 1 and 12th out of 28 participants in subtask 2. As part of future work, we aim to use information from knowledge bases such as ConceptNet. This can help extract broader concepts related to the words predicted by the masked language model.

## Abstract

This paper presents our systems for the three Subtasks of SemEval Task4: Reading Comprehension of Abstract Meaning (ReCAM). We explain the algorithms used to learn our models and the process of tuning the algorithms and selecting the best model. Inspired by the similarity of the ReCAM task and the language pre-training, we propose a simple yet effective technology, namely, negative augmentation with language model. Evaluation results demonstrate the effectiveness of our proposed approach. Our models achieve the **4th** rank on both official test sets of Subtask 1 and Subtask 2 with an accuracy of 87.9% and an accuracy of 92.8%, respectively<sup>1</sup>. We further conduct comprehensive model analysis and observe interesting error cases, which may promote future researches.

## 1 Introduction

Past decades have witnessed the huge progress of representation learning in Natural Language Processing (NLP). With pre-trained language models, machine reading comprehension (MRC) models can extract answers from given documents and even yield better performance than humans on benchmark datasets such as Squad (Rajpurkar et al., 2016). However, these successes sometimes lead to the hype in which these models are being described as “understanding” language or capturing “meaning” (Bender and Koller, 2020). Note that the intention of MRC is letting the systems read a text like human beings, extracting text information and understanding the meaning of a text then answering questions, which means the systems can not only conclude the semantic of the text but also comprehend the abstract concepts under the constraint of

general knowledge regarding the world (Wang and Jiang, 2016). Nevertheless, little works as well as benchmarks focus on this direction.

**SemEval 2021 Task4** (Zheng et al., 2021) is an MRC task that focuses on evaluating the model’s ability to understand abstract words. Reading Comprehension of Abstract Meaning (ReCAM) task is divided into three Subtasks including **Subtask 1**: ReCAM-Imperceptibility, **Subtask 2**: ReCAM-Nonspecificity and **Subtask 3**: ReCAM-Intersection. Unlike previous MRC datasets such as CNN/Daily Mail (Hermann et al., 2015), SQuAD (Rajpurkar et al., 2018), and CoQA (Reddy et al., 2019) that request computers to predict concrete concepts, e.g. named entities. This task challenges the model’s ability to fill the abstract words removed from human-written summaries based on the English context.

Note that this task’s input format is similar to the MLM pre-training task of BERT (Devlin et al., 2019), which aims to predict the mask tokens. Pre-trained language models (PLMs) such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2020), DeBERTa (He et al., 2021) have achieved success on MRC tasks. Inspired by this, we introduce a simple yet effective method, namely, Negative Augmentation with Language model (NAL) in **SemEval 2021 Task4**. Specifically, we augment the answer distribution with an additional negative candidate from the mask language model’s prediction. Previous work (Petroni et al., 2019; Zhou et al., 2020) indicates that the pre-trained language model has already captured much world knowledge. Thus, we argue that knowledge can help guide the model training and identify those ambiguous abstract meanings. Further, we introduce other technologies such as label smoothing, domain-adaptive pre-training in our system. We describe the detailed approaches used for the Subtasks in Section 3.

Equal contribution and shared co-first authorship.

<sup>1</sup>Our implementation is publicly available at <https://github.com/zjunlp/SemEval2021Task4>

We conduct comprehensive experiments in Section 3, and we achieve the 4th system for Subtask 1: ReCAM-Imperceptibility and the 4th system for Subtask 2: ReCAM-Nonspecificity in the leaderboard. In our experiments, we observe that PLMs without fine-tuning can easily get 60+% accuracy on both Subtask 1 and Subtask 2, demonstrating that pre-trained language models already capture some abstract meanings. We further find that our negative augmentation with language model can improve the performance with 2.6% in Subtask 1 and 4.6% in Subtask 2. Finally, we conduct error analysis to promote future researches.

## 2 Background

Machine reading comprehension (MRC) has received increasing attention recently, which is a challenging task. According to the type of the answer, reading comprehension tasks can be divided into four categories (Chen, 2018): 1) Cloze-style: The question contains a "@placeholder," and the system must choose a word or entity from the set of candidate answers to fill in the "@placeholder" to make the sentence complete. 2) Multiple choice: In this type of task, Choosing a suitable answer from K sets of given answers. This answer can be one word or a sentence. 3) Span prediction: This kind of task is also called (Extractive question answering), which requires the system to extract a suitable range of text fragments from a given original text based on the question as to the answer. 4) Free-form answer: This task allows the answer to be any type of text, which is necessary to mine deep-level contextual semantic information according to a given question and a collection of candidate documents, and even combine multiple articles to give the best answer.

In **SemEval 2021 Task4**, it requires the system to have a strong ability of reading comprehension not only because the task is the cloze-style format as mentioned above but also the abstract words in answers. There are two definitions of abstract words: imperceptibility and nonspecificity. Concrete words refer to things, events, and properties that we can perceive directly with our senses (Spreeen and Schulz, 1966; Turney et al., 2011). Compared to concrete words like "trees" and "red," abstract words for imperceptibility are created by humans instead of pointing the things in the natural world. For example, as shown in Table 1, "want" and "achieve" means a person's attitude towards

Table 1: Examples of the **SemEval 2021 Task 4**. Given a passage and a question, the model needs to pick the best one from the five candidates to replace @placeholder.

something and a person's accomplishment about something. Meanwhile, the abstract words for non-specificity can be described as upper words. By determining whether one word can generalize another word, we can get dictionaries of different levels. The words with higher levels are the non-specificity words. Compared to concrete concepts like groundhog and whale, hypernyms such as vertebrate are regarded as more abstract (Changizi, 2008).

The difference between Subtask 1 and Subtask 2 is the definition of abstract words. So the input of both Subtask 1 and Subtask 2 are the same. The input of these tasks are shown in Table 1, it can be represented as a triple  $\langle P, Q, A \rangle$ , where  $P = s_1, s_2, \dots, s_m$  is the passage from CNN daily (Hermann et al., 2015),  $Q$  is a human-written summary based on the passage with one abstract word replaced by "@placeholder" and  $A$  is a set of candi-

date abstract words for filling in the ”@placeholder” in the question.

### 3 System Overview

#### 3.1 Model Design

Recently, with the development of the large Pre-trained Language Models (PLMs), such as GPT (Radford et al., 2018), BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2020), DeBERTa (He et al., 2021), have overwhelm the NLP community (Zhang et al., 2020c). The powerful semantic feature extraction capabilities of the PLMs make us only need to make better use of the BERT-like model itself for downstream tasks instead of adding different layers to the model.

Similar to the normal multi-choice task, we have five candidates, one passage, and one question per sample. Here we leverage PLMs as encoders to capture the global context representation about the passage, question, and answer. Then a decoder is used to determine the score of each  $\langle P, Q, A \rangle$  pair. Since we get  $A_1, \dots, A_n$   $n$  answers, for every passage, we construct  $n$  input samples as  $[Q - A_i; P]$ , the concatenation of  $Q - A_i$  and  $P$ . Because the question is the summary with an abstract word removed. We construct  $Q - A$  by replacing ”@placeholder” with the option from the candidate set instead of concatenating  $Q$  and  $A$ . After encoding all  $n$  inputs for a single passage, we get the global representations  $T_i$  for different options in the candidate set. During fine-tuning PLMs, the first special token [CLS] represents the global meaning of the whole input. We use an dense decoder layer to compute the score for all  $T_i$ , the calculation of score is as follow:

$$T_i = PLM(Q - A; P) \quad (1)$$

$$score_i = \frac{\exp(f(T_i))}{\sum_{i'} \exp(f(T_{i'}))} \quad (2)$$

where the  $[Q - A; P]$  is the input constructed according to the instruction of PLMs and MRC tasks, and the  $T_*$  is the final hidden state of the first token [CLS]. The candidate answers with higher scores will be identified as the final prediction.

Since previous research (Gao et al., 2020; Yang et al., 2019) demonstrate that there exists a gap between language model pre-training and fine-tuning the models in the downstream task and inspire by the similar task definition as MLM, we introduce

Figure 1: The procedure of Negative Augmentation with Language Model (NAL).

the negative augmentation with language model mechanism (Section 3.2). Note that the additional label will enhance the discriminability of the abstract meanings in a contrastive manner. In other words, the model is encouraged **NOT** to generate those abstract tokens from the language model, but the golden candidates from the given documents. We further introduce the label smoothing (Section 3.3), which can enhance the model performance. Finally, we leverage task-adaptive pre-training (Section 3.4) inspired by (Gururangan et al., 2020) to obtain better performance.

#### 3.2 Negative Augmentation with Language Model

Inspired by the same format of MLM and this task, we first conduct a toy experiment to test whether a PLM can get the right answer without any supervised signal. Firstly we replace the ”@placeholder” with [MASK] to reconstruct the input and ask the BERT model with MLM head to predict the word token at the [MASK]. Then we calculate the similarity between the word model predict and the options from the set of candidate answers. We set the option with the highest similarity score as the model’s choice. Then we find that the BERT model without any fine-tuning gets **60+%** accuracy in both Subtask 1 and Subtask 2. The result above shows that PLMs have the ability to predict abstract words, and those predicted words can be leveraged as negative candidates in the fine-tuning period.

Note that huge languages have quantities of parameters; the PLMs are able to store much knowledge through pre-training tasks. However, [MASK] is not used when fine-tuning the model for downstream tasks; how to use the knowledge stored by the model on pre-training tasks more explicitly on downstream tasks has become a hot topic of current research. Motivated by this, we try to bridge the gap between pre-train and downstream tasks. Inspired by the contrastive learning (Chen

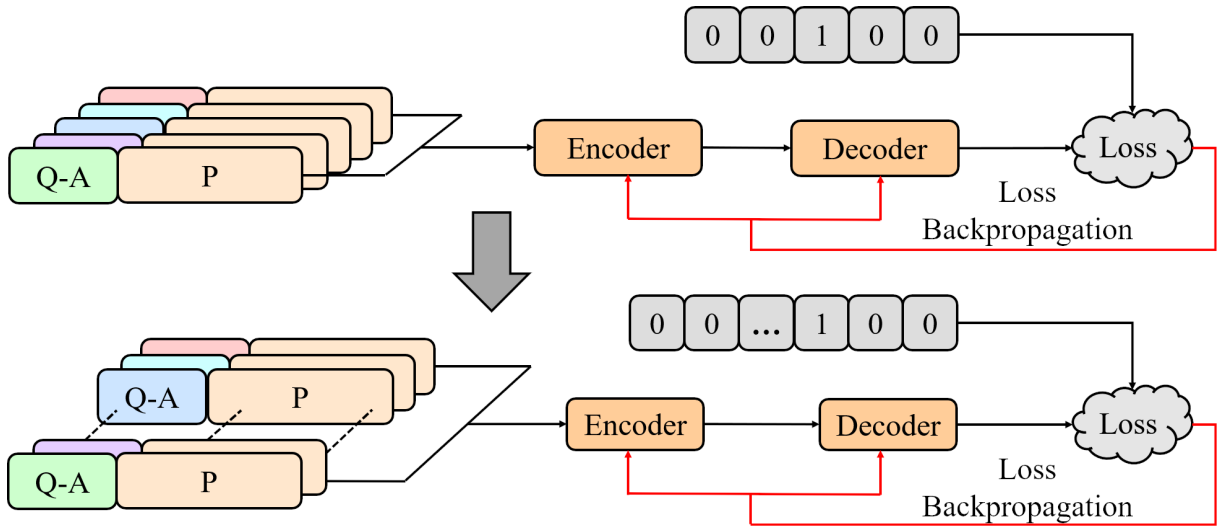

Figure 2: System overview (Best viewed in color.). The top of the Figure refers to the normal fine-tuning of multi-choice models, ignoring the form of pre-training tasks. While the bottom of the Figure refers to our system with Negative Augmentation with Language Model (NAL), which uses the abstract words predict by the original PLM as negative candidates to augment fine-tuning.

et al., 2020; Robinson et al., 2020) as stronger negative samples will help the model learning with better performance, we introduce our negative augmentation with language model method. Specifically, we let the PLMs predict the ”@placeholder” replaced with [MASK] token to generate negative candidates. Thus, we can leverage those negative words that may mislead the models to help train the models. Formally, we have:

$$P = p(m_i|\theta, [Q-A; P]), m_i \in [1, 2, \dots, |V|] \quad (3)$$

where  $P$  are the distribution of words model, predict,  $m_i$  is the token in the vocabulary, and  $|V|$  is the total number of the vocabulary. We can use the distribution to get the top confusing words to augment our models, which is described in Figure 2. Due to the limitation of GPU, we add the most possible word to augment our models.

### 3.3 Label Smoothing

Label smoothing is a well-known ”trick” to improve the model’s performance effectively. It encourages the activations of the penultimate layer to be close to the template of the correct class and equally distant to the templates of the incorrect classes (Müller et al., 2019). With more options than the original dataset by the approach mentioned in Section 3.2, label smoothing will magnify our method’s effect while fine-tuning the models. Suppose the output of the final layer and softmax layer

as follows:

$$p_k = \frac{e^{x^T w_k}}{\sum_{l=1}^L e^{x^T w_l}} \quad (4)$$

where  $p_k$  is the likelihood the model assigns to the  $k$ -th class,  $w_k$  represents the weights and biases of the last layer.  $x$  is the vector containing the activations of the penultimate layer of a neural network concatenated with ”1” to account for the bias. let us see the equitation about the cross entropy loss.

$$L = - \sum_{c=1}^M y_k \log(p_k) \quad (5)$$

The cross-entropy formula without Label smoothing only focuses on whether the positive example is true and does not pay attention to the negative examples’ relationship. We make the soft  $y$  as follows:

$$y_i = \begin{cases} (1 - \varepsilon), & \text{right answer} \\ \frac{\varepsilon}{K-1}, & \text{wrong answer} \end{cases} \quad (6)$$

We set  $\varepsilon$  as 0.1 in our models.

### 3.4 Task-Adaptive Pre-training

The BERT-like model is pre-trained in the general domain corpus such as Wikipedia. Since passages mainly come from CNN daily, the data distribution may be quite different from pre-training data. Therefore, we utilize task-adaptive pre-train BERT with masked language model and next sentence

Statistics / Dataset	Subtask 1	Subtask 2
# Train	3,227	3,318
# Trail	1,000	1,000
# Dev	837	851
# Test	2,025	2,017
Avg. # Length Per Passage	262	418

Table 2: Statistics of the **SemEval 2021 Task 4** dataset.

prediction tasks on the domain-specific data. Task-adaptive pre-training not only makes the model better fit the distribution in the domain but also helps the model to predict good negative words to enhance the original dataset, which is described in Section 3.2. We take two different approaches for task-adaptive pre-training as follows:

- 1) In-domain pre-training, we use the source data: CNN Daily to task-adaptive pre-training our base models(Sun et al., 2020).
- 2) Within-task pre-training, practically we replace the "@placeholder" with the correct answer and put the same input format as the fine-tuning steps, which is  $[Q - A; P]$  (Gururangan et al., 2020).

## 4 Experimental Setup

### 4.1 Dataset

In Subtask 1, the training/trail/development/test contains 3, 227/1, 000/837/2, 025 instances. In Subtask 2, the training/trail/development/test contains 3, 318/1, 000/851/2, 017 instances. The overall statistics can be found in Table 2.

### 4.2 Pre-processing

For data pre-processing, we use the byte-level BPE encoding (Sennrich et al., 2016), and the official vocabulary contains more than fifty thousand byte-level tokens. All tokens are stored in MERGES.TXT, while VOCAB.JSON is a byte-to-index mapping. Generally speaking, the higher the frequency, the smaller the byte index. Since the average length of the passage about Subtask 1 and Subtask 2 is 262 and 418, we divide those long context paragraphs. We limit the max number of tokens in an input sample  $[Q - A; P]$  to 256 for our system. Statically, 60% of the paragraphs exceeds the 256 tokens (including the special tokens like  $[CLS]$ ,  $[SEP]$  and so on. For these input samples, we divide them into new input samples with at most 256 tokens. To be more specific, we divide the passage to different inputs with the same question and answer.

## 4.3 Hyper-parameter Setting

Our system is implemented with PyTorch (Paszke et al., 2019) and we use the PyTorch version of the pre-trained language models<sup>2</sup>. We employ RoBERTa, ALBERT, and DeBERTa large models as our PLM encoder. We use AdamW optimizer (Loshchilov and Hutter, 2018) to fine-tune the models. We set the batch size to 1, and the max length of input to 256 for RoBERTa, 128 for ALBERT.

Usually, the batch size has a significant influence on the BERT-like model; due to the limit of GPU memory, we use gradient accumulation in our training steps. We set the gradient accumulation step as 32, which means the formal number of batch sizes is 32 in training. We pick the best learning rate from the dev set, fine-tuning the RoBERTa, ALBERT, DeBERTa with the learning rate of  $9 \times 10^{-6}$ ,  $1 \times 10^{-5}$  and  $1 \times 10^{-5}$  respectively. We set the number of epoch to 8 for ALBERT and 12 for RoBERTa and DeBERTa. Furthermore, we save the best model on the validation set for testing during training. Because the formats of both Subtask 1 and Subtask 2 are the same, we set the same batch size and max length of the input sequence for training.

## 5 Results

### 5.1 Subtask 1 Results

On Subtask 1, the ReCAM-Imperceptibility task, the evaluation results are illustrated in Table 3. We set the three baseline models: RoBERTa<sub>Large</sub>, DeBERTa<sub>Large</sub>, and ALBERT<sub>xxLarge</sub>. RoBERTa<sub>Large</sub> + NAL, DeBERTa<sub>Large</sub> + NAL, and ALBERT<sub>Large</sub> + NAL denotes the language model with our proposed negative augmentation with language model. Ensemble refers to the ensemble model of the three models as mentioned above with all strategies. We find that ALBERT achieves better performance in Subtask 1 but fails to get good performance in Subtask 2, while DeBERTa and RoBERTa have better performance in Subtask 2. Comparing with the original RoBERTa, DeBERTa, and ALBERT models, each model is hugely improved with NAL by about 2.1% accuracy. We further observe that DeBERTa and RoBERTa, which have the same architecture, obtain better performance than ALBERT in the dev and test sets. We think the possible reason is that ALBERT uses layer weight sharing, which

<sup>2</sup><https://github.com/huggingface/transformers> (version 3.3.0)

Model	Dev	Test
<i>Baseline</i>		
RoBERTa <sub>Large</sub>	83.3	-
ALBERT <sub>xxLarge</sub>	85.1	-
DeBERTa <sub>Large</sub>	84.1	-
<i>Ours</i>		
RoBERTa <sub>Large</sub> + NAL	85.9	86.1
ALBERT <sub>xxLarge</sub> + NAL	86.2	85.6
DeBERTa <sub>Large</sub> + NAL	86.7	86.8
Ensemble	<b>88.5</b>	<b>87.9</b>

Table 3: Results (Accuracy) on Subtask 1.

Model	Dev	Test
<i>Baseline</i>		
RoBERTa <sub>Large</sub>	86.7	-
ALBERT <sub>xxLarge</sub>	84.3	-
DeBERTa <sub>Large</sub>	87.7	-
<i>Ours</i>		
RoBERTa <sub>Large</sub> + NAL	91.1	89.7
ALBERT <sub>xxLarge</sub> + NAL	89.3	88.6
DeBERTa <sub>Large</sub> + NAL	91.3	90.3
Ensemble	<b>93.7</b>	<b>92.8</b>

Table 4: Results (Accuracy) on Subtask 2.

reduces the model’s generalization ability in reading comprehension, especially the abstract words meaning. Finally, the ensemble of the best model of RoBERTa, DeBERTa, and ALBERT lead to a significant improvement (**4.3%** accuracy) compared with baselines, which is also our final submission to the leaderboard.

## 5.2 Subtask 2 Results

On Subtask 2, the ReCAM-Nonspecificity task, the experiment results are showed in Table 4. Similar to the models in Subtask 1, we choose RoBERTa, DeBERTa and ALBERT as our baseline models. All RoBERTa<sub>Large</sub> + NAL , ALBERT<sub>xxLarge</sub> + NAL and DeBERTa<sub>Large</sub> + NAL are the models with negative augmentation with language model. Ensemble refers to the ensemble model of RoBERTa, DeBERTa, and ALBERT with all strategies. We notice that our proposed mechanism brings significant improvement (averaging **4.3%** of the accuracy score) compared with baselines, demonstrating the effectiveness of our proposed strategies such as negative augmentation with a language model, label smoothing, and task-adaptive pre-training. We observe

that ensemble approach of three enhanced models (RoBERTa<sub>Large</sub> + NAL, ALBERT<sub>xxLarge</sub> + NAL and DeBERTa<sub>Large</sub> + NAL) obtain the best accuracy of **92.8%** at test set, which is also our final submit to the leaderboard.

## 5.3 Subtask3 Results

Subtask3 focuses on the model’s transferability. During the evaluation period, we use the data on Subtask 2 to evaluate the models trained on the Subtask 1 and vice versa. We obtain the 82% accuracy of the model trained on Subtask 1 and evaluated on Subtask 2 on the dev set.

During experiments for all tasks, we have tried to use different decoders like MLP and other network architecture. Eventually, we find that it does not help to improve the system’s performance. An explanation is that the pre-trained language models (PLMs) have already captured global contextual sentence meaning at the [CLS] token.

## 5.4 Further Analysis

### 5.4.1 Analysis of Negative Augmentation with Language Model

During our experiments, we conduct case studies to figure out how our method of NAL helps the model to boost performance. From Table 5, we notice that the original PLM considers using the "all", "half" as its choice instead of "parts". Although fine-tuned on the downstream task, the baseline model still choose "half". In our NAL method, we add some misleading negative words to help models correct the knowledge learned from the pre-training task.

### 5.4.2 Analysis of Passage Length

In usual MRC tasks, the length of the passage is a key factor for the models to solve the problems. We conduct experiments to analyze the performance regarding different lengths of passage. Contrary to the common assumption, from Figure 3 and Figure 4, we observe that the instances with long passage obtain better performance. We think that abstract mean understanding may need comprehensive context information from the long sentence, and we will conduct further analysis in future works.

### 5.4.3 Case Study

We select four kinds of different types of error cases to promote further researches. We classify the examples according to the main causes (pre-training, fine-tuning, and so on) of the error. We

Example	
<b>Question:</b>	The Aurora Borealis, better known as the Northern Lights, was spotted across @placeholder of England on Sunday.
<b>Answer set</b>	{(A) millions, <b>(B) parts</b> , (C) half, (D) isle, (E) remains}
<b>NAL set</b>	{all, half, <b>parts</b> }
<b>Baseline</b>	(C) half
<b>Model with NAL</b>	(B) parts
<b>Question:</b>	The BBC is providing live coverage of the Scottish National Party conference in Glasgow. This live @placeholder has finished .
<b>Answer set</b>	{(A) results, (B) recording, <b>(C) event</b> , (D) action, (E) center}
<b>NAL set</b>	{blog, recording , stream}
<b>Baseline</b>	(B) recording
<b>Model with NAL</b>	(C) event

Table 5: We can clearly see the negative options can help the model better understand the abstract meaning in the passage and question. Answers are **bold** in the Table.

Figure 3: Results (Accuracy) on Subtask 1 with the length of passage.

Figure 4: Results (Accuracy) on Subtask 2 with the length of passage.

think it will help us better understand what the model learns from pre-training and fine-tuning.

### Case 1 - Influenced by the original pre-training task

- **Passage:** "...found the United States to have the highest number of sleep deprived students, with 73% of 9 and 10 year olds and 80% of 13 and 14 year olds identified by their teachers as *being adversely affected*. The BBC's Jane O'Brien reports."
- **Question:** Sleep deprivation is a significant hidden factor in lowering the @placeholder

of school pupils , according to researchers carrying out international education tests .

- **Answer:** (A) morale (B) IQ (C) mortality (D) closure (E) achievement
- **Negative augmented choice:** (F) intelligence
- **Right Option:** (E) achievement
- **Wrong Option:** (B) IQ
- **Potential causes:** After pre-training on the large general domain corpus, PLMs have a huge bias on predicting the [MASK] token. Just like the "IQ" model predict in the "@placeholder". Even after fine-tuning, our models still cannot recognize the strong evidence "being adversely affected". In our daily life, we wouldn't hold that being adversely affected by lack of sleep can lead to a decrease in IQ. We usually say that lack of sleeping may lower one's achievement in the future.
- **How to help models?** To prevent the model from relying too much on pre-training tasks, we create more negative samples to help the model to understand what is wrong or right about the abstract words.

### Case 2 - Adverse affected by fine-tuning

- **Passage:** " 17 May 2017 Last updated at 12:44 BST Adrien Gulfo, wearing red, who plays for the Swiss side Pully Football, tried to clear the ball away from his goal with a spectacular bicycle kick. Unfortunately for him it all went very wrong - watch the video... There was a happy ending to the story for Gulfo though, Pully went through to the cup final on

penalties after the match finished 3-3.”

- **Question:** You won’t believe this own goal that was @placeholder in the Swiss lower league !
- **Answer:** (A) scored (B) born (C) eliminated (D) closed (E) beaten
- **Negative Augmented Choice:** (F) scored (model predict ”scored.” Because it is the right answer, so we choose another choice ”played” as an augmented choice. )
- **Right Option:** (A) scored
- **Wrong Option:** (E) beaten
- **Potential Causes:** It is quite weird that the original PLMs can predict the right answer, but fail to make it after fine-tuning. We suppose that in the process of fine-tuning, the inconsistency of abstract vocabulary prediction and the interference of other vocabulary caused the model’s effect in some cases to decrease instead.
- **How to help models?** We could use our approach of NAL to increase the weight of the knowledge learned in the pre-training task or leverage external knowledge (Zhang et al., 2019, 2020b; Yu et al., 2020; Zhang et al., 2020a).

### Case 3 - Obscure abstract word meaning

- **Passage:** ” ...Mr Habgood said: ”We’re pretty sure it will be popular because it was when East Street was closed for other reasons and we want to make it a friendlier place to be. ”It does fit with our larger objectives to improve the town and make it safer for cyclists and pedestrians.” ...”
- **Question:** Three busy town center streets are to be pedestrianised in a bid to improve @placeholder for shoppers and cyclists .
- **Answer:** (A) opportunities (B) services (C) quality (D) disruption (E) safety
- **Negative Augmented Choice:** (F) access
- **Right Option:** (E) safety
- **Wrong Option:** (B) services
- **Potential Causes:** Due the limit of GPU memory, we cannot put the long passage into the model once a time. So during the training, the model can only see a small chunk of the passage, so that it cannot get the global representation of the passage.
- **How to help models?** We chunk those long sentences with the approach of the sliding window to help the model understanding the

whole passage.

### Case 4 - Hypernyms is not always right

- **Passage:** ” North Wales Fire and Rescue Service was called to Express Linen Services on Vale Road in Llandudno Junction just before 19:30 GMT on Thursday. North Wales Police said a man was treated at the scene for smoke inhalation. Police have asked people to avoid the area...”
- **Question:** A number of @placeholder have been evacuated as firefighters tackle a blaze at a commercial laundry firm ’s premises in Conwy county.
- **Answer:** (A) families (B) properties (C) water (D) disruption (E) vehicles
- **Negative Augmented Choice:** (F) homes
- **Right Option:** (B) properties
- **Wrong Option:** (A) families
- **Potential Causes:** Hypernyms is the main focus of Subtask 2, the model may consider the ”families” as the upper level of the ”people” occur in the passage and choose the ”(A) families” instead of the right answer ”(B) properties”.
- **How to help models?** We try to use the proposed NAL to add more abstract words learned from the pre-training to mitigate this issue.

## 6 Conclusion

This paper presents our system design for the SemEval 2021 Task4. We propose a simple yet effective method called negative augmentation with language model. Comprehensive experiments demonstrate the effectiveness of our proposed approach. We also conduct case studies and investigate why the model fails to obtain the correct prediction.

Note that language models are pre-trained from the huge corpus; recently, researchers have identified the bias in the language model, which may mislead the model prediction. Our proposed negative augmentation with language model can help the model better discriminate candidates in fine-tuning, thus boost the performance. From another perspective, as depicts in Section 3.2, the language model without any fine-tuning gets **60+%** accuracy in both Subtask 1 and Subtask 2. This indicates that bias exists in the datasets (Part of the abstract meaning can be obtained from the language model). More strong benchmarks should be constructed in the future.

## 7 Acknowledgments

We want to express gratitude to the anonymous reviewers for their hard work and kind comments. This work is funded by 2018YFB1402800/NSFC91846204/NSFCU19B2027.

## Abstract

This paper describes the winning system for subtask 2 and the second-placed system for subtask 1 in SemEval 2021 Task 4: Reading Comprehension of Abstract Meaning. We propose to use pre-trained ELECTRA discriminator to choose the best abstract word from five candidates. An upper attention and auto denoising mechanism is introduced to process the long sequences. The experiment results demonstrate that this contribution greatly facilitates the contextual language modeling in reading comprehension task. The ablation study is also conducted to show the validity of our proposed methods.

## 1 Introduction

Reading Comprehension of Abstract Meaning (ReCAM) (Zheng et al., 2021) is a cloze-style task, which takes a document and related human written abstract with one word replaced by a placeholder as input. The model is required to choose the best word from five candidates. The ReCAM consists of three subtasks. In subtask 1 and 2, participating systems are required to choose the best imperceptible concept and hyper-nyms concepts word respectively. Subtask 3 aims to evaluate performance of a system trained on one definition and test on the other.

Traditional cloze-style reading comprehension model (SA reader) (Kadlec et al., 2016) uses attention to directly pick the answer from the context, which makes model incapable to answer the question where the answer does not appear in passage. Furthermore, GA reader (Dhingra et al., 2017) adopts multi-hop attention mechanism to build query-specific representation of answer for ranking the candidates which is not part of passage.

Pre-trained language models (Radford et al., 2018; Devlin et al., 2019; Yang et al., 2019; Lan et al., 2020) have been widely adopted for context modeling in many Natural Language Processing

tasks. These models are pre-trained on huge corpora with plain texts and can better model contextual dependencies of tokens, thus enhance the performance of downstream approaches. As described in (Lai et al., 2017; Zhang et al., 2020; Chen et al., 2019; Zhu et al., 2018), they improved the performance of single-choice reading comprehension tasks by introducing pre-trained model, but they takes excessive memory for concatenating each option with the question and the passage.

GPT2 (Radford et al., 2018) has outperformed the SOTA result on cloze-style task CBT (Hill et al., 2016). As stated in (Radford et al., 2018), GPT2 computes the probability of each choice and the rest of the sentence conditioned on this choice according to the pre-trained model, the answer is the choice with highest probability. GPT2 outperforms RNN-based models without fine-tuning on CBT task, we assume that pre-trained language model has better potential to address the cloze-style problem than fine-tuning the pre-trained model with an additional ranking network.

The most relevant work to our model is Pattern-Exploiting Training (PET) (Schick and Schütze, 2020a,b), which proposed to reformulate the sentence classification task to cloze-style task with defined golden answer word as supervising signal. The comparison between PET and our proposed method is reported in section 5.

Different with PET, We propose a novel Auto Denoising Discriminator for Abstract Concept in reading comprehension (ADDAC) by fine-tuning the pre-trained discriminator of ELECTRA (Clark et al., 2020). Auto Denoising is introduced while processing long sequences. By fine-tuning the pre-trained model on its own structure with the original pre-training loss, the tasks results is significantly improved even with small train dataset, we suppose the representations stored in the pre-trained model has been maximum reserved in this way.

## 2 Background

### 2.1 Task Description

The task intends to answer a cloze-style question, the answer to which depends on the understanding of a context document provided with the question. The model is also provided with a set of possible answers from which the correct one is to be selected. This can be formalized as follows:

The training data consists of tuples  $(q, d, a, A)$ , where  $q$  is an abstract sentence of document  $d$  and one word in  $q$  is replaced with a placeholder.  $A$  is a set of possible options and  $a \in A$  is the golden answer. Both  $q$  and  $d$  are sequences of words and golden answer  $a$  does not appear in the article  $d$ .

### 2.2 ELECTRA vs ALBERT

Since the success of BERT (Devlin et al., 2019), pre-trained language models have adopted a large amount of parameters to achieve better modeling performance. ALBERT (Lan et al., 2020) uses factorized embedding parameterization and cross-layer parameter sharing to greatly reduce the amount of model parameters and achieved SOTA in multiple natural language understanding task. ALBERT outperforms other pre-trained language models which is trained by MLM(masked language model) in combination with PET method for this task.

ELECTRA (Clark et al., 2020) proposed the RTD (replaced token detection) task with adversarial learning as an alternative to the MLM task. A smaller generator is used to replace the special token [MASK] in training samples, and then a discriminator is trained to predict each word in the input is real or generated by generator. In section 3.1, we will elaborate the details about our proposed discriminator mechanisms based on ELECTRA. The performance comparison between ALBERT with PET and our proposed discriminator model on ReCAM task is reported in Section 5.

## 3 System overview

### 3.1 Pre-trained Discriminator

We approach the competition tasks as cloze-style task, which can be reformulated to masked language modeling (Devlin et al., 2019) problems. As shown in Figure 1, we replace placeholder with golden and negative options in question  $q$  denoted as  $q_A$ , which is further concatenated with corresponding document  $d$  in pre-trained model input

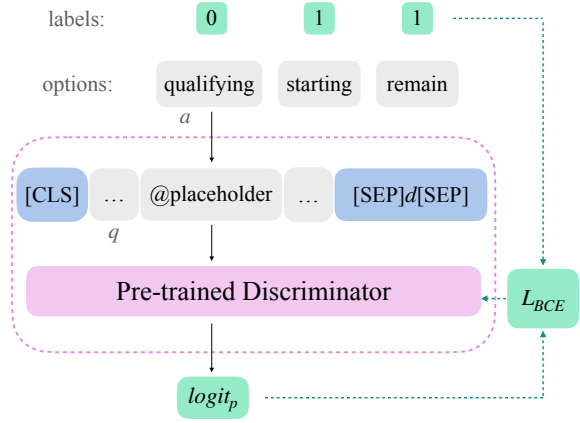

Figure 1: Discriminator overview, the placeholder in  $q$  is replaced by  $a$  which is one of candidate options, the label of golden option is 0 followed the ELECTRA pre-training setting.

style ( $[CLS]q_A[SEP]d[SEP]$ ). We ignore the part of sequence which exceed the maximum length of input sequence. The input sequence is forward to ELECTRA discriminator and the hidden states are calculated by Equation 1

$$H_{q_A} = F([q_A; d]) \quad (1)$$

$$\text{logit}_p = D(H^p) \quad (2)$$

where  $F$  is the pre-trained 24-layer transformers and  $D$  is a linear layer which classify the hidden states of replaced word from ELECTRA Discriminator.  $H_{q_A} \in \mathbb{R}^{N \times d}$  are the hidden states of input sequence, in which  $N$  and  $d$  are the maximum length of input sequence and the dimension of hidden states. Then we only use the hidden states of placeholder  $H^p \in \mathbb{R}^d$  selected from  $H_{q_A}$  as the input to  $D$ .  $BCE$  (Binary Cross Entropy) loss, which measures the Binary Cross Entropy between the golden label and the output, is used for binary classification as Equation 3.

$$L_{BCE} = BCE(\text{Sigmoid}(\text{logit}_p), l_p) \quad (3)$$

where  $l_p$  is the binary label of option word (replacing placeholder in input sequence). The label is set to 0 for golden option, 1 for negative options, which is the same as ELECTRA pre-training setting (Clark et al., 2020). While in inference, the option with lowest  $\text{logit}_p$  is regard as the right answer to the question. The experiment results show that discriminator outperforms the ranking and PET implementation on this task (see section 5).

We also implement a ranking model based on ELECTRA for single-choice reading comprehension task to compare with the Discriminator approach. The question and document is combined with each option as the input of ELECTRA encoder, which is denoted as  $S \in \mathbb{R}^{N \times m}$ , where  $N$  is the length of sequences and  $m$  is the number of options. A linear layer and a softmax layer is added after ELECTRA encoder as the ranking network, which use the hidden states of [CLS] in  $S$  as input.

### 3.2 Processing Long Input Sequence

Most of the pre-trained models have a limitation in processing long sequences. The maximum sequence length of ELECTRA is 512, which is much shorter than the maximum length of input sequence (i.e. concatenation of question and document). We propose two methods for processing long input sequences: 1) document is segmented to shorter passages, which leads to the problem of mislabel samples. We introduce an auto denoising mechanism to address the problem. 2) We adopt an upper attention upon transformers.

**Auto Denoising** The whole document  $d$  is segmented into a set of fragments  $\{s_1^d, s_2^d, \dots, s_k^d\}$  with a fixed window size. Then, these fragments combine  $q_a$  to form model input sequence. In the inference phase, the lowest predicted logit is selected from all results of fragments as Equation 4.

$$\text{logit}_p = \min_{i=1}^k D(F([q_A; s_i^d])) \quad (4)$$

where  $q$  with placeholder replaced by a specific option from  $A$  denote as  $q_A$ . However, this method causes the noisy-label problem. Supposed that the answer  $a$  just finds proof from fragment  $s_1^d$ , which results in other samples  $(0, [q_a; s_{i \neq 1}^d])$  to be mislabeled samples, which significantly impact training of model and decrease the prediction accuracy. Therefore, we take the advantage of a noise-tolerant loss (bi-tempered logistic loss, BT (Amid et al., 2019)) and a noise detection method (over-fitting to under-fitting, O2U (Huang et al., 2019)) in this work. The BT logistic loss lowers gradient on noisy samples which relieve the negative effects on model training via adjusting bi-temperature. The O2u makes full use of the property that model is easier to forget the mislabeled samples than the clean samples, to identify and filter the mislabeled samples.

**Upper Attention** The long sequence of input is segmented into small segments with the length of 512 tokens and each segments are concatenated with same question to form the input sequences, which are encoded into hidden states  $H_i \in \mathbb{R}^{d \times 512}$ , where  $i$  is the index of segments of passage, the  $d$  is the dimension of hidden states and 512 is the sequence length. The hidden states of placeholder is denoted as  $H_i^p \in \mathbb{R}^d$ . We use a 1-layer multi-head self-attention block to fuse the hidden states of placeholder from multiple segments output.

$$H_{fuse}^p = A_g(H_1^p, H_2^p \dots H_k^p) \quad (5)$$

where  $k$  is the number of segments,  $A_g$  is 1-layer multi-head-attention, without residual connection.  $H_{fuse}^p$  is applied in Equation 2 and Equation 3 for training.

### 3.3 Optimizer

The ELECTRA-large which has large amount of parameters tends to over-fit on small training dataset. We utilize RecAdam (Chen et al., 2020) to fine-tune the pre-trained model to address the over-fitting problem. RecAdam optimizer is proposed to address the catastrophic forgetting problem of sequential transfer learning paradigm by introducing a recall and learn mechanism into Adam optimizer, which maintain the learned knowledge in pre-trained model while learning a new task.

### 3.4 Data augmentation

To further boost the performance of our proposed model, we conduct data augmentation. We random pick 3000 articles in CNN/DailyMail (Hermann et al., 2015), and crawl 824 latest articles from BBC news website. The CNN news is much longer than the training samples, while the length of BBC news is approximately same. The extra training samples are generated in following steps: 1) The title of news article is used as abstract. 2) We pick one most meaningful word from abstract by TF-IDF scores and the origin word is used as golden option. 3) We use words with same category of POS (Part Of Speech) from other documents as negative options. We train models on the extra to dataset as warming up and further train the models with training dataset. Unfortunately, extra training data did not effectively improve the performance of our model on this task. We just use extra data in models ensemble phase.

## 4 Experimental setup

### 4.1 Data

We use the official released dataset of SemEval2021 Task4 for experiments. The dataset of subtask 1 contains 3227/837/2025 samples for train, dev and test data. The subtask 2 dataset contains 3318/851/2017 samples for train, dev and test data. The maximum/mean length of subtask 1 and subtask 2 training data are 2275/374.34 and 2274/578.31, respectively. The statistics of sample length shows that length of article in subtask 2 is much longer than the length in subtask 1. The rate of the sequences exceeding 512 tokens is 13.95% in subtask 1, 42.46% in subtask 2, which may cause that the methods for processing long sequences are more effective in subtask 2.

Since the provided dataset is small, we apply data augmentation in model ensemble to further improve generalization of the model (see Section 3.4).

### 4.2 Parameter settings

Our implementation is based on the Pytorch framework for transformer-based models(Wolf et al., 2020). We trained our model based on the pre-trained ELECTRA-Large discriminator, and adopt the same model structure for subtask 1 and subtask 2. We use Adam optimizer with a learning rate of 1e-5, batch-size of 32 to train the baseline model, which is actually the ELECTRA discriminator. The max sequence length is 512 and the epoch of training is set to 5. To address the overfitting problem, we apply RecAdam with sigmoid annealing function, where the annealing rate is 0.01 and the annealing time-step is 500. The coefficient of the quadratic penalty is set to be 5,0000. For Auto Denoising, the two temperatures and label smoothing of BT are equal to 0.9, 1.5 and 0.1 respectively. The maximum learning rate, minimum learning rate and epochs in cyclical round about O2U are set to be 5e-5, 1e-6 and 5.0 respectively.

Since only 5 submissions are permitted in submitting phase, we trained multiple models under different settings for model ensemble. We also adopt 8-fold cross-validation training to improve the model generalization.

### 4.3 Ensemble

Two strategies are used for our final submissions on test data: 1) we ensemble all 8 models from 8-fold cross-validation training by averaging their outputs,

which is trained on the train data of each subtask; 2) we trained multiple models on the train data and the augmented data with different model structures. 7 top different models are selected based on the dev accuracy for models ensemble, then average their outputs as the final output. Moreover, the model trained in cross-validation is Discriminator with Auto Denoising and RecAdam optimizer for subtask 2, and Discriminator with RecAdam for subtask 1. While in top ensemble, the techniques of Discriminator, Auto Denoising, RecAdam and Upper Attention are applied in different models.

## 5 Results and Analysis

### 5.1 Single Model Performance

We implement two baseline models for comparison with our proposed method. The ALBERT PET is the combination of PET method (Schick and Schütze, 2020a,b) and ALBERT-xxlarge model, which is trained by the MLM. The golden answer of training dataset is used as the target for MLM, but the negative ones are omitted in training. The ELECTRA Rank reformulates the cloze-style task to single-choice task, which is described in section 3.1.

Label accuracy is the official metric of the tasks and Table 1 shows the results on development dataset. Task3(1-2) is the subtask 3 which is trained on subtask 1 dataset and test on subtask 2, Task3(2-1) means train on subtask 2 and test on subtask 1. It is obvious that our proposed ELECTRA Discriminator significantly improve the performance of all tasks and outperform the best baseline by 4.7%/1.16%/3.76%/8.85% in subtask1/subtask2/subtask3(1-2)/subtask3(2-1) respectively. This confirms our hypothesis that pre-trained language model has more potential for cloze-style task. The PET with ALBERT is not suitable for this task because it can not utilize the negative options. The ELECTRA Rank performance is unsatisfactory, suggesting that fine-tuning on ranking network damage the knowledge stored in the pre-trained model.

The results of ablation study are also reported in Table 1. Disc (Discriminator) with RecAdam achieves further improvement in all tasks by 0.25% / 0.53% / 0.25% / 0.26% in subtask1 / subtask2 / subtask3(1-2) / subtask3(2-1) respectively, which prove the RecAdam optimizer is more effective for pre-trained model and also promotes the model generalization. Disc+Upper,

Table 1: Single Model Performance on dev dataset, the ablation study is demonstrated below.

Method	Task1	Task3(1-2)	Task2	Task3(2-1)
ALBERT PET	89.25	83.31	90.48	82.80
ELECTRA Rank	88.53	88.13	90.24	83.75
ELECTRA Discriminator	93.42	90.71	93.88	91.16
+RecAdam	<b>93.66</b>	91.19	94.12	91.40
+Upper	93.54	89.54	<b>94.35</b>	91.39
+Upper+RecAdam	93.31	<b>91.42</b>	94.12	91.51
+AutoDenoise+RecAdam	93.55	<b>91.42</b>	94.01	<b>91.88</b>

Table 2: Ensemble Performance on dev and test dataset, where 8-fold is the models from 8-fold cross-validation training, top ensemble means that ensemble the models with top dev accuracy.

	Method	Task1	Task3(1-2)	Task2	Task3(2-1)
Dev set	8-fold ensemble	92.47	-	92.94	-
	top ensemble	94.50	-	95.53	-
Test set	8-fold ensemble	<b>93.04</b>	93.90	94.99	91.35
	top ensemble	92.74	94.19	<b>95.29</b>	91.65

Disc+AutoDenoise+RecAdam achieve the best results in task2 and task3(2-1) respectively. This prove the validity of the two methods we proposed for long sequences. The Upper Attention achieve the best result on task2, while AutoDenoise achieve the best result on task3. We ensemble them to produce a stronger system. The Upper and AutoDenoise do not effectively improve the baseline in subtask 1, since the mean length of subtask 1 is 374.34 which is much shorter than the max sequence length of original pre-trained model.

## 5.2 Ensemble Performance

The performances of ensemble models are shown on Table 2, which is obtained from the competition leader-board. Our system got the first place in subtask 2 and the second place in subtask 1. For the subtask 3, our ranking is first place in subtask3(2-1), and second place in subtask3(1-2), that indicates our system has strong transfer capability in abstractive reading comprehension tasks. Ensemble results on dev dataset are exhibited for comparison, and we do not experiment model ensemble on dev data of subtask 3.

## 5.3 Memory-Efficiency

We trained all compared models on 16GB Tesla-V100 GPU, except for ELECTRA Rank which takes 17GB with batch size set to 1. Our proposed Discriminator only take 9GB, since one option with article and question is considered as single training

sample for binary classification task. In contrast, ELECTRA Rank is required to encode the input sequence with different options at once to learn the ranking function between positive and negative options. ELECTRA Discriminator is much faster than ELECTRA Rank to converge. The epoch of training ELECTRA Discriminator is less than 5 and ELECTRA Rank needs at least 10 train epochs to converge.

## Conclusion

In this paper, we propose an effective framework of combining ELECTRA discriminator with denoising learning method to boost the performance of cloze-style reading comprehension task. Our proposed model outperforms all others participating system on subtask 2 and gets the second-placed on subtask 1. We have conducted an ablation study, demonstrating the validity of Discriminator, Upper attention and Auto denoising. Pre-trained models have made great performance gain compared to traditional neural network models in many natural language tasks and is able to build comprehensive hidden representation of input text. The above experiment results may suggest that the current pre-trained model mechanism still has room for improvement.

## Abstract

SemEval task 4 aims to find a proper option from multiple candidates to resolve the task of machine reading comprehension. Most existing approaches propose to concat question and option together to form a context-aware model. However, we argue that straightforward concatenation can only provide a coarse-grained context for the MRC task, ignoring the specific positions of the option relative to the question. In this paper, we propose a novel MRC model by filling options into the question to produce a fine-grained context (defined as summary) which can better reveal the relationship between option and question. We conduct a series of experiments on the given dataset, and the results show that our approach outperforms other counterparts to a large extent.

## 1 Introduction

In order to make the computer understand, represent and express better, we study the ability of MRC to understand Abstract definitions (Spren and Schulz, 1966; Changizi, 2008) in the Reading Comprehension of Abstract Meaning task (ReCAM). In ReCAM task, there are two kinds of abstract definitions, one is imperceptibility and the other is nonspecificity. To evaluate the model performance comprehensively, three subtasks are designed (Zheng et al., 2021):

Subtask 1) ReCAM-Imperceptibility - A passage, a question with a placeholder, and answers used to fill in the placeholder are given. The answers are all imperceptibility words so as to evaluate the model's ability to comprehend these imperceptibility words.

Subtask 2) ReCAM-Nonspecificity - A passage, a question with a placeholder, and answers used to fill in the placeholder are given. The answers are all Nonspecificity words so as to evaluate the

model's ability to comprehend these Nonspecificity words.

Subtask 3) To provide more insights into the relationship between two abstract views, it requires to test the performance of the model trained on one data set and evaluated on the other one.

Because question is obtained by hollowing out summary of passage and answer is abstract words to fill in (Zheng et al., 2021), there is a semantically complementary relationship between the question and answer. As shown in the Figure 1, in the previous work (Jin et al., 2020; Zhu et al., 2020), the model inputs passage, question and answer independently. It can only provide a coarse-grained context for the MRC task, ignoring the specific positions of the option relative to the question. Question cannot be a complete sentence, and the answer lacks contextual information about the question. To solve this problem, we introduce **Complete Summary Representation by Filling Answers into Question for Matching Reading Comprehension (ComSR)**. ComSR convert the original question and answer into summary. In this way, we can turn the problem into matching correct summary for the passage. By replacing the answer option into the question placeholder, the original question has higher semantic integrity, and the original answer obtains the context information from the question to eliminate language ambiguity such as polysemy.

Based on the results, ComSR is superior to pre-trained language models and the latest MRQA models, with the accuracy rate of 64.76% in subtask 1, 64.86% in subtask 2, and shows great generalization ability in Subtask 3.

## 2 System overview

Figure 2 illustrates the overall structure of ComSR. Since just one summary option belongs to the pas-

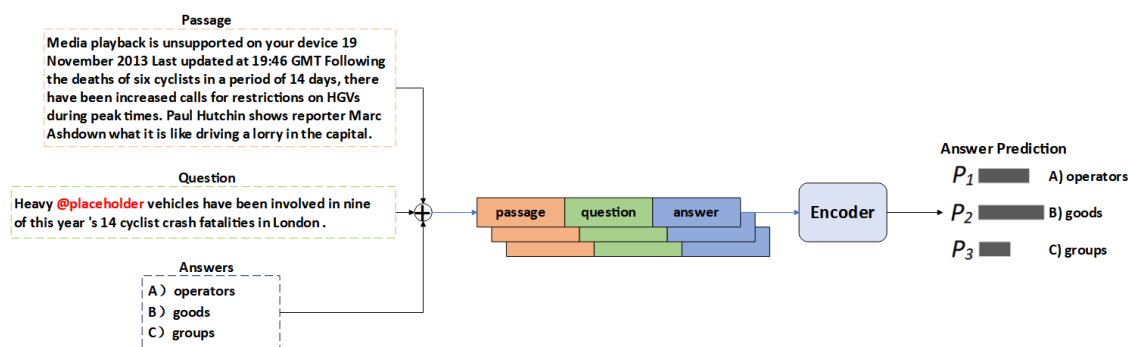

Figure 1: The framework of previous MCQA model. The abstract word in answer has a polysemy phenomenon. Entering question and answer separately cannot eliminate ambiguity.

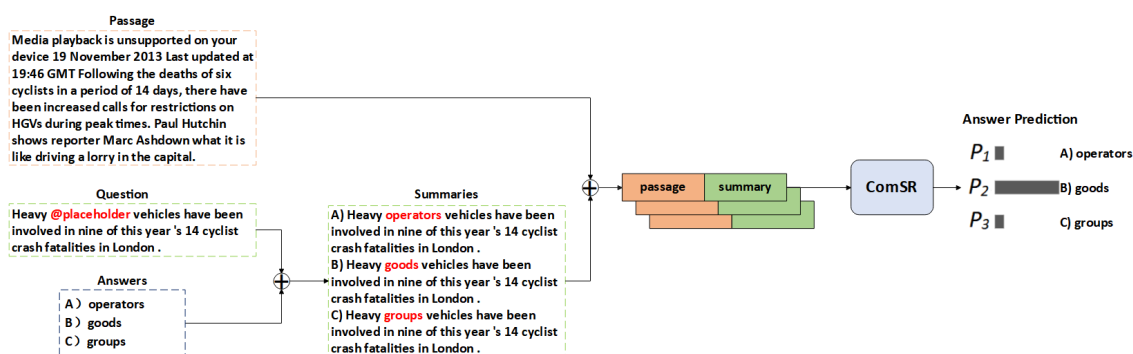

Figure 2: The framework of our model. By replacing the answer option into the question placeholder, answer obtains the context information from question, so the ambiguity is eliminated.

sage, we input passage and summary together to better reflect the corresponding relationship between the passage and the summaries. As BERT has been shown to be a powerful feature extractor for various tasks (Ran et al., 2019), we use BERT as the encoder to extract the vector representation of the semantic meaning of the passage and the summaries, as well as the relationship between the passage and the summaries. Finally, we use a classifier layer to convert the hidden state into the final selection of the model.

## 2.1 Input Layer

The initial question uses ”@placeholder” to represent the abstract word, which makes the question sentence not a complete sentence. We replace the ”@placeholder” in question with the answer word to get the summary  $S$ . As a complete sentence,  $S$  provides rich context information to answer, thus effectively eliminating the ambiguity caused by polysemy in answer. Then the passage  $P$  and the summary  $S$  are concatenated, using [CLS] at the beginning and [SEP] at the end of sentences to get input vector.

$$x = [p; s] \quad (1)$$

where  $x$  denotes input vector,  $p$  denotes passage vector and  $s$  denotes summary vector.

## 2.2 Encoder

Although Pre-trained language models have achieved good results in various NLP tasks, most existing MCQA datasets are small in size, pre-trained language models are hard to get adequate training. To solve this problem, we use the encoder obtained through multi-stage multi-task learning in MMM (Jin et al., 2020) as the initial encoder<sup>1</sup>. The reasons are as follows. First, the use of multiple data sets for training makes up for the shortcomings of the small amount of data in a single data set. It uses four similar task data sets, MultiNLI (Williams et al., 2017), SNLI (Young et al., 2014), DREAM (Sun et al., 2019), and RACE (Lai et al., 2017) for training, which has significantly more data than a single MCQA data set, thus solving the defect of insufficient data in a single data set. Second, the model uses two natural language inference datasets, MNLI and SNLI, as out-of-domain

<sup>1</sup>[https://drive.google.com/drive/folders/1EECS9na9PpX9CO\\_cCzYj9FDkiBvOpyxv](https://drive.google.com/drive/folders/1EECS9na9PpX9CO_cCzYj9FDkiBvOpyxv)

source datasets for Coarse-tuning, and two MCQA datasets, DREAM and RACE, as in-domain source datasets for Multi-task learning. The characteristics of different data sets make the model have better generalization ability (Jin et al., 2020). Third, because these data sets are highly related to ReCAM, it is suitable to use MMM encoder as initial encoder of ComSR.

$$\mathbf{H}^p = Bert(\mathbf{p}), \quad \mathbf{H}^s = Bert(\mathbf{s}) \quad (2)$$

where  $Bert(\cdot)$  indicate BERT model which return the last attention layer.  $\mathbf{H}^p \in R^{l \times |p|}$ ,  $\mathbf{H}^s \in R^{l \times |s|}$  are sequence representation of the passage and summary.  $|p|$ ,  $|s|$  are the length of the passage and summary.  $l$  is the dimension of the hidden state.

### 2.3 Answer Prediction

In the answer prediction module, we pass the output of the encoder through a fully connected layer and a pooling layer to finally get the score of each option.

$$s_k = \mathbf{v}_s^T \tanh(\mathbf{W}_k [\mathbf{H}^p; \mathbf{H}^s] + \mathbf{b}_k) \quad (3)$$

where  $s_k$  is score of the answer,  $\mathbf{v}_s^T$  and  $\mathbf{W}_k$  are learnable parameters.  $\tanh(\cdot)$  performs tanh activation function,  $\mathbf{W}_k \in \mathbf{R}^{l \times l}$ ,  $\mathbf{b}_k \in \mathbf{R}^l$ ,  $\mathbf{v}_s^T \in \mathbf{R}^l$ .

The probability  $P(k | P, S)$  of summary  $S_k$  to be the correct answer is computed as

$$P(k | P, S) = \frac{\exp(s_k)}{\sum_{i=1}^{N=5} \exp(s_i)} \quad (4)$$

Then according to  $P(k | P, S)$ , the loss function is defined as

$$J(\theta) = -\log(P(k | P, S)) \quad (5)$$

## 3 Experimental setup

### 3.1 Dataset

The data set of Reading Comprehension of Abstract Meaning (ReCAM) is provided by the organizer of the competition containing a large number of abstract words in answers. Abstract words refer to thoughts and concepts that are far from immediate perception. In ReCAM, we divide abstract words into Imperceptibility words and Nonspecificity words, and provide two data sets, respectively. The accuracy we showed in the paper was tested on the dev dataset.

#### 3.1.1 ReCAM-Imperceptibility

Imperceptible words are the words of being Imperceptibility by eyes or senses, such as experience, success, significant, challenge. This data set provides a passage, a question with a placeholder and five answers with an imperceptibility word. The training set/test set/validation set contains 3227/2025/837 pieces of data respectively.

#### 3.1.2 ReCAM-Nonspecificity

Nonspecific words are words with very broad concepts, and hypernyms are often words of this type, such as food, jewelry, people, and vehicle. This data set provides a passage, a question with a placeholder and five answers with a Nonspecificity word. The training set/test set/validation set contains 3318/2017/851 pieces of data respectively.

### 3.2 Implementation Details

In the test method, we use the accuracy of the model in the answer option of the data set as the measurement standard. For model training, we will train each tested model for 10 epochs at a learning rate of  $3e-05$ , use cross-entropy to calculate loss, and use Adam optimizer (Kingman and Ba, 2015) for fine-tuning. On hardware devices, we use GeForce RTX-2080Ti to provide computing.

## 4 Results

### 4.1 Comparison with Baselines

Since our model uses BERT as encoder, we use the original BERT (Devlin et al., 2018) for comparison. As pre-trained language models like BERT, we use ALBERT (Lan et al., 2019) and RoBERTa (Liu et al., 2019) in the experiment. In addition, we also adopt MMM (Jin et al., 2020) that performed well in multi-choice data sets such as RACE (Lai et al., 2017) and DREAM (Sun et al., 2019) to do experiments.

Model	Subtask	
	1(%)	2(%)
BERT-base	47.19	50.65
RoBERTa	22.34	22.44
ALBERT	36.91	37.25
MMM+BERT-base	57.11	59.11
ComSR+BERT-base(ours)	<b>64.76</b>	<b>64.86</b>

Table 1: Experimental results on ReCAM. The overall best results are in bold face.

Model	I→N (%)	N→I (%)
ComSR(Passage + summary)(ours)	50.65(14.11 ↓)	51.73(13.13 ↓)
ComSR(Passage + summary + question)	48.53(17.18 ↓)	49.94(15.51 ↓)
ComSR(Passage + summary + answer)	44.89(18.55 ↓)	46.71(18.38 ↓)
MMM(Passage + question + answer)	39.48(17.63 ↓)	43.73(15.38 ↓)

Table 2: Comparison generalization on ReCAM. I→N denotes training on the Imperceptibility dataset and testing on the Nonspecificity dataset, N→I is the opposite. ↓ represents the drop for a model compared to the test in its own test set and + denotes concatenation.

Table 1 show that the model has similar features in task1 and task2. In the experimental results of task1 and task2, we can find that (1) Although pre-trained language models have slightly different results depending on the models, the overall level is low on the small data set. (2) MMM proposed for the MCQA task performs better than the pre-trained language model on ReCAM. This is because the encoder of MMM uses the Multi-stage Multi-task Learning to train on NLI data sets such as MNLI and SNLI and on MCQA data sets such as DREAM and RACE, which is more suitable for ReCAM. (3) The performance of ComSR is better than other baselines, and it has significantly improved. It can be seen that, under the condition of using the same encoder, replacing the placeholder of question with answer is more conducive to understand sentence meaning.

## 4.2 Analysis Studies

### 4.2.1 The completeness of the semantic expression of summary

Converting question and answer into summary input improves semantic integrity and the model’s ability to understand sentences. However, is the semantics provided by summary complete? To study this problem, we set up the following experiment.

Model	Subtask 1(%)	Subtask 2(%)
ComSR(Passage + summary)(ours)	64.76	64.86
ComSR(Passage + summary + question)	65.71	65.45
ComSR(Passage + summary + answer)	63.44	65.09

Table 3: Comparison among different implementation of the input method on ReCAM. + denotes concatenation.

If there is a loss of semantics in the synthesis of the summary, then the summary can be supplemented when the original question and answer are used, thereby improving the performance of the model. However, it can be seen from the table 3 results that some of the experimental results of the passage+ summary+answer and passage+summary+question groups are equal to passage+summary and even slightly lower than passage+summary. Therefore, the conversion of question and answer into summary makes the semantics of options more complete, and there is no semantic loss.

### 4.2.2 Research on model generalization

To study the generalization ability of the model, (1) we use the ReCAM-Imperceptibility data set to train and test it in the ReCAM-Nonspecificity data set. (2) we use the ReCAM-Nonspecificity data set to train and test it in the ReCAM-Imperceptibility data set. In order to study the most suitable input form, we use passage+summary+question, passage+summary+answer and MMM (passage+question+answer) model for comparison.

According to the experimental results in table 2, after switching the data set for testing, the highest accuracy is ComSR(Passage + summary). Although the results of the test in another data set have dropped, the ComSR using the Passage and summary received the least impact. In summary, ComSR(Passage + summary) performs best in the above models, and the method of matching summary and Passage alone has stronger generalization ability.

### 4.2.3 Case Analysis

Table 4 shows a passage and its corresponding question and answers. To understand ComSR’s ability to disambiguate, we specifically selected samples that contained polysemous words in answers. In this example, the answer ”goods” is a typical polysemous word.

<b>Passage</b>	Media playback is unsupported on your device 19 November 2013 Last updated at 19:46 GMT Following the deaths of six cyclists in a period of 14 days, there have been increased calls for restrictions on HGVs during peak times. Paul Hutchin shows reporter Marc Ashdown what it is like driving a lorry in the capital.
<b>Question</b>	Heavy @placeholder vehicles have been involved in nine of this year 's 14 cyclist crash fatalities in London.
<b>Answers</b>	(a) operators (b) goods (c) groups (d) patrol (e) air

Table 4: Example of ReCAM.

Models take the logarithm of the value to get the predictions. Because many of the predictions are negative, we add bias = 12.5 to the predictions for easy viewing and show it in Figure 3.

Figure 3: Prediction distributions in different models. The model selects the answer with the highest predicted value as the output option.

We observe that although MMM selects the right option, the difference between the correct answer and other option values in the probability distribution is not obvious. On the contrary, correct

prediction value is much higher than other values in ComSR. By combining question and answer into summary, ComSR can not only improve the semantic integrity of the sentence, but also eliminate the ambiguity caused by the polysemy of the original answer. Therefore, even for polysemous words that are prone to ambiguity, ComSR can obtain accurate answers by fully understanding the summary representation.

## 5 Conclusion

We proposed ComSR for multiple choice reading comprehension to complete summary representation. Merging the separated question and answer into a summary could improve semantic integrity and better reveal the relationship between option and question. Results showed that our model can achieve relatively high performance compared to the latest baseline in terms of accuracy and generalization ability.

## Abstract

In recent years, the widespread use of social media has led to an increase in the generation of toxic and offensive content on online platforms. In response, social media platforms have worked on developing automatic detection methods and employing human moderators to cope with this deluge of offensive content. While various state-of-the-art statistical models have been applied to detect toxic posts, there are only a few studies that focus on detecting the words or expressions that make a post offensive. This motivates the organization of the SemEval-2021 Task 5: Toxic Spans Detection competition, which has provided participants with a dataset containing toxic spans annotation in English posts. In this paper, we present the WLV-RIT entry for the SemEval-2021 Task 5. Our best performing neural transformer model achieves an 0.68 F1-Score. Furthermore, we develop an open-source framework for multilingual detection of offensive spans, i.e., MUDES, based on neural transformers that detect toxic spans in texts.

## 1 Introduction

The widespread adoption and use of social media has led to a drastic increase in the generation of abusive and profane content on the web. To counter this deluge of negative content, social media companies and government institutions have turned to developing and applying computational models that can identify the various forms of offensive content online such as aggression (Kumar et al., 2018, 2020), cyber-bullying (Rosa et al., 2019), and hate speech (Ridenhour et al., 2020). Prior work has either designed methods for identifying conversations that are likely to go awry (Zhang

et al., 2018; Chang et al., 2020) or detecting offensive content and labelling posts at the instances level – this has been the focus in the recent shared tasks like HASOC at FIRE 2019 (Mandl et al., 2019a) and FIRE 2020 (Mandl et al., 2020), GermEval 2019 Task 2 (Struß et al., 2019), TRAC (Kumar et al., 2018, 2020), HatEval (Basile et al., 2019a), OffensEval at SemEval-2019 (Zampieri et al., 2019b) and SemEval-2020 (Zampieri et al., 2020).

With respect to identifying offensive language in conversations, comments, and posts, noticeable progress has been made with a variety of large, annotated datasets made available in recent years (Pitenis et al., 2020; Rosenthal et al., 2020). The identification of the particular text spans that make a post offensive, however, has been mostly neglected (Mathew et al., 2021) as current state-of-the-art offensive language identification models flag the entire post or comment but do not actually highlight the offensive parts. The pressing need for toxic span detection models to assist human content moderation, processing and flagging content in a more interpretable fashion, has motivated the organization of the SemEval-2021 Task 5: Toxic Spans Detection (Pavlopoulos et al., 2021).

In this paper, we present the WLV-RIT submission to the SemEval-2021 Task 5. We explore several statistical learning models and report the performance of the best model, which is based on a neural transformer. Next, we generalise our approach to an open-source framework called MUDES: Multilingual Detection of Offensive Spans (Ranasinghe and Zampieri, 2021a). Alongside the framework, we also release the pre-trained models as well as a user-friendly web-based User Interface (UI) based on Docker, which provides the functionality of automatically identifying the offensive spans in a given input text.

WARNING: This paper contains text excerpts and words that are offensive in nature.

## 2 Related Work

**Datasets** Over the past several years, multiple post-level, offensive language benchmark datasets have been released. In [Zampieri et al. \(2019a\)](#), the authors compiled an offensive language identification dataset with a three-layer hierarchical annotation scheme – profanity, category, and target identification. [Rosenthal et al. \(2020\)](#) further extended the dataset using a semi-supervised model that was trained with over nine million annotated English tweets. Recently, [Mathew et al. \(2021\)](#) released the first benchmark dataset which covered the three primary areas of online hate-speech detection. The dataset contained a 3-class classification problem (hate-speech, offensive, or neither), a targeted community, as well as the spans that make the text hateful or offensive. Furthermore, offensive language datasets have been annotated in other languages such as Arabic ([Mubarak et al., 2017](#)), Danish ([Sigurbergsson and Derczynski, 2020](#)), Dutch ([Tulkens et al., 2016](#)), French ([Chiril et al., 2019](#)), Greek ([Pitenis et al., 2020](#)), Portuguese ([Fortuna et al., 2019](#)), Spanish ([Basile et al., 2019b](#)), and Turkish ([Çöltekin, 2020](#)).

Apart from the dataset released for SemEval-2021 Task 5, HateXplain ([Mathew et al., 2021](#)) is, to the best of our knowledge, the only dataset that we could find that has been annotated at the word level. The dataset consists of 20,000 posts from Gab and Twitter. Each data sample is annotated with one of the hate/offensive/normal labels, communities being targeted, and words of the text are marked by the annotators who support the label.

**Models** In the past, trolling, aggression, and cyberbullying identification tasks on social media data have been approached using machine and deep learning-focused models ([Kumar et al., 2018](#)). Across several studies ([Malmasi and Zampieri, 2017, 2018](#); [Waseem and Hovy, 2016](#)) researchers have noted that  $n$ -gram based features are very useful when building reliable, automated hate-speech detection models. Statistical learning models aided with natural language processing (NLP) techniques are frequently used for post-level offensive and hateful language detection ([Davidson et al., 2017](#); [Indurthi et al., 2019](#)). Given the increased use of deep learning in NLP tasks, offensive language identification has seen the introduction of methods based on convolutional neural networks (CNNs) and Long Short-term Memory

(LSTM) networks ([Badjatiya et al., 2017](#); [Gambäck and Sikdar, 2017](#); [Hettiarachchi and Ranasinghe, 2019](#)). The most common approach has been to use a word/character embedding model such as Word2vec ([Mikolov et al., 2013](#)), GloVe ([Pennington et al., 2014](#)), or fastText ([Mikolov et al., 2018](#)) to embed words/tokens and then feed them to an artificial neural network (ANN) ([Zampieri et al., 2019b](#)).

With the introduction of BERT ([Devlin et al., 2019](#)), neural transformer models have become popular in offensive language identification. In hate speech and offensive content identification in Indo-European languages, the BERT model has been shown to outperform GRU (Gated Recurrent Unit) and LSTM-based models ([Ranasinghe et al., 2019](#)). In [Mandl et al. \(2019b\)](#), the best performing teams on the task employed BERT-based pre-trained models that identified the type of hate and target of a (text) post.

The SemEval-2019 Task 6 ([Zampieri et al., 2019b](#)) presented the challenge of identifying and categorizing offensive posts on social media, which included three sub-tasks. In sub-task A: offensive language identification, [Liu et al. \(2019a\)](#) applied a pre-trained BERT model to achieve the highest F1 score. In Sub-task B: automatic categorization of offense types, BERT-based models also achieved competitive rankings. We noticed similar trends in SemEval-2020 Task 12 ([Zampieri et al., 2020](#)) as well. Not limited to English, transformer models have yielded strong results in resource-scarce languages like Bengali ([Ranasinghe and Zampieri, 2020](#)) and Malayalam ([Ranasinghe et al., 2020](#)) along with cross-lingual transfer learning from resource-rich languages ([Ranasinghe and Zampieri, 2020, 2021b](#)). Nonetheless, despite the recent success of statistical learning in offensive language detection problems, due to the lack of finer-grained, detailed datasets, models are limited in their ability to predict word-level labels.

## 3 Task and Dataset

In the SemEval-2021 Task 5 dataset, the sequence of words that makes a particular post or comment toxic is defined as a *toxic span*. The dataset for this task is extracted from posts in the Civil Comments Dataset that have been found to be toxic. The practice dataset has 690 instances out of which 43 instances do not contain any toxic spans. The training dataset has a total of 7,939 instances and

Post	Offensive Spans
Stupid hateries have completely fucked everything	[0, 1, 2, 3, 4, 5, 34, 35, 36, 37, 38, 39]
Victimitis: You are such an asshole.	[28, 29, 30, 31, 32, 33, 34]
So is his mother. They are silver spoon parasites.	[]
You're just silly.	[12, 13, 14, 15, 16]

Table 1: Four comments from the dataset along with their annotations. The offensive words are displayed in red and the spans are indicated by the character position in the instance.

comprises 485 instances without any toxic spans. Each instance is composed of a list of toxic spans and the post (in English). In Table 1, we present four randomly selected examples from the training dataset along with their annotations.

Figure 1: The Bi-LSTM-CRF model. Green squares represent the top CRF layer. Non-offensive and offensive tokens are shown as 0 and 1, respectively.

## 4 Methodology

### 4.1 Lexicon-based Word Match

Lexicon-based word-matching algorithms often achieve balanced results. For the lexicon, we collected profanity words from online resources<sup>1,2</sup>. Then, we added the toxic words present in the training dataset and we run a simple word matching algorithm the trie data structure. As anticipated, the algorithm does not evaluate the toxic spans contextually and misses censored swear words. For instance, the word  $f^{**}k$  is missed, which is not present in the lexicon. Nonetheless, this result provides as a useful baseline performance measurement for the task.

### 4.2 Recurrent Networks: Long Short-Term Memory

Long Short-term Memory (LSTM) is a recurrent neural network model that uses feedback connec-

<sup>1</sup><https://www.cs.cmu.edu/~biglou/resources/bad-words.txt>

<sup>2</sup><https://github.com/RobertJGabriel/Google-profanity-words>

tions to model temporal dependencies (past-to-present) in sequential data. Bidirectional LSTM (Bi-LSTM) is capable of learning contextual information both forwards and backwards in time compared to conventional LSTMs. In this study, we used the Bi-LSTM architecture given this bidirectional ability to model temporal dependencies. Conditional random fields (CRF) (Lafferty et al., 2001) are a statistical model that are capable of incorporating context information and are highly used for sequence labeling tasks. A CRF connected to the top of the Bi-LSTM model provides a powerful way to model relationships between consecutive outputs (across time) and provides a means to efficiently utilize past and future tag information to predict the current tag.

The final hybrid model is comparable to the previous state-of-the-art sequence tagging Bi-LSTM-CRF model (Huang et al., 2015). Figure 1 presents the Bi-LSTM-CRF architecture we designed for this study, which has 4.2 million trainable parameters. We trained the model on mini-batches of 16 samples with a 0.005 learning rate for 5 epochs with a maximum sequence length of 200.

### 4.3 Neural Transformers

Recently, pre-trained language models have been shown to be quite useful across a variety of NLP tasks, particularly those based on bidirectional neural transformers such as BERT (Devlin et al., 2019; Li et al., 2019). Transformer-based models have also been shown to be highly effective in sequence classification tasks such as named entity recognition (NER) (Luoma and Pyysalo, 2020). In our work, we extend the BERT model by integrating a token level classifier. The token-level classifier is a linear transformation that takes the last hidden state of the sequence as the input and produces a label for each token as its output. In this case, each token will be predicted to have one of two possible labels – toxic or not toxic. We fine-tuned the uncased BERT transformer model with a maximum

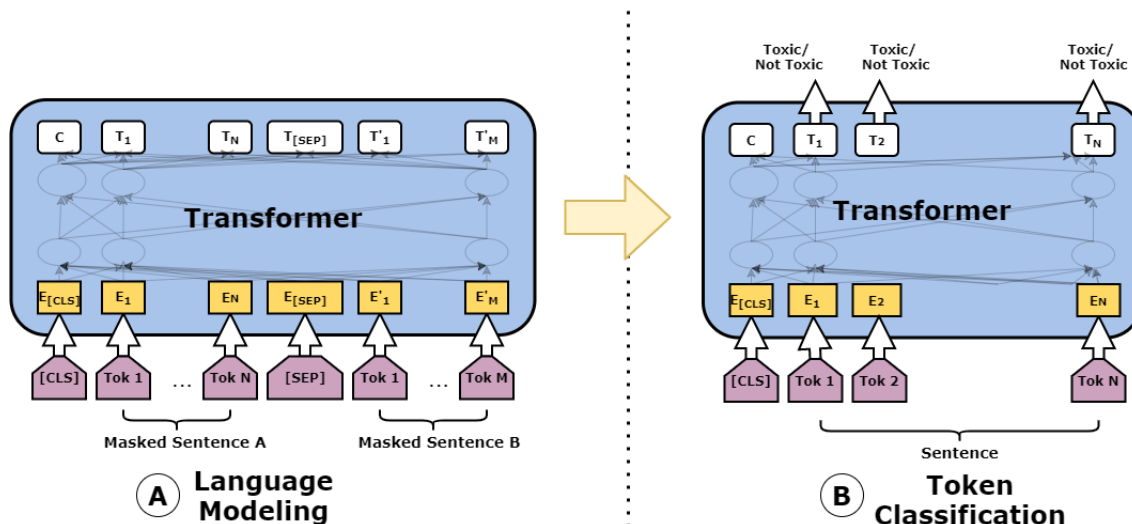

Figure 2: The two-part model architecture. Part A depicts the language model and Part B is the token classifier. (Ranasinghe and Zampieri, 2021a)

sequence length of 400 with batches of size of 16.

We also experimented with customising the layers in between the BERT transformer and token-classification layer by adding a CRF layer between them given that it has been shown that BERT-CRF architectures often outperform BERT baselines in similar sequence labeling tasks (Huang et al., 2019; Souza et al., 2020). Therefore, we added a sequential CRF layer on top of the BERT transformer and further incorporated dropout (probability of dropping a neuron was 0.2) to introduce some regularization. Unfortunately, in our experiments, we found that adding a CRF layer does not significantly improve the final generalization results. Additionally, we experimented with transfer learning to identify if a further boost in model generalization was possible if we first trained a basic BERT transformer on HateXplain (Mathew et al., 2021) and then fine-tuned it using our extended architecture as described above. However, the transfer learning process did not improve results any further.

**Development of MUDES** Given the success we observed using neural transformers such as BERT, we developed a (software) framework we call MUDES (Ranasinghe and Zampieri, 2021a): Multilingual Detection of Offensive Spans, an open-source framework based on transformers to detect toxic spans in texts. MUDES offers several capabilities in addition to the (automatic) token classification we described earlier. MUDES has the following components: *a) Language Modeler*: Fine-tuning transformer models using masked language

modeling before performing the downstream task often leads to better results (Ranasinghe and Hettiarachchi, 2020) and MUDES incorporates this, *b) Transformer Type Variety*: since there are many varieties of neural transformers, e.g., XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019b) that have been shown to outperform BERT-based architectures (Ranasinghe and Hettiarachchi, 2020; Hettiarachchi and Ranasinghe, 2020a), our software framework provides support for these architectures, and, finally, *c) Model Ensembling*: multiple MUDES models with different random seeds can be trained and the final model prediction is the majority vote from all the models, aligning with the approach taken in Hettiarachchi and Ranasinghe (2020b, 2021); Jauhainen et al. (2021).

The complete architecture of MUDES is depicted in Figure 2. We used several popular transformer models including BERT (Devlin et al., 2019), XLNET (Yang et al., 2019), RoBERTa (Liu et al., 2019b), SpanBERT (Joshi et al., 2020), and ALBERT (Lan et al., 2020). We compared these transformer architectures against the spaCy token classifier baseline (reported by the competition organisers) and report these results in Section 5. Since adding a CRF layer did not improve the results in our models, we do not add this to MUDES.

Parameter optimization involved mini-batches of 8 samples using the Adam update rule (global learning rate was  $2e-5$  and a linear warm-up schedule over 10% of the training data was used). Models were evaluated using a validation subset that contained 20% of the training data. Early stopping

was executed if the validation loss did not improve over 10 evaluation steps. Models were trained for 3 epochs on an Nvidia Tesla K80 GPU using only the training set provided.

## 5 Evaluation and Results

For evaluation, we followed the same procedure that the task organisers have used to evaluate the systems.

Let system  $A_i$  return a set  $S_{A_i}^t$  of character offsets for parts of a text post that have been found to be toxic. Let  $G_t$  be the character offsets of the ground truth annotations of  $t$ . We compute the F1 score of system  $A_i$  with respect to the ground truth  $G$  for post  $t$  as mentioned in Equation 1 where  $|\cdot|$  denotes set cardinality.  $P^t$  and  $R^t$  measure the precision and recall, respectively.

$$F_1^t(A_i, G) = \frac{2 \cdot P^t(A_i, G) \cdot R^t(A_i, G)}{P^t(A_i, G) + R^t(A_i, G)} \quad (1)$$

Model	Trial F1	Test F1
MUDES RoBERTa	0.6886	0.6801
MUDES BERT	0.6771	0.6698
MUDES SPANBert	0.6751	0.6675
MUDES XLNet	0.6722	0.6653
BERT	0.6738	0.6538
BERT-CRF	0.6643	0.6517
BERT HateXplain	0.6387	0.6326
spaCy baseline	0.5976	0.5976
Bi-LSTM-CRF	0.5631	0.5398
Lexicon word match	0.3378	0.4086

Table 2: Results ordered by test F1 score. The Trial F1 column shows the F1 scores on the trial set and the Test F1 column shows the F1 scores for test set.

Observe in Table 2 that all of our deep neural-based models outperformed the spaCy baseline while the lexicon-based word match algorithm provided fairly good results despite it being an unsupervised method. Our best model is the MUDES RoBERTa model which scored 0.68 F1 score in the test set and is very compatible with the 0.70 F1 score that the best model scored in the competition. Furthermore, it is clear that the additional features supported by our MUDES framework, e.g., language modeling and ensembling, improves the results over a vanilla BERT transformer.

## 6 Conclusion and Future Work

In this paper, we presented the WLV-RIT approach for tackling the SemEval-2021 Task 5: Toxic Spans Detection. SemEval-2021 Task 5 provided participants with the opportunity of testing computational models to identify token spans in toxic posts as opposed to previous related SemEval tasks such as HatEval and OffensEval that provided participants with datasets annotated at the instance level. We believe that word-level predictions are an important step towards explainable offensive language identification.

We experimented with several methods including a lexicon-based word match, LSTMs, and neural transformers. Our results demonstrated that transformer models offered the best generalization results and, given the success observed, we developed MUDES, an open-source software framework based on neural transformers focused on detecting toxic spans in texts. With MUDES, we release two English models that performed best for this task (Ranasinghe and Zampieri, 2021a). A large model; en-large based on roberta-large which is more accurate, but has a low efficiency regarding space and time. The base model based on xlnet-base-cased; en-base is efficient, but has a comparatively low accuracy than the en-large model. All pre-trained models are available on Hugging Face Model Hub (Wolf et al., 2020)<sup>3</sup>. We also make MUDES available as a Python package<sup>4</sup> and set up as an open-source project<sup>5</sup>. In addition, a prototype User Interface (UI) of MUDES has been made accessible to the general public<sup>6</sup> based on Docker<sup>7</sup>.

In terms of future work, we would like to experiment with multi-task (neural) architectures that can be used for offensive language identification capable of carrying out predictions at both the word-level and post-level jointly. Furthermore, we would like to evaluate multi-task architectures on multi-domain and multilingual settings as well as broaden our experimental comparison to other types of recurrent network models, such as the Delta-RNN (Ororbia II et al., 2017).

<sup>3</sup>Available on <https://huggingface.co/mudes>

<sup>4</sup>Available at <https://pypi.org/project/mudes/>

## Abstract

Toxic span detection requires the detection of spans that make a text toxic instead of simply classifying the text. In this paper, a transformer-based model with auxiliary information is proposed for SemEval-2021 Task 5. The proposed model was implemented based on the BERT-CRF architecture. It consists of three parts: a transformer-based model that can obtain the token representation, an auxiliary information module that combines features from different layers, and an output layer used for the classification. Various BERT-based models, such as BERT, ALBERT, RoBERTa, and XLNET, were used to learn contextual representations. The predictions of these models were assembled to improve the sequence labeling tasks by using a voting strategy. Experimental results showed that the introduced auxiliary information can improve the performance of toxic spans detection. The proposed model ranked 5th of 91 in the competition. The code of this study is available at [https://github.com/Chenrj233/semEval2021\\_task5](https://github.com/Chenrj233/semEval2021_task5)

## 1 Introduction

Existing toxicity detection datasets and models classify the entire comment or document and do not identify the range that makes the text toxic. A system that accurately locates the toxicity range in the text is crucial in achieving semi-automatic review. As a complete submission for the shared task, systems are required to extract a list of toxic spans or an empty list per text. We define a sequence of words that attribute to the text’s toxicity as the toxic span. Table 1 shows two toxic spans, ”stupid” and ”a!@#!@,” which have character offsets from 10 to 15 (counting starts from 0) and from 51 to 56, respectively. Systems are then expected to return the offset list for this text.

<b>Text</b>
This is a stupid example, so thank you for nothing a!@#!@.
<b>Offset List</b>
[10,11,12,13,14,15,51,52,53,54,55,56]

Table 1: Example of toxic spans detection shared task.

The main purpose of this task is to identify the toxic spans in a given text; this can be transformed into a sequence labeling task in natural language processing. Unlike normal sequence labeling tasks, this task is more challenging because the toxic spans in the text may involve a word, phrase, or even a sentence. Traditional methods used to address the problem of sequence labeling include conditional random fields (CRF) (Lafferty et al., 1999), combined models of both long-short-term memory and CRF (LSTM-CRF) (Gupta et al., 2019), and bidirectional encoder representation from transformers (BERT) (Devlin et al., 2019).

In this study, we use BERT, ALBERT (Lan et al., 2019), RoBERTa (Liu et al., 2019), and XLNET (Yang et al., 2019) to solve this problem. Compared with the conventional model, our model adds auxiliary information to improve the performance in this task. After a simple analysis of the text data, it can be found that not all the words in the toxic span have a toxic meaning, and some toxic meanings occur in a specific context or semantic conditions. Therefore, if the tokens can be classified with the auxiliary information such as sentence representation, the performance of the model will improve. The results of the experiment prove that some of the proposed methods are effective. By using ensemble learning, we merge the results of the BERT, ALBERT, RoBERTa, and XLNET models into the final prediction, obtaining the 5th rank out of 91 and a  $F_1$  score of 0.696.

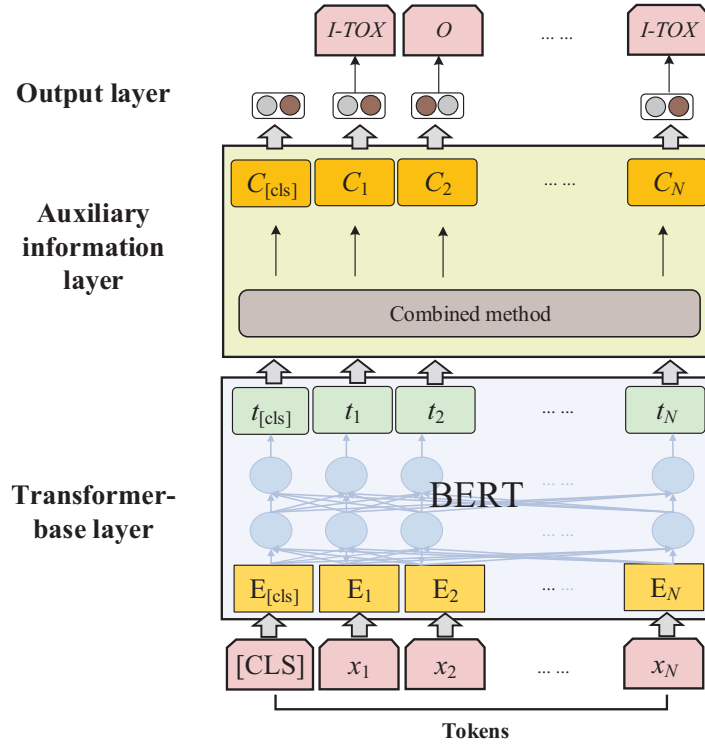

Figure 1: Overall architecture of the proposed transformer-based model with auxiliary information.

The remainder of this paper is organized as follows. Section 2 describes the specific structure of the adopted model. The experimental results are summarized in Section 3. Finally, Section 4 presents the conclusions of the study.

## 2 Transformer-based Model with Auxiliary Information

Figure 1 shows the architecture of the proposed model, which consists of three layers: a transformer-based layer, an auxiliary information layer, and an output layer. The transformer-based layer can be BERT, ALBERT, RoBERTa, XLNET, or any other transformer-based model. In the auxiliary information layer, several approaches are applied to combine token representation. The combined token representations are used in the output layer to output the label of each token.

### 2.1 Transformer-based Layer

The transformer-based layer is the first part of the model. The purpose of this layer is to obtain the representation of tokens and the entire text. For illustration, we can use the BERT-large (Devlin et al., 2019) model to produce token representations from each layer. With BERT-large, 25 layers of token representation vectors can be obtained: one embed-

ding representation and twenty-four hidden states. Unlike previous methods, 25 layers of token representation vectors are combined by using several methods in the next layer. The representations produced by the transformer-based layer are then fed into the next layer.

### 2.2 Auxiliary Information Layer

The traditional method directly passes the token representation vectors to the classification layer. To improve the performance of the model, we attempt to combine token representation vectors and the sentence representation vector in different ways. Figure 2 depicts the attempted methods, which are described as follows:

- **Method 1.** Token vector of the last layer and the sentence vector.
- **Method 2.** Token vector of the last layer concatenated with the sentence vector.
- **Method 3.** Linear combination of the token vector of each layer.
- **Method 4.** Linear combination of the token vector of each layer and the sentence vector.

The combined representation of tokens passes on to the next layer.

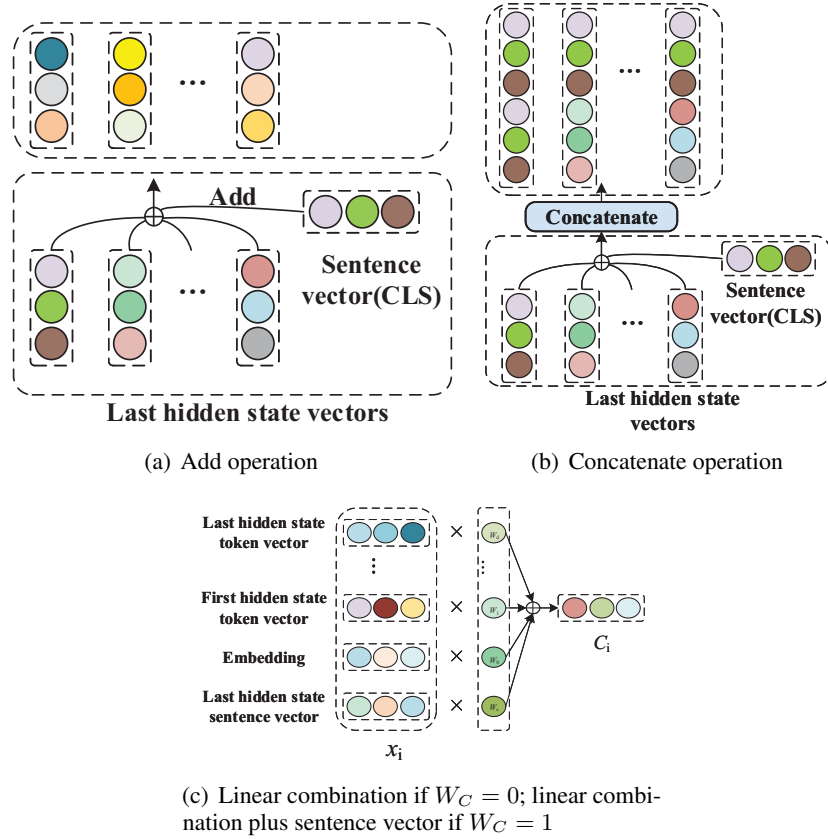

Figure 2: Different types of representations in auxiliary information layer.

### 2.3 Output Layer

The output layer is a fully connected dense layer with softmax activation. It aims to classify whether a token belongs to the toxic span in a text. The combined representation of each token passed by the auxiliary information layer is the input of this layer, and the output layer predicts the labels for the candidate tokens. The loss function of the proposed model is the categorical cross-entropy.

## 3 Experimental Results

In this section, we present the comparative results of the proposed model.

### 3.1 Dataset

During the competition, we used only the data (Pavlopoulos et al., 2021) provided by the task organizer for the experiments. This task involves trial data (which include 689 posts and spans), training data (which include 7939 posts and spans), and test data (which include 2000 posts). We used the training data as the training set and trial data as the validation set. We needed to find the subscript offset set of the toxic spans of each post in the test

data.

As this is a sequence labeling task, a common data preprocessing method is to use the BIO tagging format. We observed better performance when the IO tagging format was adopted during the actual training process. Therefore, our output layer was a two-classification layer that outputs the probability of a token belonging to a toxic span.

### 3.2 Evaluation Metrics

For this task, we employed the  $F_1$ -score metric (da San Martino et al., 2020) to evaluate the responses of a system participating in the challenge.

For each post,  $t_i$ , the predicted span was a set,  $S_i$ , of character offsets and  $G_i$  was the character offset of the groundtruth annotations of  $t_i$ . The  $F_1$  score of  $t_i$  was calculated as follows:

$$F_1(S_i, G_i) = \frac{2 * P(S_i, G_i) * R(S_i, G_i)}{P(S_i, G_i) + R(S_i, G_i)} \quad (1)$$

where  $P(S_i, G_i)$  and  $R(S_i, G_i)$  are respectively precision and recall scores defined as follows:

$$P(S_i, G_i) = \frac{|S_i \cap G_i|}{|S_i|} \quad (2)$$

Transformer model	Auxiliary information	Validation set	Test set
<b>BERT-large</b>	None	0.649	0.679
	Add sentence vector	0.670	0.679
	Concatenate sentence vector	0.671	0.671
	Linear combination	0.661	0.683
	Linear combination plus sentence vector	0.672	0.679
<b>ALBERT-xlarge</b>	None	0.659	0.675
	Add sentence vector	0.665	0.665
	Concatenate sentence vector	0.656	0.668
	Linear combination	0.648	0.667
	Linear combination plus sentence vector	0.657	0.670
<b>RoBERTa-large</b>	None	0.656	0.676
	Add sentence vector	0.620	0.662
	Concatenate sentence vector	0.610	0.673
	Linear combination	0.663	0.667
	Linear combination plus sentence vector	0.667	0.667
<b>XLNET-large</b>	None	0.659	0.679
	Add sentence vector	0.674	0.674
	Concatenate sentence vector	0.669	0.669
	Linear combination	0.674	0.675
	Linear combination plus sentence vector	0.678	0.681

Table 2:  $F_1$ -score of different models on validation set and test set.

$$R(S_i, G_i) = \frac{|S_i \cap G_i|}{|G_i|} \quad (3)$$

If  $G_i$  is empty for some post  $t_i$ , we set  $F_1(S_i, G_i) = 1$  if  $S_i$  is also empty and  $F_1(S_i, G_i) = 0$  otherwise. Finally, we averaged  $F_1(S_i, G_i)$  over all posts  $t_i$ .

### 3.3 Implementation Details

Each model was fine-tuned for eight epochs. We used the Adam (Kingma and Ba, 2015), AdamW (Loshchilov and Hutter, 2017), and Stochastic Gradient Descent (SGD) algorithm for optimization. The final one used was AdamW with a learning rate of  $5e - 6$ .

In the training process, we attempted to use the cross-entropy loss, focal loss (Lin et al., 2020), and Dice loss (Li et al., 2020). The results on the validation set showed that the focal loss and Dice loss are better than the cross-entropy loss. This may be due to an imbalance between the toxic and nontoxic categories in the text. In order to compare with the baseline model, we finally used the cross-entropy loss function to train all models.

### 3.4 Comparative Results

We used BERT, ALBERT, RoBERTa, and XLNET as the transformer-based layers. The model exhibit-

ing the best performance on the validation set in the eight epochs was used to predict the spans on the test set in the competition. The results on the test set are presented in Table 2. The model that performed the best on the test set over the eight epochs is also presented in Table 2.

In terms of the performance on the validation set, the BERT and XLNET models with the auxiliary information layer are better than those without. Method 4, mentioned earlier, achieves the highest  $F_1$  score. In case of ALBERT, only method 1 improves the performance. Methods 3 and 4 can improve the performance of RoBERTa.

Regardless of the performance on the validation set, the  $F_1$  score increases by 0.004 when using method 3 in the BERT model and increases by 0.002 when using method 4 in XLNET. The auxiliary information layer does not improve the performance of ALBERT and RoBERTa.

The results show that the performance of the best-performing model on the validation set is significantly different from that of the best-performing model on the test set. The reason for this difference may be the inconsistent data distribution of the validation and test sets.

However, the results indicate that when the validation set is not appropriate, the auxiliary informa-

tion layer can effectively improve the performance of the baseline model on the validation set. The BERT and XLNET models are the most suitable for the auxiliary information layer.

## 4 Conclusion

In this paper, we introduce the method we used in SemEval-2021 Task 5. We improved the performance of the basic model by reducing the number of categories for each token, selecting the appropriate loss function, adding some additional information to the representation vector of the tokens during classification, and finally obtaining a model that can detect the toxicity in a text. Our experimental results showed that adding auxiliary information to the original token representation vector is helpful in sequence labeling tasks.

In addition, we found that the model has some limitations. After analyzing the prediction results, we observed that although the model can learn the representation of each token well, token classification errors can occur when some tokens are toxic without the entire text being toxic. One possible solution for this is to add a text classification task to train the model.

## Abstract

We present our works on SemEval-2021 Task 5 about Toxic Spans Detection. This task aims to build a model for identifying toxic words in whole posts. We use the BiLSTM-CRF model combining with ToxicBERT Classification to train the detection model for identifying toxic words in posts. Our model achieves 62.23% by F1-score on the Toxic Spans Detection task.

## 1 Introduction

Detecting toxic posts on social network sites is a crucial task for social media moderators in order to keep a clean and friendly space for online discussion. To identify whether a comment or post is toxic or not, social network administrators often read the whole comment or post. However, with a large number of lengthy posts, the administrators need assistance to locate toxic words in each post to decide whether a post is toxic or non-toxic instead of reading the whole post. The SemEval-2021 Task 5 (Pavlopoulos et al., 2021) provides a valuable dataset called Toxic Spans Detection dataset in order to train the model for detecting toxic words in lengthy posts.

Based on the dataset from the shared task, we implement the machine learning model for detecting toxic words posts. Our model includes: the BiLSTM-CRF model (Lample et al., 2016) for detecting the toxic spans in the post, and the ToxicBERT (Hanu and Unitary team, 2020) for classifying whether the post is toxic or not. Before training the model, we pre-process texts in posts and encode them by the GloVe word embedding (Pennington et al., 2014). Our model achieves 62.23% on the test set provided by the task organizers.

## 2 Related works

Many corpora are constructed for toxic speech detection problems. They consist of flat label and

hierarchical label datasets. The flat label datasets only classify one label for each comment in the dataset (e.g., hate, offensive, clean), while hierarchical datasets can classify multiple aspects of the comment (e.g., hate about racism, hate about sexual oriented, hate about religion, and hate about disability). For flat label, we present several datasets including the two datasets which are provided by Waseem and Hovy (2016) and Davidson et al. (2017) in English, the dataset of Albadi et al. (2018) in Arabic, and the dataset of by Alfina et al. (2017) in Indonesian. For the hierarchical label, we introduce the dataset constructed by Zampieri et al. (2019) in English, the dataset provided by Fortuna et al. (2019) in Portuguese, and the CO-NAN dataset by Chung et al. (2019), which is the multilingual corpus (constructed in Italian, English, and French).

In addition, many of shared tasks about hate speech and abusive languages are organized, such as the SemEval-2019 Task 5 (Multilingual) (Basile et al., 2019), the SemEval-2019 Task 6 (English) (Zampieri et al., 2019), the PolEval 2019 Shared task 6 (Polish) (Ptaszynski et al., 2019), the GermEval 2018 (Germany) (Wiegand et al., 2018), EVALITA 2019 (Italian) (Bosco et al., 2018), Toxic Comment Classification Challenge<sup>1</sup>, and VLSP 2019 Shared task (Vietnamese) (Vu et al., 2019).

Besides, SOTA approaches like deep learning (Badjatiya et al., 2017) and transformers models (Isaksen and Gambäck, 2020) are applied in the hate speech detection and toxic posts classification. However, these models only classify based on the whole posts or documents. For the Toxic Spans Detection task, we adapt the mechanism from Sequence tagging (Wang et al., 2020) and Name entities Recognition (Lin et al., 2017) for detecting toxic words from posts.

<sup>1</sup><https://www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge>

### 3 Dataset

The dataset is provided from the SemEval-2021 Task 5: Toxic Spans Detection (Pavlopoulos et al., 2021). It includes the training and the test sets. Both of them consist of two parts: the content of posts and the spans denoting the toxic words in the posts. Spans represent toxic words in the posts as a set of character indexes. Table 1 illustrates several examples from the training set.

Figure 1: Number of toxic words in spans for each post in the training set.

Figure 2: Number of toxic words in spans for each post in the test set.

According to Table 1, a post contains multiple spans of toxic words. For each span, it contains a single word, a phrase, or a sentence. As described in Figure 1, most of the spans in the training set are single words, which account for 67.65%, while only 20.06% of spans contains two words, and 6.1% of spans is empty. Posts whose spans contain more than two words in the dataset are few. Espe-

cially in the training set, there is a post in which spans contain 25 words.

Besides, Figure 2 illustrates the number of toxic words in spans per post for the test set. Spans containing single words account for the highest percentage (70.35%) in the test set, and are higher than in the training set, while the multiple-word spans are few. Also, the empty spans in the test set are higher than the training set, and the longest post in the test set contains only seven words.

### 4 System description

#### 4.1 Data preparation

With the given dataset from the SemEval-2021 Task 5 about Toxic Spans Detection (Pavlopoulos et al., 2021), we firstly transform spans into a set of words. Then, we pre-process the posts as follows: (1) Segmenting the posts by the TweetTokenizer from nltk<sup>2</sup>, and (2) Changing texts to lower case.

#### 4.2 Feature extraction

We use the glove.twitter.27b.25d word embedding<sup>3</sup> to construct the dictionary and encode the text of posts. Posts are encoded by the dictionary of the word embedding. The  $\langle UNK \rangle$  tokens are added if a word in posts is not found in the dictionary. To make sure all vectors are the same length, we add the  $\langle PAD \rangle$  token. Then, we set the maximum length of vectors equal to 128. Spans are transformed into a one-hot vector corresponding to each word in posts where toxic words are denoted as 1 and others are denoted as 0. Table 2 illustrates an example of encoding data in our system.

#### 4.3 Training models

**Detection model:** BiLSTM-CRF is a deep neural model used for Named-entity recognition task (Lample et al., 2016). We implement this model for the task of detecting toxic words in documents. The model includes three main layers: (1) The word representation layer uses embedding matrix from the GloVe word embedding, (2) The BiLSTM layer for sequence labeling, and (3) The Conditional Random Field (CRF) layer to control the probability of output labels. The output is a binary vector, in which each value determines whether

Spans	[31, 32, 33, 34, 35, 36, 37, 38, 39, 45, 46, 47, 48, 49, 50, 51, 52, 53]	['i', 'only', 'use', 'the', 'word', 'haole', 'when', ' <b>stupidity</b> ', 'and', ' <b>arrogance</b> ', 'is', ...] <b>Vector:</b> [0, 0, 0, 0, 0, 0, 0, 0, 1, 0, 1, 0, 0 ...]

Table 2: Example of encoding data into vectors.

a word is toxic or non-toxic. The architecture of BiLSTM-CRF is described in Figure 3.

**Classification model:** The ToxicBERT model (Detoxify) is introduced by Hanu and Unitary team (2020) with the purpose to stop online abusive comments. It is a pre-trained model and is easy to use by using transformers library<sup>4</sup>. The model is trained on the Toxic Comments Classification Challenge datasets provided by Jigsaw.

Our system combines the detection and classification model together. The detection model (BiLSTM-CRF) returns the toxic spans from the post, while the classification model (ToxicBERT) classifies whether a post is toxic or non-toxic. If a post is non-toxic, the classification model returns an empty span. By contrast, it reserves the spans of the detection model. Then, predicted spans are decoded to character indexes for submission. Our system is illustrated in Figure 4

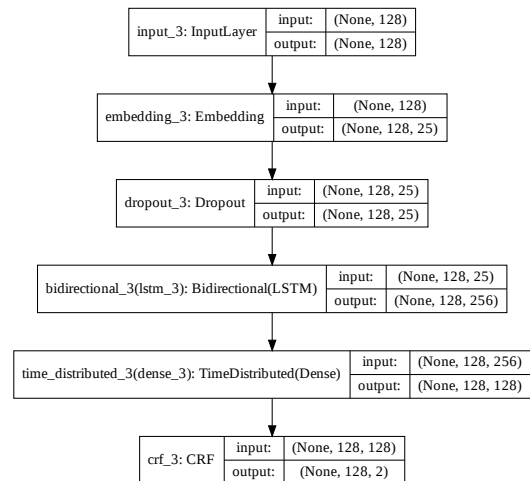

Figure 3: The BiLSTM-CRF model architecture.

<sup>4</sup><https://huggingface.co/unitary/toxic-bert>

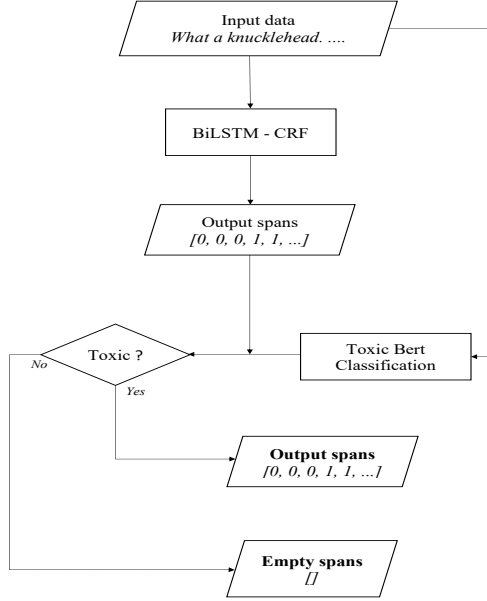

Figure 4: Our system architecture.

## 5 Experimental results

### 5.1 Evaluation metric

The variant version of F1-score is used to evaluate the results of the competition (Da San Martino et al., 2019). Let  $T$  is the total of post in the dataset,  $T = [t_1, t_2, \dots, t_n]$ ,  $n$  is the number of posts,  $A$  is spans given by the model, and  $G$  is ground truth spans.

The F1-score over the dataset is defined as:

$$\frac{1}{|T|} \sum_t F_1^t = 2 * \frac{P^t(A, G) * R^t(A, G)}{P^t(A, G) + R^t(A, G)} \quad (1)$$

In the Equation 1,  $P^t$  determines the precision, and  $R^t$  determines the recall of the post  $t$ . The precision and recall are calculated as Equation 2 and Equation 3, respectively. The  $S^t$  in both Equation 2 and Equation 3 is set of toxic characters of post  $t$  (span).

$$P^t(A, G) = \frac{|S_A^t \cap S_G^t|}{S_A^t} \quad (2)$$

$$R^t(A, G) = \frac{|S_A^t \cap S_G^t|}{S_G^t} \quad (3)$$

### 5.2 Main result from task

Model	Result (%)
BiLSTM-CRF	61.32
<b>BiLSTM-CRF + ToxicBERT</b>	<b>62.23</b>
Top 1 rank	<b>70.83</b>

Table 3: Experimental results obtained by our system in comparison with Top 1 rank result.

According to Table 3, when only BiLSTM-CRF is used, the result by F1 score is 61.32%. The result increases up to 62.23% when we applied ToxicBERT Classifier, and this is our final result of the shared task (ranked 63<sup>th</sup> among 92 teams).

### 5.3 Error analysis

According to Table 4, the appearance of the ToxicBERT classifier can make a better prediction for the non-toxic posts (See example No. 1). This increases the performance of our system, however, not significantly, because the number of empty toxic span comments in the test set is not too much (as described in Section 3). Apart from empty spans, wrong predictions are fell into the case as example No.3. Although the ToxicBERT model predicts this example as non-toxic, the BiLSTM-CRF model predicts it as empty spans, and thus the result is empty spans according to the result of the BiLSTM-CRF model. For example No.2, the system returns wrong spans for the first span in the post. Finally, our system cannot predict well for spans that contain more than two words. It returns spans, but not enough, as shown in examples No.4 and No.5 from Table 4.

## 6 Conclusion

We use the BiLSTM-CRF and ToxicBERT models for detecting toxic words in the posts. Our model achieves 62.23% by F1-score from the competition. From the error analysis, we found that our model predicts well just for single-word spans and empty spans.

In further researches, we improve the performance of the detection model by applying the attention mechanism and using the character-level representation combining with word-level representation. Character-level models like CharBERT (Ma et al., 2020) is a potential approach to increase the performance of toxic spans detection tasks.

No.	Posts	Gold span	Prediction span: BiLSTM-CRF	Prediction span: BiLSTM-CRF+ ToxicBERT

## Abstract

This paper discusses different approaches to the Toxic Spans Detection task. The problem posed by the task was to determine which words contribute mostly to recognising a document as toxic. As opposed to binary classification of entire texts, word-level assessment could be of great use during comment moderation, also allowing for a more in-depth comprehension of the model's predictions. As the main goal was to ensure transparency and understanding, this paper focuses on the current state-of-the-art approaches based on the explainable AI concepts and compares them to a supervised learning solution with word-level labels. The work consists of two xAI approaches that automatically provide the explanation for models trained for binary classification of toxic documents: an LSTM model with attention as a model-specific approach and the Shapley values for interpreting BERT predictions as a model-agnostic method. The competing approach considers this problem as supervised token classification, where models like BERT and its modifications were tested. The paper aims to explore, compare and assess the quality of predictions for different methods on the task. The advantages of each approach and further research direction are also discussed.

## 1 Introduction

The popularity of social media platforms has been continuously increasing over time. As reported by [Social \(2020\)](#), 3.8 billion people have been active users of social media in January 2020. While user inter-connectivity carries a lot of positive effects, there is still a significant threat of cyberbullying and harassment caused by the illusion of anonymity online. Statistics released by Facebook ([Richter, 2020](#)) identified that in the first quarter of 2020, there were 2.3 million bullying/harassment posts

and 9.6 million hate speech posts detected as a violation of Community Standards.

The importance of keeping the online community safe for users has caused many researchers to focus their work on detecting toxic contents in order to assist moderators in their difficult and mentally exhausting work. A lot of progress has been done in the task of toxic comment classification, but unfortunately, complex models still lack clear explanation and cannot gain much moderators' trust. A step towards increasing the transparency and therefore trust in automatic comment classifiers would be extending current approaches to operate on word-level rather than document-level. The ability to extract and highlight key text fragments that cause the toxic character of a comment could be of great use in post moderation.

The lack of extensive datasets for word-level toxicity detection poses an obstacle to traditional, supervised learning classification, as current state-of-the-art models are very complex and normally require large-scale data. Therefore, with the subject of this task being defined in terms of understanding and transparency for endpoint users, the authors decided to explore the explainable AI methodology. Ongoing research in xAI community examines many different approaches, with the two of them being in the focus of current work: model-specific attention-based ([Mohankumar et al., 2020](#)) and model-agnostic ([Lundberg and Lee, 2017](#)) explanations. This paper aims to compare the results obtained by these methods on Toxic Spans Detection task ([Pavlopoulos et al., 2021](#)) for the English language using supervised models ([Devlin et al., 2018](#)), acting as a baseline approach.

This paper is organised as follows. Related works and the backgrounds of discussed methods are described in Section 2. Section 3 presents three approaches to toxic spans detection, each with method-specific details in the corresponding

subsection. Finally, the results of the experiments are included in Section 4, with the discussion and conclusions in Section 5 and 6 respectively.

## 2 Related work

Pavlopoulos et al. (2017) introduced the application of a GRU-based Recurrent Neural Network for toxicity detection in documents. This approach was compared to the previous state-of-the-art for this task, presented in Wulczyn et al. (2017), which involved the use of Logistic Regression and Multi-layer Perceptron and operated on n-grams. Another model compared in their work was a Convolutional Neural Network with pretrained word embeddings. RNN model outperformed other approaches, and it was further extended by the attention module, which improved the quality of classification.

Attention has been commonly used by many researchers as a medium of explanation for the predictions made by the model (Ghaeini et al., 2018). It allows to analyse what part of the input the model focuses on the most while making a prediction. Current research does not provide a unified answer to whether the attention mechanism in models is a good source of explanation. Experiments carried out in Jain and Wallace (2019) point out that attention might not be a reliable method for interpreting the model's predictions. This was due to the fact that the attention distribution did not align well with other feature-importance measures. The other argument was that providing very different attention distribution often does not impact the predictions made by the model significantly. However, Wiegrefe and Pinter (2019) challenges the aforementioned work, claiming that while the answers given by attention should not be uncontrollably trusted and the definition of explanation must be clearly stated, it could still be a useful tool for model understanding and should not be disregarded easily.

An alternative formulation of the Toxic Spans Detection is to treat it as a supervised learning task, which involves training the models to predict the toxicity of each word separately. Previously used, Recurrent Neural Networks have been replaced as the state-of-the-art approach for many tasks by transformer-based models (Vaswani et al., 2017). Transformer architecture, consisting of an encoder and decoder enriched with multi-head attention modules, turned out to outperform previous approaches on a series of NLP tasks. Bidirectional

Encoder Representations from Transformers (Devlin et al., 2018) has been proposed as a powerful tool for many language-based problems. Typically, BERT is pre-trained on two unsupervised tasks when it is fed with large-scale text corpora and later adapted to a specific task during the fine-tuning stage, requiring much less data and computing time.

## 3 Toxic Spans Detection

This section describes the following approaches: analysing the attention of an LSTM model with orthogonalization of hidden states 3.1; using SHAP to provide explanation of BERT predictions for toxic comment classification 3.2; training BERT for classification of toxic tokens 3.3.

### 3.1 Orthogonal LSTM

As stated in the previous section, attention in RNN models is still a questionable medium of explanation. An interesting approach to LSTM with attention has been proposed in Mohankumar et al. (2020). The authors claim, that attention vectors in LSTM models are too similar to each other and therefore, cannot be used to explain the predictions. They propose an orthogonalization technique to increase the conicity of hidden states, enabling better interpretability. The equations of LSTM units are updated in order to orthogonalize the hidden state at a given time with respect to the previous states. The implementation used in this work has been adapted from the source code<sup>1</sup> provided by the authors of the original paper (Mohankumar et al., 2020).

During the preprocessing stage, the inputs with toxicity higher than 0.5 were considered as toxic examples. Due to the memory limitations of our computing architecture, the entire CivilComments (Borkan et al., 2019) dataset could not be used for training. Therefore, Random Undersampling (Cochran, 1977) of majority class was performed. The resulting set consisted of 350000 examples. The text was tokenized using spaCy tokenizer, special characters were removed as well as newline characters, multiple spaces were compressed to one space and capital letters were replaced by a lowercase equivalent. Finally, tokens were represented using FastText embeddings (Bojanowski et al., 2016) with the size of 300. The data was

<sup>1</sup><https://github.com/akashkm99/Interpretable-Attention> at commit 2d8dd37.

Figure 1: The chart of span-level F1 score with respect to the threshold for OrthoLSTM. Results obtained on the validation set.

split into training, validation and testing sets with the 80:10:10 ratio.

The model consisted of 1-layered orthogonal LSTM followed by the dense layer and was trained using Adam optimizer with learning rate of  $1e-3$ , weight decay of  $1e-5$  and the batch size 32. This model has obtained 0.957 ROC AUC for comment-level classification. The performance of the model proved it to be sufficient for further analysis of the attention. The key parameter to obtain token-level prediction was setting a threshold for toxic token selection based on the attention value. Two approaches were investigated:

- value-based: all tokens with an attention score higher than the certain threshold were selected as toxic
- cumulative: sorting the tokens by the highest attention score, each token was added to the toxic set as long as the cumulative value of attention was not covered (e.g. 70% of the whole model’s attention)

The span-level F1 score on the validation set with different threshold values for both approaches is presented in Figure 1. The best results were obtained by 0.12 threshold for the value method and 0.48 threshold for the cumulative method.

### 3.2 SHAP

Shapley Additive Explanations (Lundberg and Lee, 2017) method has been introduced as a model-agnostic framework that provides interpretation for model predictions. The authors of SHAP recognise

Figure 2: The chart of span-level F1 score with respect to the threshold for SHAP. Results obtained on the validation set.

that common feature importance measures rely on the same explanation model and propose a new method consisting of Shapley values approximated with kernel methods e.g. LinearLIME.

The authors decided to apply SHAP framework to explain the BERT model, trained for toxic comment classification. An implementation provided by Hanu and Unitary team (2020) in Detoxify<sup>2</sup> repository was used. The model is the `bert-base-uncased`<sup>3</sup> from `transformers` library trained on Wikipedia Comments (Wulczyn et al., 2017) using Adam optimizer with learning rate  $3e-5$  and weight decay  $3e-6$ . The model obtains 0.909 ROC AUC in the binary classification task on CivilComments dataset (Borkan et al., 2019).

As in the previous method, the problem of threshold selection has been a significant bottleneck of this approach as well. The difference, as opposed to LSTM with attention, is that SHAP scores do not sum up to 1. This allowed to treat the values in two more ways: operating on unchanged values or rescaling them to sum up to 1 and performing operations in the previous fashion. The results are presented in Figure 2. Overall, the scaled approaches outperformed methods using raw SHAP scores.

### 3.3 Token classification

As opposed to explanation-based solutions presented in the previous section, the authors also

<sup>2</sup><https://github.com/unitaryai/detoxify> at commit 18fd29e.

<sup>3</sup><https://huggingface.co/bert-base-uncased>

tested a classic, supervised learning approach to the task. This solution is based on pre-trained BERT model (Devlin et al., 2018), which is fine-tuned to predict toxic spans.

The trial part of the dataset was used for validation, where the training and testing parts were used according to their purpose. Due to the size of the training set, a model as complex as BERT is prone to overfitting. Therefore, the training time of the model consisted of 3 epochs and the learning rate started from  $4.7e-5$  and was divided by 10 after each epoch. The authors also proposed data augmentation to deal with this problem which was described in details in Section 3.3.3. As optimizer AdamW was used and batch size was set to 8.

### 3.3.1 Dealing with long inputs

The dataset for the task contained many comments with a noticeably large number of tokens. However, the BERT model is limited to 512 tokens for input data. The problem was solved by reformatting the input to fit the given size. A sample was built by adding whole sentences from the input as long as the size limit was not exceeded. A set of possible breakpoints consisted of end of sentence positions to ensure that each sentence is not split in half. Chosen breakpoints and sentence IDs were remembered in order to calculate the span-level F1 score. The length of the preprocessed samples did not have to be based only on BERT limitations and can be adjusted for better training complexity. The shorter splits were tested as a way to speed up the learning process. The results were presented in Table 1. The training time was reduced by 40%, but the decrease in quality of prediction appeared due to the much narrower context fed into the model.

	Time [m]		span-level F1
Tokens	128	43	0.660
	512	72	0.672

Table 1: The learning time in minutes and span-level F1 score on validation set according to the length of input in tokens.

### 3.3.2 BERT extensions comparison

Furthermore, given promising results obtained by BERT, the authors have decided to compare it to other BERT-based models. The models selected for testing were ELECTRA (Clark et al., 2020), XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019), SqueezeBERT (Iandola et al., 2020) and

for each of them the implementation from the `transformers`<sup>4</sup> library was taken. The models were tested in the same manner as BERT. The hyperparameters learning rate, batch size etc. were also the same. The results are presented in Table 2. One can notice that models with a higher number of parameters tend to work better. However, learning curves analysis indicates that they are also more prone to overfitting.

Model	span-level F1
XLNet	0.678
RoBERTa	0.676
BERT	0.672
SqueezeBERT	0.657
ELECTRA	0.646

Table 2: The comparison of BERT and BERT-based models on the validation dataset.

### 3.3.3 Data augmentation

In order to deal with overfitting, the authors decided to apply a simple augmentation method. The augmentation is performed by random swaps of words appearing in text no further than 3 words from each other. The number of swaps depends on the length of the input, for each input it is calculated as follows:  $alpha * number\_of\_tokens$ . The results obtained while using augmentation presented in Table 3 are ambiguous and do not give a clear answer whether it helps or not. However, after a thorough analysis of train vs. loss curves, the authors noticed that the model does not overfit quite as much and the metric have smaller fluctuations. Therefore, the authors decided to use this technique during further training whenever it helps on the validation dataset.

alpha	span-level F1
0	0.672
0.2	0.669
0.5	0.675

Table 3: The span-level F1 score on validation set for BERT model with augmentation with a given alpha.

### 3.3.4 Filling empty spaces in between spans

While analysing the labels provided for the training set, the authors noticed that at times, whole text

<sup>4</sup><https://huggingface.co/transformers> at version 4.0.1

fragments were labelled as toxic, including spaces in between words. Further analysis showed that 9.54% spans in the training set are spaces. Due to the fact that tokenization resulted in omitting those spaces, an experiment had been performed in order to deal with this problem. If the output contained toxic spans separated by one or two characters, the character was also considered toxic. This technique slightly improved the performance as noted in Table 4, therefore the authors decided to include it in the final solution.

Chars	span-level F1
0	0.6720
1	0.6735
2	0.6730

Table 4: The results of marking the given number of characters in between toxic spans as toxic by BERT on validation set.

### 3.3.5 Ensemble

Models previously described in Section 3.3.2 were concatenated into an ensemble. The aggregation of predictions was performed with hard voting - a span was considered toxic only when 3 out of 5 models returned a toxic prediction.

## 4 Results

The results obtained by different methods on the test set are presented in Table 5. The highest performing model in this paper turned out to be an ensemble of different BERT-based models scoring **13th out of 91** solutions. The source code for all approaches is publicly available on GitHub<sup>5</sup>.

<sup>5</sup><https://github.com/hancia/ToxicSpansDetection>

Figure 3: Confusion matrices for each method. 1 refers to toxic class, non-toxic samples are marked by 0.

Method	span-level f1
OrthoLSTM	0.4970
SHAP	<b>0.5987</b>
BERT	0.6513
XLNet	0.6624
BERT + aug 0.5 + fill 1	0.6780
Ensemble	<b>0.6859</b>

Table 5: The comparison of selected models' performance on the test dataset. Ensemble consists of all models stated in the section 3.3.2 - BERT was used with augmentation ( $\alpha=0.5$ ) and filling chars ( $char=1$ ), other models were only used with filling chars ( $char=1$ ).

## 5 Discussion

As presented in the previous section, the supervised solution to token classification outperformed both xAI approaches. The BERT model was trained specifically to solve this type of problem and therefore achieved a score slightly better than LSTM or SHAP. High labelling costs need to be taken into account when comparing those solutions, as training a robust BERT model would require much more data, that would not be necessary for xAI approaches, which are generally unsupervised.

Surprisingly, a model-agnostic approach turned out to perform much better than the attention-based solution, even though the explained models achieved very similar results on the toxic comment detection task. In Figure 3 one can see that the number of false negatives was significantly higher while relying on attention than it was while using Shapley values. This could be because the model might pay a significant portion of attention to a very toxic word, which is enough to recognise the comment as toxic. While analysing the model's focus can improve the understanding of how the model works, it might not necessarily be enough to

translate into clear decisions for each of the input components. Furthermore, the need for threshold tuning somehow forced explainable approaches to mark a certain number of tokens as toxic, which could be reflected in a slightly higher number of false positives. Visualisations of example predictions can be seen in Table 6.

While xAI approaches might not be fitted to solve the problem of predicting the toxicity of each input word, they might still be useful for improving the transparency and understanding of predictions made by comment-level models. As recognised in error analysis, the number of false negatives was significantly higher for LSTM and SHAP. But in terms of explanation, it might be enough for the user to obtain the few most toxic words per comment, rather than marking all of them, no matter how low the toxicity score is. This would not only provide the explanation on what the model considered while making a prediction but would also be a clear and transparent answer for the user in many real-time use cases. Further examination might need to be done in order to assess the performance of those methods for a task specified in the aforementioned way.

## 6 Conclusions

This work discussed different approaches to the Toxic Spans Detection task. Supervised toxic token classification and xAI methods were examined to compare the results and assess whether explaining high-performing models can lead to a similar quality of prediction as models dedicated to a more detailed task. The supervised approach using the BERT model achieved the best result in this task, but the xAI methods have proven to be an interesting alternative that could reduce data preparation costs and improve transparency and understanding of the model's predictions. While not currently outperforming BERT, explainable methods can be sufficient for many tasks where binary decision models are used. A system for toxic spans detection was prepared, achieving a 0.6859 span-level F1 score and placing 13th out of 91 in the overall ranking.

## Abstract

Many new developments to detect and mitigate toxicity are currently being evaluated. We are particularly interested in the correlation between toxicity and the emotions expressed in online posts. While toxicity may be disguised by amending the wording of posts, emotions will not. Therefore, we describe here an ensemble method to identify toxicity and classify the emotions expressed on a corpus of annotated posts published by Task 5 of SemEval 2021—our analysis shows that the majority of such posts express anger, sadness and fear. Our method to identify toxicity combines a lexicon-based approach, which on its own achieves an F1 score of 61.07%, with a supervised learning approach, which on its own achieves an F1 score of 60%. When both methods are combined, the ensemble achieves an F1 score of 66.37%.

## 1 Introduction

Healthy conversations are only possible when people feel safe from abuse and do not resort to using violent language. Regrettably, violent and inflammatory language is becoming increasingly common online. Indeed, the rhetoric of violence recently employed on social media has persuaded platforms, such as Twitter, to create new policies to prevent the use of threatening language (Twitter, Inc., 2021). A jargon word, *cyberbullying*, has been coined lately to refer to the use of electronic communication to send or post messages of an intimidating or threatening nature (Zaheri et al., 2020).

Along with cyberbullying, other forms of verbal abuse employed on social media, such as online harassment and hate speech, are now being collectively referred to as *toxicity* in language (Mohan et al., 2017). We are interested in developing algorithms to recognise toxicity and measure its impact on the sentiment expressed.

Most of the data available to investigate toxicity classify whole comments or documents (Wulczyn et al., 2017; Borkan et al., 2019), and do not identify “spans”—that is, the precise word sequences that make a text toxic. Given how important such spans are for the implementation of semi-automated moderation, we have participated on Task 5 (Toxic Spans Detection) of the *International Workshop on Semantic Evaluation (SemEval) 2021* (Pavlopoulos et al., 2021). Thus far, we have concentrated on the combination of two approaches: a lexicon-based approach and a supervised learning approach to identify toxic spans.

Although the identification of toxic spans in online posts can be aided by a suitable lexicon of toxic words, such words can easily be concealed through minor changes—for instance, “fck urself” is a toxic span that would evade detection based on basic lists of profane words. However, emotions are harder to conceal. Hence, we are interested in using opinion mining to uncover the emotions expressed in text. Emotions may be able to identify toxicity, regardless of wordings and spellings. Thus, we dedicate part of this study to measure the correlation between toxicity and emotions.

The remainder of this paper is organised as follows: Section 2 reviews the related work. Section 3 describes the datasets that we used for our experimentation. Section 4 is dedicated to explain our algorithm for the identification of toxic spans. Section 5 presents our results and, finally, Section 6 offers our conclusions.

## 2 Background

The existing literature on toxicity focuses on two main aspects: the compilation and annotation of corpora for research purposes (Fortuna et al., 2020; Waseem, 2016); and the automatic detection of different types of toxic text.

Among the different types of toxic text under scrutiny, we may include hate speech (Badjatiya et al., 2017; Davidson et al., 2017; Del Vigna et al., 2017), online harassment (Golbeck et al., 2017), racism (Waseem, 2016), sexism (Jha and Mamidi, 2017), abusive language (Mehdad and Tetreault, 2016) and cyberbullying (Zhong et al., 2016).

At present, the detection of toxicity is largely based on state-of-the-art natural language processing techniques, typically involving machine learning. The main drawback of such techniques resides in the limited generalisation potential of trained machine learning models (Fortuna et al., 2020). To overcome this weakness, we have integrated into our research the use of a lexicon-based approach, where toxic language is identified with the help of a dictionary of words associated with toxic text (De Smedt et al., 2020).

Combining lexicons with machine learning approaches has already been evaluated by other researchers, remarkably Pamungkas and Patti (Pamungkas and Patti, 2019), though they employed a lexicon originally built for the Italian language, and then translated it into other languages, whereas we focus on English from the start. Various other lexicons, handcrafted by domain experts who specialise on the identification of toxicity have been published too—for example, *Textgain’s Profanity and Offensive Words* lexicon (De Smedt et al., 2020)—but many of them are not available for free.

In an attempt to mitigate toxicity and promote work on this area, the research community has released a number of annotated datasets for investigating different forms of toxicity (Waseem and Hovy, 2016; Waseem, 2016; Golbeck et al., 2017). However, they all follow different labelling conventions. Consequently, they cannot be analysed using a uniform method.

Overall, toxicity detection and classification lacks a consistently labelled standard dataset for comparative evaluation (Schmidt and Wiegand, 2017). Therefore, the data provided by Task 5 (Toxic Spans Detection) of SemEval 2021 is very well regarded (Pavlopoulos et al., 2021).

### 3 Experimental Setup

Task 5 of SemEval 2021 uses posts from the publicly available *Civil Comments* dataset (TensorFlow, 2021). Such a dataset comprises annotations indicating which entire posts are toxic, but it does not label particular toxic spans within the posts.

The Civil Comments platform (Drupal, 2021), which is where the posts come from, is a commenting plugin for independent news websites. All the comments were created between 2015 and 2017, and they appeared on approximately 50 English language websites across the world. When Civil Comments shut down in 2017, the comments became publicly available in an open archive for future research (TensorFlow, 2021).

To build the dataset, SemEval retained only posts that were found toxic—or severely toxic—by at least half of the annotators involved in Borkan, *et al.*’s annotation (Borkan et al., 2019). This comprises 30k toxic posts, approximately, out of the original 1.2M. Then, a random subset of 10k posts from these 30k toxic posts were chosen for toxic spans annotation (CodaLab, 2021).

## 4 System Overview

Although machine learning technology is being widely employed to detect toxic text automatically, the use of a lexicon to identify and prevent toxicity in social media still constitutes a valuable approach. Indeed, the number of lexicons specialised on the detection of profanity, offensive speech and toxicity in general has grown steadily in recent times (De Smedt et al., 2020).

Lexicons are not susceptible to algorithmic bias (Hajian et al., 2016), and are not limited to the domain and scope of the training data, which has previously raised a number of ethical concerns, given how much training data is historically associated with particular communities (Hao, 2019). Hence, we employ a lexicon as our first step in the detection of toxic spans.

Originally, our lexicon was made, specifically, for Task 5 of SemEval 2021, as we compiled it by extracting all the toxic words available in the training and trial datasets for Task 5—we considered a word as a *toxic* word if it was included in a toxic span identified by the annotators.

Upon compiling all the toxic words available in the training and trial datasets (1,287 words), we proceeded to extend our lexicon with words listed in other lexicons. While there are many freely-available lexicons of toxic words, we favoured those that maintained the accuracy of the detection of toxic spans achieved by our lexicon. Table 1 shows the F1 scores achieved by each of the lexicons considered, when combined with our lexicon to evaluate them on the training dataset.

Lexicon	F1 Training	Number of words
Task 5 Lexicon	64.30%	1,287
<b>Banned Word List</b>	<b>64.30%</b>	1,332
Offensive/Profane Word List	61.25%	2,516
<b>Google’s Profanity Words</b>	<b>64.30%</b>	1,681
Insult.wiki	63.94%	1,846
Compiled_bad_words	63.99%	2,546
<b>Swear Word List &amp; Curse Filter</b>	<b>64.30%</b>	1,580

Table 1: F1 score per lexicon (evaluated on the training dataset).

The first row of Table 1 refers to the lexicon we created after compiling all the toxic words available in the training and trial datasets of Task 5 of SemEval 2021—we named this lexicon the *Task 5 Lexicon*. Using bold font, we have highlighted the details of the lexicons that achieved the same F1 score as the Task 5 Lexicon, when combined with it to evaluate them on the training dataset. Such lexicons are the ones that we decided to use, namely, the *Banned Word List* (<http://www.bannedwordlist.com/>), *Google’s Profanity Words* (<https://github.com/RobertJGabriel/Google-profanity-words>), and the *Swear Word List & Curse Filter* (<https://www.noswearing.com/dictionary>). Table 1 also displays the number of words available in each of the lexicons evaluated, when combined with the Task 5 Lexicon.

As shown in Table 1, the *Offensive / Profane Word List* (<https://www.cs.cmu.edu/~biglou/resources/>) and the *Compiled\_bad\_words* ([https://github.com/minerva-ml/open-solution-toxic-comments/blob/master/external\\_data/compiled\\_bad\\_words.txt](https://github.com/minerva-ml/open-solution-toxic-comments/blob/master/external_data/compiled_bad_words.txt)) have a negative impact on the performance of toxicity detection, even if it is only by a small margin. Thus, we discarded these lexicons.

After creating our lexicon, we manually removed from it words that were part of the toxic spans annotated in Task 5 of SemEval 2021, but were not included in the three lexicons displayed in bold font in Table 1. For example, the word “mistake” located in the post “They elected Trump, which was certainly a mistake” was considered toxic by the annotators, in the context of the post. However, we removed it from our lexicon, because “mistake” does not appear in any of the three lexicons mentioned above. Our lexicon comprises a total of 1,929 words, and we refer to it as the *Orthrus* lexicon—it is available at <https://github.com/Orthrus-Lexicon/Toxic>.

While our lexicon-based approach was considerably useful to identify toxicity, as we will show in Section 5, we recognise the value of machine learning approaches. The success of the *Perspective* project undertaken by Google and Jigsaw to rate toxicity by means of machine learning (Jain et al., 2018), as well as the impact of the *Perspective API* to mitigate toxicity using machine learning certainly deserve our attention. Therefore, we opted to employ *spaCy* (Explosion, 2021b), an open-source software library for natural language processing, to develop a supervised learning approach for the identification of toxicity.

Our choice of *spaCy* was further motivated by the organisers of Task 5 of SemEval 2021, who released a Python script referring, precisely, to this library (Task 5, 2021). Initially, we employed `en_core_web_sm`, which is a *spaCy* model for the English language (Explosion, 2021a). We employed this model, because it was the one used in the code provided by the organisers of Task 5 as a solution for some NLP tasks—namely, POS tagging, NER and dependency parsing (Task 5, 2021). However, given that `en_core_web_sm` is based on a small English corpus, we also tested `en_core_web_lg`, which is *spaCy*’s large English model (Explosion, 2021a).

Despite *spaCy*’s large English model being understandably slower, it did not appear to improve the performance of our implementation. The F1 score achieved, on average, by *spaCy*’s small English model after 10 executions (59.61%) was approximately the same as the score achieved by the large English model under the same circumstances (59.95%). Thus, we favoured the choice of the small model, as it was faster to train.

## 5 Results

Table 2 shows the F1 score achieved by our implementation when evaluating it on the test dataset.

Approach	F1 Score
Orthrus Lexicon	61.07%
Orthrus Lexicon + spaCy Model (Union)	61.53%
Orthrus Lexicon + spaCy Model (Intersection)	66.37%

Table 2: Evaluation on the test dataset.

As shown in Table 2, our lexicon achieves, on its own, an F1 score of 61.07%. By combining our lexicon with the supervised learning approach implemented using spaCy, we achieve two results: 61.53%, if we consider the union of the results yielded by the lexicon and the supervised learning approach; and 66.37%, if we consider the intersection of the results yielded by the lexicon and the supervised learning approach.

We are interested in the identification of emotions expressed in text, because concealing emotions may be harder than disguising toxicity. For example, the post “*uh, no, he’s a belligerent buffoon (and a traitor)*”, which is post 1,928 of the training dataset of Task 5 of SemEval 2021, lacks any recognisable toxic features, such as insults or swear words. Hence, it is classified as non-toxic by any of the lexicons highlighted in bold font in Table 1. Moreover, this post does not have any toxic spans marked by the annotators. Nevertheless, the negative sentiment of “belligerent buffoon” and “traitor”—words which are not typically found in any abusive word list—guarantees that the message conveyed is definitely toxic; otherwise, it would not be part of the training dataset.

If we included emotion information in our analysis, we could immediately detect the negative tone of the post mentioned above. Indeed, the probability of such a post to communicate anger is 1.0, according to `text2emotion`, a Python package to extract emotions from text (Python Software Foundation, 2021). The expression of anger is so evident in this case that the post can be marked as a candidate to be considered toxic.

Using `text2emotion`, we assigned each post in the test dataset a probability associated with each of the emotions reported in Figure 1. The values shown in Figure 1 represent the addition of the probabilities of each emotion to occur in each of the posts of the test dataset. Clearly, fear, sadness and anger—the three emotions combined together—are more likely to occur than happiness and surprise—the two emotions combined together—which may characterise the toxicity of the dataset.

Figure 1: Emotion expressed on the test dataset.

## 6 Conclusions

In this paper, we have described the creation of a lexicon of toxic words and a supervised learning approach to identify toxicity in online posts. Our lexicon, along with the supervised learning approach, achieved an F1 score of 66.37% on Task 5 of SemEval 2021. We have also explored the relationship between emotions and toxicity. Although our study is still in progress, preliminary results indicate that there exists a correlation between emotions such as sadness and fear and toxicity.

## Abstract

Toxic spans detection is an emerging challenge that aims to find toxic spans within a toxic text. In this paper, we describe our solutions to tackle toxic spans detection. The first solution, which follows a supervised approach, is based on SpanBERT model. This latter is intended to better embed and predict spans of text. The second solution, which adopts an unsupervised approach, combines linear support vector machine with the Local Interpretable Model-Agnostic Explanations (LIME). This last is used to interpret predictions of learning-based models. Our supervised model outperformed the unsupervised model and achieved the f-score of 67,84% (ranked 22/85) in Task 5 at SemEval-2021: Toxic Spans Detection.

## 1 Introduction

By dint of the massive production of user-generated content in social media, moderation becomes crucial to promote healthy online discussions by removing toxic posts and contents. However, it is nearly impossible for a human to keep tracking user-generated content. Thus, the need for the right tools and technologies to help in such a task becomes a necessity.

The Toxic Spans Detection task aims to detect the spans that make a text toxic. While several toxicity detection datasets (Wulczyn et al., 2017; Borkan et al., 2019) and models (Pavlopoulos et al., 2017a, 2019; Schmidt and Wiegand, 2017; Pavlopoulos et al., 2017b; Zampieri et al., 2019; Alami et al., 2020) have been released. However, these works estimate the likelihood of a document being toxic with weak interpretability. In fact, highlighting toxic spans can assist human moderators who often deal with lengthy comments, and who prefer attribution instead of just a system-generated unexplained toxicity score per post.

\*contributed equally

In this paper, we propose two solutions to tackle toxic spans detection (Pavlopoulos et al., 2021). The first solution, which follows a supervised approach, is based on SpanBERT (Joshi et al., 2020) model that is pre-trained on span boundary objective and considers masks contiguous spans. Therefore, SpanBERT gives better spans representations and predictions. The second solution, which adopts an unsupervised approach, combines linear support vector machine (Fan et al., 2008) with the Local Interpretable Model-Agnostic Explanations (LIME) (Ribeiro et al., 2016). LIME is an explanation technique that seeks to faithfully interpret the predictions of any classifier.

This paper is organized as follows: Section 2 describes the proposed methods; Section 3 presents the experimental results; Finally, Section 4 concludes and outlines future directions.

## 2 Methods

In this section, we describe the proposed solutions including SpanBERT-based method which is based on supervised approach, and SVM and LIME-based method that is based on unsupervised approach.

### 2.1 SpanBERT-based method

We use SpanBERT (Joshi et al., 2020) a pre-trained model built to improve spans of text representation and prediction. It differs from BERT (Devlin et al., 2019) as it (1) masks contiguous random spans, instead of random tokens; and (2) is trained on span-boundary objective, i.e., the model is optimized to predict the masked span given tokens at its boundary. We considered the toxic span text detection as a sequence labeling task. Thus, we performed a transformation to the dataset and fine-tuned SpanBERT to this specific task.

### 2.1.1 Data preparation

The raw dataset consists of a set of toxic texts where each element is annotated with an array that contains characters' indices. These indices are considered as the toxic span of text. In order to train SpanBERT on this dataset, we applied the pre-trained SpanBERT tokenizer to tokenize sentences, and we built the target arrays by annotating words that contain toxic characters' indices. For instance, given a sentence that contains  $n$  tokens, then the target array contains  $n$  elements, where the elements that contain a toxic character are labeled as positive "1" otherwise they are labeled as negative "0". Figure 1 illustrates the pipeline of dataset preparation.

Figure 1: The pipeline of dataset preparation

### 2.1.2 Toxic spans detection

We considered the toxic span detection as a sequence labeling task. Therefore, we fine-tuned SpanBERT pre-trained model on token classification task. First, we tokenize the sentence and map its tokens into indices according to SpanBERT vocabulary. Next, we fed the model with tokens indices. Then, it computes tokens embeddings by applying SpanBERT pre-trained model. After that, we compute the probability if a given token is toxic by applying a linear layer followed by a softmax on tokens embeddings. Finally, the model is trained to optimize the cross-entropy loss. Figure 2 shows the flowchart of the SpanBERT-based model. It is worth noting that we filter predicted spans by removing toxic character offsets that have a size equal to one.

## 2.2 SVM and LIME-based method

### 2.2.1 Data preparation

The data preparation for our unsupervised method can be summarized as follows:

Figure 2: The flowchart of SpanBERT-based model

1. We combine both SemEval 2021 Task 5: Toxic Spans Detection training set which contains 7939 toxic comments, SemEval 2021 Task 5: Toxic Spans Detection test set that contains 2000 toxic comments, and 159571 comments (16225 toxic comments and 143346 non-toxic comments) from Kaggle Jigsaw Toxic comment classification challenge <sup>1</sup> in order to use them for training the linear support vector machine classifier. Later, We label the toxic comments with 1 and non-toxic comments with 0.
2. Word-level uni-grams and bi-grams are extracted, then vectorized using TF-IDF scores.

### 2.2.2 Toxic spans detection

The toxic spans detection task adopted by our unsupervised method can be summarized as follows:

1. We train the linear support vector machine classifier on 26164 toxic comments and 143346 non-toxic comments (the combination of SemEval 2021 Task 5: Toxic Spans Detection training set, SemEval 2021 Task 5: Toxic Spans Detection test set, and a subset of Kaggle Jigsaw Toxic comment classification challenge dataset).

<sup>1</sup><https://raw.githubusercontent.com/iampukar/toxic-comments-classification/master/train.csv>

- We apply the trained model on the SemEval 2021 Task 5: Toxic Spans Detection test set comments to predict their toxicity, then, we use the LIME technique to explain the predictions (Figure 3).
- We discard words that contribute less to the toxic category by applying a thresholding technique. Words with a high influence score, greater or equal to the threshold, are considered toxic, therefore, we retrieve their character offsets (toxic spans).

Figure 3: Lime explanations

By training the linear support vector machine classifier on the SemEval 2021 Task 5: Toxic Spans Detection test set, we guarantee that the model accurately predicts the toxicity of its comments with precision, recall, f-score, and accuracy of 1 (the model correctly predict the toxicity of all 2000 reviews in the test set). Besides, we ensure that the LIME explanations are somewhat accurate. In fact, if the model misclassifies the toxicity of the comments, the LIME explanations will be inaccurate since the latter will explain wrong predictions.

From Figure 3, we can see that the words "silly" and "stupid" contribute to the toxic category 42% and 23% respectively in the following toxic comment "Please people, stop using these silly, stupid emoticons". Since we only consider words with high influence scores for the toxic category (greater or equal to 0.13), we keep the two words "silly" and "stupid", and we discard the remaining words. Next, we retrieve their character offsets from the comment as shown in Table 1.

### 3 Experimental results

We experimented our models on the SemEval 2021 Task 5: Toxic Spans Detection dataset. The training set and test set contain 7939 and 2000 toxic

comments labeled with their toxic spans. All our experiments have been conducted in Google Colab environment<sup>2</sup>, The following libraries: Hugging Face<sup>3</sup>, LIME<sup>4</sup>, Scikit-Learn<sup>5</sup>, and PyTorch<sup>6</sup> were used to train and to assess the performance of our models.

#### 3.1 Evaluation Metric

In order to measure the performance of our models, we employ the F1 score proposed in (Da San Martino et al., 2019). Considering a post  $t$  and a system  $A_i$  which predict a set  $S_{A_i}^t$  of toxic character offsets. Let denote by  $G^t$  the expected character offsets. Then, the F1 score of the model  $A_i$  with respect to  $G$  for  $t$  is computed in the following manner:

$$P^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_{A_i}^t|} \quad (1)$$

$$R^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_G^t|} \quad (2)$$

$$F_1^t(A_i, G) = \frac{2 \cdot P^t(A_i, G) \cdot R^t(A_i, G)}{P^t(A_i, G) + R^t(A_i, G)} \quad (3)$$

where  $|\cdot|$  denotes set cardinality.

#### 3.2 Performance Evaluation

On the one hand, we compared various pre-trained models, including BERT-base, BERT-large, DistilBERT (Sanh et al., 2019), and SpanBERT-large, to compute tokens embeddings. All the models are based on transformers (Vaswani et al., 2017) technique. The SpanBERT model achieves the best results due to the fact that is trained with contiguous masked spans and optimizes the span boundary objective. On the other hand, we compared the logistic regression LIME (LR-LIME) to linear support vector machine LIME (LSVM-LIME). The latter produces superior scores. Table 2 reports the obtained results for both supervised and unsupervised techniques. SpanBERT outperforms all the models by scoring about 0.6783 F1 score. During the fine-tuning of SpanBERT model, we set the hyper-parameters as follows:  $1.5e - 5$  as the learning rate, 3 epochs, 256 as the max sequence length, 4 as batch size, 476 as the warmup steps, and 0.01

Comment	Toxic spans
Please people, stop using these <b>silly</b> , <b>stupid</b> emoticons.	[32, 33, 34, 35, 36, 38, 39, 40, 41, 42, 43, 44]

Table 1: Example of unsupervised toxic spans detection

Method	F1 score
LR-LIME	0.5887938605
LSVM-LIME	0.592141639
DistilBERT	0.6636129383
BERT-base	0.6714433707
BERT-large	0.6677294902
SpanBERT-large	0.6783641122

Table 2: Toxic spans detection results

as the weight decay. For the unsupervised technique, several experiments have been conducted to reach the suitable threshold. Actually, 0.12 and 0.13 thresholds achieved the best performances for LR-LIME and LSVM-LIME, respectively.

## 4 Conclusion

In this paper, we described our models for tackling SEMEval 2021 Task 5: Toxic Spans Detection. Two approaches have been employed. A supervised approach based on transformers technique, where toxic sequences are tokenized and embedded using pre-trained models. We optimize the likelihood of a token to be toxic by minimizing the cross-entropy loss. SpanBERT scored the best results by achieving about 0.6783 F1 score. An unsupervised approach based on shallow machine learning and LIME, which is an explanation technique that explains the prediction of any classifier in an interpretable and faithful manner. Since the top-ranked score was about 0.7083 F1 score, future studies and works will focus on improving the performance of toxic spans detection task.

## Abstract

This paper introduces our system at SemEval-2021 Task 5: Toxic Spans Detection. The task aims to accurately locate toxic spans within a text. Using BIO tagging scheme, we model the task as a token-level sequence labeling task. Our system uses a single model built on the model of multi-layer bidirectional transformer encoder. And we introduce conditional random field (CRF) to make the model learn the constraints between tags. We use ERNIE as pre-trained model, which is more suitable for the task according to our experiments. In addition, we use adversarial training with the fast gradient method (FGM) to improve the robustness of the system. Our system obtains 69.85% F1 score, ranking 3rd for the official evaluation.

## 1 Introduction

With the prosperity of the Internet, it is easier and easier for people to get information and publish their opinions online. However, sometimes users' opinions can be offensive to others. Because toxic posts will have a negative impact on the network environment, and manual identification is time-consuming and expensive, automatic detection of these behaviors has attracted researchers' attention.

After adapting the hate-speech problem to the problem of word sense disambiguation, an approach to detect hate speech in online text is presented (Warner and Hirschberg, 2012), which uses template-based strategy to generate features and an SVM classifier to identify whether the text is toxic or not. In SemEval-2020 Task 12 (Zampieri et al., 2020) and SemEval-2019 Task 6 (Zampieri et al., 2019), which also related to offensive statements,

transformer-based methods were the most popular approaches for their great advantages in learning word representations in context.

In Semeval-2021 task 5: Toxic Spans Detection (Pavlopoulos et al., 2021), the organizers use posts from the publicly available Civil Comments dataset (Borkan et al., 2019), which already comprises post-level toxicity annotations. After manual annotation, character-level annotation results are obtained, which are the toxic spans we need to locate. The task extends the prior work by identifying spans that make a text toxic, which can better explain why posts are offensive rather than just giving a system-generated unexplained toxicity score.

We model the task as a sequence labeling task because toxic spans are contextually influenced. Our model is in Transformer-CRF architecture, and we try different pre-trained models as the transformer's initialization to fine-tune model suitable for toxic spans detection. The Conditional Random Fields (CRF) (Lafferty et al., 2001) allows the model to learn the constraints between tags. We also use the Fast Gradient Method (FGM) (Miyato et al., 2016) as adversarial training strategy, which applies perturbation to word embedding to enhance the robustness of the model.

The paper is organized as follows: Section 2 briefly introduces the Toxic Spans Detection shared task. Section 3 talks about our system, including pre-processing and post-processing. Section 4 shows our experiment results. Finally, the conclusion and future work are drawn in Section 5.

## 2 Toxic Spans Detection

The research of automatic offensive language detection has gained attention in the past decade. Instead of just classifying the whole comments or documents, the Toxic Spans Detection task requires the system to detect the spans that make a text toxic.

\* Equal contribution.

† Corresponding author.

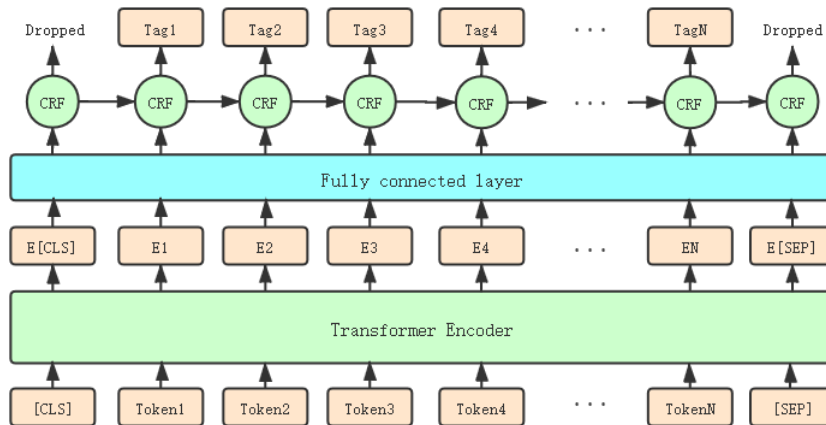

Figure 1: Model structure of Transformer-CRF. In our system, the transformer encoder is ERNIE. “[CLS]” and “[SEP]” are the special input tokens, “TokenN” means the Nth token in tokenized text. “E[CLS]”, “E[SEP]” and “EN” means the output of “[CLS]”, “[SEP]” and the Nth token’s embedding after Transformer Encoder. The output of Transformer-CRF is “TagN”, which is “B-toxic”, “I-toxic” or “O”.

People often judge offensive sentences in terms of words, therefore the toxic spans in this task are always associated with words. In this task, the input sentence may contain no toxic span, which means it is not offensive. On the other hand, there may be more than one word that shows the author’s malice in the sentence. Considering toxic spans are contextually influenced, we model the task as a token-level sequence labeling task and use BIO tagging scheme.

### 3 System description

Our system uses a single model to get the result, which is in Transformer-CRF architecture. In our system, we utilize a pre-trained contextualized language model, namely ERNIE 2.0 (Sun et al., 2019), to identify the toxic tokens. And we introduce CRF to learn the constraints between tags. In addition, we use adversarial training with the FGM to improve our performance.

#### 3.1 Data pre-processing

Toxic spans detection is a character-level task. Considering transformer architecture requires token-level inputs, we choose token-level sequence labeling instead of character-level. When converting character-level sequence labels to token-level, the tokenizer we use is the one used in pre-training. And we lowercase the text before tokenized.

After tokenizing the text, we tag the tokens. If one of the token’s spans is tagged as toxic in the original dataset, considering the tag of the previous token, the token will be tagged as “B-toxic” or “I-toxic” in pre-processed data. If the token’s spans are not tagged as toxic in the original dataset, the token will be tagged as “O” in pre-processed data. Some typical examples are shown in Table 1.

#### 3.2 Transformer-CRF architecture

Our system uses a single model to get token-level predictions. The model is in Transformer-CRF architecture. As shown in Figure 1, it consists of three components: transformer encoder, fully connected layer, and a CRF layer.

First, the transformer encoder is used to extract representations of the input tokens. Based on multi-layer bidirectional transformer encoder, we use ERNIE as pre-trained model to encode. During pre-training, transformer-based language models always use inputs with special tokens (such as [CLS] or [SEP]). Therefore, after tokenizing text into tokens, we insert “[CLS]” at the beginning of the token list and “[SEP]” at the end to make our input closer to what it would be when ERNIE was pre-trained. When we train the model, the tag of “[CLS]” and “[SEP]” is “O”, and we drop the tags of them during predicting.

After we get the embeddings of tokens, the representations are fed into a fully connected layer to

Origin tags	Origin data	Tokens and tags
8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, ...	Another violent and aggressive immigrant killing a innocent and intelligent US Citizen....	another O violent B-toxic and I-toxic aggressive I-toxic ... ..
7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17	What a knucklehead. How can anyone not know this would be offensive??	what O a O kn B-toxic ##uck I-toxic ##le I-toxic ##head I-toxic ... ..

Table 1: Typical Examples, where “Origin tags” means the toxic spans given in the dataset, “Origin data” means the comment given in the dataset, “Tokens and tags” means the tokens and tags after tokenized and tagged.

reduce dimension. Finally, the CRF layer decodes the reduced representations into the most probable tag sequence using the Viterbi algorithm. Using only the fully connected layer may output illegal tags (e.g. “... O I-toxic O ...”), while introducing the CRF layer allows the model to learn the constraints between tags. When fine-tuning the pre-trained model, the layer closer to the input is more likely to learn more simple features. We want to modify the deeper weights more to adapt to the target task. Therefore, we use different learning rates for different parts of the network. The transformer encoder has a lower learning rate, while the fully connected layer and the CRF layer have a higher learning rate.

We train the model maximizing the log-likelihood of the given sequence of tags, as compared to the gold training labels. Except that, we use the FGM as an adversarial training strategy to improve the performance of our system. FGM applies perturbation to word embedding to enhance the robustness of the model.

Given a token sequence  $S = t_1, t_2, \dots, t_N$  as input where  $N$  denotes the sequence length. The process for the model to obtain token-level results is as follows:

$$e_i = \text{transformer\_encoder}(t_i) \quad (1)$$

$$\text{out}_i = W_o e_i + b_o \quad (2)$$

$$\text{tag}_i = \text{crf}(\text{out}_i) \quad (3)$$

Where  $t_i$  is the current token, and  $e_i$  denotes the output of transformer encoder. Then  $e_i$  is fed into

fully connected layer to reshape into  $\text{out}_i$ . After that, the CRF layer use  $\text{out}_i$  to get token-level result  $\text{tag}_i$ .

### 3.3 Post-Processing

Our model produces token-level predictions, but detecting toxic spans within the text is a character-level task. To get the results, we use the opposite way of pre-processing to get spans from model’s predictions. Particularly, we assume the blank between toxic tokens should be tagged as toxic, too. This is observed from the spans of the dataset.

## 4 Experiment

### 4.1 Dataset

We trained our models by SemEval-2021 Task 5 training data which consists of 7,939 samples with a total of 139,115 toxic spans. We convert the span from character-level to token-level, as described in section 3.1. Then we get a total of 31,114 toxic tokens, with an average of 3.92 per sample. And each sample contains an average of 48.50 tokens.

### 4.2 Metric

Let system  $A$  return a set  $S_A^t$  of character offsets, for the post  $t$  that found to be toxic. Let  $S_G^t$  be the set of character offsets of the ground truth annotations of  $t$ . We compute the F1 score of system  $A$  with respect to the ground truth  $G$  for post  $t$  as follows, where  $|\cdot|$  denotes set cardinality.

$$P^t = \frac{|S_A^t \cap S_G^t|}{|S_A^t|} \quad (4)$$

Method	F1
BERT-CRF	0.6933
ELECTRA-CRF	0.6944
ERNIE-CRF	<b>0.6985</b>
ERNIE-CRF w/o-adv	0.6964
ERNIE-CRF nltk-preprocessing	0.6557

Table 2: Results on the official evaluation testing data. “w/o-adv” means no adversarial training. “nltk-preprocessing” means using NLTK for pre-processing.

$$R^t = \frac{|S_A^t \cap S_G^t|}{|S_G^t|} \quad (5)$$

$$F_1^t = \frac{2 \cdot P^t \cdot R^t}{P^t + R^t} \quad (6)$$

If  $S_G^t$  is empty for some post  $t$  (no gold spans are given for  $t$ ), we set  $F_1^t = 1$  if  $S_A^t$  is also empty, and  $F_1^t = 0$  otherwise. We finally average  $F_1^t$  over all the posts  $t$  of an evaluation dataset  $T$  to obtain a single  $F_1$  score for system  $A$ .

$$F_1 = \frac{\sum_{t \in T} F_1^t}{|T|} \quad (7)$$

### 4.3 Experiment Settings

We try different pre-trained model as the transformer’s initialization such as BERT (Devlin et al., 2018), ELECTRA discriminator (Clark et al., 2020) and ERNIE 2.0 (Sun et al., 2019). We find that the models initialized with ERNIE 2.0 always achieve better performance. So we select ERNIE 2.0 as the transformer’s initialization, which has 768 hidden units, 12 heads, 12 hidden layers.

For other parameters, we use streams of 256 tokens, a mini-batch of size 32, transformer’s learning rate of  $3e-5$ , CRF’s learning rate of  $1e-3$ , the epoch of 3, and the random seed of 42.

### 4.4 Testing Results

As shown in Table 2, we build five systems including: (1) **BERT-CRF** means model using BERT (Devlin et al., 2018) as the transformer’s initialization; (2) **ELECTRA-CRF** means model using ELECTRA discriminator (Clark et al., 2020) as the transformer’s initialization; (3) **ERNIE-CRF** means model using ERNIE 2.0 (Sun et al., 2019) as the transformer’s initialization; (4) **ERNIE-CRF w/o-adv**; (5) **ERNIE-CRF nltk-preprocessing**. All models are Transformer-CRF architecture. All models use adversarial training with the FGM except **ERNIE-CRF w/o-adv**. All models convert character-level sequence labels to token-level with

tokenizers used in pretraining, except for **ERNIE-CRF nltk-preprocessing**, which uses NLTK (Bird et al., 2009) for pre-processing.

Table 2 shows the overall performances of our models on the official evaluation testing data. The ERNIE based model achieves better performance than both the BERT based model and the ELECTRA based model. We conjecture that ERNIE 2.0 is pre-trained through multi-task learning, which allows it to capture lexical, syntactic, and semantic information, such as named entities and discourse relations. And this makes it more suitable for Toxic Spans Detection task.

Adversarial training proved to be effective. Although only a small improvement has been achieved, experiments show that FGM can always achieve a stable improvement. Adversarial training adds some perturbation to the input, which makes the model more robust and has a better performance on the unknown test set.

**ERNIE-CRF** achieves more than 4 points improvements over **ERNIE-CRF nltk-preprocessing**, which proves the importance of choosing the correct method to convert character-level sequence labels to token-level. We conjecture that there is a mismatch between the word segmentation results of NLTK and the input required by the Transformer model.

### 4.5 Attempts with no obvious improvement

It is worth mentioning that the best performance of our system is based on a single model. We tried model ensemble to improve the performance of the single model but failed. Due to the limitation of time and submission, we did not find an ensemble method with obvious improvement.

The BiLSTM network has a strong ability to capture long-term dependencies of the input sequence for sequence labeling task (Huang et al., 2015). We tried to add BiLSTM layer after transformer. But this resulted in overfitting, and the training speed

was greatly reduced.

We also tried to combine the information from word embedding with the information from the deep layer. It is proved that, in the machine translation task, the low layers of the network are more focused on lexical information, while deeper layers pay more attention to word meaning (Belinkov et al., 2017). In toxic spans detection task, we consider the information from the lower layers to be important. So we concatenate the word embedding layer with the output of ERNIE, but this didn't work.

## 5 Conclusion and Future Work

The paper describes our system at SemEval-2021 Task 5, which integrating Transformer and CRF for Toxic Spans Detection task. It is shown that, in this task, using ERNIE as pre-trained model achieves better performance in Transformer-CRF architecture. We convert the character-level sequence labeling task into token-level, and prove the importance of preprocessing method. We also use adversarial training with the FGM to improve the robustness of the system. Our system achieves the third F1 score in official evaluation.

Since the best performance of our system is based on a single model, we are planning to find an effective ensemble method to improve the performance of the single model in the future.

## Abstract

This paper describes our contribution to SemEval-2021 Task 5: Toxic Spans Detection. Our solution is built upon RoBERTa language model and Conditional Random Fields (CRF). We pre-trained RoBERTa on Civil Comments dataset, enabling it to create better contextual representation for this task. We also employed the semi-supervised learning technique of self-training, which allowed us to extend our training dataset. In addition to these, we also identified some pre-processing steps that significantly improved our F1 score. Our proposed system achieved a rank of 41 with an F1 score of 66.16%.

## 1 Introduction

In recent years there has been an exponential increase in the use of social network platforms. With rising abusive language and hate on such platforms, it is more important than ever to maintain online conversations constructive and inclusive. This problem can be tackled by filtering toxic comments/posts. The massive volume of data generated at a fast pace makes manually filtering each comment complicated and time-consuming. This process can be automated by modelling it as a supervised classification problem. A similar task was proposed in SemEval-2019 Task 6: Identifying and Categorizing Offensive Language in Social Media (OffensEval) (Zampieri et al., 2019). Most of the top-ranked teams in this task used transformer language models (Liu et al., 2019a; Zhu et al., 2019; Pelicon et al., 2019; Wu et al., 2019) or an ensemble of CNN and RNN (Mahata et al., 2019; Mitrović et al., 2019) to classify the sentences.

The problem with the above approach is that it doesn't give moderators much knowledge about the reason for a sentence's toxicity. Highlighting

Equal Contribution. Author order determined by a coin flip

toxic spans can help human moderators who frequently deal with long comments and prefer attribution rather than just an unexplained toxicity score. SemEval 2021 Task 5: Toxic Span Detection (Pavlopoulos et al., 2021) gave a chance to propose NLP systems to solve this problem. The task is concerned with developing systems that can recognise spans that contribute to the text's toxicity.

This task had a few challenges. Since the samples were from an online commenting platform, they were grammatically incorrect and consisted of many out of vocabulary words. The noisy and ambiguous structure of comments significantly hampers the performance of general NLP models. The training dataset had a little less than 8000 samples. Thus, there was a need to select systems that can produce meaningful results, even with a limited number of training samples. Undoubtedly, the hardest part is to identify spans that can account for the toxicity of the sample. The span could be as small as a single token and as large as the sample itself. The linguistic variations in the usage of words and phrases make such attribution even more difficult.

We formulated the task as a sequence tagging problem and used RoBERTa (Liu et al., 2019b), a pre-trained Transformer-based (Vaswani et al., 2017) language model as our base model. We further pre-trained RoBERTa on the Civil Comments Dataset as a masked language model (Devlin et al., 2018) to create a domain-specific model. We employed a Conditional Random Field (CRF) layer (Lafferty et al., 2001) for predicting the most probabilistic sequence of labels for each input sequence. We also applied a few pre-processing steps, which lead to significant performance improvements. Lastly, we leveraged the semi-supervised learning technique of self-training (Yarowsky, 1995; Liao and Veeramachaneni, 2009; Jurkiewicz et al., 2020) by training our model on the manually annotated

Figure 1: Our Model Architecture. We used RoBERTa as our transformer. Classifier constitutes two dense layers and a CRF layer with three labels.

dataset and using it to further extend the training set by generating toxic spans for other unannotated datasets. We have made our system’s implementation available through GitHub<sup>1</sup>.

The rest of the paper is organised as follows. Section 2 explains our model implementation in detail. Section 3 and 4 presents our experimental setup and achieved results, respectively. In section 4, we perform error analysis, followed by conclusions in the last section.

## 2 System Description

### 2.1 Pre-Training

Toxic comments have a different language construct from the general language. Their slang and obfuscated content (van Aken et al., 2018) make it difficult for the language models pre-trained on broader datasets to understand them. Similar to other domain-specific models (Beltagy et al., 2019; Lee et al., 2020; Paraschiv et al., 2020), we pre-trained the RoBERTa-base model on the Civil comments dataset using Masked Language Modelling (MLM) (Devlin et al., 2018) to provide the necessary domain knowledge and created our model RoBERTa(p). The original weights of RoBERTa-base served as the starting point for the pre-training. The pre-training was done for 0.2 million steps with a batch size of 32 and a learning rate of  $2e-5$ .

<sup>1</sup>[https://github.com/jain-abhinav02/Toxic\\_Spans\\_Detection](https://github.com/jain-abhinav02/Toxic_Spans_Detection)

### 2.2 Fine-Tuning

We formulated the task as a token level sequence tagging problem where we classify each token as Begin, Inside or Outside (BIO scheme). Having begin and end tags helps formulate the notion of spans better and creates dependencies between various tokens of a toxic span (Singh et al., 2020), allowing it to perform better than other alternatives such as IO (Inside Outside).

**Pre-Processing:** We applied a few pre-processing steps before fine-tuning RoBERTa on the input text samples. First, we converted all the text samples to lowercase. We observed that punctuation marks did not add any significant information to the semantics of a sentence. Therefore, as a part of the data cleaning, punctuation marks such as commas and dashes were removed. We also collapsed multiple space characters into a single space.

**Model:** We provided the text samples as input to our pre-trained RoBERTa(p) model to get 768-dimensional contextual embeddings for each token. These contextual embeddings were passed through two dense layers of 512 and 128 dimensions, followed by a Conditional Random Fields (CRF) (Lafferty et al., 2001) layer with three labels (B-Begin, I-Inside or O-Outside). The CRF layer models the correlation between the labels predicted for the individual tokens. It receives the logits for each input token and predicts the most probabilistic sequence

Model	Tag	F1	Precision	Recall
RoBERTa	IO	0.6091	0.5831	0.7224
RoBERTa(p)	IO	0.6183	0.5841	<b>0.7408</b>
RoBERTa(p) + PP	IO	0.6376	0.6259	0.7264
RoBERTa(p) + PP + CRF	IO	0.6422	0.6323	0.7246
RoBERTa(p) + PP + CRF	BIO	0.6566	0.6512	0.7203
RoBERTa(p) + PP + CRF + ST(1)	BIO	0.6613	0.6537	0.7295
RoBERTa(p) + PP + CRF + ST(2)	BIO	<b>0.6634</b>	<b>0.6590</b>	0.7262

Table 1: Our model results on Test Set. RoBERTa(p) is our model pre-trained on domain-specific data. PP stands for Pre-processing. ST(1) and ST(2) represents self-training first and second iteration results, respectively.

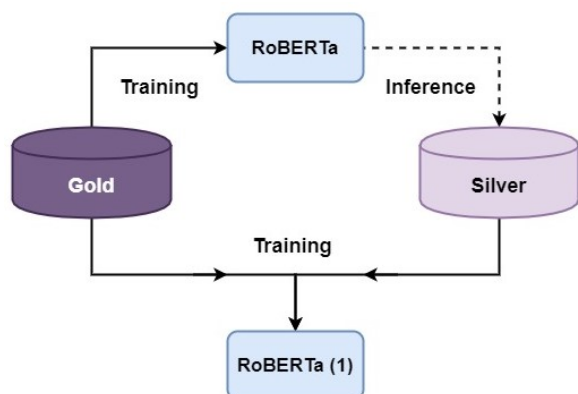

Figure 2: Self-Training of RoBERTa

of labels for each input sequence. Figure 1 shows our model architecture.

**Post-Processing:** The tokens decoded as B-Begin or I-Inside were marked as toxic. The character spans corresponding to these toxic tokens were added to the predicted spans. Two consecutive spans were merged if separated by at most five characters, provided all of them are non-alphabetic.

### 2.3 Self-Training

The best performing model on the manually annotated dataset (gold dataset) was used to generate toxic spans for the unannotated dataset. When selecting the unannotated data, we followed the process similar to the one used for creating the gold dataset (Pavlopoulos et al., 2021) that is, filter the most toxic samples (toxicity  $\geq 0.80$ ) from the Civil Comments dataset and select a random set of 10,000 samples. This process allowed the silver data to have similar toxicity distribution as the gold data. The newly generated annotations (silver dataset) were then used along with the gold dataset to train a new model. The model trained on the combined gold and silver dataset gave better performance (F1 score: 66.13%) than the one trained

only on the gold dataset (F1 score: 65.66%). We repeated this process for one more iteration with another random set of 10,000 samples (F1 score: 66.34%). Figure 2 gives a simplistic idea of self-training.

## 3 Experimental Setup

**Data:** Each training example consisted of a text sample in English, and its ground truth toxic span provided as a list of character offsets (possibly empty). The posts were sampled from the publicly available Civil Comments dataset. The training set consisted of 7939 samples. We randomly sampled 20% of it as the development set. The test set for the evaluation phase had 2000 samples. In the training dataset, sample length varies from 1 to 421 tokens, with an average length of 47 tokens when tokenized using the RoBERTa-base tokenizer. Nearly 10% of all tokens in the training dataset are marked as toxic. The mean span length is 17.5 characters and 485 samples have empty spans. Further details about the dataset can be found in the task description paper (Pavlopoulos et al., 2021).

**Evaluation measures:** The evaluation measure for a sample is the F1 score between the predicted spans and the ground truth spans as defined in the SemEval-2021 Task 5 paper (Pavlopoulos et al., 2021). The overall score is obtained by taking the mean of the F1 score of all samples in the test set.

**Implementation details:** Since the text samples were lengthy, we split them into sentences. We used spacy’s sentence tokenizer for this purpose. Adam (Kingma and Ba, 2014) was used as the optimizer with a learning rate of  $1e-5$ . The batch size was set to 32. All the model variants were trained for at most five epochs. We used the RoBERTa-base tokenizer and model implementation provided

Table 2: Common errors made by our model. Spans are made bold and are present in between square brackets.

by Huggingface<sup>2</sup>. The RoBERTa model was followed by two dense layers with 512 and 128 units with relu (Agarap, 2018) as the activation function and a dropout rate of 0.1. The output layer had two or three labels depending on the tagging scheme. We applied the post-processing steps mentioned in section 2.2 for all the model variants.

## 4 Results

Table 1 shows that our RoBERTa(p) model outperforms the original RoBERTa model. As suggested earlier, domain-specific pre-training allows the model to understand the language construct of toxic comments better. Additionally, we observe a significant increase in performance by adding pre-processing steps as it makes the model more robust to the noise present in the text samples. Adding the CRF layer further improves the F1 score by eliminating the problem of independent label prediction. It is evident from table 1 that the BIO tagging scheme performs better than the IO tagging scheme when working with CRF, suggesting it can better understand the span nature of the output. Finally, using two rounds of self-training helped us achieve our best F1 score, 66.34%<sup>3</sup>.

One interesting observation that can be drawn from Table 1 is that for almost all the models, the

<sup>2</sup><https://github.com/huggingface/transformers>

<sup>3</sup>We achieved an F1 score of 66.16% in the official competition. However, our model achieved a even higher F1 score 66.34%, when the predictions of a different epoch were used for evaluation.

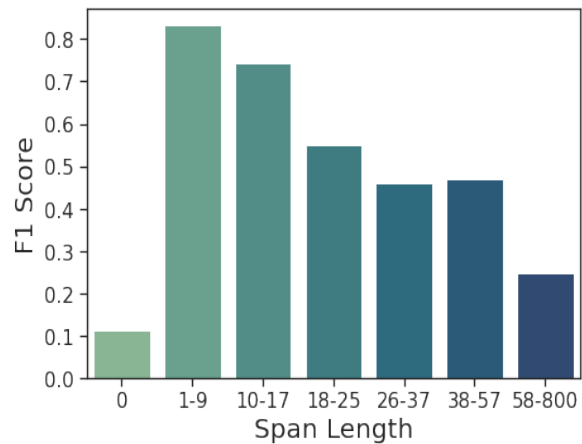

Figure 3: Distribution of F1 Score across different span lengths. Here span length refers to the total length of the toxic span in each sample. The value represented is the mean F1 score of all the text samples whose toxic span length falls in a particular range.

recall remains constant and improvement in F1 is due to improvement in precision. The constancy of recall indicates that few spans are not captured as toxic by any of the models.

## 5 Error Analysis

Figure 3 shows the variation of the F1 score across different toxic span lengths on the test dataset. Our model achieved a very high F1 score when one (Span Length 1-9, Mean F1 Score: 83.17%) or two (Span Length 10-17, Mean F1 Score: 74.44%) words are marked as toxic in a text sample. As the number of characters marked as toxic increases,

the F1 score falls drastically, reaching as low as 24.82% when more than 58 characters are marked as toxic. There are two main reasons for this. First, it is easier for the model to capture short-term dependencies than long-term dependencies. Second, only 10% of the training data has a span length of more than 25 characters making the model less equipped to capture such toxic spans.

To investigate our model’s most problematic cases, we analysed the samples for which our model gave a zero F1 score. There were 447 such samples, of which 349 samples did not have any toxic span in the ground truth. This is also reflected in Figure 3, as the mean F1 score of all the samples with zero span length is 11.42%. Further analysis revealed that our model tends to mark those tokens as toxic, which were frequently found to be toxic elsewhere. A few samples with empty toxic spans had doubtful gold annotations. However, in other samples, our model failed to capture the sentence’s context precisely and predicts tokens that were not used in a toxic sense.

Table 2 shows other standard errors our model makes. It seems that our model has a problem with small sentences. More often than not, it misses the toxic span present in it and returns an empty span. A similar case occurs when it encounters text samples with rare toxic words. These words may be present in very few examples or be completely absent from the training dataset, making our model less endowed to understand them. Other than these, our model sometimes misses the non-swear words in a toxic span.

## 6 Conclusion

This paper described our system developed for SemEval-2021 Task 5: Toxic Span Detection. We built our solution on the RoBERTa language model and Conditional Random Fields (CRF). Though RoBERTa alone can achieve great results, we highlighted the benefits of using external datasets and the performance improvements it can help us achieve. We pre-trained RoBERTa on the Civil Comments dataset to impart domain-specific knowledge to it. We also employed the semi-supervised learning technique of self-training to extend our training dataset. In addition to these, we also discovered some pre-processing steps that significantly improved our F1 score. Experimenting with different tagging schemes, we found out that the BIO scheme works the best with CRF.

In future, we plan to experiment with other language models such as T5 (Raffel et al., 2019), XLNet (Yang et al., 2019) and DeBERTa (He et al., 2020). The system could also benefit from the addition of syntactic and semantic features at the word and sentence level.

jonathan-rusert@uiowa.edu

## Abstract

We leverage a BLSTM with attention to identify toxic spans in texts. We explore different dimensions which affect the model’s performance. The first dimension explored is the dataset the model is trained on. Besides the provided dataset, we explore the transferability of 5 different toxic related sets, including offensive, toxic, abusive, and hate sets. We find that the solely offensive set shows the highest promise of transferability. The second dimension we explore is methodology, including leveraging attention, employing a greedy remove method, using a frequency ratio, and examining hybrid combinations of multiple methods. We conduct an error analysis to examine which types of toxic spans were missed and which were wrongly inferred as toxic along with the main reasons why they occurred. Finally, we extend our method via ensembles, which achieves our highest F1 score of 55.1.

## 1 Introduction

Social media platforms (e.g. Twitter) benefit from a welcoming environment. Toxicity introduced by users can drive new (or existing) users away. Therefore, it is beneficial for platforms to moderate the amount of toxic language allowed. Often human moderators are employed to address this. However, as the numbers of users increase on a platform, it can be difficult for human moderation as the sheer amount of content generated increases as well. Thus platforms employ automated assistance (Terdiman, 2018).

While automated toxic language classifiers have made strides at determining if text is toxic (Yenala et al., 2018; Zhang et al., 2018), much work is still left for humans who are reviewing the text. In large texts, the reason for toxicity might only be one or two words, however, the moderator will have to

Text	Toxic Span
What a jerk!	[7, 8, 9, 10]
“Trump is up to the task” LMAO, you are an idiot	[44, 45, 46, 47, 48]
Canada: Institution- alised mediocrity.	[ ]
Contrary to popular be- lief not all criminals are stupid. Fortunately, there are plenty like this moron that are.	[49, 50, 51, 52, 53, 54, 98, 99, 100, 101, 102]

Table 1: Examples of toxic spans in toxic texts. The numbers indicate the character position of the toxic span. Empty brackets indicate no specific span.

scan the entire text to find the toxicity. Repeating this process across many texts is cumbersome. Automated systems could assist human moderators further by noting which areas in the text are toxic, thus allowing the human to quickly check text for toxicity. Finding these toxic areas is the task that is proposed by (Pavlopoulos et al., 2021). Specifically, given English toxic text, determine where the “toxic spans” occur, where a “toxic span” is the character positions in the text where the toxicity appears. For example, in “your an idiot, this is a tax based on a lie”, the toxic span would be [8, 9, 10, 11, 12] or the character positions of “idiot”. Note that not all toxic texts have toxic spans. For example, “Religious people no longer have a place in this country.” is a toxic phrase, yet no specific words are themselves toxic. More examples can be found in Table 1.

To find toxic spans in text, we employ a Bidirectional Long Short-term Memory model (BLSTM) with attention. We examine several indirect methods which align with the BLSTM, including using the attention layer for information. While the provided dataset allows for direct methods, i.e. meth-

ods which directly use the given spans for training, this span format is new to this task. Thus many previously developed toxic datasets would need to be converted to be useful to a direct model (since they are binary labeled sets, not span labeled sets). However, the indirect methods we explore can leverage previously developed datasets, which opens up research possibilities. Therefore, we examine how well toxic texts other than the provided training data transfer to this task. An additional benefit is that since toxicity can be subjective (Aroyo et al., 2019), examining how different datasets transfer to this task will help illuminate the similarities and differences between definitions of toxicity. Finally, we provide our code and outputs for reproducibility<sup>1</sup>.

## 2 Approach

We expand on the approach we use to identify toxic spans. We examine both different toxic based datasets as well as different BLSTM based methods.

### 2.1 Base Architecture

We leverage a bidirectional LSTM (BLSTM) with attention as our base architecture. The BLSTM has a hidden layer size of 200. We use glove embeddings<sup>2</sup> (Pennington et al., 2014) of size 200 trained on Wikipedia and Gigaword corpora. We train our system over 10 epochs with a batch size of 64.

### 2.2 Toxic Datasets

We examine the provided training set as well 5 different toxic-based data sets. All are in English to match the provided test set. Each additional dataset is explicitly toxic or in a related area (e.g. offense). The dataset chosen can affect performance on the test data as data can vary in their definitions of toxicity. The datasets examined are:

**Toxic Train:** The training set provided by the task organizers. This set had no non-toxic examples thus we pulled non-toxic examples from the Kaggle Toxic set at a 1-to-1 ratio. This results in a training set size of 15,878.

**OLID:** (Zampieri et al., 2019a) A dataset composed of offensive and non-offensive tweets. It was used in both OffensEval 2019 (Zampieri et al., 2019b) and OffensEval 2020 (Zampieri et al., 2020)

(offense language classification tasks). The training set is composed of 13,240 tweets.

**Kaggle Toxic:** Comments from Wikipedia’s talk page edits, presented in the Kaggle toxic classification challenge<sup>3</sup>, labeled as toxic or not toxic (as well as further divided into subcategories). The training set is 159,571 comments.

**Founta:** (Founta et al., 2018) A dataset of tweets annotated via the CrowdFlower platform. The labels are hateful, abusive, or none. For training, we combine hateful and abusive into a single toxic category. The training set is of size 85,966.

**Davidson:** (Davidson et al., 2017) Annotated tweet dataset composed of offensive, hatespeech, and neither tweets. Our training set combines offense and hate into a single toxic label and is of size 24,783.

**Gab Hate:** (Kennedy et al., 2018) A dataset from Gab social network<sup>4</sup>. Each post is annotated by at least 3 annotators as either hateful or not. Similar to prior research, our positive (toxic) labeled are those for which the majority of annotators agree. The training set is of size 27,665.

### 2.3 Methods

We leverage previously examined methods in areas such as robustness (Hsieh et al., 2019) and style transfer (Xu et al., 2018; Wu et al., 2019). Each method stems from the BLSTM, but some can be adapted for other machine learning systems.

**Attention:** Previous work has used attention for robustness attacks (Hsieh et al., 2019) and style token masking (Xu et al., 2018). Following these, we leverage the attention layer in the BLSTM. Each token (word) has an attention score used to generate the class label (toxic, non-toxic). We use this score to determine if a given token is toxic. We label each token with an attention score of greater than the average attention score as part of the toxic span.

**Frequency Ratio:** In theory, a toxic token should exist more frequency in toxic texts, compared to non-toxic texts. Following previous research (Wu et al., 2019), we generate a frequency score for each token:

$$s_c(u, a) = \frac{\text{count}(u, D_a) + \lambda}{(\sum_{a' \in A, a' \neq a} \text{count}(u, D_{a'})) + \lambda} \quad (1)$$

where  $u$  is the token,  $a$  is an attribute (e.g. toxic or non-toxic),  $D_a$  represents the texts with attribute  $a$ ,

		Toxic Datasets						Average
		Train	OLID	Kaggle-Toxic	Founta	Gab	Davidson	
Methods	Attention	50.1	50.1*	39.4	35.2	17.4	22.8	35.8
	Greedy Remove	38.3	44.7	43.3	41.9	20.8	18.6	34.6
	Frequency Ratio	41.5	45.5	22.5	44.3	19.7	8.0	30.3
	Simple Hybrid	38.4	45.5	41.7	39.6	17.7	21.7	34.1
	Recall Hybrid	37.9	45.2	38.4	34.6	17.8	22.7	32.8
	Precision Hybrid	<b>50.7</b>	49.8	44.6	42.6	20.8	19.0	<b>37.9</b>
	Average	42.8	<b>46.8</b>	38.3	39.7	19.0	18.8	
	Top System	70.8						

Table 2: Full Results on the provided Toxic Span Test Set. Results are F1 scores. \* - Version submitted to task organizers. Top System is the highest result submitted by another team to the task organizers.

and  $\text{count}(u, D_a)$  represents the number of times  $u$  appears in  $D_a$ . The score ( $s_c(u, a)$ ) is then measured against a threshold to determine whether the token is representative of that attribute. For our method, we chose a threshold of 5, such that, if  $s_c(u, a) \geq 5$ , then  $u$  is considered part of the toxic span.

**Greedy Remove:** Also seen as “Greedy select” (Hsieh et al., 2019) or “Important Score” (Lee, 2020) in previous research, greedy remove determines the amount each token is contributing to the text by removing each token one-by-one (each token is replaced after drop is noted) and noting the drop in toxic probability. The token with the highest probability is removed (i.e. added to the toxic span) and then the BLSTM classification is checked. If the text is no longer considered toxic, the toxic span is returned, otherwise the next token with the highest drop is removed and it is added to the toxic span. This process is continued until the text is no longer considered toxic by the BLSTM.

**Simple Hybrid:** We combine the greedy remove and attention approaches. We first obtain the spans from the greedy remove. If the span is empty (i.e. “[ ]”), then we choose the spans found by the attention method, otherwise we choose the spans obtained from the greedy remove method.

**Recall Hybrid:** Similar to the simple hybrid, however, we aim to maximize recall. We obtain spans from both the greedy remove and attention approaches and return the union of the two sets.

**Precision Hybrid:** Similar to the simple hybrid, however, we aim to maximize precision. We obtain spans from both the greedy remove and attention approaches and return the intersection of the two sets.

### 3 Experimental Results

#### 3.1 Experiments

We train corresponding BLSTMs on each of the 6 presented datasets (Section 2.2). We test the methods of each BLSTM on the provided toxic test set. The test set contains 3,180 texts. The score used is the F1 for a given text  $t$ , where  $A_i$  is the system and  $G$  is ground truth, and  $S^t$  is the set of toxic spans:

$$F_1^t(A_i, G) = \frac{2 \cdot P^t(A_i, G) \cdot R^t(A_i, G)}{P^t(A_i, G) + R^t(A_i, G)} \quad (2)$$

$$P^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_{A_i}^t|} \quad (3)$$

$$R^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_G^t|} \quad (4)$$

When  $S_G^t$  is empty and  $S_{A_i}^t$  is empty, then  $F_1^t(A_i, G) = 1$ , otherwise  $F_1^t(A_i, G) = 0$ . Finally, to obtain a single score, the F1’s are averaged across texts.

#### 3.2 Results

We examine the performance of various combinations of approaches on the test data. Full results are found in Table 2.

**Provided Train Data + Precision Hybrid Approach achieves highest F1.** Our highest achieved F1 score, on the test data, is 50.7. This is achieved via a BLSTM trained on the provided training data (Toxic Train) which uses the precision hybrid approach to find toxic spans. The next highest was from both the OLID BLSTM and Toxic Train BLSTM both using attention and achieving an F1 of 50.1.

Missed Spans
See a shrink you <i>*pathetic*</i> <troll>.
<Total> <i>*rubbish*</i> ! The birther bit was started by Crooked Hillary and perpetuated by Zero his own damn self.
and he is to <i>*stupid*</i> to know it. The guy is a total <poser> and a <i>*fool*</i>
Along with 'fat, dumb and happy'. Or maybe ' <i>*stupid*</i> ' is as <i>*stupid*</i> does'?
<Your an> <i>*idiot*</i> . The top 1% will get the biggest break while the rest of us struggle to pay rent.
In this case, anyway, I have bad news for you. <URStupid>
Sick <f**ks> like this should just be shot. What a waste of skin, air, and taxpayers money.
Falsely Detected Spans
Yes....it is to be expected....oddly enough it happens every time he opens his mouth and says <dumb> >thin<gs.
"""">Trump< is up to the task"" LMAO, you are an id <i>*iot*</i> >,"<
You are a <i>*simpleton*</i> , who is full of racial >hatred<. That is too bad. You make America a worse place.
I always knew you were a >dirty< cop.
By the way, Nazis were and are fascists so if you are one, your a <i>*fascist*</i> . >Scum< like this and Trumpler need to be run out of our country and given to ISIS to use as chew toys
McCain is a >pig<.
LNG is much better for the environment than diesel, yet these >stupid< hippies complain.

Table 3: Examples of missed spans and falsely detected spans. <Red> indicates missed tokens. *\*Blue\** indicate correctly identified spans. >Green< indicates wrongly asserted spans. Note that \*\*, <>, >< are not originally in text and are included for accessibility.

**OLID shows strongest transferability.** The OLID trained BLSTM achieved the highest F1 scores across all methods versus the other transfer sets, with an average of 46.8 (range: 44.7 - 50.1). The next highest set was Founta (avg: 39.7, range: 34.6 - 44.3). Surprisingly, Kaggle-Toxic (avg: 38.3, range: 22.5 - 44.6) arrives at third highest. This is surprising because the goal of the task is to identify “toxic” spans and Kaggle is toxic data, while OLID is offense, and Founta is abuse/hate data. The Gab and Davidson BLSTMs perform poorly in comparison only achieving average F1s of 19.0 and 18.8 respectively.

**Precision Hybrid Averages Highest F1 Score.** On average, the precision hybrid method outperforms other methods across datasets. The precision hybrid approach averages a F1 score of 35.4 (range: 19.0 - 49.8). The attention approach is second highest (avg: 35.8, range: 17.4 - 50.1), followed by the greedy remove (avg: 34.6, range: 18.6 - 44.7). This points to precision hybrid as a solid approach when the transfer strength is unknown.

**Indirect methods pale in comparison to more direct systems.** Although we examined various combinations of systems, our highest F1 (50.7) is still far less than the top submitted system (HITSZ-

HLT) 70.8. This difference is most likely due to our system aiming to find toxic spans indirectly, rather than directly training on the spans.

## 4 Error Analysis

To determine how to improve our system, we examine the spans commonly missed in the test set as well as spans commonly predicted wrongly. We examine errors in our top system (Toxic Train - Precision Hybrid).

### 4.1 Spans Missed

We find our system misses spans for several reasons. We present examples in Table 3.

#### Translation from tokens to character positions.

One reason for missed spans is the difficulty between translating toxic tokens to toxic spans. As our methodology finds specific tokens toxic, it needs to back-translate that to character positions in the original text. However, the text is pre-processed to help our system analyze it and therefore problems occur when lining up the characters.

**Toxic words are part of a phrase.** Another reason for missed spans is they are part of a toxic phrase and others part of the phrase are more toxic. For example, “Total rubbish” is marked as entirely toxic, however, our system marks only “rubbish”.

Spans Missed			
Translation	Part of Phrase	Overshadowed by more toxic words	Non Standard Words
75	8	25	2
Spans Falsely Detected			
Non-Toxic becoming Toxic	Translation	Unclear Why Not Toxic	Toxic word in not toxic usage
19	23	22	30

Table 4: Frequencies of errors on 100 sampled texts. Note that multiple errors can exist in one text. Also, not all sampled texts have one of the prominent errors.

Another example is our system marking “pathetic” correctly but not “troll” in “pathetic troll”. Our system misses that these non-toxic words (e.g. “total”) can become toxic when combined in a phrase.

**Certain words overshadowed by more toxic words.** Some of the tokens which remain (e.g. “poser”) seem to be overshadowed by a stronger toxic word. For example, “and he is to stupid to know it. The guy is a total poser and a fool”, is marked as having three toxic spans (stupid, poser, fool), however, our system labels “stupid” and “fool” as toxic spans but not “poser”. This is most likely because our system views “stupid/fool” as more toxic words and thus assigns higher attention scores than for “poser”.

**Toxic words are non standard words.** Since the BLSTM uses word embeddings, non standard words are missed by our system. For example, “In this case, anyway, I have bad news for you. URStupid”, “URStupid” is marked as toxic, but it is a non standard word.

## 4.2 Spans Falsely Detected

Table 3 also contains examples of wrongly predicted spans by our system. We’ve identified reasons for these errors as well.

**Non-toxic words become associated with toxicity in training set.** Depending on the training set, our model can learn non-toxic words as toxic if they occur more frequently with the toxic label compared to the non-toxic. An interesting example is “trump” being marked as a toxic span, which means the training data provides “trump” in enough toxic texts for our system to associate that with toxicity.

**Translation to character indexing.** Similar to missing gold spans, our system’s predicted spans are often shifted off of the correct token. For example, in the phrase “dumb things”, our system correctly identifies that “dumb” is a toxic span, but during translation back to character index, it

is shifted 4 characters to the right, so instead our system says “thin” (part of “things”) is the toxic span. This issue causes many similar misses.

**Toxicity is not always clear.** Another reason for wrongly identified spans is that the toxicity isn’t always clear. That is, words which appear to be toxic, are marked as non toxic in the gold labels. For example, in “I always new you were a dirty cop.”, calling someone a “dirty cop” is arguably toxic, and our system marks “dirty” as toxic, but the gold standard labels indicate there is no toxic span in the text. This could be attributed to toxicity being a subjective idea (Aroyo et al., 2019).

**Toxic words used in non-toxic ways.** A final prominent reason for falsely predicted spans is words that are sometimes toxic, appear in non toxic sentences. For example, in “... Gotta ask, you got back flow preventer on your plumbing or is that some of the stupid you can’t fix?”, our classifier tags “stupid” as toxic, but it is not. This category has an overlap as well with the previous unclear category since toxicity can be subjective. Where the annotators might label a word are being used in a non-toxic way, we might label it as toxic and therefore say it is unclear why the span is not counted correctly.

## 4.3 Quantifying Errors

To obtain an understanding of the frequency of the different types of errors we randomly sample 100 texts which contained missed spans and 100 texts which contained falsely predicted spans. The results can be found in Table 4.

For missed spans, we see the translation from tokens to character positions causing the largest problems, as it occurs in 75 out of 100 samples. Words overshadowed by more toxic words was the next highest error appearing in 25 of 100 samples.

For falsely detected spans, the errors are more evenly spread out. Toxic words used in non-toxic

manners caused the most false predictions (30 out of 100), followed by the translation from tokens to spans (23 out of 100). These errors highlight the importance of the translation step, and where our system could benefit the most for improvement in the future.

## 5 Leveraging Multiple Views via Ensemble of Datasets

Ensemble	F1
Train + OLID + Kaggle-Toxic	54.0
Train + OLID + Kaggle-Toxic + Founta	49.6
Train + OLID + Founta	53.6
All	39.3
Train + Kaggle-Toxic + Founta	50.7
OLID + Kaggle-Toxic + Founta	49.5
Train + OLID-Att + Kaggle-Toxic	<b>55.1</b>
Top Solo (Toxic Train - Prec. Hybrid)	50.7

Table 5: F1 scores of ensemble models. All systems use the Precision Hybrid method, except for OLID-Att which uses the attention method. Train = Toxic Train

As toxicity can vary, it follows that different toxic datasets can identify different aspects of toxic spans. We explore this idea further by creating a simple majority voting ensemble model. The ensemble model takes in the predictions of multiple models trained on different datasets, then indices are included if a simple majority votes for the index. A summary of the performance of these models is found in Table 5. Due to its performance, the Precision Hybrid method is used in all instances except OLID-Att which leverages the attention method.

**Ensemble outperforms top solo model.** The top ensemble combination achieves an F1 score of 55.1, which is higher than the top solo F1 of 50.7. This ensemble consists of top scoring solo datasets and their top scoring respective methods: Toxic train - Precision Hybrid, OLID - Attention, and Kaggle-Toxic - Precision Hybrid. This higher score helps demonstrate how the various toxic-based datasets can bring useful perspectives to the solution.

**Lower systems reduce performance of ensemble.** While an ensemble can increase performance, not all toxic-based datasets help the model. While the top three solo datasets achieve an F1 score of 54, adding Founta reduces it to 49.6. Adding the lowest performing sets (Gab and Davidson), reduces F1 to 39.3. Thus the datasets used in the ensemble require much consideration.

## 6 Related Work

We provide a brief look at work related to ours and highlight recent related ideas.

**Toxic Language:** In recent years toxic language classification has seen much focus. Organized tasks for offensive language classification were seen multiple years in a row in GermEval (Wiegand et al., 2018), OffensEval 2019 (Zampieri et al., 2019b), and OffensEval 2020 (Zampieri et al., 2020). Additionally, hate and abuse have been the focus of classification (Founta et al., 2018) (Davidson et al., 2017). For toxicity specifically, Karan and Šnajder (2019) examine detecting threads that could lead to toxic language in the future. van Aken et al. (2018) present specific challenges that remain for toxic classification.

**Methodology:** Our work draws from both robustness and text style transfer work. Robustness work looks at attacks of adversaries against classification (and other) systems. Hsieh et al. (2019) look at the robustness of attention based systems. Their “greedy-select” method for selecting words to change in obfuscation, is similar to our “greedy-remove” method. Style transfer often focuses on transferring text from one style to another. To change the style, some authors first remove or mask words which indicate the initial style from the text. Wu et al. (2019) accomplish this by leveraging both a frequency ratio method (same as ours) and attention. Though, the methodology is similar, we examine it in terms of toxic span identification where it has not been done before.

## 7 Conclusion

We leveraged various BLSTM methods to identify toxic spans. We find that a combination of a “Greedy-Remove” and “Attention” based methods with a focus on precision produces the highest overall results.

We examined how well various toxic related datasets are able to transfer to this task. We find that OLID, an offensive labeled dataset, transfers the highest, achieving an F1 only 0.6 lower than the provided dataset. Furthermore, we found that combining the viewpoints of the datasets in an ensemble model can increase the performance (F1 to 55.1).

Finally, we examined the errors our system made and the causes. We found that many errors were made when translating from tokens to character index. Future work would improve on this translation step to tighten the span indication.

## Abstract

The SemEval 2021 task 5: Toxic Spans Detection is a task of identifying considered-toxic spans in text, which provides a valuable, automatic tool for moderating online contents. This paper represents the second-place method for the task, an ensemble of two approaches. While one approach relies on combining different embedding methods to extract diverse semantic and syntactic representations of words in context; the other utilizes extra data with a slightly customized Self-training, a semi-supervised learning technique, for sequence tagging problems. Both of our architectures take advantage of a strong language model, which was fine-tuned on a toxic classification task. Although experimental evidence indicates higher effectiveness of the first approach than the second one, combining them leads to our best results of 70.77 F1-score on the test dataset.

## 1 Introduction

Social Network sites are an integral part of our society. These platforms are often designed to maximize user interaction without sufficient means to moderate such interactions. The amount of users being cyber-bullied by toxic comments has reached an alarming proportion (Chan et al., 2021). To efficiently maintain the health of online communities, an automatic online-content filtering tool needs to be developed. Numerous previous attempts to resolve this issue have focused on toxic comment classification (Georgakopoulos et al., 2018; Chu et al., 2017; Pham et al., 2020; Risch and Krestel, 2020). Although these classification models are capable of detecting toxic comments, their outputs are not interpretable (Mathew et al., 2020).

On the other hand, Toxic Spans Detection (Pavlopoulos et al., 2021) is a task of locating toxic

segments in texts. With such a system, the moderators can easily highlight offensive words in comments, which is an essential and explainable assistance for automated comment rating. In this paper, we propose our two approaches to resolve the task. Our contributions are as follows:

- We investigate the effectiveness of our slightly customized Self-training (Wei et al., 2021) technique for a sequence tagging problem - Toxic Spans Detection.
- We explore the benefits of combining different word representations including Byte Pair Encoding (Sennrich et al., 2015), contextual character-level (Akbik et al., 2018), FastText (Bojanowski et al., 2016) and RoBERTa (Liu et al., 2019) word embeddings in order to utilize different syntactic and semantic information learned by these embedding methods.
- Taking advantage of a well-domain-adaptive pre-trained language model on a classification task (Unbiased-toxic-RoBERTa (Hanu and Unitary team, 2020)), we successfully integrate our two above-mentioned methods to achieve a high F1-score of 70.77 and rank 2nd at the Semeval 2021 Task 5: Toxic Spans Detection.
- Numerous exciting insights of the system's performance have been drawn with detailed error analysis.

## 2 Related Work

### 2.1 Word representation learning

Word2Vec (Mikolov et al., 2013) is among the earliest models for extracting continuous word representations. Although there have been numerous modern pre-trained text embeddings that outperformed Word2Vec in downstream tasks, it is still widely

---

\*equal contribution

used due to its simplicity and effectiveness (Akbik et al., 2018). However, Word2Vec fails to handle rare or out-of-vocabulary words. To address this problem, FastText (Bojanowski et al., 2016) learn a word representation as sum of its character n-grams embeddings. On the other hand, (Sennrich et al., 2015) utilizes Byte Pair Encoding, an alternative approach for learning sub-word representations.

Recent pre-trained language models learn context-sensitive word representations by utilizing different pretext tasks namely autoregressive language modeling (Radford et al., 2019; Akbik et al., 2018), masked language modeling (Devlin et al., 2018) on a large amount of unlabeled data. Those methods have led to significant improvements in a wide range of downstream tasks, including Text Classification (Howard and Ruder, 2018), Question Answering (Devlin et al., 2018) and Named Entity Recognition (Akbik et al., 2019b).

Unbiased Toxic RoBERTa (Hanu and Unitary team, 2020) is a language model that utilizes general pre-trained RoBERTa (Liu et al., 2019) to continually pre-train a toxic comment classification task on Civil Comments Dataset <sup>1</sup>. This toxic-domain-adaptive language model can be successfully employed to Toxic Spans Detection task whose domain is a subset of Civil Comments.

## 2.2 Self-training

Self-training, a semi-supervised method, incorporates the prediction of teacher models on extra available in-domain unlabeled data into the training of a student model (Wei et al., 2021). Self-training has been recently successfully applied in both Computer Vision and Natural Language Processing tasks, including Image Classification (He et al., 2018), Object Detection (Xie et al., 2020), Machine Translation (He et al., 2020), ect. Despite its merits, issues such as the lack of in-domain unlabeled data (Du et al., 2020) and unreliable-pseudo labels (Pham et al., 2021) are the main obstacles for the success of Self-training.

For sequence-tagging problems, there are various methods of coping with noisy-pseudo labels. Unlike classification tasks, noisy self-labeled data can be easily eliminated by removing those which have low confidence scores; there is a lack of a comprehensive means to determine this score for a sequence-labeling data point. In several recent re-

search, a deep reinforcement learning (Chen et al., 2018) and meta-learning (Wang et al., 2020) has been proposed to reduce “error propagation from noisy pseudo-labels” for sequence labeling tasks.

## 3 Methodology

In this section, we describe our proposed framework in detail. Firstly, we develop a simple but strong baseline to discover the effectiveness of different backbone models. Consequently, we build, extend, and customize our two methods on top of the best backbone and baseline model.

### 3.1 Baseline

We consider this task as a word-level binary classification problem even though the label annotation of the dataset is at character-level. Therefore, we first align character annotations to word annotations. We utilize a straightforward architecture, with a pre-trained language model as the backbone and a simple classifier on top of it. Specifically, let denote  $\mathbf{w} = \{w_1, w_2, \dots, w_m\}$  and  $\mathbf{y} = \{y_1, y_2, \dots, y_m\}$  with  $w_i, y_i$  is the word and its label at position  $i$  respectively, and  $\mathbf{x} = \{x_1, x_2, \dots, x_n\}$  with  $x_j$  is the  $j^{th}$  subword tokens. Notice here that  $m$  and  $n$  can be different because language models learns subword representations instead of word-embeddings.  $\mathbf{h} = \{h_1, h_2, \dots, h_n\}$  is the set of contextual embedding for all tokens in  $\mathbf{x}$  (taken from the last layer’s output of the backbone) and  $\mathbf{p} = \{p_1, p_2, \dots, p_m\}$  with  $p_i$  is the set of all subword positions of the word at position  $i$ . To obtain a word-level embedding, we took the sum of its corresponding subword embeddings.

$$e_i = \sum_{j \in p_i} h_j$$

Then probability distribution of the word at position  $i$  is formulized as follow.

$$p(w_i) = \text{Softmax}(W_c \text{ReLU}(W_h e_i + b_h) + b_c)$$

With  $W_c, b_c$  and  $W_h, b_h$  are the learnable weights and bias respectively. We optimize the model by minimize the Cross Entropy loss between the ground-truth and model predictions.

### 3.2 Method 1: Feature-based Learning

We customize and extend the baseline model by constructing a standard Named Entity Recognition

<sup>1</sup><https://www.kaggle.com/c/jigsaw-unintended-bias-in-toxicity-classification>

Figure 1: An illustration of our method. We start with a baseline, a simple sequence tagger utilizing Toxic RoBERTa as the backbone. In the Self-training branch, the teacher- the best-scored baseline, generates soft pseudo labels for the student to learn. On the other hand, the Feature-based Learning model concatenates the input vector with different embedding methods i.e. Flair, FastText and BPE, then trains the Named Entity Recognition task. Predicted character offsets (for each sentence) of two models are combined using Intersection Union (Ensemble Section) to obtain the final prediction.

model using Flair package (Akbik et al., 2019a)<sup>2</sup> in which each span is an entity encoded in IOB format. The model consists of two parts: input representation using diverse embeddings and a feature-based model.

### 3.2.1 Input Representation

In represent both syntactic and semantic information of a word, we combine embeddings extracted by different word embeddings methods. These representations strengthen advantages of each other while mutually easing their weaknesses.

These word embeddings and their usage in our works are as follows:

- **Flair:** Contextual Flair model works on character level. We fine-tune two models ‘news-forward’ and ‘news-backward’, on the Next Character Prediction task (Akbik et al., 2018), with 600K toxic texts from the Civil Comment Dataset to adapt them to toxic comment domain.
- **Toxic RoBERTa:** To utilize contextual embeddings from Toxic RoBERTa, besides fea-

tures derived from the last layer as our baseline, we concatenate two more layers: the first one (layer 1) and the middle one (layer 6). This choice allows the feature learning to understand three levels of context-specificity (Ethayarajh, 2019). The final word representation is obtained by taking the sum of its subword embeddings.

- **FastText with Byte Pair Embedding:** It has been practically proven that combining contextual embeddings with static embeddings improves the performance of many NLP downstream tasks (Peters et al., 2018). We discard subword part, take only word vector part of a FastText model (pre-trained on Common Crawl dataset) for word representation and utilize an external English Byte Pair Embedding for out-of-vocabulary functionality. This combination performs as well as the original FastText while effectively reduces memory usage.

All of the above embeddings are concatenated to form a long vector for each word, which is digested by a feature learning model.

<sup>2</sup><https://github.com/flairNLP/flair>

### 3.2.2 Feature Learning

The feature learning part is a sequence-to-sequence model that takes a sequence of word vectors and learns higher-level features and inferences tags. We use a linear layer to reproject the word embeddings onto a vector space with dimensions equal to the length of concatenated word embeddings. Two follow-up BiLSTM (Hochreiter and Schmidhuber, 1997) (Dyer et al., 2015) blocks are added to learn high-level semantic-syntactic dependencies of the sequence. Finally, a Conditional Random Fields (Sutton and McCallum, 2010) layer, placed on top of the BiLSTMs, makes tag prediction for each word.

### 3.3 Method 2: Self-training With In-domain Unlabeled Data

#### 3.3.1 In-domain data retrieval

In-domain unlabeled data is one of the determining factors for Self-training. The Toxic Spans Detection task’s labeled dataset is a subset of toxic-and-severe-toxic-labeled data in Civil Comment Dataset (Pavlopoulos et al., 2021). To retrieve additional data, we first selected posts classified as toxic by at least half of its toxicity annotators. After removing texts in both train and trial labeled datasets from the retrieved data, we randomly select a subset of 30,000 unseen texts for the task. The choice of extra datasets’ size is heuristic and limited due to low-computing resources.

#### 3.3.2 Data filtering and soft label

We slightly customized the pseudo-labels distillation process applied in classification tasks (He et al., 2018) for the sequence-tagging problem. Instead of evaluating and selecting each text in unlabeled data, we use the teacher model’s post-softmax class probabilities to evaluate and select each word in a context. Specifically, if each word’s confidence score is greater than a threshold, we keep the back-propagation process through that word; otherwise, we ignore it. Notice here that the probabilities mentioned above are also utilized as confidence scores and pseudo-labels for the student training.

#### 3.3.3 Combine generated-labeled data with original-labeled data

The student model is trained on a combination of original-labeled and synthetic-labeled datasets. It has the same architecture as the teacher model except for increases in dropout rates of dropout layers and the hidden size in the model’s head classifier.

We chose the best checkpoint of the baseline model as teacher model.

### 3.3.4 Post-processing

For each continuous toxic-predicted span, we eliminate any existing punctuation at both its beginning and end. Additionally, to partially prevent our model from predicting common toxic comments’ targets as toxic spans, we exclude any predicted span in our predefined list of targets (described in details in the Appendices section). This list is based on the identity-targets list of toxic comments in the Civil Comments Dataset.

### 3.4 Ensemble Learning

We combine our two approaches by taking intersection (Intersection Ensemble) or the union (Union Ensemble) of predicted character offsets generated by best model results, from each method, to obtain the final offsets for each sentence.

$$\mathbf{S}_I = \mathbf{S}_1 \cap \mathbf{S}_2 = \{x : x \in \mathbf{S}_1 \text{ and } x \in \mathbf{S}_2\}$$

$$\mathbf{S}_U = \mathbf{S}_1 \cup \mathbf{S}_2 = \{x : x \in \mathbf{S}_1 \text{ or } x \in \mathbf{S}_2\}$$

With  $\mathbf{S}_I$ ,  $\mathbf{S}_U$ ,  $\mathbf{S}_1, \mathbf{S}_2$  are the intersection, union Feature-based Learning and Self-training offset predictions for one sentence of the ensemble model respectively.

Figure 1 illustrates our composed framework: the two approaches, built and extent on top of the baseline, are combined for the final predictions.

## 4 Experiments

### 4.1 Dataset

The original dataset contains 7939 annotated samples for training and 2000 unlabeled samples for testing. We use a small trial dataset, given by the task organizer which consists of 690 labeled samples, as our development set. We train our models on the training set, use the development set to find the best hyper-parameters, and finally make our submission on the private test set.

### 4.2 Experiment setup

This section focused on the hyper-parameters configurations of our two methods and is mentioned in the Appendices section.

### 4.3 System Configuration

Our experiments are conducted on a computer with Intel Core i7 9700K Turbo 4.9GHz, 32GB of RAM, GPU GeForce GTX 2080Ti, and 1TB SSD hard disk.

#### 4.4 Evaluation Metric

The evaluation metric of our system is defined, by the task organizer (Pavlopoulos et al., 2021), as follow:

$$F_1^t(A_i, G) = \frac{2 \cdot P^t(A_i, G) \cdot R^t(A_i, G)}{P^t(A_i, G) + R^t(A_i, G)}$$

$$P^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_{A_i}^t|}$$

$$R^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_G^t|}$$

$$\text{if } S_G^t = \{\phi\} \Rightarrow F_1^t(A_i, G) = \begin{cases} 1 & \text{if } S_{A_i}^t = \{\phi\} \\ 0 & \text{otherwise} \end{cases}$$

$$F_1^T(A_i, G) = \frac{1}{n} \sum_{t=1}^n F_1^t(A_i, G)$$

With:

- $S_{A_i}^t$ : character offsets of toxic post  $t$ , output of system  $A_i$
- $G^t$ : ground truth character offsets of toxic post  $t$
- $F_1^t(A_i, G)$ :  $F_1$  score of system  $A_i$ , with respect to ground truth  $G^t$  of post  $t$
- $F_1^T(A_i, G)$ :  $F_1$  score of system  $A_i$  on dataset  $T$
- $|\cdot|$ : set cardinality

#### 4.5 Results

##### 4.5.1 Baseline result

Table 1 indicates the performances of our baseline model with two different backbones, RoBERTa (Liu et al., 2019) and Unbiased Toxic RoBERTa (which is referred as Toxic RoBERTa for the rest of the paper) (Han and Unitary team, 2020). The toxic domain-adaptive pre-trained language model outperforms general RoBERTa by a large margin (up to 0.68), which sheds light on the necessity of adapting universal representations to task-specific domains.

Backbone	Private test F1-score
RoBERTa	68.62
Toxic RoBERTa	<b>69.30</b>

Table 1: Performances of the baseline model with two different backbones.

##### 4.5.2 Feature-based Learning result

We froze Toxic RoBERTa backbone in all experiments of feature-based learning except the last one. This latest experiment compares the differences in model performances between tuning and not tuning Toxic RoBERTa.

Word Embeddings	Private test score
Toxic RoBERTa	69.89
FastText w/ BPE	67.89
Flair	67.92
Toxic RoBERTa + Flair	69.99
Toxic RoBERTa + FastText w/ BPE	69.95
Toxic RoBERTa + Flair + FastText w/ BPE	<b>70.26</b>
Toxic RoBERTa (fine-tuned) + Flair + FastText w/ BPE	67.37

Table 2: Results of different embedding combinations for method one

Table 2 shows the feature-based model’s performance with different word embeddings and the gap in F1-score between feature-based and fine-tuning models. Our findings are as follows:

Toxic RoBERTa was the best feature extractor since using it achieved a competitive F1-score of 69.89. On the other hand, using only Flair results in a slightly better performance than FastText with BPE (67.92 and 67.89 respectively).

Adding more features (learned by Flair or FastText with BPE embeddings) to ones learned by Toxic RoBERTa improved F1-score (69.99 and 69.95 respectively). Ultimately, combining all the word-representations obtained the highest score at 70.26.

Fine-tuning RoBERTa dramatically decreased the performance (up to 3-4).

### 4.5.3 Self-training result

Table 3 presents the performance result of the 2nd method. Our choice of the teacher was the best-performed baseline model with 69.30 F1-score. Post-processing enhanced this performance, resulted in 69.44 F1-score. Self-training only leads to a better student with an improvement of 0.1 compared to the post-processed teacher model. We suspect that this unimpressive increase is due to the teacher model’s confirmation bias and the unsolved issue of noisy-pseudo labels (Pham et al., 2021).

Backbone	Private test F1-score
Teacher w/o Post processing	69.30
Teacher w/ Post processing	69.44
Student	<b>69.54</b>

Table 3: Performances of the teacher model with and without post-processing and student model.

### 4.5.4 Ensemble learning result

Table 4 illustrates the effectiveness of our ensemble methods. Intersection Ensemble results in a significant improvements of our system prediction (0.51 and 1.23 compared to Feature-based Learning and Self-training respectively) while Union Ensemble leads to a substantial decrease of F1-score (-1.14 and -0.42 compared to method 1 and 2 respectively). This exciting finding indicates that Intersection Ensemble can rule out numerous falsely positive tokens of our two models whereas Union Ensemble worsen the performance by integrate these false positives.

Method	Private test F1-score
Feature-based Learning	70.26
Self-training	69.54
Union Ensemble	69.12
Intersection Ensemble	<b>70.77</b>

Table 4: Performance of ensemble models with different ensemble methods.

## 5 Error Analysis

Carefully analyzing errors made by our ensemble model on the test dataset has shed light on our sys-

Figure 2: Analysis of the detection of lengthy toxic spans.

tem’s weaknesses. The following terms are defined to aid the reading of this section:

- Toxic span: ground-truth toxic span.
- Long span: contains at least two words.
- True positive span: all words in the span are correctly predicted as toxic.
- False negative span: at least one word in the toxic span are predicted as non-toxic.

### 5.1 Unsuccessful detection of lengthy toxic spans

Among false negative spans in our system’s predictions, 218 spans are short spans, which constitutes a small portion of the total short spans of the test set. In contrast, the other 158 spans are long spans while the total number of long spans of the test set is 200. This means our model had a bad performance on lengthy toxic spans with false negative rate up to 79%.

Figure 2 further investigates on long span failure. While 90% (38 spans/42 spans) of our correctly predicted long spans contains only two word, this numbers for false-negative spans decrease to 62% (98 spans/158 spans). Longer spans are harder to predict. Failing to detect spans with more than three words contributes approximately 38% to the model’s false-negative.

Table 5 demonstrates several instances of the failure.

### 5.2 False negatives due to post-processing

Although experimentally showed its effectiveness, post-processing after Self-training inevitably excluded continuous predicted spans such as “NIGGERS” and “MUSLIMS” which are potentially a part of ground-truth toxic spans.

Ground-truth	Prediction
Bunch of cowards	cowards
burn them at the stake	burn them
big, fat, orange buffoon	None
you're a fecking write-off	None

Table 5: Several instances of errors in detecting long-spans

I wish <u>this moron</u> would have been shot to death by the US soldier instead of the other way around. I hope that 10 million is given to the soldier's family who actually deserve it.
Our <u>ignorant</u> , clueless legislators are working hard to ensure that Alaskans are as <u>ignorant</u> and clueless as the legislators themselves are. <u>Stupid</u> Alaskans are the only way these <u>moronic</u> legislators will continue to get re-elected.
<u>Trash</u> , and just not the regular <u>bigoted</u> flatulence, this crap you write is evil trash

Note: Underlines are the prediction of our models and bold text are our manually annotated toxic-spans.

Table 6: Several examples of our model predictions on no-span texts, which may have been mis-annotated

### 5.3 Failure due to mis-annotated spans

We notice our model predicted false positive tokens in 469 toxic comments and most of them (308 comments) are humanly annotated with no toxic spans. In our opinion, many of these texts are mis-annotated, which potentially lower the precision of our system.

Table 6 presents several examples of this issue. The underlines are our model predictions, while the bold text spans are our opinion of what toxic annotations should be for the given text. All these texts contain no toxic spans, according to the dataset's annotators.

## 6 Conclusion

In this paper, we proposed a system to resolve the SemEval task 5: Toxic Spans Detection. Our method utilized a pre-trained language model in toxic-domain and successfully combined two approaches Self-training and Feature-based Learning to achieve a high F1-score of 70.77. Finally, we provided insights into failure of the system and the task's potential falsely-negative annotations issue with careful error analysis.

Despite our success on the leader board, in future research, we determine to improve our model as follow:

- Investigate a solution for the noisy-pseudo label issue to enhance the performance of the

Self-training method.

- Combine Self-training with Feature-based Learning to learn a more robust toxic-span detection model.

## A Appendices

To form our target list in 3.3.4, we include original form, plural form, upper or lower case of each word in the table 7 to that list.

Target Identities	Male, female, transgender, heterosexual, homosexual, gay, lesbian, bisexual, Christian, catholic, jewish, Muslim, Islam, hindu, buddhist, atheist, black, white, asian, latino, Nigger, Mexican.
-------------------	--

Table 7: Common target identities in Civil Comment dataset.

Table 8 describes hyperparameter configuration for training. For Feature-based Learning, Flair embeddings are fine-tuned before training the NER model. Turn into Self-training, the best baseline model is used as the teacher. If not specified, the corresponding hyper-parameter value is used for training both baseline and student models

Task	Hyperparameter	Value	Description
Fine-tune Flair	pre-trained weights	"news-forward"/ "news-backward"	Initial weights of the Flair models.
	sequence_length	250	Length of character sequences
	mini_batch_size	500	Size of batches during training
	learning_rate	20	Initial learning rate
	patience	10	Number of epochs without improvement
	max_epochs	5	Number of maximum training epochs
	optimizer	SGD	Optimizer used for training
	scheduler	AnnealOnPlateau	Learning rate scheduler
Train NER model	dropout	0.3995	Probability of an element to be zeroed
	locked_dropout	0.4413	Probability of entire parameters in embedding space to be zeroed
	word_dropout	0.0677	Probability of entire words (or characters) in embedding space to be zeroed
	learning_rate	0.0005	Initial learning rate
	min_learning_rate	1e-07	Minimum learning rate to terminate training
	mini_batch_size	32	Size of batches during training
	max_epochs	50	Number of maximum training epochs
	optimizer	AdamW	Optimizer used for training
scheduler	AnnealOnPlateau	Learning rate scheduler	
Baseline + Self-training	hidden_size_T	150	Size of the linear projection of the teacher's head classifier
	hidden_size_S	160	Size of the linear projection of the student's head classifier
	learning_rate	1e-05	The learning rate used for training
	optimizer	AdamW	Optimizer used for training
	scheduler	None	No learning rate scheduler used
	dropout_T	0.3	Dropout rate of all dropout layers in the teacher head classifier
	dropout_S	0.4	Dropout rate of all dropout layers in the student head classifier
	max_epochs	5	Total training epochs
	label_smoothing	0.15	Label smoothing coefficient
	confidence_threshold	0.7	Use in obtaining extra data for student model, all words with post-softmax score (calculated by the teacher model) less than this threshold will be ignored
batch_size	8	Size of batches during training

# UAntwerp at SemEval-2021 Task 5: Spans are Spans, stacking a binary word level approach to toxic span detection

Ben Burtenshaw and Mike Kestemont

Antwerp Centre for Digital Humanities and Literary Criticism

University of Antwerp

Prinsstraat 13, 2000

Antwerp (Belgium)

firstname.lastname@uantwerpen.be

## Abstract

This paper describes the system developed by the Antwerp Centre for Digital humanities and literary Criticism [UAntwerp] for toxic span detection. We used a stacked generalisation ensemble of five component models, with two distinct interpretations of the task. Two models attempted to predict binary word toxicity based on ngram sequences, whilst 3 categorical span based models were trained to predict toxic token labels based on complete sequence tokens. The five models' predictions were ensemble within an LSTM model. As well as describing the system, we perform error analysis to explore model performance in relation to textual features. The system described in this paper scored **0.6755** and ranked **26<sup>th</sup>**.

## 1 Introduction

**SemEval 2021 Task 5:** Toxic Spans Detection was organised by John Pavlopoulos and colleagues, and described in detail in their task description paper (Pavlopoulos et al., 2021). Competing teams were asked to develop systems capable of detecting spans of toxic text. Predictions were evaluated using a pairwise F1-score of toxic character offset predictions, described in section 5.1.

**Initial analysis** of the development data revealed that toxic spans were varied in content and not limited to single words. Though most examples contained single toxic words or phrases, others contained longer spans and complete sentences. Figure 1 illustrates this phenomena. With this in mind, we sort a strategy that combined longer span based detection with binary word classification.

Table 1 reveals that toxic spans were on average  $\tilde{3}$  times longer in the development set, whilst stop words were  $\tilde{4}$  times more frequent. Figures 8 and 9 shows the frequency of these features in relation to model performance.

```
# 38 | ... while brutal scum hold sway in our institu-
      | tions.
# 36 | Why even bother to give this woman a time of day.
      | Bury her in the cotton field where she belong.
# 31 | other religions aren't carrying
      | out the violent and extremist
      | doctrines as Islamists are.
# 34 | I hope he and other car theves read this,
      | I'll shoot you if I catch you in my vehicles
      | stealing then call the police.
```

Figure 1: Example of possible annotation rationales.

		dev			test

NOT	words	32.52	258165	34.39	31.44	62884	30.87
	stop_ws	16.19	128533	17.55	15.45	30909	15.75
support		7939			2000		

Table 1: Macro values for toxic and non-toxic spans for development and test data. Mean average, total number, and standard deviation are shown for all words and stop words. Support is shown from development and test data as the total number of samples

**Strategy** We combined models that used antithetical contexts, i.e. full sequences, and shorter ngram sequences before and after a given word. This approach is based on the hypothesis that their predictions would have a low correlation, and in turn, they would create ideal ensemble components.

**Results** The system described in this paper scored **0.6755** and ranked **26<sup>th</sup>**. We discovered that model correlation did play a factor in the accuracy of an ensemble approach; however, much of this performance increase was lost in transition to test data, where correlation increased on the most frequent type of examples. In section 5.3 we analyse model performance and correlation in relation to textual features.

## 2 Background

Toxic span detection is a development of binary toxicity detection which has garnered recent attention, in the form of shared-tasks and datasets (Wulczyn et al., 2017; Zampieri et al., 2019).

**Features** Teams were supplied with development data consisting of 7939 text samples in varying lengths up to 1000 characters, and tested on 2000 text samples.

**Target** Span detection asks systems to detect which specific series of characters are toxic, irrespective of the text’s overall toxicity. Figure 2 illustrates the target value for SemEval 2021 Task 5. Unlike Named Entity Recognition, systems were not scored on their performance at negative, beginning, middle, or end token detection. This target definition led to a focus on positive optimisation, where false positives were of more importance than true negatives. In section 5.3 on error analysis we compare model scores using a binary word level representation of toxicity, that scores both positive and negative prediction.

0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20

Figure 2: Illustration of toxic span character offsets.

## 3 System overview

Figure 3: Model Diagram including all component models. Colours represent layer types and arrows represent training pipeline.

**Task Interpretations** We used two types of component models; binary word level models and categorical span based models, and combined those

in an LSTM network (Hochreiter and Schmidhuber, 1997). We used two word based models [GLOV, BERT] and three span based models [ALBE, ROBE, ELEC], the softmax output of all models were concatenated and supplied to an LSTM model [ENSE].

**Motivation** We intended for the word based models to learn local features in the tokens nearest the target word, and for the span based to learn the overall features that affected sub and multi word toxicity.

### 3.1 Baselines

To interpret the task we relied on the Spacy implemented baseline shared by the organizers and described in the task description paper (Pavlopoulos et al., 2021; Honnibal et al., 2020). The approach retrained the RoBERTa based `en_core_web_trf` model’s `ner`, `trf_wordpiecer`, and `trf_tok2vec` components, producing f1-scores of 0.5630 on the development data and 0.6305 on test data. To Interpret the problem further, we implemented two simple baselines.

**Lexical Lookup** Using a subset of samples from the development data, we created a toxic words list from all words within toxic spans, except for stop words<sup>1</sup>. On the test data, we then classified words as toxic if they appeared within the aforementioned toxic words list. We then converted word offsets into character offsets. This approach achieved an F1-score of 0.4161 on the test data.

**SVM** Using Term Frequency to Inverse Document Frequency we created two document vector representations of toxic and non-toxic spans. Using a Support Vector Machine, we predicted the probability that a word vector appeared within a toxic or non-toxic document (Salton and McGill, 1986; Wu et al.). We then used a binary threshold of 0.5 and class weights based on relative label frequency to predict whether a word was toxic. This approach achieved an F1-score of 0.5489 on the test data.

### 3.2 Component Models

#### 3.2.1 Span Prediction

Span prediction models used the complete sequence of words, up to a maximum length, to pre-

<sup>1</sup>The toxic words list was created from the first 5800 samples of the development data. We used Spacy tokenisation and English stop words list, and we removed space and character offsets from predictions.

Figure 4: Illustration of toxic span prediction based on complete sequence.

dict toxic character offsets. Sequences were represented as token reference indexes, described in section 4.1. The target sequence was processed from character offsets into categorical arrays for toxic, non-toxic, and padding tokens. 4.1.

**Transformer Models** We selected three pre-trained transformer models (ALBERT, RoBERTa, ELECTRA) and fine-tuned them for this task with extra linear layers. We performed separate hyperparameter optimisation for each model, detailed in section 4.2. ALBERT is a lightweight implementation of a BERT model (Lan et al., 2020; Devlin et al., 2019) that uses feature reduction to reduce training time. ELECTRA is a further development of the BERT model that pre-trains as a discriminator rather than a generator (Clark et al., 2020). RoBERTa develops the BERT model approach for robustness, (Liu et al., 2019). During development we found that these three transformer models achieved the highest f1-scores in relation model correlation compared to alternatives. All models used the Adam optimizer (Kingma and Ba, 2017).

### 3.2.2 Binary Word Prediction

Figure 5: Illustration of toxic word prediction based on sequence before and after target word.

The binary word level models treated the task as word toxicity prediction based on a sequences of words before and after the target word. Figure 5 illustrates this approach. The target word toxicity was represented as a binary value. The sequence length before and after the target word was optimised for each model, and described in section 4.2.

### Siamese-LSTM with Glove Word Embeddings

A Siamese LSTM model used two networks based on separate glove embeddings of the sequence of

Task Representation	
input_text	"There are still morons"
target_labels	17, 18, 19, 20, 21, 22

BERT Representation					
input_tokens	there	are	still	mor	##ons
word_ids	0	1	2	3	3
target_labels	0	0	0	1	1

Figure 6: Input features and target labels for an example sequence, comparing a BERT specific token representation with the character offset representation defined by organisers (Pavlopoulos et al., 2021).

words before and after the target words (Bao et al., 2018; Baziotis et al., 2017).

**LSTM Finetuning BERT-base** An LSTM model was trained based on the output of a BERT-base model. The words before and after the target word were used as model features, and the target word toxicity was represented as a binary value (Devlin et al., 2019).

### 3.3 Ensemble Model

A Bidirectional LSTM model was used to predict token toxicity based on tokenised word features and component model predictions. The model used transformer style feature representations to predict a sequence of categorical representations for token toxicity, as described in section 4.1. The ensemble model relied on five fold cross validation, as described in section 4.2.

#### 3.3.1 Component model Predictions

Component model predictions were concatenated together as categorical representations of labels (not toxic, toxic, padding : 0,1,2). Each model's 3 dimensional output (number of samples, sequence length, number of labels) was permuted into a 4 dimensional matrix (number of samples, sequence length, number of labels, number of models).

## 4 Experimental setup

### 4.1 Pre-Processing

**Tokenisation** Text sequences were tokenised into character sequences using a BERT tokenizer and excess characters were replaced with a # character, as shown in Figure 6 (Devlin et al., 2019). Sequences were padded and truncated for uniformity to a length of 200 tokens. Longer sequences were handled separately, and predictions were combined in post-processing, described in section 4.4.

**Target Label Representation** To best suit the component models, we used a target representation based on the character sequences from the BERT tokenizer. Each word-like sequence was given a label based on its `word-id`, and converted into categorical binary arrays, or one-hot vectors. This is illustrated in Figure 6.

## 4.2 Training and Optimisation

**Cross Validation** We used stratified  $k$  fold validation of the development data to train all models. After optimisation, each component model’s predictions on the *test* portion of fold  $k$  were added to the *train* portion of the other folds. Producing unseen training features for the ensemble model. This process avoids overfitting in component models, and facilitates training an ensemble model on the complete development data (Fushiki, 2011; Pedregosa et al., 2011).

**Hyper-Parameter Optimisation** Model parameters were optimised for each fold of the development data and the best models were used by the ensemble model. Table 2 shows the optimum parameters for each model used on the test data. We used Bayesian optimization for each fold of the development data to find optimum parameters (Snoek et al.). Component models were selected based on their f1-score and prediction correlation to other models. The ensemble model was trained on the predictions of the optimum model for each fold of the development data, expanded on in Section 4.3.

method	span-based			word-based		
	ELEC	ROBE	ALBE	GLOV	BERT	ENSE
dropout	0.05	0.40	0.23	0.4	0.3	0.23
epochs	4	4	4	20	6	4
layers	2	2	3	3	3	3
nodes	9	3	6	20	3	6
neg_weight	1.00	0.92	1.12	0.6	1.0	1.0
pos_weight	1.00	1.24	0.94	6.0	1.0	1.0
dev_F1	0.665	0.663	0.682	0.647	0.656	0.702
test_F1	0.673	0.662	0.672	0.637	0.634	0.675

Table 2: Table of the best model parameters. Pairwise F1 scores are shown for all span based models.

## 4.3 Prediction

To predict spans for submission, a version of each component model optimised for each fold of the development data was supplied the test data and their outputs were averaged. The ensemble model

was then supplied component model predictions and tokenised text sequences.

## 4.4 Post-processing

Model output was converted from 2 dimensional token-level categorical arrays ( $n$  tokens,  $n$  labels) into character offsets. The character offsets of each positively labeled token was then added to a list, as illustrated in Figure 6. The predictions of sequences that had been truncated during pre-processing, were combined and duplicates were removed.

## 5 Results

Table 3 reveals that the ensemble model achieved a similar score on both development and test data, while the ALBERT, ELECTRA, and baseline models improved in testing. Crucially, the  $\approx 5\%$  increase in f1-score from component models to ensemble, that we see on the development data, was not transferred to the test data.

	dev			test		
	F1	P	R	F1	P	R
<b>ENSE</b>	0.6736	0.6664	0.7000	<b>0.6755</b>	0.6538	0.7182
<i>ALBE</i>	0.6284	0.6966	0.6677	0.6684	0.6695	0.6995
<i>ELEC</i>	0.6390	0.6975	0.6936	0.6668	0.6459	0.7296

BASE	0.5523	0.6247	0.5630	0.6305	0.5969	0.6548

Table 3: Scores on development and test data. The final submitted system predictions [ENSE] are shown in bold and component models are shown in italic.

## 5.1 Task Specific Evaluation Metrics

Systems are evaluated with an F1 score of character offsets (Pavlopoulos et al., 2021). In cases where predicted spans are empty, 1 is given when true spans are empty and 0 is given if there are any true spans.

## 5.2 Model Correlation

Figure 7 reveals that the ensemble and ALBERT models have a high correlation, a logical outcome of their shared base layers; whilst word based models [BERT, GLOV] have a low correlation, reflecting their diverse interpretations.

ENSE	1	0.9	0.86	0.83	0.8	0.7	0.75
ALBE	0.9	1	0.85	0.82	0.79	0.7	0.74
ELEC	0.86	0.85	1	0.83	0.76	0.65	0.74
ROBE	0.83	0.82	0.83	1	0.72	0.61	0.71
BERT	0.8	0.79	0.76	0.72	1	0.76	0.72
GLOV	0.7	0.7	0.65	0.61	0.76	1	0.65
BASE	0.75	0.74	0.74	0.71	0.72	0.65	1
	ENSE	ALBE	ELEC	ROBE	BERT	GLOV	BASE

Figure 7: Model Correlation calculated using a macro average f1-score

### 5.3 Error Analysis

We performed error analysis to interpret the hypothesis that there are multiple annotation rationales; single toxic words, and longer offensive sentences, illustrated in Figure 1.

**Toxic Span Length** Figure 8 reveals that the length of toxic spans had an impact on model performance. Models were less accurate at detecting longer spans on both development and test data. Furthermore, the impact of this effect on test data was decreased as there were fewer longer toxic spans.

Figure 8: Model F1 score at  $n$  tokens per toxic span. Bars show the frequency of  $n$  tokens in development and test data. Shaded areas shows standard deviation of the f1-score for the ensemble model.

**Stop Words in Toxic Spans** The frequency of stop words in toxic spans also affected model performance. Figure 9 reveals that, where present, spans with more stop words caused lower model accuracy.

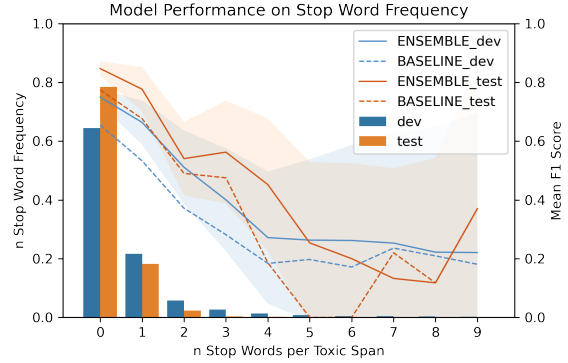

Figure 9: Model F1 score at  $n$  stop words per toxic span, and  $n$  stop word frequency.

**Binary Token Level Evaluation** By using token level scoring we are able to reveal how the models perform on both positive and negative tokens. Here, the target labels are represented as binary arrays; 1 for toxic tokens and 0 for non-toxic. We can not expect these calculations to align with character offsets, due to variance in tokenisation and parsing.

	NOT	TOX	NOT	TOX	
Baseline	0.93	0.55	0.97	0.63	Precision
	0.93	0.64	0.98	0.63	Recall
	0.97	0.57	0.97	0.69	f1-score
Ensemble	0.93	0.64	0.97	0.67	Precision
	0.93	0.71	0.98	0.68	Recall
	0.96	0.69	0.97	0.71	f1-score

Figure 10: Binary token level scores for precision, recall, and f1-score.

## 6 Conclusion

Our initial hypothesis, that combining word based and span based approaches would yield a significant performance boost, did not stand up. We measured a  $\tilde{5}\%$  increase in f1-score on development data, but this was not transferred to test data. In future work, we would look to a strategy that incorporated model transferability in component model selection, with the intention of better handling fluctuations in annotation rationale. Drawing on recent work (Fortuna et al., 2021).

# hub at SemEval-2021 Task 5: Toxic Span Detection Based on Word-Level Classification

Bo Huang, Yang Bai, Xiaobing Zhou\*

School of Information Science and Engineering

Yunnan University, Yunnan, P.R. China

\*Corresponding author: zhouxb@ynu.edu.com

## Abstract

This article introduces the system description of the hub team, which explains the related work and experimental results of our team's participation in SemEval 2021 Task 5: Toxic Spans Detection. The data for this shared task comes from some posts on the Internet. The task goal is to identify the toxic content contained in these text data. We need to find the span of the toxic text in the text data as accurately as possible. In the same post, the toxic text may be one paragraph or multiple paragraphs. Our team uses a classification scheme based on word-level to accomplish this task. The system we used to submit the results is ALBERT+BILSTM+CRF. The result evaluation index of the task submission is the F1 score, and the final score of the prediction result of the test set submitted by our team is 0.6640226029.

## 1 Introduction and Background

From the popularization of the Internet to the first year of the mobile Internet in 2011, the number of online social media and social media users has continued to grow. In the context of the ever-expanding user base, coupled with the free and interactive features of online social media communication. Therefore, online social media has exposed many issues worthy of our attention, such as the lack of communication standards and the out-of-control of information dissemination, which makes the dissemination of online social media prone to various negative functions (Baccarella et al., 2018).

The task of toxic span detection is to detect the span of text with toxic information in the text (Pavlopoulos et al., 2021). The goal of the task is to predict the beginning and ending character positions in the text as accurately as possible. Reviewing the content in online media can effectively avoid the spread of a series of negative information such as cyber violence, cyberbullying, and

false news. Audits are essential to promote healthy online discussions. However, the content and number of posts in social media are too large, and the manual review method obviously cannot achieve a good effect. Therefore, in combination with the development of modern technology, achieving a semi-automatic audit is the best solution.

## 2 Related Work

There are many different kinds of methods for identifying negative information in social media, but usually, these methods mainly focus on supervised learning. Simple SurfaceFeatures similar to the bag of words model can provide very clear and easy-to-understand information in text processing tasks. The general approach of this method is to merge multiple larger n-grams into a feature set (Nobata et al., 2016; Djuric et al., 2015). Use the artificial neural network method to train the word embeddings in the corpus. The purpose is to use the distance between vectors to indicate the semantic similarity of different words. Djuric et al. proposed a method of directly using embedding to represent the entire text and showed us the effect of this method (Sun et al., 2019).

Negative information in the text can be detected by the above methods. But more information needs to be obtained according to the context. The pre-trained language model based on the Transformer architecture has great advantages both at the word level and in context information (Wang et al., 2019). Therefore, in this task, we try to combine the pre-trained language model to complete the detection of toxic content.

## 3 Data and Methods

In this section, we introduce the data provided by the task organizer team to the participating teams, as well as the models and methods we use.

Figure 1: A word cloud diagram of the training set text data provided by the task organizer team. The result shown in the figure is the data after removing the stop words.

Figure 2: A word cloud diagram of the test set text data provided by the task organizer team. The result shown in the figure is the data after removing the stop words.

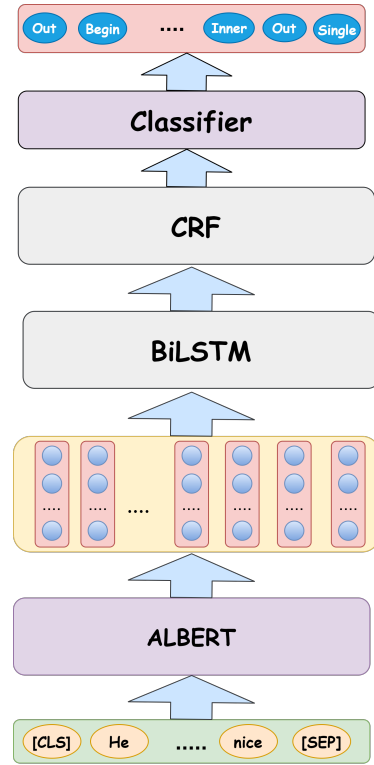

Figure 3: The model structure and data flow we used in the task.

### 3.1 Data Description

The task organizer team provides each team with training data sets and test data sets related to the “Toxic Spans Detection” task. The training data set consists of two parts, one is the text data of the post, and the other is the index position of the span of Toxic Spans. Each post corresponds to an index span data. There are some posts in the training set that do not contain toxic content, and there are one or more pieces of toxic content in the remaining posts. Also, in the index range of these toxic content, it may be a phrase, a sentence, or a word. The length of the post is not the same. Compared with the training data set, the test set only contains the text data of the posts. We need to use our method to predict the index span of the toxic content of posts in the test set. Table 1 shows the sample data of the data we used in the task.

There are 7939 and 2000 pieces of data in the training set and test set, respectively. We visualize the text data in the training set and the text data in the test set using word cloud graphs. The word cloud image clearly shows us the characteristics of word frequency distribution in the text data set. Regardless of the text data in the training set data or the text data in the test set data, some insulting

Figure 4: The BiLSTM structure and data flow

vocabulary, as well as some neutral vocabulary and human names (Trump) appear most. Those sentences with insulting words are usually detected as text with toxic spans. Some short sentences composed of words with neutral meanings and other phrases may also be recognized as text with toxic spans. The reason is because these sentences combined with some background information will convey unfriendly information. Figure 1 and Figure 2 show the word frequency information in the training set and the word frequency information in the test set.

Data category	Text	Spans
train	““““who do you think should do the <i>kill</i> ing?””””	[32, 33, 34, 35, 36, 37, 38]
train	“CROOKED Trump = GUILTY as hell. <i>pathetic</i> ”	[32, 33, 34, 35, 36, 37, 38, 39]
train	He is a scary maniac with a psychopath attitude.	[]
test	This <i>idiot</i> has no clue.	[5, 6, 7, 8, 9]

Table 1: Part of the data samples in the training set and test set provided by the task organizer team.

### 3.2 Methods

In our system, we use pre-processed data as the input to ALBERT. The architectures of ALBERT base and BERT base are both composed of 12-layer Transformer (Devlin et al., 2018; Lan et al., 2019). Compared with the BERT model, the result of the original embedding parameter  $P$  is the product of the vocabulary size  $V$  and the hidden layer size  $H$ . ALBERT factorizes the Embedding matrix by using a lower-dimensional embedding space of size  $E$  and then project it to the hidden space.

$$V * H = P \quad \rightarrow \quad V * E + E * H = P \quad (1)$$

Different from  $H=E$  in BERT, when  $H \gg E$ , the number of parameters of ALBERT has a significant reduction. Another big difference from BERT is that ALBERT’s default decision is to share all parameters across layers (Lan et al., 2019). Based on these improvements, the training effect of ALBERT is better than that of BERT. In terms of memory usage, the ALBERT pre-training model is also smaller than the BERT pre-training model.

Based on the structural characteristics of the RNN artificial neural network, the RNN network has great advantages in processing text data (Zaremba et al., 2014). But in the actual training process, a simple RNN network is difficult to converge. Because the loss value of the RNN network is continuously accumulated as the text sequence increases. Compared with the RNN network, LSTM artificial neural network has great advantages in model convergence and processing long text (Gers et al., 1999; Olah, 2015). LSTM is mainly composed of two key points, one is the cell state, the other is the gate unit. The information learned by the LSTM unit will be directly stored in the cell state, and we can input and update the value in the cell state. The gating unit plays a role in controlling how to update the value in the cell state. These gating units are composed of forget control gate, input control gate, and output control gate. The key

to the composition of the gating unit is the sigmoid function.

In our system, first, we use the preprocessed data as the input of ALBERT. Then, use the output of ALBERT as the input of BiLSTM. Next, the output of the BiLSTM model is used as the input of CRF. Finally, a classifier is used to classify the output results of CRF. The classifier needs to classify each word in the text into one of four different categories. These four categories are the beginning of the text span, the inside of the text span, the outside of the text span, and the toxic span formed by a single word. The architecture of BiLSTM, our model architecture and data flow can be seen in Figure 3 and Figure 4.

## 4 Experiment and Results

In this section, we will introduce the data preprocessing methods and experimental settings we used in the task and the final results.

### 4.1 Data Preprocessing

Because our model and method are to classify content at the word level. So we preprocessed the text data provided by the task organizer team. Preprocessing mainly involves dividing all words in each post into one of four categories (Begin, Out, Inner, Single). These four categories represent our specific description in Section 3.2, paragraph 4. Then split the processed training set into a new training set and a validation set. The split rule is to randomly extract part from the training set as the validation set, and the ratio of the training set to the validation set is 8: 2.

### 4.2 Experiment setting

We use preprocessed data as input to the model. During the training process, we adjust the parameters of the model according to the results of the model on the validation set. The learning rates used by the ALBERT-base, BiLSTM, CRF and classifier modules in the model are not the same. The learning rate used by ALBERT-base and BiL-

STM is  $3e-5$ , and the learning rate used by CRF and classifiers is  $1e-4$ . The maximum length of sentences input in the model is fixed at 120 words. The choice of this length comes from the length of the text in the data and the memory size of the GPU. Sentences that do not reach 120 words in length will be supplemented with zeros. Sentences longer than 120 words will be deleted. The epoch and batch during training are 10 and 32, respectively. The optimizer used in our experiment is Radam (Liu et al., 2019).

### 4.3 Results evaluation method

The evaluation index announced by the task organizer team is the F1 score. Let system  $A_i$  return a set  $S_{A_i}^t$  of character offsets, for parts of the post found to be toxic. Let  $G$  be the character offsets of the ground truth annotations. We compute the F1 score of system  $A_i$  with respect to the ground truth  $G$  for post  $t$  as follows, where  $|\cdot|$  denotes set cardinality.

$$F_1^t(A_i, G) = \frac{2 \cdot P^t(A_i, G) \cdot R^t(A_i, G)}{P^t(A_i, G) + R^t(A_i, G)} \quad (2)$$

$$P^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_{A_i}^t|} \quad (3)$$

$$R^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_G^t|} \quad (4)$$

If  $S_G^t$  is empty for some post  $t$  (no gold spans are given for  $t$ ), we set  $F1^t(A_i, G) = 1$  if  $S_{A_i}^t$  is also empty, and  $F1^t(A_i, G) = 0$  otherwise. We finally average  $F1^t(A_i, G)$  over all the posts  $t$  of an evaluation dataset  $T$  to obtain a single score for system  $A_i$  (Da San Martino et al., 2019).

### 4.4 Results

In the final results list announced by the task organizer team, a total of 91 team results are presented in the list. Our team’s F1 result score was 0.6640226029, ranking 37th. Table 2 presents the result score of our system on the validation set and the result score on the test set. Compared with the results of the top 3 teams in the ranking, our result is 0.0442802224 different from the optimal result. Table 3 shows the scores of the top three teams and our team on the test set.

Data	F1 score
Validation set	0.6821240031
Test set	0.6640226029

Table 2: The scores obtained by our system on the validation set and test set. The validation set comes from 20% of the training set provided by the task organizer team.

team	F1 score	Rank
HITSZ-HLT	0.7083028253	1
S-NLP	0.7077035474	2
hitmi&t	0.6984762534	3
hub(our method)	0.6640226029	37

Table 3: In the result list released by the task organizer team, the top 3 submitted test set prediction results scores and our submitted test set prediction results scores. A total of 91 participating teams submitted the prediction results of the test set.

## 5 Conclusion

This paper presents the system description submitted by our team to SemEval 2021 Task 5: Toxic Spans Detection. Our goal is to use our system to detect the span of toxic content as accurately as possible. We use a classification scheme based on word-level to complete the task. The system combines the pre-training language model (ALBERT) and BiLSTM+CRF commonly used in NLP tasks. The results we submitted proved the feasibility of our system, but compared with the optimal results, our method still has room for improvement. In future work, we will try to improve our methods to achieve better results.

## Abstract

This paper describes our contribution to SemEval-2021 Task 5: Toxic Spans Detection. Our approach considers toxic spans detection as a segmentation problem. The system, Waw-unet, consists of a 1-D convolutional neural network adopted from U-Net architecture commonly applied for semantic segmentation. We customize existing architecture by adding a special network block considering for text segmentation, as an essential component of the model. We compared the model with two transformers-based systems RoBERTa and XLM-RoBERTa to see its performance against pre-trained language models. We obtained 0.6251 f1 score with Waw-unet while 0.6390 and 0.6601 with the compared models respectively.

## 1 Introduction

Unlike the text classification problems targeting to classify whole documents (Borkan et al., 2019; Schmidt and Wiegand, 2017; Pavlopoulos et al., 2019), toxic span detection is an NLP task focusing on capturing granular contents that make a text toxic. Proposed solutions may contribute to managing semi-automated moderations such as online discussions or news portals that are open to large participation and user comments. Therefore, the evaluation of systems that could accurately locate toxic spans within a text is considered a crucial step for this task (Pavlopoulos et al., 2021).

We adapt two solution approaches for the task. For the first approach, we consider toxic spans detection as a segmentation problem while in the second one we use transformers-based models. Our proposed model for the first approach uses character-based tokenized chunks as an input and outputs segmented text. The system uses a 1-dimensional (1-D) convolutional neural network adopted from U-Net architecture (Ronneberger

et al., 2015) commonly applied for semantic segmentation. We previously studied this approach, as we call Waw-unet, on text parsing problems for unstructured postal addresses, and achieved remarkable results (Delil et al., 2020).

In our second approach, we consider toxic spans as a single label Named-Entity Recognition problem. We employ several different transformers-based models and obtained better scores with RoBERTa (Liu et al., 2019) and XLM-RoBERTa (Conneau et al., 2020) network architectures. To see the difference between our main system and transformers-based models, we compared model achievements, and obtained 0.6251 f1 score with Waw-unet while 0.6390 and 0.6601 with the other models respectively. Following the final rankings, our best score ranked 44th among 91 submissions<sup>1</sup>.

## 2 Waw-unet Architecture

Waw-unet is a fully convolutional neural network architecture we designed by taking inspiration from U-Net architecture which was firstly developed for segmentation problems (Ronneberger et al., 2015). The U-Net network architecture is composed of two symmetric parts, which uses dimension reduction for the first half of the network, and then increases its dimension in the second half. In this architecture, the connections are taken from the convolutional layers on the encoding part, which also feeds each corresponding layer of the decoding part.

Similar to the pixel-based image segmentation, Waw-unet takes input samples, in our case text, and generates homogeneous masked regions for the targeted segment. However, unlike image processing which has multi-channel input, the network has 1-D input due to the single-dimensional nature of text

<sup>1</sup>Source code for our model is published on [https://github.com/birolkuyumcu/wawunet\\_for\\_toxicspan](https://github.com/birolkuyumcu/wawunet_for_toxicspan)

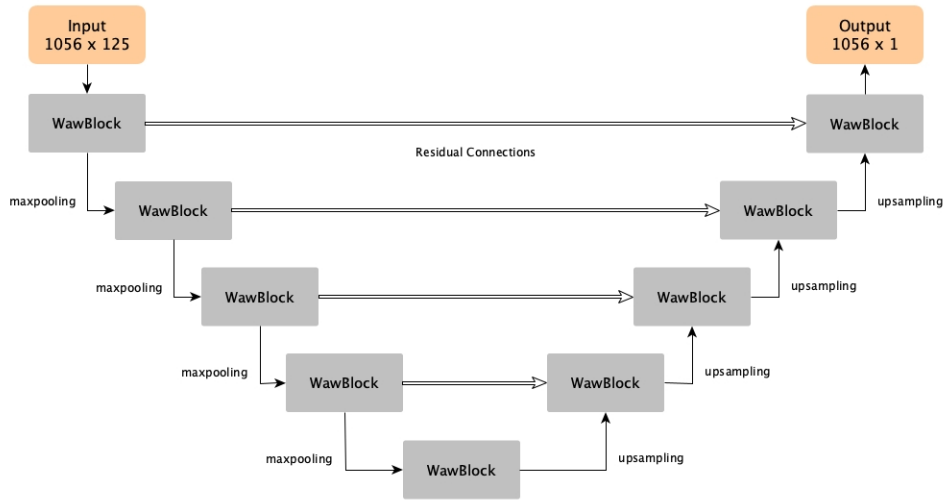

Figure 1: Waw-unet network architecture

data (Fig. 1). The outputs of the convolution layers are combined and passed through a 1-D convolution layer, and then we use batch normalization to accelerate training and prevent the objective function from getting stuck in local minima. After this stage, before the outputs send to the next block, if the output is in the encoder part their dimensions are reduced in half using max pooling, while doubled if it's in the decoder part by upsampling.

Although its architecture adapted from U-Net, we customize existing architecture by adding a special network block for text segmentation, as an essential component of the model. Waw-unet uses a special network block, which we call it Waw-block, to extract the attributes in the targeted text patterns. In our architecture, each waw-block contains three convolutional layers with different kernel sizes. Waw-unet learns input features through filter sizes of the 3, 5, and 7 as shown in Fig. 2.

## 2.1 Data Preparation

As we use a character-based system in our model, the total number of characters in the dataset and the maximum character length for each sample need to be determined. In the training dataset, the former was 1047, while the latter calculated as 125. Since our model has encoder-decoder architecture, to prevent matrix dimension problems, the input size has to be selected so that it can be divided by 2 until the end of the encoder part. Therefore, we defined max input size, the closest value as 1056, and the input matrix dimension as 1056 x 125. In accordance with the segmentation logic, the output character positions contain toxic spans masked as 1

and the other parts of the text masked as 0 (Fig. 3).

## 2.2 Model Training

The Tversky similarity index (TI) is used to calculate the loss function for training the network. It is an asymmetric similarity measure that is a generalization of Dice coefficient and Jaccard index (Tversky, 1977). To define Tversky loss function we use the following formulation:

TI : Tversky Index

TP : True Positive

FP : False Positive

$$TI = TP / (TP + a * FN + b * FP)$$

$$b = 1 - a$$

Here, we use  $1 - TverskyIndex$  as the loss function. The parameters  $a$  and  $b$  are used to provide weight to the represented classes. In our case, we determine  $a = 0.7$  to give weight to the false-negative classification so that the loss function is modified accordingly. Additionally, Dice similarity coefficient was used as a metric to judge the performance of the model training.

## 3 Transformers Models for NER

Toxic span detection can be adopted to NER problems by considering targeted toxic part of text as a predefined named-entity. We experiment with transformers models as an alternative for our model to see its performance. We use pre-trained models RoBERTa (Liu et al., 2019) and XLM-RoBERTa (Conneau et al., 2020) in our study utilising HuggingFace Trainer class.

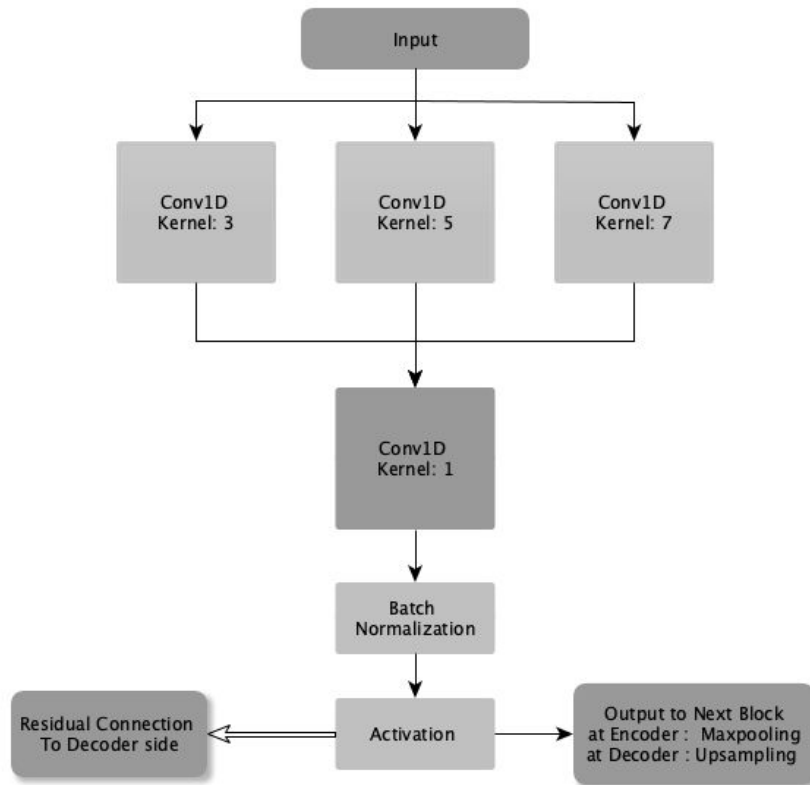

Figure 2: Waw-block architecture

Figure 3: Waw-unet: Character-based masking

RoBERTa is an extension of pre-trained transformer model BERT with over more data and some configuration changes to the pre-training stages. The modifications include such as training longer and bigger batches, dynamically changing the masking pattern, and training on longer sequences (Liu et al., 2019). On the other hand, XLM-RoBERTa uses self-supervised training techniques designated to solve the cross-lingual understanding task. The model improves upon previous multilingual approaches by incorporating more training data and languages (Conneau et al., 2020).

To prepare toxic spans dataset for training, word labeling operation carried out by converting toxic spans into toxic words based on whether more than 50% of their characters labeled as toxic (Fig.4).

We use the Simple Transformers library (Rajapakse, 2019) to prepare our data for pre-trained models. Tokenized input containing the 3 columns—sentence\_id, words, and labels. Each value in words has a corresponding label value. In

Figure 4: Transformers NER model: Word-based entity labeling

this data format, the sentence\_id determines which words belong to a given sentence (Fig. 5). We use the maximum sequence length of 128 for training and evaluation dataset.

## 4 Results

We evaluate our system as well as transformers models' performance on the SemEval-2021 Task 5: Toxic Span Detection trail dataset and also report the evaluation result on the blind test dataset. We use standard train/test split of the official release dataset of the Task for experiments.

For our main system model, Waw-unet, we start model training with 300 epochs and utilize early

stopping and learning pause using Keras’s learning callbacks (Chollet et al., 2015). On the other hand, we trained transformers models with 8 batch size with 17 epochs. We gained the best score in 7th epoch on both pre-trained language models.

XLM-RoBERTa model gained best score 0.6601 while waw-unet and RoBERTa reached 0.6251 and 0.6390 respectively as shown in Table 1.

F1 For	Waw-Unet	RoBERTa	XLM-RoBERTa
Train	0.812	0.803	0.806
Trial	0.602	0.645	0.643
Test	0.625	0.639	0.660

Table 1: Model results

## 5 Conclusion

We framed the problem as a semantic segmentation task, and developed a unique approach to extract targeted spans from provided text data. Proposed system performs relatively well than expected against pre-trained transformers. Our models do not use any of the external dataset or automatic linguistic annotations, such as PoS or named entity tags. Overall, we showed that segmentation based systems can be used to address the toxic detection task. Our best submitted result was ranked 44th among 91 submissions, obtaining an average F1 score of 0.6601, 4.82 points behind the first ranked system.

For future studies, we’re planning to work on unsupervised training of the Waw-unet architecture on large datasets to compete with the pre-trained general language models.

## Abstract

This paper describes our system for SemEval-2021 Task 5 on Toxic Spans Detection. We developed ensemble models using BERT-based neural architectures and post-processing to combine tokens into spans. We evaluated several pre-trained language models using various ensemble techniques for toxic span identification and achieved sizable improvements over our baseline fine-tuned BERT models. Finally, our system obtained a F1-score of 67.55% on test data.

## 1 Introduction

Toxic speech has become a rising issue for social media communities. Abusive content is very diverse and therefore offensive language and toxic speech detection is not a trivial issue. Besides, social media moderation of lengthy comments and posts is often a time-consuming process. In this regard, the task of detecting toxic spans in social media texts deserves close attention.

This work is based on the participation of our team, named MIPT-NSU-UTMN, in SemEval 2021 Task 5, “Toxic Spans Detection” (Pavlopoulos et al., 2021). Organizers of the shared task provided participants with the trial, train, and test sets of English social media comments annotated at the span level indicating the presence or absence of text toxicity. We formulated the task as a token classification problem and investigated several BERT-based models using two-step knowledge transfer. We found that preliminary fine-tuning of the model on data that is close to the target domain improves the quality of the token classification. The source code of our models is available at <https://github.com/morozowdmitry/semEval21>.

The paper is organized as follows. A brief review of related work is given in Section 2. The definition of the task has been summarized in Section 3. The

proposed methods and experimental settings have been elaborated in Section 4. Section 5 contains the results and error analysis respectively. Section 6 is a conclusion.

## 2 Related Work

Computational approaches to tackle text toxicity have recently gained a lot of interest due to the widespread use of social media. Since moderation is crucial to promoting healthy online discussions, research on toxicity detection has been attracting much attention. Our work is also related to hate speech and abusive language detection (Fortuna et al., 2020).

The toxic speech detection task is usually framed as a supervised learning problem. Moreover, fairly generic features, such as bag of words (Harris, 1954) or word embeddings (Mikolov et al., 2013), systematically yield reasonable classification performance (Fortuna and Nunes, 2018; Schmidt and Wiegand, 2017). To better understand the mechanisms of toxic speech detection, some scholars (Waseem et al., 2017; Lee et al., 2018; Karan and Šnajder, 2018; Swamy et al., 2019) compared different techniques for abusive language analysis. Neural architectures and deep learning methods achieved high results in this domain. Thus, Pavlopoulos et al. (2017a,b) explored the possibilities of deep learning and deep attention mechanisms for abusive comment moderation. Park and Fung (2017) proposed an approach to performing classification on abusive language based on convolutional neural networks (CNN). Chakrabarty et al. (2019) used Bidirectional Long-Short Term Memory network. Castelle (2018) experimented with CNN and Gated Recurrent Units. Some recent studies (Mozafari et al., 2019; Risch et al., 2019; Liu et al., 2019a; Nikolov and Radivchev, 2019) utilized pre-trained language models such as Bidirec-

tional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) to detect offensive or abusive language.

In recent years, the task of detecting and analyzing abusive, toxic, or offensive language has attracted the attention of more and more researchers. The shared tasks based on carefully curated resources, such as those organized at the SemEval (Zampieri et al., 2019; Basile et al., 2019), GermEval (Wiegand et al., 2018), EVALITA (Bosco et al., 2018), and OSACT (Mubarak et al., 2020) events, have significantly contributed to the progress of the field and to the enrichment of linguistic resources. In addition to the corpora collected for these shared tasks, Rosenthal et al. (2020) released a large-scale dataset for offensive language identification. Ibrohim and Budi (2018); Leite et al. (2020); Pitenis et al. (2020); Komalova et al. (2021) presented various datasets for abusive speech detection in non-English languages. Most of these datasets classify whole texts or documents, and do not identify the spans that make a text toxic.

### 3 Shared Task

The task focuses on the evaluation of systems that detect the spans that make a text toxic, when detecting such spans is possible. The goal of the task is to define a sequence of words (character offsets) that attribute to the toxicity of the text, for example:

- **Input.** “This is a stupid example, so thank you for nothing a!@#!@”.
- **Output.** [10,11,12,13,14,15,51,52,53,54,55, 56].

The sources of data were various posts (comments) from publicly available datasets. The provided dataset contains 10,629 posts split into training (7939), trial (690), and test (2000) subsets.

Inspired by Da San Martino et al. (2019), the organizers proposed to employ the F1-score for evaluating the responses of a system participating in the shared task. Let system  $A_i$  return a set  $S_{A_i}^t$  of character offsets, for parts of the post found to be toxic. Let  $G^t$  be the character offsets of the ground truth annotations of  $t$ . The F1-score of system  $A_i$  is calculated with respect to the ground truth  $G$  for post  $t$  as follows, where  $|\cdot|$  denotes set cardinality.

$$F_1^t(A_i, G) = \frac{2 \cdot P^t(A_i, G) \cdot R^t(A_i, G)}{P^t(A_i, G) + R^t(A_i, G)},$$

$$P^t(A_i, G) = \frac{S_{A_i}^t \cap S_G^t}{S_{A_i}^t},$$

$$R^t(A_i, G) = \frac{S_{A_i}^t \cap S_G^t}{S_G^t}.$$

The final F1-score is an average  $F_1^t(A_i, G)$  over all the posts  $t$  of an evaluation dataset  $T$  to obtain a single score for system  $A_i$ .

## 4 Methodology

The stated problem was modified from char-level to token-level binary-classification. The proposed solution utilizes a pre-trained language model with a classification head to classify tokens. Different configurations of BERT pre-trained as masked language models were considered as a backbone.

Due to the lack of available token-level labeled public datasets for toxic comment and the relatively small size and sparsity of dataset provided by the competition, the following training pipeline was proposed to enhance knowledge transfer. First, fine-tune pre-trained BERT on a larger-scale task of *toxic comment classification*, using the Jigsaw dataset<sup>1</sup> from which the competition data were constructed. Second, fine-tune obtained model to solve the actual *toxic tokens classification* problem. The exact training parameters are to be found below.

For the first step:

- remove texts occurred in spans dataset from classification dataset to prevent data leakage (so as spans dataset is sampled from classification dataset);
- 4 epochs, 200 tokens max length, 64 batch size, 10 gradient accumulation, mixed-precision FP16;
- default AdamW (Loshchilov and Hutter, 2017) with lr = 4e-5, Layer-wise Decreasing Layer Rate (Sun et al., 2019) with decay  $\eta = 0.95$  and cosine learning rate (LR) schedule with T = 4 epochs and constant LR after epoch 3;
- selected bert-base-uncased as best performance / speed ratio;
- the best model on validation selection each 0.1 epoch by AUC.

For the second step:

- hold-out  $\approx 14\%$  of data to train ensemble of models later;

<sup>1</sup><https://www.kaggle.com/c/jigsaw%2Dtoxic%2Dcomment%2Dclassification%2Dchallenge>

- out-of-5-fold training on the residual  $\approx 86\%$  of data;
- 4 epochs, 512 tokens max length, 16 batch size, 10 gradient accumulation, mixed precision FP16;
- default AdamW with  $lr = 4e-5$ , Layer-wise Decreasing Layer Rate with decay  $\eta = 0.95$  and cosine LR schedule with  $T = 4$  epochs;
- the best model on validation selection each 0.1 epoch by F1-score.

The final solution contains  $N \times K$  models, where  $N$  is the number of different backbone BERT architectures,  $K$  is the number of folds (5 in the current experiments). Obtained models are further to be ensembled using different strategies with validation on the single hold-out dataset:

- hard voting: final spans are selected as at least one model (spans union), as all the models (spans intersection) or as some intermediate methods with at least  $m$  models;
- soft voting: final probability is calculated as a weighted sum of models probabilities;
- train meta classifier.

## 5 Experiments and Results

Three pre-trained backbone BERT architectures were considered: bert-base-uncased, bert-large-uncased (Devlin et al., 2018), and bert-base pre-trained for Hate Speech Detection (dehate-bert) (Aluru et al., 2020). First step setup and results:

- select subset of Jigsaw toxic classification data: all the targets with toxicity score  $\geq 0.5$  ( $L = 135168$  objects) as class 1 and randomly sampled  $3 * L$  objects with toxicity score  $< 0.5$  as class 0;
- stratified 80% train, 20% validation;
- 0.968 AUC bert-base, 0.968 AUC bert-large, 0.942 AUC dehate-bert.

So as models except bert-base-uncased did not show compatible performance for token classification (and later for tests on the fold 0 did not show good F1-score for the actual task as well), later experiments were continued only for bert-base-uncased pre-trained model fine-tuned on token classification.

For step two results are following:

- train + trial, 8621 comments;
- average F1-score over 5 folds is 0.6714.

The experiments were conducted with Hugging-face transformers library (Wolf et al., 2019).

Many patterns in our results are expected, but some stand out. In general, our model is good at detecting obscene language and utterances that demean honor and dignity or denote low moral character. We noticed that our model is not very good at identifying the posts that have no toxic span annotations. According to the corpus description, in some toxic posts, the core message is conveyed may be inherently toxic. Thus, a sarcastic post can indirectly claim that people of a particular origin are inferior. Hence, it was difficult to attribute the toxicity of those posts to particular spans. In such cases, the corresponding posts were labeled as not containing toxic spans. Among our results, there are many examples where the model detected spans in not annotated posts, for example:

- “uhhh Hillary Clinton is a serial killer and thief”: [] (true annotation), [26, 27, 28, 29, 30, 31, 33, 34, 35, 36, 37, 38, 44, 45, 46, 47, 48] (our annotation, “uhhh Hillary Clinton is a **serial killer** and **thief**”);
- “This goes way beyond just being an asshole skipper, dude must have some serious mental issues”: [] (true annotation), [35, 36, 37, 38, 39, 40, 41] (our annotation, “This goes way beyond just being an **asshole** skipper, dude must have some serious mental issues”).

In addition, some texts in the dataset raise questions of the annotation credibility, for example:

- “How the hell is this news? Am I supposed to be shocked that the Crown Prince of Bahrain or one of the world’s biggest celebrity superstars get’s better access to the State Department then I do? During which administration has this ever not been true? The media’s desperation to keep this election close is far past ridiculous” (training set, the toxic span annotation is underlined);
- “Yup. NVN used the Press. The Press was USED. Used like their sister on prom night! Idiots. All faux-erudite, not realizing they were being played” (training set, the original annotation is underlined);

Rank	Team	F1-score
1	HITSZ-HLT	0.7083
26	UAntwerp	0.67552
<b>27</b>	<b>MIPT-NSU-UTMN</b>	<b>0.67551</b>
28	NLRG	0.67532
	Avg result	0.57805

Table 1: Results on the test set.

- “And you are a complete **moron** who obviously doesn’t know the meaning of the word **narcissist**. By the way your bias is showing” (test set, the original annotation is underlined, the annotation of our model is highlighted in bold).

The final result of our model is presented in Table 1. As can be seen from the table, the systems of the participants produce close results. Our system achieved 67.55% of F1-score on the test set of this shared task that attracted 91 submitted teams in total. This value exceeded the average result by almost 10%.

## 6 Conclusion

This paper introduces our BERT-based model for toxic spans detection. As expected, pre-training of the BERT model using an additional domain-specific dataset improves further toxic spans detection performance. Experimenting with different fine-tuning approaches has shown that our BERT-based model benefits from the two-step knowledge transfer technique. An ensemble with spans intersection obtained our best result on the test data.

In our future work, we will evaluate various language models, such as distilled versions of BERT (Sanh et al., 2019; Jiao et al., 2020) and RoBERTa (Liu et al., 2019b).

## Abstract

The increment of toxic comments on online space is causing tremendous effects on other vulnerable users. For this reason, considerable efforts are made to deal with this, and SemEval-2021 Task 5: Toxic Spans Detection is one of those. This task asks competitors to extract spans that have toxicity from the given texts, and we have done several analyses to understand its structure before doing experiments. We solve this task by two approaches, Named Entity Recognition with spaCy's library and Question-Answering with RoBERTa combining with ToxicBERT, and the former gains the highest F1-score of **66.99%**.

## 1 Introduction

The world of social media is overgrowing, and users easily express their opinions or feelings toward topics that they are concerned about. However, because of the freedom of speech, lots of toxic comments or contents are uncontrollably increasing. There are several kinds of research about the effect of toxic speech on users' health. In 2017, research about the impact of toxic language on health was conducted (Mohan et al., 2017). Sometimes, with toxic words, conversations can become cyberbullying, cyber threats, or online harassment, which are harmful to users. To reduce those negative impacts, there are abundant researches for classifying contents into toxic or non-toxic, and then they hide the whole text if it is toxic. However, that action may inhibit the freedom of speech. As a result, censoring only toxic spans is the better solution for this problem. Therefore, in SemEval-2021 Task 5: Toxic Spans Detection (Pavlopoulos et al., 2021) we try to realize it.

About toxic contents on the internet, researches were only about binary toxicity classification. Still,

in task 5 of SemEval-2021, which is about toxic spans detection, we conduct more in-depth research into the toxicity, find exactly which parts of the text are toxic. As the NER approach and Question-Answering (QA) approach, we propose two approaches for solving this problem. We use RoBERTa (Liu et al., 2019) combining with ToxicBERT (Hanu and Unitary team, 2020), transfer learning models, for QA approach and spaCy's library (Honnibal and Montani, 2017) for NER approach.

We organize the paper as follows. Section 2 is related works that we consult for building the systems. The dataset and analyses are defined in Section 3. In section 4, we introduce our two proposed systems for toxic spans detection. Section 5 describes the results of the studies and analyses. Finally, in Section 6, we bring our work to a close.

## 2 Related Works

Researchers around the world these days have started to concentrate on toxic speech. It inflicts individual and group harm, damaging our social fabric (Tirrell, 2018). Several datasets for classifying toxicity on toxic speech on online forums, such as the dataset provided by Waseem and Hovy (2016) for English, BEEP! dataset for Korean by Moon et al. (2020), the dataset for Russian provided by Smetanin (2020), ToID-Br dataset for Brazilian Portuguese by Leite et al. (2020), and UIT-VICTSD, a dataset about constructive and toxic speech detection for Vietnamese (Nguyen et al., 2021).

Besides, there are shared tasks about toxic speech as well as hate speech such as these from SemEval, includes SemEval-2019 Task 5 Multilingual Detection of Hate (Basile et al., 2019), SemEval-2019 Task 6 Identifying and Catego-

ricing Offensive Language in Social Media (Of-fensEval) (Zampieri et al., 2019), SemEval-2020 Task 12 Multilingual Offensive Language Identification in Social Media (Zampieri et al., 2020), and SemeEval-2021 Task 5 Toxic Spans Detection (Pavlopoulos et al., 2021), which is the current task we have to deal with in this paper.

### 3 Dataset

The origin of this SemEval-2021 Task 5 dataset comes from the publicly available Civil Comments dataset (Borkan et al., 2019), which consists of 1.2M posts and comments. The data in this public dataset have no annotation of any toxic spans in toxic posts but do have post-level toxicity annotations, which mean showing which posts or entire of them are toxic. And the holders of this task retain 30K of them, which were annotated to be toxic or severely toxic by at least half of the crowd-raters from annotations of Borkan et al.

The task holders then randomly keep 10K posts from the 30K posts for annotating toxic spans. They employ three experienced crowd-raters per post from a third-party crowd-annotation platform, and they warn them about adult content. However, task organizers also claim that not all toxic posts are annotated with toxic spans.

The task for crowd-raters is to highlight toxic sequences of the comments, and if the comment is not toxic or should annotate the whole of it, crowd-raters have to check the appropriate box without highlighting any spans. Consequently, we have two columns, the spans column and the text column. The spans column has lists of numbers or null that reference toxic character offsets in the text column, and some of the given data are shown in the following table.

spans	text
[7, 8, 9, 10, 11, 12]	Pretty <b>damned</b> eloquent ... :)
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28]	<b>He might fire you to the moon</b> , but you already have a head full of cheese!
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 98, 99, 100, 101, 102, 103, 104, 105, 106]	<b>Nauseating</b> and <b>disgusting</b> . Thank goodness the First Amendment permits people to demonstrate their <b>stupidity</b> .
[]	Not if they shoot you first...

Table 1: Examples for the given data.

The competitors receive two separate training

and test sets from organizers. In the training set, there are 7,939 records, and in the test set, there are 2,000 records. Furthermore, as mentioned in the data annotating process, one text that possibly has multiple toxic spans is highlighted. Figure 1 and Figure 2 illustrate the distribution of spans in the training and the test sets.

Figure 1: Distribution of spans in the training set.

Figure 2: Distribution of spans in the test set.

For more details, according to Figure 1 and Figure 2, there is a significant number of single spans in each post, and it accounts for nearly 68.8% and 70.8% in the training set and the test set, respectively. It is also interesting to notice that the number of zero spans is not tiny, and the proportion of it in the training set is less than in the test set, more specifically, 19.7% in the test set and 6.15% in the training set.

Moreover, we also calculated the Jaccard score of text and spans in the given dataset for more in-depth analysis. The Jaccard score, also known as the Jaccard index or Jaccard similarity coefficient, was developed by Paul Jaccard (Jaccard, 1912) and it is a statistic used for measuring the similarity and diversity of sample sets as follows.

$$J(A, B) = \frac{|A \cap B|}{|A \cup B|} = \frac{|A \cap B|}{|A| + |B| - |A \cap B|} \quad (1)$$

Figure 3: Histogram of Jaccard score of each record in the training set and the test set.

The histogram in Figure 3 illustrates that most of the data points have Jaccard scores in the range of 0 to 0.35, and the peak is at 0 to 0.05, which means toxic character offsets are just a fraction in each post even there are records annotated all characters of the post are toxic. There are 16 records in the test set and 212 records in the training set with Jaccard scores at 0.95 to 1.0. For that reason, just the toxic part(s) of the comments needs to be censored rather than the whole comment as in the traditional method.

## 4 Systems

In this paper, we propose two systems for the toxic spans detection task with NER and QA approaches. The first system is the QA approach based on RoBERTa and the second system is the NER approach based on spaCy’s library.

### 4.1 Question-Answering Approach Based on RoBERTa

With the QA approach, we use RoBERTa combining with ToxicBERT as the basis for the system. RoBERTa (Liu et al., 2019) is a transfer learning model and it is a replication study of BERT (Devlin et al., 2019). Unlike BERT, to improve the training performance, RoBERTa eliminates the Next Sentence Prediction (NSP) task of the pre-trained model BERT. ToxicBERT (Hanu and Unitary team, 2020) is also a transfer learning model, and it uses BERT as the main model for classifying toxicity. ToxicBERT has an outstanding performance for the task of Jigsaw Unintended Bias in Toxicity Classi-

fication<sup>1</sup> on Kaggle, which uses the same dataset with SemEval-2021 Task 5, with 93.64% F1-score. We use two models for our QA approach system, and the overview of the system with training and testing phases is described in Figure 4.

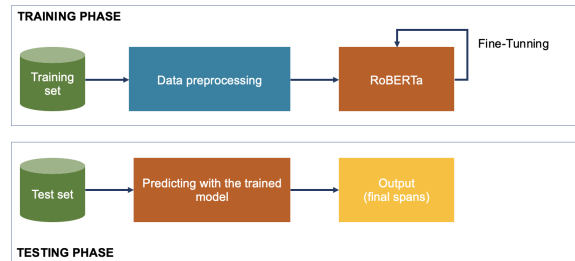

Figure 4: Training and testing phases of toxic spans detection with RoBERTa based system.

Figure 5: Data preprocessing of RoBERTa based system for toxic spans detection.

Firstly, we preprocess the training set with techniques to get the right format for the RoBERTa model, mentioned in Figure 5. The model we used only approve one spans, but several examples have more than one in the training set, and we called it "multi-span". Hence, we split multi-span (\*) into single spans (\*\*) (\*\*\*) as below.

- Plain text:
  - (\*) This bitch is so fucking idiot.
- After splitting:
  - (\*\*) This **bitch** is so.
  - (\*\*\*) This is so **fucking idiot**.

After splitting texts, we tokenize the dataset with a subword model as Byte-Pair Encoding (BPE) (Sennrich et al., 2016). Then, we feed the data into a pre-trained RoBERTa model and fine-tune it with suitable parameters. We analyze the length of the texts in the dataset and set max\_length=512 and epochs=5 for the model. After searching for extensive hyper-parameters, we set the learning\_rate and drop\_out equal to 3e-5 and 0.1, respectively. We also train the model with 5-fold cross-validation. After the training phase, the trained RoBERTa model is used for predicting new toxic spans.

<sup>1</sup><https://www.kaggle.com/c/jigsaw-unintended-bias-in-toxicity-classification>

Figure 6: Predicting toxic spans with trained model by QA approach.

In the testing phase, besides using RoBERTa, we use another transfer learning model is ToxicBERT (Hanu and Unitary team, 2020) for identifying toxic comments. With ToxicBERT, we classify the input text into toxic or non-toxic labels before predicting spans. If the result is non-toxic, we stop the prediction, and the result is an empty spans. If it is toxic, we feed the text into the RoBERTa model to predict toxic words. After having the spans, to ensure that the text still has toxic words, we remove the predicted toxic word(s) from the processing text and then recheck its toxicity by ToxicBERT and re-predict its remaining toxic words (if any).

Because final results are words, we transform them into spans for the requirement of this task.

## 4.2 NER Approach Based on spaCy’s Library

In this approach, we tag all the characters spans with text as TOXIC to train the model, and we predict all TOXIC tags in the text set of texts.

For solving this, we choose version 2.2.5 of spaCy’s NER Model (Honnibal and Montani, 2017) because of its exceptionally efficient statistical system in both speed and accuracy for this named-entity recognition. Apart from default entities such as location, person, organization, and so on, spaCy also enables training the model with new entities by updating it with newer examples.

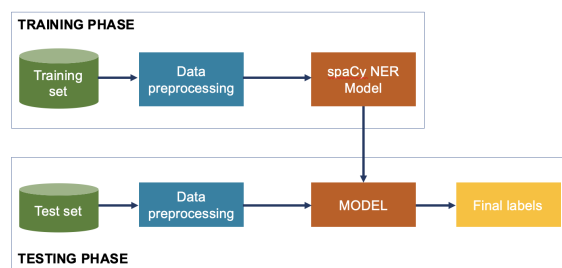

Figure 7: Training and testing phases of toxic spans detection with spaCy based system.

The above Figure 7 shows the process of our spaCy based system. Both training and test sets have to be tokenized before feeding them into the spaCy NER model or being predicted by the TOXIC entities. For more details, in the training phase, the input data have to be in the right format for the spaCy NER model as in the following Figure 8.

spans	text
[7,8,9,10,11,12]	Pretty <b>damned</b> eloquent ... :

```

Figure 8: Process of re-formatting data for spaCy based system.

SpaCy has not published the architecture of their models yet, but they do have a brief explanation about how their models work, especially the NER model, through a four-step formula: embed, encode, attend, and predict.

Figure 9: Diagram of how spaCy’s models work.

As in Figure 9, spaCy’s model is fed with unique numerical values (ID) which address a token of a corpus or a class of the NLP task (named entity class). In the first embed stage, word similarities are revealed by extracting hash, which is collected by extracting word features as the lower case, the prefix, the suffix, and the shape. The encode stage is fed with a sequence of word vectors from the previous stage to calculate a representation which is named sentence matrix. In the sentence matrix, the meaning of each token in the context of neighboring tokens is represented in each row, and this is done by using a bidirectional RNN (Schuster and Paliwal, 1997). The output matrix from the second stage is injected into the Attention Layer of the CNN after summarized by a query of vectors. Finally, to predict the toxic class, a softmax function is utilized. After the model is trained, the CNN model is now used for the NER task to extract the toxic class.

The given toxic spans dataset is fed into spaCy’s library for training with a suitable format. During the contest, my team was using spaCy’s library for a small model for English (en\_core\_web\_sm) at version 2.2.5, and we tried different parameters to get the optimal result. When training, the dataset is shuffled and passed through spaCy’s training algorithm in batches with an increment of batch sizes from 4.0 to 32.0 and step of 1.001. Moreover, the drop rate is consistently at 0.5, and most of the experiments loop 45 times.

## 5 Experiments

After building two such systems, we start to experiment on the test set, and the following subsections discuss our results.

### 5.1 Evaluation Metrics

Before going through experimental results, we first discuss the evaluation metrics used in this SemEval-2021 Task 5.

In this task, all of the responding systems from participants are evaluated by **F1** score (Da San Martino et al., 2019). Assuming the system  $S_i$  returns

$C_{S_i}^t$ , which is a toxic character offsets of the post. Let  $G^t$  be the character offsets of the ground truth annotation of  $\mathbf{t}$ . In the following formulas, the **F1** score of system  $S_i$  is computed regarding ground truth  $\mathbf{G}$  of post  $\mathbf{t}$  ( $|\cdot|$  indicates set cardinality).

$$F_1^t(S_i, G) = \frac{2 \cdot P^t(S_i, G) \cdot R^t(S_i, G)}{P^t(S_i, G) + R^t(S_i, G)} \quad (2)$$

$$P_1^t(S_i, G) = \frac{|C_{S_i}^t \cap C_G^t|}{|C_{S_i}^t|} \quad (3)$$

$$R_1^t(S_i, G) = \frac{|C_{S_i}^t \cap C_G^t|}{|C_G^t|} \quad (4)$$

If  $S_G^t$  is empty for posts  $\mathbf{t}$ , we set  $F_1^t(S_i, G) = 1$  and if  $S_{A_i}^t$  is empty,  $F_1^t(S_i, G) = 0$ . Finally, we calculate average of  $F_1^t(S_i, G)$  of all over the posts  $\mathbf{t}$  if test set to get a single **F1** score of the system  $S_i$ .

### 5.2 Experimental Results

The results of our systems compared with other teams’ are shown in Table 2.

Rank	Team name	F1-score
1	HITSZ-HLT	70.83
2	S-NLP	70.77
33	lz1904	67.00
34	UIT-E10dot3	spaCy 66.99
		RoBERTa 52.12
		17.00±1.

Table 2: The results of our systems compared with other teams by F1-score (%).

During the SemEval-2021 Task 5, with the spaCy base system, we achieved rank 34 out of 91 teams, and in the table above, we have shown our result with the spaCy based system and the RoBERTa based system in comparison with rank 1, 2, 33 and random baseline of this task. The F1-score of our best system is 66.99%, 3.84% lower than the first rank team, and 49.09% higher than the baseline model.

### 5.3 Result Analyses

After analyzing our most effective system based on spaCy’s library, we spot crucial errors in predicting and datasets by comparing predicted spans to gold spans. Several records in the given data are standing alone without the context that leads to confusing or multi-meaning. Moreover, comments are using slang(s) or idiom(s), causing null output for our system. We also realize a lack of consistency or highlighting non-toxic spans when annotating data about the datasets. Likewise, several words in the text have spelling mistakes that intentionally also impair our system performance. Evidence for those errors are in Table 3, Appendix.

## 6 Conclusion and Future Work

In this paper, we introduced two proposed systems for toxic spans detection based on named entity and question-answering approaches. We obtained the highest results with the SpaCy’s library based system with the F1-score of **66.99%** and ranked 34 out of 91 teams in SemEval-2021 Task 5.

In future, we plan to improve our systems by implementing various SOTA models for toxic spans detection. With the built systems, we can create friendly online conversations and make social media forums safer for users.

## Abstract

This work describes the participation of the Skoltech NLP group team (Sk) in the Toxic Spans Detection task at SemEval-2021. The goal of the task is to identify the most toxic fragments of a given sentence, which is a binary sequence tagging problem. We show that fine-tuning a RoBERTa model for this problem is a strong baseline. This baseline can be further improved by pre-training the RoBERTa model on a large dataset labeled for toxicity at the sentence level. While our solution scored among the top 20% participating models, it is only 2 points below the best result. This suggests the viability of our approach.

## 1 Introduction

Toxicity and offensive content is a major concern for many platforms on the Internet. Therefore, the task of toxicity detection has attracted much attention in the NLP community (Wulczyn et al., 2017; Hosseini et al., 2017; Dixon et al., 2018). Until recently, the majority of research on toxicity focused on classifying entire user messages as toxic or safe. However, the surge of work on text detoxification, i.e., editing of text to keep its content and remove toxicity (Nogueira dos Santos et al., 2018; Tran et al., 2020), suggests that localizing toxicity within a sentence is also useful. If we know which words of a sentence are toxic, it is easier to “fix” this sentence by removing or replacing them with non-toxic synonyms. Mathew et al. (2020) make human labelers annotate the spans as rationales for classifying a comment as hateful, offensive, or normal. They show that using such spans when training a toxicity classifier improves its accuracy and explainability and reduces unintended bias towards toxicity targets.

This year the SemEval hosts the first competition on toxic spans detection, namely, SemEval-2021

Task 5<sup>1</sup> (Pavlopoulos et al., 2021). It provides training, development, and test data for English. As far as we know, it is the first attempt to explicitly formulate toxicity detection as sequence labeling instead of classification of sentences.

Multiple NLP tasks recently benefited from transfer learning — transfer of probability distributions learned on some task to another model solving a different task. The most common example of transfer learning is the use of embeddings and language models pre-trained on unlabeled data (e.g. ELMo (Peters et al., 2018), BERT (Devlin et al., 2019) and its variations, T5 (Raffel et al., 2020), etc.) on other tasks (e.g. He et al. (2020); Wang et al. (2020) *inter alia* use pre-trained BERT models to perform tasks from the GLUE benchmark (Wang et al., 2018)).

Word-level toxicity classification can be formulated as a sequence labeling task, which also actively uses the pre-trained models mentioned above. BERT comprises the versatile information on words and their context, which allows to successfully use it for sequence labeling tasks of different levels: part-of-speech tagging and syntactic parsing (Koto et al., 2020), named entity recognition (Hakala and Pyysalo, 2019), semantic role labeling (He et al., 2019), detection of Machine Translation errors (Moura et al., 2020).

This diversity of applications suggests that word-level toxicity detection can also benefit from pre-trained models. Besides that, toxicity itself has been successfully tackled with BERT-based models. Research on sentence-level toxicity extensively used BERT and other pre-trained models. Both language-specific and multilingual BERT models were used to fine-tune toxicity classifiers (Leite et al., 2020; Ozler et al., 2020). This shows that BERT has information on toxicity.

<sup>1</sup><https://competitions.codalab.org/competitions/25623>

Thus, we follow this line of work. Namely, we fine-tune a RoBERTa model (Liu et al., 2019) to perform a sequence labeling task. Besides that, we train a model for sentence classification on the Jigsaw dataset of toxic comments and use the information from this model to detect toxicity at the subsentential level. This helps us overcome the insufficient data size.

This is in line with previous work, which has shown that sentence-level labels can be used in combination with token labels (Rei and Søgaard, 2019) or completely substitute them (Rei and Søgaard, 2018; Schmaltz, 2019).

In our experiments, we test the hypothesis that the sentence-level toxicity labeling can be used for a sequence labeler that recognizes toxic spans in text. We suggest three ways of incorporating this data: as a corpus for pre-training, pseudo-labeling, and for joint training of sentence-level and token-level toxicity detection models. Our experiments show that the latter method yields the best result. Moreover, we show that using sentence-level labels can dramatically improve toxic span prediction when the dataset with token-level labels is small.

The contributions of this work are the following:

- We successfully use the dataset labeled for toxicity at the sentence level for token-level toxicity labeling,
- We propose a model for joint sentence- and token-level toxicity detection,
- We analyze the performance of our models, showing their limitations and reveal the ambiguities in the data.

## 2 The task

The training data of the task comprises 7,940 English comments with character-level annotations of toxic spans. The labeling was performed manually by crowd workers.

The spans labeled as toxic often contain rude words: “*Because he’s a moron and a bigot. It’s not any more complicated than that.*” (toxic spans are underlined). Other toxic spans consist of words that become toxic in context: “*Section 160 should also be amended to include sexual acts with animals not involving penetration”.* Borders of some toxic spans fall in the middle of a word; we treat such cases as markup errors.

As a development set, we use the trial dataset of 690 texts provided by the task organizers. We

evaluate our final models on the hidden test set of the task consisting of 2,000 texts.

## 3 Pre-training for toxic span detection

Here we give the motivation behind our models and describe their architecture and training setup.

### 3.1 Motivation

Our intuition is that the toxicity is often lexically-based, i.e., there are certain words that are considered offensive and make the whole sentence toxic. In this case, we expect that as we add extra data to our toxic span dataset, after some point, the vocabulary of toxic words in it will saturate and stop increasing. However, Figure 1 shows that the size of the toxic vocabulary linearly depends on the dataset size, which suggests that its size is insufficient for the task. In this case, the model will often need to label unseen words. To mitigate the lack of data, we leverage the additional dataset with toxicity information, namely, the Jigsaw toxic comments dataset<sup>2</sup> which features 140,000 user utterances labeled as toxic or safe.

Figure 1: Size of the toxic vocabulary as a function of the corpus size.

### 3.2 Transfer learning for spans detection

Our base model is RoBERTa. We fine-tune roberta-base model on the toxic spans training set for sequence labeling task (further denoted as **RoBERTa tagger**). This model already gives promising results. We further improve it by providing it with the additional training signal from the

<sup>2</sup><https://www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge/data>

Jigsaw toxic comments dataset. We propose three ways of incorporating this data.

The first way is **pseudo-labeling** (Lee et al., 2013). We apply the **RoBERTa tagger** to predict the toxic spans in the Jigsaw dataset. We use these predictions to further train the model.

Another option is to use the Jigsaw data to fine-tune RoBERTa with it. We suggest two scenarios. The first is to fine-tune the model on the Jigsaw dataset for the sentence classification task, and then on the toxic spans dataset — this model is referred to as **RoBERTa classifier + tagger**. In this case, the model has different output layers for the two tasks, and other layers are shared.

Finally, we propose a novel architecture for joint token- and sentence-level classification, where the score  $\mathbf{y}$  for a sentence  $\mathbf{x} = \{x_1, x_2, \dots, x_n\}$  is computed as the average of word-level scores:

$$\hat{\mathbf{y}} = \sigma \left( \alpha + \beta \frac{1}{n} \sum_{i=1}^n \hat{y}_i^\gamma \right)$$

where  $\alpha$ ,  $\beta$  and  $\gamma$  are trainable parameters, and  $\sigma$  is the logistic function. This model does not need to be trained on the data with token-level labeling but can get token-level toxicity information from sentence labels. We fine-tune this model both on Jigsaw and toxic spans datasets. The model is referred to as **tagging classifier**.

### 3.3 Working with spans

To reformulate toxic spans detection as a token classification problem, we label a token as toxic if at least one of its characters is toxic. When projecting the predicted token-level labels back to the character level, we try two strategies:

1. Consider a token to be toxic if its toxicity score is higher than the threshold, do not force the labels of tokens within a word to agree with each other.
2. Consider a word to be toxic if the aggregated toxicity score of all its tokens is higher than the threshold. We try four different aggregation functions: min, max, mean, and the simplified naive Bayes formula:

$$\tilde{x} = \frac{\prod_i x_i}{\prod_i x_i + \prod_i (1 - x_i)}.$$

In both methods, we label a space character as toxic only if the characters both to the right and to the left of it are toxic.

## 4 Baselines

In this section, we present a set of common baseline approaches used for sequence tagging, such as CRF and LSTM with pretrained word embeddings. We implement them in order to analyze the performance of our methods in the context of other techniques.

**Word-based LogReg** This is a vocabulary-based method: we label words as toxic if they appear in our toxic vocabulary. The vocabulary is created as follows. We create a set of toxic and safe phrases, where toxic phrases are toxic spans from our data and safe phrases are sentences from our data with removed toxic spans. We then train a binary logistic regression classifier of toxic and safe phrases using words as features. The by-product of this classifier is the list of weights for all words from the data. We consider words with weights greater than a threshold as toxic.

**Attention-based LogReg** Another approach to represent words is to take their attention weights from a RoBERTa-based sentence-level toxicity classifier (we train it on the Jigsaw dataset). We assemble attention weights from all RoBERTa heads and layers in a single vector of dimension 144. These vectors are used as features in a logistic regression classifier. This approach is motivated by the fact that a RoBERTa model trained to recognize toxicity puts more emphasis on certain words associated with sentence-level toxicity. Surprisingly, this model underperforms the logistic regression classifier, which uses words as features.

**Conditional Random Fields** We suggest that the toxicity level of a word can be context-dependent, so we also experiment with sequence labeling models. We try Conditional Random Fields (CRF) (Lafferty et al., 2001) model. It uses the following features: the word itself, the word’s part of speech, whether the word is a digit and consists of uppercase letters. Each word is represented with these features of the current, previous, and next words. The model performs closely to the attention-based classifier.

**Sequence labeling with LSTM** Finally, we experiment with the LSTM architecture (Hochreiter and Schmidhuber, 1997). We implement a Bi-LSTM network and also train an LSTM tagger from the AllenNLP library.<sup>3</sup> We do not use any pre-

<sup>3</sup><https://github.com/allenai/allennlp>

trained embeddings in the Bi-LSTM model and use two versions of the AllenNLP LSTM: without pre-trained embeddings and with GloVe embeddings (Pennington et al., 2014).

## 5 Evaluation

### 5.1 Experimental Setting

For each transfer learning model, we use two-stage fine-tuning. We first train only the output layers of the models with the learning rate of  $10^{-3}$ , and then the whole models with the learning rate of  $10^{-5}$ . In both cases, we use linear learning rate warm-up for 3000 steps. We use the AdamW optimizer (Loshchilov and Hutter, 2019) and the batch size of 8, and early stopping to determine the number of training steps. We use the `transformers`<sup>4</sup> library for training.

For all the models which use the additional data from Jigsaw, we apply this scheme twice. The **pseudo-label** model is first fine-tuned on the original toxic spans dataset, and then on the self-labeled Jigsaw dataset, whereas the **RoBERTa classifier + tagger** and **tagging classifier** are first fine-tuned on the Jigsaw dataset (as classifiers), and then on the toxic spans dataset (as taggers).

### 5.2 Results

The scores of our models and the competing systems are shown in Table 1. Our best submitted system (**tagging classifier**) had the  $F_1$ -score of 0.681 on the test set, while the best team over the whole task got 0.708. This brings our team to the top 20% of the leaderboard. The pseudo-labeling approach was only marginally worse, scoring 0.674. Simply fine-tuning RoBERTa only on the tagging problem scored 0.668. On the other hand, none of our baselines could approach this result. Our best baseline is the word-based LogReg classifier. Apparently, other models fail to learn even the toxic vocabulary because their word representations are not informative enough.

While our best-performing model is only 18th best out of 92 participating systems, the results of the top systems are fairly close to ours (the difference is less than 2.5%). The variation of deep learning models often falls in this margin (Reimers and Gurevych, 2017). For our models, the sample standard deviation of the  $F_1$ -score is about 0.9%, so the difference between their performance is likely to be statistically insignificant.

<sup>4</sup><https://huggingface.co/transformers>

LSTM Glove embeddings	0.497

Table 1: Performance of our models (baselines and RoBERTa-based models) and their comparison with the 5 best-performing participants. Models within each section are sorted from best to worst.

An important hyper-parameter of the models is the probability threshold. It is usually fine-tuned on the development set. However, the development set provided for the task is too small. The threshold fine-tuned on it performs even worse than the standard threshold of 0.5. Thus, during the evaluation period of the competition, we tried submitting models with different threshold values. While this is not a completely fair practice because we indirectly used the test for tuning a model parameter, we suspect that many teams were overfitting to the test set in a similar way. We suggest that in order to make the evaluation fair, the results of the models on the final test set should not be available before the end of the competition, even in the indirect way (i.e., in the form of teams ranking without scores as it was done in this competition).

The best results which we report here were achieved with the threshold of 0.6 (see Table 1). We compare these results with those of the same models with the default threshold of 0.5 in Table 3. It shows that these scores are lower by up to 1%.

Another hyper-parameter of our models is the method of converting token-level labels to

Aggregation Type	F <sub>1</sub> score
No aggregation	0.685
<b>Aggregation of word-level scores</b>

average token scores	0.670
naive Bayes	0.653

Table 2: Scores of the **tagging classifier** model with different token aggregation methods (computed on the development set).

Model	threshold	
	0.5	0.6
tagging classifier	0.681	<b>0.683</b>
pseudo-labeling	0.674	0.682
RoBERTa tagger	0.668	0.678
RoBERTa classifier + tagger	0.664	0.670

Table 3: F<sub>1</sub>-scores of models with different probability thresholds.

character-level labels. We compare different methods on the development set (see Table 2). Surprisingly, the prediction of labels for each token individually with no aggregation works better than assigning labels to the whole words. This might happen because the attempts to decode words consistently lead to the propagation of wrongly predicted labels. Following this observation, we use the no-aggregation strategy for all models.

### 5.3 Efficiency of pre-training

To understand the effect of the use of additional sentence-labeled data, we compare the performance of **RoBERTa tagger** (a model which uses only the toxic span dataset) and **tagging classifier** (a model which uses sentence-labeled Jigsaw data in addition to the toxic span dataset) models trained on subsets of the data of different sizes. We would like to see if the usefulness of additional sentence-labeled data reduces as we get more data with token-level labeling.

Figure 2 plots the F<sub>1</sub>-scores of the two models trained on datasets of sizes between 10 and 7,940 sentences. It shows that when the training set size is between 10 and 1,000, pre-training with sentence-level annotations gives a considerable boost in performance. However, the effect of this pre-training becomes insignificant after the size of the data with

word-level labeling reaches around 3,000. Thus, this pre-training strategy is efficient only in cases when the size of the data with word-level labeling is very small.

Figure 2: Learning curves for two transfer learning models, with (**tagging classifier**) and without (**RoBERTa tagger**) additional sentence-level data.

### 5.4 Error analysis

We analyze the errors of our best submitted system (**tagging classifier**) by comparing its predictions with the ground truth labels released after the end of the competition.

The vocabulary of false negative spans (527 unique tokens) is more diverse than that of false positives (275 unique tokens), while the number of false positives and false negatives in the test set is comparable (860 vs 813 tokens). It may indicate that the model is cautious and prefers to highlight only the hypotheses which have high confidence, while human annotators are more creative in their analysis. We give some examples of correct and incorrect labelings by our model in Table 4.

The most frequent false positive words characterize incompetence or lack of mental capacities: *stupid, idiot, ignorant, moron, dumb*, etc. Other frequent false positives are derogatory (*pathetic, ridiculous, ass, garbage, loser*, etc.), denounce particular misdeeds (*liar, troll, racist, hypocrite*, etc.), or express general negativity (*damn, fuck*, etc.). It is not obvious why human annotators label them as toxic in some cases, and as non-toxic in other cases. We suspect that inter-annotator agreement on such words is not very high.

The most frequent false negative words are function words: *and, the, are, a, you* etc. It happens because annotators sometimes label the whole text

Correct labeling
See a shrink you <u>pathetic troll</u> . They're not patriots. They're <u>vandals</u> , <u>thieves</u> , and <u>bullies</u> . Trudeau and Morneau are fiscally and economically <u>inept</u> and <u>incompetent</u> .
Incorrect labeling
That's right. They are not normal. And I am starting from the premise that they are <u>ABNORMAL</u> . Proceed with the typical racist, <u>bigot</u> , <u>sexist rubbish</u> . Thanks! ADN is endorsing, without officially endorsing. <u>Bunch of cowards!!!</u> Rabidly <u>anti-Canadian troll</u> .

Table 4: Examples of ground truth (underlined) and predicted (**in bold**) toxic spans

Top 20 false positive words		Top 20 false negative words	
stupid	ass	and	of
idiot	liar	the	have
ignorant	garbage	are	loser
moron	loser	a	crap
dumb	fools	ignorant	all
idiots	troll	racist	chemical
fool	crap	you	that
pathetic	damn	in	not
stupidity	fuck	is	bunch
ridiculous	clown	to	dumb

Table 5: The most common false positive and false negative words

or a large chunk of it as toxic. The more meaningful false negatives belong to the same classes as the false positives (*ignorant*, *racist*, *loser*, etc.). The most common false positive and false negative words are listed in Table 5.

In general, the performance on this task might be limited to 0.7  $F_1$ -score (the quality of the best-performing model) by the ambiguity of the annotations. In future work, it

## 6 Conclusions

We present a number of models for the detection of toxic spans within toxic sentences. All models are RoBERTa language models fine-tuned on the data with character-level labeling of toxic spans. In addition to that, we perform fine-tuning on an additional dataset with sentence-level toxicity labeling. This yields an improvement. However, our analysis shows that the effect of such pre-training is marginal when the main dataset size exceeds 1,000 samples. Therefore, substantial improvement is observed for small dataset sizes. Nevertheless, the models we propose can be useful in extremely

low-resource scenarios.

Our model performs closely to the winning systems. We suggest that the differences between the 20 top models might be attributed to the variation of deep learning models and overfitting the test set. In addition to that, the error analysis shows that some errors in our model might be due to inconsistencies in the test data.

We release the code required to reproduce our experiments online.<sup>5</sup>

## Abstract

Detection of toxic spans - detecting toxicity of contents in the granularity of tokens - is crucial for effective moderation of online discussions. The baseline approach for this problem using the transformer model is to add a token classification head to the language model and fine-tune the layers with the token labeled dataset. One of the limitations of such a baseline approach is the scarcity of labeled data. To improve the results, We studied leveraging existing public datasets for a related but different task of entire comment/sentence classification. We propose two approaches: the first approach fine-tunes transformer models that are pre-trained on sentence classification samples. In the second approach, we perform weak supervision with soft attention to learn token level labels from sentence labels. Our experiments show improvements in the F1 score over the baseline approach. The implementation has been released publicly.<sup>1</sup>

## 1 Introduction

The growth of social media platforms has led to an increase in hate speech and abusive language in online communities, primarily due to the anonymity provided on such platforms (Mollas et al., 2020). Since manual moderation is not feasible for the gigantic amount of textual data, automated toxicity detection has received significant attention with numerous datasets being released in recent years (Pavlopoulos et al., 2020). However, most of the existing work on toxicity detection labels the entire comment as toxic or non-toxic and does not provide information about which specific part of the comment is toxic. In practice, human moderators (e.g., news portals moderators) can benefit from information on which character indices of the

part of the comment that is toxic instead of just a system-generated unexplained toxicity score per post. Designing models that can accurately locate toxic spans within a text is thus a crucial step towards successful semi-automated moderation. This is challenging because of the scarcity of datasets that are labeled on a segment or token level.

This paper explains our approaches for the SemEval-2021 Task 5 which requires us to identify the character offsets for the toxic spans within a comment (Pavlopoulos et al., 2021). We explore possible techniques for improving the results of the vanilla transformer model by leveraging several available public datasets.

## 2 Related Work and Background

**Sequential adaptation** Using pre-trained language models has recently proved to be effective for language understanding tasks (Phang et al., 2018). The supplementary training is particularly beneficial when labeled data is scarce (Phang et al., 2018). A popular transfer learning technique in Natural Language Processing (NLP) has been to pre-train sentence encoder neural networks, such as BERT (Devlin et al., 2019), on unsupervised tasks and then fine-tune the encoders for the target supervised learning task. However, this approach can be found inadequate if the input distribution for the target task is considerably different from that of the corpus used for pre-training. Phang et al. (2019) suggested that training on related data-rich supervised tasks as an intermediate step can help in making the final trained model more robust and effective. This approach is called *Supplementary Training on Intermediate Labeled-data Tasks*. This can also help the model in learning the domain knowledge when in-domain data is available.

**Weakly Supervised Learning** Zhou (2018) defined *inexact* supervision as a type of weakly super-

<sup>1</sup><https://github.com/vaibhav29498/Toxic-Spans-Detection>

vised learning in which coarse-grained labels are used to train for a more specific problem. [Rei and Søgaard \(2018\)](#) used this approach for inferring token-level labels by training a sentence classification model. They used a bidirectional LSTM to get a contextual representation  $\tilde{h}_i \in \mathbb{R}^m$  for every token  $w_i$ , and pass it through a fully-connected layer with hyperbolic tangent activation to obtain  $h_i \in \mathbb{R}^n$ :

$$h_i = \tanh(W_h \tilde{h}_i + b_h) \quad (1)$$

where  $W_i \in \mathbb{R}^{n \times m}$  and  $b_i \in \mathbb{R}^n$ .

They then used a two-layer feed forward neural network followed by a soft-attention layer to get a single-valued attention score  $a_i$  for each token:

$$e_i = \tanh(W_c h_i + b_c) \quad (2)$$

$$\tilde{e}_i = W_{\tilde{c}} e_i + b_{\tilde{c}} \quad (3)$$

$$\tilde{a}_i = \sigma(\tilde{e}_i) \quad (4)$$

where  $W_c \in \mathbb{R}^{p \times n}$ ,  $b_c \in \mathbb{R}^p$ ,  $W_{\tilde{c}} \in \mathbb{R}^{1 \times p}$ ,  $b_{\tilde{c}} \in \mathbb{R}$ , and  $\tilde{a}_i$  is the normalized attention score. These scores indicate the importance of the tokens towards predicting the sentence class and can be considered as the token-level predictions. Their normalized forms are used for constructing a weighted average sentence representation  $c$ , which is used to compute the prediction score  $y$  with a value higher than 0.5 indicating a positive class:

$$a_i = \frac{\tilde{a}_i}{\sum_{k=1}^N \tilde{a}_k} \quad (5)$$

$$c = \sum_{i=1}^N a_i h_i \quad (6)$$

$$d = \tanh(W_d c + b_d) \quad (7)$$

$$y = \sigma(W_y d + b_y) \quad (8)$$

where  $W_d \in \mathbb{R}^{q \times n}$ ,  $b_c \in \mathbb{R}^q$ ,  $W_y \in \mathbb{R}^{1 \times q}$ , and  $b_y \in \mathbb{R}$ . The authors used a modified loss function to ensure that the model learns high-quality token labels:

$$L = \sum_j [(y^{(j)} - \tilde{y}^{(j)})^2 + \lambda(\min_i(\tilde{a}_i)^2 + (\max_i(\tilde{a}_i) - \tilde{y}^{(j)})^2)] \quad (9)$$

where  $y^{(j)}$  is the predicted score,  $\tilde{y}^{(j)}$  is the ground-truth,  $\min_i(\tilde{a}_i)$  and  $\max_i(\tilde{a}_i)$  are the lowest and highest attention scores respectively for the  $j^{th}$  sentence.

[Karamanolakis et al. \(2019\)](#) used a modified version of this approach to generate segment labels for text review classification problems. The segment embeddings are generated by feeding the word embeddings into a convolutional neural network. The output of the convolution neural network is passed through a single layer with softmax activation to get the segment-level prediction. Additionally, the word embeddings are passed through a bidirectional GRU network with sigmoid attention to find the attention weights. These weights are used to aggregate the segment-level predictions into a single prediction for the entire review.

### 3 Methodology and Experimental Setup

In this section, we will present our two solutions. Both of our approaches are using BERT pre-trained language model. In the first approach, we first fine-tune the BERT model with additional labeled data explained in Subsection 3.1 and then perform another round of fine-tuning using token classification head with task training data. In the second approach, we apply weak supervision to learn token labels for the additional dataset. We then use the augmented labeled token dataset to fine-tune the token classifier head and use it to predict labels for the task test data set.

#### 3.1 Datasets

As the main data source for training our models, we used SemEval-2021 Task 5 data. Additionally, we used five publicly available English-language datasets for sentence classification to improve our results.

##### 3.1.1 Token-level Labelled Data

We used two token-level labeled datasets, the first being the one provided by the SemEval-2021 Task 5 organizers which are composed of 9,939 English posts along with their toxic spans. The span for a single post is a possible-empty list of character indices that have been marked as toxic by crowd-annotators. The dataset has been divided into training and test sets with 2,000 samples in the latter.

The second dataset used is HateXplain ([Mathew et al., 2020](#)) which is composed of 20,148 tweets and Gab posts, each of which is classified as hateful,

offensive, or normal, by three annotators. If an annotator masks a post as either hateful or offensive, they are also asked to mark the span (*rationale*) which influenced their decision. We considered a token to be toxic if it was included in at least one annotator’s rationale, and excluded all posts with no toxic token, which left us with 11,415 posts.

### 3.1.2 Sentence-level Labelled Data

We used five other datasets which consisted of only sentence-level labels:

- Jigsaw/Conversation AI toxic comment classification challenge dataset<sup>2</sup> - Composed of Wikipedia’s talk page edits, it labels 223,549 posts into zero or more categories of toxicity (toxic, severely toxic, obscene, threat, insult, and identity hate). We bundled each of them into a single category, and 22,468 posts were categorized as toxic.
- Hate speech and offensive language dataset (Davidson et al., 2017) - 24,783 tweets categorized to hate speech, offensive language, or neither. We labeled 20,620 belonging to the former two categories as toxic.
- Online harassment dataset (Golbeck et al., 2017) - Composed of 20,360 tweets out of which 5,285 have been labeled as harassing.
- Impermium dataset for detecting insults in social commentary<sup>3</sup> - 6,594 comments from online forums, out of which 1,742 were identified as insulting to at least one of the participants.
- OffensEval-2020 subtask-A extended test dataset - 5,993 tweets out of which 3,002 have been labeled as offensive.

Merging these five datasets resulted in a collection of 281,279 comments out of which 53,117 were labeled as toxic.

## 3.2 Approach 1: Sequential fine tuning

In approach 1, we first fine-tune the sentence classification model with additional data. The sentence classification model is built upon the base uncased

<sup>2</sup>[www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge/data](https://www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge/data)

<sup>3</sup>[www.kaggle.com/c/detecting-insults-in-social-commentary/data](https://www.kaggle.com/c/detecting-insults-in-social-commentary/data)

BERT model, which maps every sentence to a vector of size 768. A two-layer sentence classifier is added to the BERT base model. The first layer of the head is a linear layer with leaky ReLU activation (negative slope of 0.1) that maps it to a vector of size 64. The second layer of the head is a dense layer that maps 64 nodes to a single-valued prediction score with sigmoid activation. The model is shown in Figure 1.

Figure 1: Model for sentence classification

We used the pre-trained BERT language model as the starting point for the BERT model. The layers of sentence classification head were randomly initialized. We applied the WordPiece tokenizer and added the special BERT tokens *[CLS]* and *[SEP]* to each sentence. We removed 5,136 samples as their number of tokens exceeded the base BERT model’s maximum limit (512). The model was trained for a single epoch using the AdamW optimizer (Loshchilov and Hutter, 2019) with a batch size of 16.

The fine-tuned model was used to predict token classes. To predict token classes, a token classification was used. The token classification head architecture is similar to the sentence classification head with two linear nodes. The first layer maps 768-dimensional inputs to 64 nodes and applies the ReLU activation function with the negative slope of 0.1. The second layer maps input to a single token prediction score with a sigmoid activation function.

### 3.3 Approach 2 : Augmenting token labels with weak supervision

In our second approach, we first augment our training set with imperfect labels that we learn by weak supervision. We then use the augmented training set to fine-tune the token classifier model and use it to predict the labels of our test data. The model used for augmenting token labels using sentence-level labeled dataset described in Section 3.1.2, is loosely based upon the solution proposed by Karamanolakis et al. (2019). The model is shown in Figure 2. We first obtain the initial token embeddings from a pre-trained BERT model and input it to the token augmentation network shown in Fig 2. The input is connected on one side to token labels as well as to sentence-level predictions through two BiGRU layers. The GRU layers generate an attention weight for every token. These weights are used for finding a weighted average of the token-level predictions, which is used to calculate the prediction for the entire sentence.

Equation 9 is used as the loss function to train the weights of the model. The sentence labels are calculated from token labels following equations 5 to 8. The loss function optimizes the sentence and token labels. first, it makes sure sentence classifications are closest to the sentence labels. Second, it optimizes token labels by considering the minimum values of token labels in each sentence. It makes sure the minimum label of the tokens in a single sentence is zero to make sure all tokens in a sentence do not have a positive sentiment. It makes sure the most toxic token in the sentence has the same label as the label for the sentence. We trained the model for five epochs using the AdamW optimizer with a batch size of 16.

The token labels generated by the model described above are used as additional training data. The BERT base model is initialized with the publicly available pre-trained version. Only those artificially-generated samples in the sentences with the correctly predicted label (prediction score  $\geq 0.5$ ) are used. We used the prediction scores as the labels for the additional dataset instead of having discrete values of zero and one based on some threshold. We also subtracted the value of 0.1898 from these labels to make their mean equal to that of the labels of the contest dataset.

For generating the character offsets, we considered an entire word as toxic if any single of its subword tokens were identified as toxic.

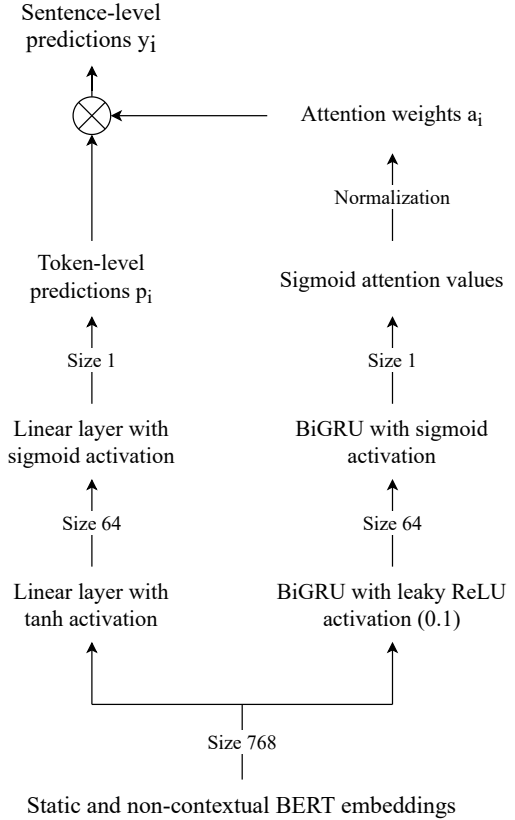

Figure 2: Model for generating token labels

## 4 Results

**Disclaimer:** The section contains offensive, obscene, and hateful content; however this is necessary to showcase the results of this work.

The contest organizers used the average F1 score as the performance metric. For a sample  $S_i$ , if  $\tilde{Y}_i$  and  $Y_i$  are the predicted and actual set of character offsets, then the F1 score  $F_1^i$  is calculated as

$$F_1^i = \frac{2 \cdot P^i(\tilde{Y}_i, Y_i) \cdot R^i(\tilde{Y}_i, Y_i)}{P^i(\tilde{Y}_i, Y_i) + R^i(\tilde{Y}_i, Y_i)} \quad (10)$$

$$P^i(\tilde{Y}_i, Y_i) = \frac{|\tilde{Y}_i \cap Y_i|}{|\tilde{Y}_i|} \quad (11)$$

$$R^i(\tilde{Y}_i, Y_i) = \frac{|\tilde{Y}_i \cap Y_i|}{|Y_i|} \quad (12)$$

Our best-scoring solution submitted to the contest achieved an F1-Score of 0.6561 and a rank of 49 amongst 91 submissions. After the contest, we excluded the HateXplain dataset from the token-classification training process to make the model more suited for the contest dataset and masked out the padding tokens while calculating  $\min_i(\tilde{a}_i)^2$  in Equation 9. We also developed a baseline model

which does not use any additional datasets by training the pre-trained base BERT model with the token-level labeled dataset described in Section 3.1.1. The training hyper-parameters were the same as our other approaches. The F1 scores for the baseline model and the two approaches discussed in Sections 3.2 and 3.3, namely the *sequential adaptation* and the *weakly supervised learning* approaches have been plotted for various thresholds in Figure 3.

Figure 3: F1 score plotted against threshold

The F1 score at threshold value 0.5 and the maximum F1 score for each approach have been mentioned in Table 1.

Approach	$F1_{0.5}$	$F1_{max}$
Baseline model	0.6224	0.6289
Weakly Supervised	0.6644	0.6799
Sequential adaptation	0.6678	0.6861

Table 1: F1 score metrics for various approaches

Using sentence-level labeled data to incorporate domain-specific knowledge improves the results by a considerable margin. The increase in performance over the baseline model is more profound for the higher threshold value. This can be attributed to the comparatively higher toxicity of the sentence-level labeled datasets when compared with the contest dataset, which makes the models more expert on detecting highly toxic spans. We observe that the sequential adaptation approach outperforms the weakly supervised learning approach. However the latter might be more suitable for large-

scale datasets due to less training time: the sentence classification model has to be trained on the entire sentence-labeled dataset in which the majority of the samples are non-toxic, whereas the model for generating token labels is trained only on toxic samples. In our experiments, the former took 4.25 hours for a single epoch of training and the latter took 1.5 hours for five epochs of training. Even though training the token classification model takes more time in the weakly supervised approach due to larger volume of data samples, the training time difference was only 48 minutes. All the models were trained on the Kaggle Notebooks<sup>4</sup> platform using GPUs.

The model for generating token labels (described in Section 3.3) did not perform as we expected. Out of the 52,640 toxic samples, only 7,629 samples were given a toxicity score of more than 0.5, thus greatly reducing the size of the additional dataset for token classification. However it was successful in correctly identifying the toxic spans. For example, the highlighted parts were given a toxicity score of more than 0.9 in the following sample:

admins **suck!!** the **fucking** admins **suck ass!** i **fucking hate** the people who delete my **fucking shit!!!!!!!**<sup>5</sup>

## 5 Conclusion and Future Work

In this paper, we proposed two solutions to improve the baseline transformer model fine-tuning for the span toxicity detection task. In the first approach, we performed sequential fine-tuning with an additional fine-tuning of the sentence classifier with supplemental public data. In the second approach, we augmented the labeled token dataset with weak supervision and then performed the fine-tuning token classification on the augmented dataset. Our experimental results show that the first approach improves the baseline fine-tuning results by a 0.0572 F1 score and the second approach improves the baseline results by a 0.051 F1 score. An interesting future direction is to improve the weak supervision technique - possibly using other objective functions for relating token labels and sentence labels - and multi-task learning.

## Abstract

With the rapid growth in technology, social media activity has seen a boom across all age groups. It is humanly impossible to check all the tweets, comments and status manually whether they follow proper community guidelines. A lot of toxicity is regularly posted on these social media platforms. This research aims to find toxic words in a sentence so that a healthy social community is built across the globe and the users receive censored content with specific warnings and facts. To solve this challenging problem, authors have combined concepts of Linked List for pre-processing and then used the idea of stacked embeddings like BERT Embeddings, Flair Embeddings and Word2Vec on the flairNLP framework to get the desired results. F1 metric was used to evaluate the model. The authors were able to produce a 0.74 F1 score on their test set.

## 1 Introduction

Modernization has awarded us with the technology capable of communicating with masses across huge distances in an instant by the touch of a single finger in our palms, the smartphone. With all this innovation every day, it is now more accessible than ever, even in the most rural parts of the world and at very reasonable costs. It has enabled a vast population to share their thoughts and views on popular topics in public forums. People can express themselves in the most creative ways and talk to each other about movies, research, politics, the economy and much more. Some of the key forums and platforms for such activities are Facebook, Twitter, YouTube, Reddit. They allow users to participate in various discussions, discussions that at times may not be very decent. This creates an issue for these platforms as they usually have some of the other policies against indecent content posted by users. On average there are about

350,000 tweets, 510,000 comments, 293,000 status updates on Facebook and Twitter in every 60 seconds (Sayce, 2020). It is humanly impossible for these platforms to check each and everything posted by the users for hate or toxicity. They require an automated method to flag such content.

The motivation for this research task is to achieve some degree of automatic moderation in the social web. It is crucial to moderate social media sites such as Facebook, Twitter and Reddit to be healthy and inclusive. This includes filtering and censoring toxic and hateful content posted online on these public forums. There are automated hate detection NLP models like (Zhang and Luo, 2018) capable of identifying toxic content with acceptable performance. However, they do not identify the specific spans of text that are toxic. This task tries to identify these spans that can be used further to provide insights into a generic text toxicity score. More about the study that this paper is based on can be found from the task organizers paper (Pavlopoulos et al., 2021).

This paper proposes linked lists for data pre-processing and a stacked embedding approach to training this automated system.

The authors' experiment and code for the models ready to be reproduced can be found using the authors' [Github](#) repository.

This paper is organized as follows. It starts with a short abstract describing the paper at a very high level. Then the first section introduces the problem at hand and the task to accomplish. It mentions the authors' approach and the link to their code and models. The second section talks about the background research performed for the task and explains the existing solutions and how this paper is different from them. The third section gives an in-depth understanding of the system approach to solving the tasks where it talks about the embeddings and the stacking method. The fourth section

tells us about the dataset, how it was presented, what it consisted of, the data processing applied to it, the experimental setup and the evaluation metrics. The fifth section is about the methodology, followed by the results section. The seventh section concludes the system description. Finally, we get the references.

## 2 Background research and related works

This problem tackles the challenge of accurately identifying the parts of a toxic text and contributing to making the complete text toxic. There, however, exist systems that can score the toxicity of a full text, sentence or comment like (Zhang and Luo, 2018), but they don't identify the exact part of that sentence that is toxic. There also are systems that can accurately say if a statement is toxic or not and even go on to the extent of identifying the emotion projected by it, for example, if it is positive, negative, humorous, sarcastic, offensive or funny and even the level of these emotions as seen in (Gupta et al., 2020).

A widely known methodology to identify parts of a text is Named Entity Recognition (NER) (Yamada et al., 2020) and its types like the speech (POS) tagging method. NER is a sequence labelling task that recognises entities as per the types of entities it is trained on. These are usually nouns or particular words like names of people or places or organisations and values like monetary numbers and currencies. The sequence labelling task considers a text sequence in which part of it needs to be tagged differently according to the embeddings. Long short term memory, LSTMs (Hochreiter and Schmidhuber, 1997) are usually used for sequence labelling. A variant of LSTMs, the bi-directional recurrent neural network-based BiLSTM, has proved to be very successful at performing accurately at such tasks. It is also seen to be combined with the conditional random field(CRF) decoding layer as seen in (Ma and Hovy, 2016) to get better results.

Open-source tool, Spacy (Honnibal et al., 2020) is a leading tool to create effective and lightweight NER models for datasets with such challenges.

## 3 System Overview

For this task, the authors have used the flairNLP platform (Akbik et al., 2018a) to stack BERT and flair embeddings and create a Named Entity Recognition (NER) model. They have morphed the origi-

nal aim of the NER type tasks to train a model capable of identifying toxicity in a text that is already classified as toxic as a whole. This was possible because, finally, we were using the different embeddings related to toxic parts of the text. These were the embeddings that were trained, which made the task very similar to a NER task. The model created also had a conditional random field layer. Its purpose was to better understand the context around the text's selected parts by considering the neighbouring words.

For this task of sequence labelling, we have stacked embedding by concatenating BERT and flair embedding. This helps in getting a better semantic context out of the concatenated embedding word vectors. Following is a brief about flair and BERT embeddings.

### 3.1 Flair Embedding

Flair embedding (Akbik et al., 2018b) are a type of contextual embedding in which sentences are passed as character into a character level language model to generate word embedding. Contextual string embedding are generated through LSTM because of its ability to keep long term dependency within their hidden state. In Figure 1

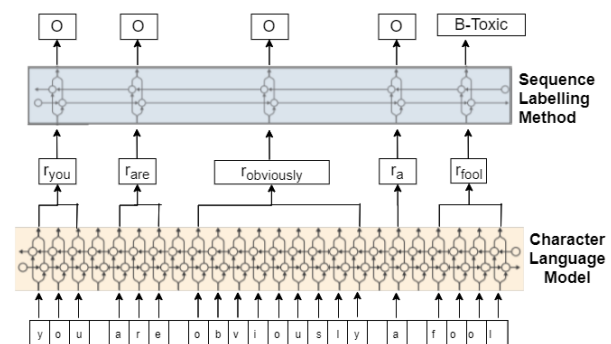

Figure 1: A word is passed as characters to generate flair embedding. After that a CRF layer is used to convert this into a NER problem.

We can see each character of the text "you are obviously a fool" is passed through a bidirectional character-level neural language model, and each word is retrieved. Then it is given to the CRF layer(sequence labelling). Following is a brief explanation of the mathematics behind generating these embedding. In LSTM, the hidden state  $h_t$  represents the past sequence of the character. Both forward and backward language model is used to create these embedding. The mathematical equation of the hidden layers of the forward and back-

Figure 2: Generating Contextual String Embeddings for the word "obviously". In the forward language model (represented in red), the output hidden state is extracted after the last character in that word. For the backward Language Model (represented in blue), the output hidden state is extracted before the word's first letter. These two output layers are concatenated to form the final embedding

ward model can be seen in equation 1 and 2 respectively.

$$h_t^f = f_h^f(x_{t-1}, h_{t-1}^f, c_{t-1}^f, \theta) \quad (1)$$

$$h_t^b = f_h^b(x_{t+1}, h_{t+1}^b, c_{t+1}^b, \theta) \quad (2)$$

In the above equation,  $f$  and  $b$  are the forward and backward model's notations. Memory cell and parameters of the model are represented by  $c_t$  and  $\theta$ , respectively. The output of the hidden state from both the forward and backward language model are concatenated. In the forward language model, the hidden state output is extracted after the word's last character. Subsequently, for the backward language model, the hidden state's output is extracted before the first character of the word. Both the language model captures the semantic information and then are concatenated to generate the word embedding for that particular word. Let us suppose individual word string begin with  $t_1 \dots t_n$  then the contextual word embedding can be seen in equation 3

$$w_i^{charLM} = \left\{ \begin{array}{c} h_{t_{i+1}-1}^f \\ h_{t_i-1}^b \end{array} \right\} \quad (3)$$

To better understand the concept, figure 2 explains the process by taking an example, and the forward language model is shown in red colour. The backward language model is shown in blue colour. To have a complete understanding of how the contextual word embedding work, one can refer to the (Akbik et al., 2018b) paper.

### 3.2 BERT Embedding

Unlike Flair embedding, BERT embedding (Devlin et al., 2019) are word-level embedding, and it

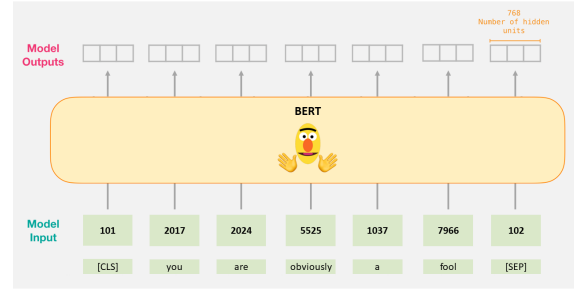

Figure 3: Example Illustrating the process of generating BERT Embedding.

only contains the encoder part of the transformers (Alammar, 2018). In this paper, the authors have used 2 BERT models, i.e. BERT-base, which contains 12 layers, produces an output of 768 units and BERT-Large, which contains 24 layers, produces an output of 1024 units. Generating word embedding can also be classified as feature extraction in which embedding are generated and are fed into the neural network. For the BERT-base model, each layer produces 768 units for every word. To generate BERT embedding, authors have concatenated the last 4 hidden layers. BERT paper (Devlin et al., 2019) also shows that concatenating the last 4 layers yield the best results. BERT has around 30,000 words vocabulary. If the word is not in the vocabulary, then the BERT tokenizer converts it into a sub-word or characters. For example - Word "un-recognized" will be represented as ['un', 're', 'co', 'gni', 'zed']. The first token of a sentence is always ([CLS]), which indicates the sentence's starting. Two separate sentences are separated with ([SEP]) tokens. An example of how the BERT model works is shown in figure 3 which is adopted from (Alammar, 2019) where authors have used "you are obviously a fool" as an example sentence. We can see first the sentence is converted into the sentence convention used by BERT, i.e. adding the required tokens. After adding the tokens, BERT tokenization is used, i.e. words are converted into numbers by referring to the BERT dictionary. BERT tokenization also converts any words in sub-words or character if the required word is not present in the vocabulary file. The ids are then fed into the BERT model, and desired output, i.e. BERT embedding, are generated. Each layer produces 768 units for a single word. The last four (4) hidden layers have been concatenated to get the word embedding in the paper. Now we can put these words embedding to our model to generate results. Figure 4 shows

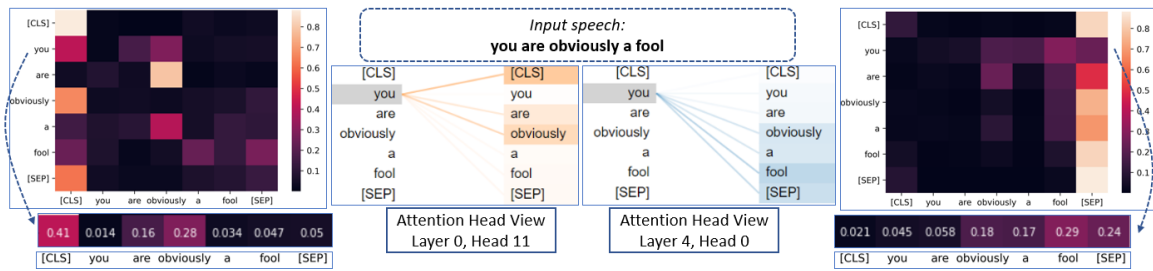

Figure 4: Visualization of Attention in BERT-Base model. Lighter points in the heatmap represents more attention value

the visualization of attention using BERT. The heatmap shows how BERT correlates one word with other.

## 4 Experimental Setup

This section presents a brief overview of the data, the pre-processing it went through and challenges faced in doing so, information about the experiment environment and the evaluation metrics used.

### 4.1 Data

The data was provided to the authors by the task organizers who had acquired it from the Civil Comments Dataset (Borkan et al., 2019). The task organizers then filtered all the text level toxic-labelled text that had been labelled toxic by more than half the annotators, which was around 30,000 in number from a total of 1.2 million posts. Out of these 30,000 text posts, random 10,000 posts were selected and given to crowd annotators to mark the toxic spans from the text. More information about this can be found in the task description paper (Pavlopoulos et al., 2021). The authors finally received a CSV file with two columns with headers as 'spans' and 'text'. Spans column contained a list of character level indices of the toxic entities. Next to it was the complete text that was found to be toxic. For some texts, there existed a corresponding list of empty spans if no toxic span was annotated. Authors randomly collected 558 data points from the dataset (CSV) as a testing set and were left with 5339 data points as the training set.

### 4.2 Linked-list based Pre-processing

The pre-processing stage involved coming up with a method to map the spans before and after cleaning the text. The data provided had a column full of rows with toxic text collected from social media and hence it was naturally in need of cleaning as it contained a lot of abbreviations, punctuation, some

foreign characters, numbers and special characters that were not supposed to be present there as they would create ambiguity to the model. Removing these would bring some uniformity to the model input. In this approach authors faced majorly two (2) challenges.

1. Removing unwanted characters from the original text will produce a cleaner text and that text will be shorter in length as compared to the original text. This will create discrepancy from the spans column, as the spans are given was according to the length of the original sentence.
2. While pre-processing it was important to maintain the sequence of the words in a sentence. For example "You are an Idiot", we have to make sure that after the first word "You" the second word is "are" only.

To tackle the first problem we replaced unwanted(punctuation, numerals etc.) characters with whitespace character so that the length of the sentence remains the same.

**Text :** You.... are, idiot !!

**Pre-processed text :** You are idiot

**Ground spans =** [12,13,14,15,16] = ['idiot']

In the above text, we can see that the unwanted characters are replaced by whitespace character which solves our first problem.

For the second problem, we implemented a linked list data structure. After tokenizing the sentence on whitespace we stored individual word in a single node. The head of the node is attached to the next node which helps us to maintain the sequence

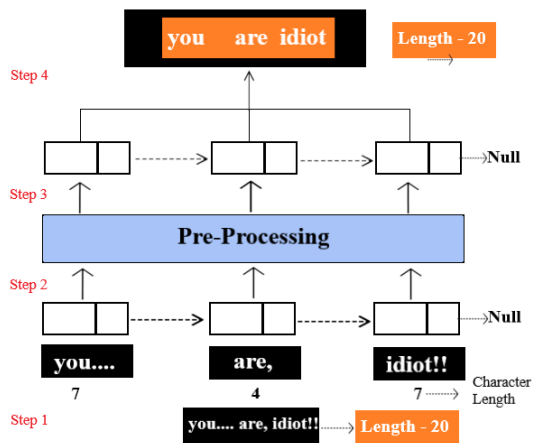

Figure 5: Implementation of linkedlist data structure for pre-processing

of words in a sentence, hence solving our second problem.

This is described stepwise in figure 5

**Step 1:** The original sentence is tokenized on "whitespace". In the example, the length of the original text is 20.

**Step 2:** After tokenization, each word is stored in a node of a linked list data structure and each word from each node is pre-processed i.e. unwanted characters are removed.

**Step 3:** To maintain the sequence of words another linked list is made but in this linked list each word is cleaned. The unwanted characters are replaced with whitespaces in the pre-processing block.

**Step 4:** Words are joined back to form a proper sentence, and the length of the new sentence is 20 as it was of the original sentence.

After getting the pre-processed text, it is ready to be fed into the model.

### 4.3 Experiment Environment

The experimental environment set up by the authors included the use of Python, mostly for scripting along with some of the well known and commonly used python libraries like NumPy, pandas, flair(flairNLP), re(regex). They used Jupiter notebook for python ide along with python version 3.7. Google Colab (GPU and TPU) was also used for training the models.

### 4.4 Evaluation metrics

Authors have used F1 score (Da San Martino et al., 2019), precision and recall (Goutte and Gaussier, 2005) in order to evaluate the performance of the models. The task organisers also used F1 score to evaluate and rank the challenge responses. Equation 4 represents the mathematical formula of calculating the F1 score.

$$F_1^l = \frac{2 \cdot P^l(X_i, Y) \cdot R^l(X_i, Y)}{P^l(X_i, Y) + R^l(X_i, Y)} \quad (4)$$

In equation 4,  $F_1^l$  represents F1 score of the system  $i$ , which is calculated for the text  $l$ . The predicted values are represented by  $X_i$  whereas the ground truth is represented by  $Y$ .  $P$  and  $R$  represents Precision and Recall values with their mathematical calculations shown in equations 5 and 6 respectively where  $S$  represents the Set function.

$$P^l(X_i, Y) = \frac{|S_{X_i}^t \cap S_Y^t|}{|S_{X_i}^t|} \quad (5)$$

$$R^l(X_i, Y) = \frac{|S_{X_i}^t \cap S_Y^t|}{|S_Y^t|} \quad (6)$$

Here,  $|\cdot|$  represents Cardinality which can be interpreted as the length of the finite set.

The overall F1, precision and recall of the models' performance was obtained by calculating the mean of individual scores of every text in our test set of 558 data points.

## 5 Methodology

In this paper authors have used the concept of stacked embeddings i.e. to generate a particular embedding for a word, flair gives you the flexibility to concatenate different word embeddings together to get better results. Equation 7 depicts concatenating flair and GloVe embedding.

$$we_i = \left\{ \begin{array}{l} we_i^{Flair} \\ we_i^{GloVe} \end{array} \right\} \quad (7)$$

Here word embedding is denoted by  $we$ . In this paper, the result of four (4) models have been displayed. Table 1 shows different parameters used by authors in different models. The concept of early stopping and adaptive learning rate are used to generate these results. The learning rate would be halved if the model does not show improvement consecutively 4 times in a row. In this case, the training automatically stops when the learning rate becomes too small for example  $LR=6.2500e-05$ .

Parameters	Model 1	Model 2	Model 3	Model 4
Epochs	30	39	30	36
Learning Rate	0.001	0.001	0.001	0.001
Mini Batch Size	8	8	8	8
Embeddings	Flair,BERT-large-uncased, CharacterEm-beddings	Flair,BERT-large-uncased, CharacterEm-beddings,GloVe	Flair,BERT-base-uncased, CharacterEm-beddings,GloVe	Flair,BERT-base-uncased, CharacterEm-beddings

Table 1: Parameters of different Proposed Models

## 6 Result

The parameter details of the 4 different models and the embeddings used are listed in table 1. It lists the number of epochs the model was trained on with the initial learning rates and batch sizes. Model 2 ran for the most epochs before being auto-stopped as no improvements were seen in the last 4 epochs and the learning rate parameter got too small due to the adaptive learning rate function. All the models had Flair and Character embeddings with the variation of GloVe and BERT-uncased embeddings. Table 2 lists different models used

Model	F1	Precision	Recall
Model 1	0.748	0.971	0.929
Model 2	0.737	0.967	0.925
Model 3	0.726	0.968	0.916
Model 4	0.724	0.973	0.909

Table 2: Experimental results

and their respective F1-scores, precision and recall values for our test set. It can be inferred that model 1 i.e. stacked embeddings with Flair, BERT-large-uncased, CharacterEmbedding performed the best with an F1 score of 0.748 with precision and recall of 0.971 and 0.929 respectively. It was able to predict toxic spans closest to the ground truth. The other models are not too behind than this but it seems that model 4 did not have too much of a difference when stacked with GloVe embeddings as seen in model 3.

Figure 6 presents the comparative analysis of F1 scores achieved by the 4 models proposed by the authors in table 1 and the best performing model from the NLRG system (Chhablani et al., 2021) and the UniParma system (Karimi et al., 2021). The authors of NLRG have used a BERT based RoBERTa token classification method to reach their best F1 score of 0.689. The authors of

Figure 6: Comparative Analysis of F1 scores

UniParma have used CharacterBERT and the bag of words(BOW) method to get their F1 score of 0.66. Proposed model 1 (highlighted in red) was the best performing model with a 0.748 F1 score.

**Text :** You.... are, idiot !!

**Pre-processed text :** You are idiot

**Ground spans**=[12,13,14,15,16]=['idiot']

**Predicted spans**=[12,13,14,15,16]=['idiot']

The above example displays the input text, the pre-processed clean text with the toxic word "idiot" highlighted in red. Below them is the ground truth for the spans of this toxic word and then there are the correct predicted spans for it.

## 7 Conclusion

We support the systematic development for identifying toxic spans. We have successfully been able to deploy a linked list approach to prepare the data and then train it using the stacked embeddings method and produce empirical results. This task can prove to be useful in providing a better analysis in the censoring of toxic posts on the internet.

## Abstract

Toxic Spans Detection(TSD) task is defined as highlighting spans that make a text toxic. Many works have been done to classify a given comment or document as toxic or non-toxic. However, none of those proposed models work at the token level. In this paper, we propose a self-attention-based bidirectional gated recurrent unit(BiGRU) with a multi-embedding representation of the tokens. Our proposed model enriches the representation by a combination of GPT-2, GloVe, and RoBERTa embeddings, which led to promising results. Experimental results show that our proposed approach is very effective in detecting span tokens.

## 1 Introduction

With the massive increase in social interactions on online social networks, keeping discussions fruitful is a central concern for platform providers. Indeed, abusive (e.g., bullying, profanity, hate speech), damaging the reputation of a platform. Thus, it is necessary to be detected by automated machine learning systems because of huge amount of data. However, the previous works mostly focus on whether the given document(e.g. comment) is toxic or not. Detecting the span tokens in the document may be more beneficial. For example, it can prevent users to use span tokens before they send their post. Also, it is useful to filter span tokens before learning AI chatterbots instead of removing the whole documents.

In this paper, we propose a self-attention-based bidirectional gated recurrent unit (BiGRU) with a multi-embedding representation of the tokens. Our proposed model enriches representation showed very promising results.

The rest of the paper is organized as follows. Section 2 provides background and presents some related works on TSD in general. Section 3 intro-

duces our BiGRUs model. Results are covered in Section 4. In Section 5 we draw a conclusion.

## 2 Related Research

A toxic post (comments) is defined as a rude, disrespectful, or unreasonable comment that is likely to make other users leave a discussion. A goal of toxic comment classification is to give a right to freedom of expression on the web.

Training complex neural networks (NN) requires enough datasets of toxic comments. Word embeddings are the basis of the NNs when working with text data. NNs for toxic comment classification use Recurrent Neural Networks (RNN) layers such as Long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) or Gated Recurrent Unit (GRU) (Chung et al., 2014) layers. Similarly, the attention mechanism for NNs has been successfully applied to toxic comment classification (Pavlopoulos et al., 2017; van Aken et al., 2018). In semi-automated content-moderation, attention can be considered as a highlighter of abusive or toxic words.

Badjatiya et al. (2017) proposed a system for a hate-speech task based on deep-learning with a combination of LSTM, random embedding, and gradient boosted decision trees as the best model. They used random embedding, GloVe (Pennington et al., 2014), and FastText (Bojanowski et al., 2016) representation for experimentation. They concluded that a combination of CNN and LSTM with FastText or GloVe embedding as features for gradient boosted decision trees can not yield better results.

van Aken et al. (2018) held an in-depth error analysis, and based on their comparance with different deep learning and shallow approaches; they observed three common challenges: out-of-vocabulary words, long-range dependencies, and

multi-word phrases. They experimented with various deep learning models, including CNN, LSTM, BiLSTM, GRU, BiGRU, and Attention mechanism with GloVe and FastText embeddings to tackle these challenges. Their experimentation on two datasets showed that BiGRU with Attention mechanism with GloVe and FastText representations achieved promising results with respect to other models. However, in the final, they proposed an ensemble approach that outperforms all individual models.

In (Pavlopoulos et al., 2017) they proposed a deep classification-specific attention mechanism with BiGRU to highlight suspicious words for automatic and semi-automatic content moderations.

### 3 Proposed Method

In this section, we describe the details of our proposed neural network model. Our proposed approach aims to predict whatever the tokens of given comments are toxic or not. Figure 1 depicts an overview of our proposed method.

At first, in a dataset, original posts are tokenized and preprocessed. Each token at each post is labeled as a toxic or not toxic token by their spans. Then, a multi-embedding representation of tokens is created. Next, the Bidirectional GRUs (BiGRUs) models are applied to extract the higher-level feature sequences with sequential information from multi-embeddings. After that, a self-attention mechanism computes attention weight between each pair of elements in a single sequence. Finally, the generated output feature sequences from self-attention-based BiGRUs are fed into the fully-connected dense layer and then into the final prediction module to determine the prediction. In the following, we describe each component elaborately.

#### 3.1 Preprocessing

First, each comment is tokenized into words with their spans. Next, tokens are preprocessed; the preprocessing consists of lowercasing and removing punctuations, special characters, numbers, Unicodes, smileys, and emojis. After preprocessing, empty tokens are removed (tokens which empty spaces). Finally, for a post, toxic or not-toxic labels based on grand truth assigned to preprocessed tokens. In total, we obtained **21790** unique words. The obtained words are used as a vocabulary. In the next step, a multi-embedding is used to extract

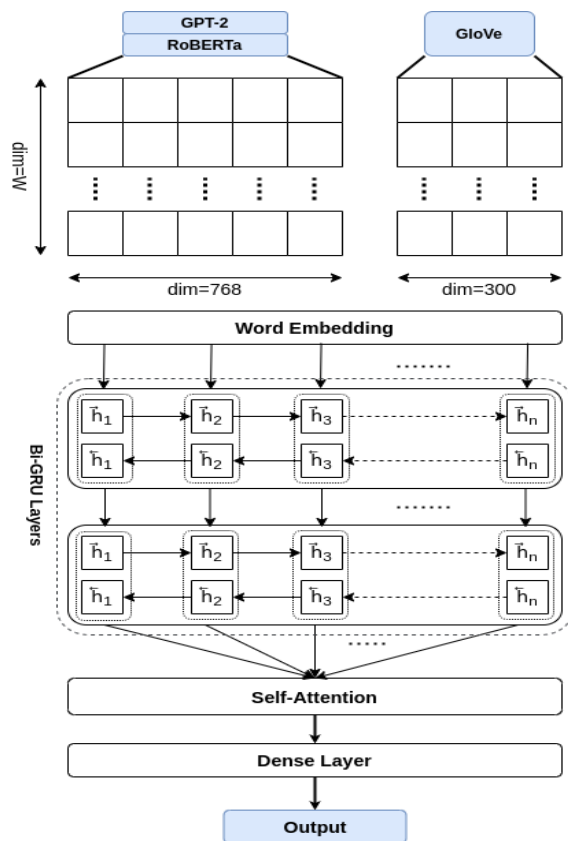

Figure 1: Architecture of Proposed Model

features for unique words to create an embedding matrix for modeling.

#### 3.2 Multi-Embedding Layer

Toxic comments often use obfuscations, for example, "f\*k u", "Son of a B\*\*\*\*", "\*\*\*\*k them.". Also, misspelled and abbreviation words are common in online discussions. Word2Vec (Mikolov et al., 2013) and GloVe fail to find a good representation of these words because words never occurred in training time. These words are out-of-vocabulary (OOV) (Risch and Krestel, 2020). However, we can take advantage of failing representations to represent toxic tokens that are not in vocabulary by setting their representations to zero. Regarding this hypothesis, if GloVe or Word2Vec contains OOV, we can set their token representations to zero and use language model embeddings to find subset word representation. By concatenating these two types of representation for each token in the sequence, we can build awareness representation of sequences.

For this purpose, we used the multi-embedding representation of tokens.

**GloVe** is a global log-bilinear regression model

with a weighted least-square objective that combines the advantages of global matrix factorization and local context windows. It leverages statistical information by training only on the nonzero elements in a word-word co-occurrence matrix in a large corpus.

**GPT-2** (Radford et al., 2019) is an unsupervised transformer language model for general-purpose learners. It is trained on WebText, which contains over 8 million documents.

**RoBERTa** (Liu et al., 2019) is an optimized version of BERT (Devlin et al., 2018) model. It builds on BERT’s language masking strategy. RoBERTa modifies key hyperparameters in BERT, including removing BERT’s next sentence pretraining objective and training with much larger mini-batches and learning rates.

To empower representation, we combined RoBERTa and GPT-2 representations (by summing) and then concatenated them with GloVe (840B tokens, 2.2 vocab). We achieved representation matrix with  $W \times 1068$  dimension for training vocabs, where  $W$  is the number of vocabs in training. During analysis, we found nearly  $6k$  OOV words in training, which GloVe does not produce a representation for them. It is a significant number regarding the training vocabulary size.

### 3.3 Bidirectional GRUs

Bidirectional Gated Recurrent Unit (BiGRU) in the central part of Figure 1 is a bidirectional version of GRU. The GRU allows to adaptively capture dependencies from large sequences of data without discarding information from earlier parts of the sequence. BiGRU combines the forward hidden layer with the backward hidden layer, which can process each sequence in both left-to-right and right-to-left order to embed the sequential dependencies in both directions. The first BiGRU layer is used to process each sequence token-by-token and produce an intermediate representation. Then, this intermediate representation is used as input for the second BiGRU layer.

### 3.4 Self-Attention Layer

The words in sequences sometimes are related to each other, like "Son", "of", "B\*\*\*" and sometimes are not related. To determine how two tokens are related, Self-Attention Networks (SANs) (Luong et al., 2015) produce the output with the same size as input sequences by considering the attention

of all input tokens with each other. It learns the important interactions between tokens.

### 3.5 Dense Layer

The dense layer or feed-forward layer is the most general-purpose deep learning layer. The dense layer consists of 50 neurons for the weighted linear combination of inputs with the activation function of tanh to squashes the input to the range  $[0, 1]$ .

### 3.6 Prediction Module

The final layer of the network has three neurons, and its returned value is a continuous numerical value. We used the sigmoid activation function to produce a probability vector. For loss function and optimization, we employ Sparse Categorical Cross entropy and RMSprop, respectively.

## 4 Results

### 4.1 Dataset

For toxic span detection tasks (Pavlopoulos et al., 2021) posts from publicly available Civil Comment dataset are used for annotations of particular toxic spans in toxic comments. The task consists of 7939 annotated comments with their toxic spans for training and 2000 for the test. However, we treat 690 samples of trial data as a development set for our investigations.

### 4.2 Evaluation

For evaluation of participating systems in the challenge, F1 score presented in (Da San Martino et al., 2019) was used. If we consider  $A_i$  to return a set  $S_{A_i}^t$  of character offsets for the part of the post found to be toxic, and similarly  $G^t$  be the character offset of the grand truth annotation of  $t$ . We can compute F1 score of system  $A_i$  with respect to the  $G$  for post  $t$  as follows:

$$F_1^t(A_i, G) = \frac{2 \cdot P^t(A_i, G) \cdot R^t(A_i, G)}{P^t(A_i, G) + R^t(A_i, G)}$$

$$P^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{S_{A_i}^t}$$

$$R^t(A_i, G) = \frac{|S_{A_i}^t \cup S_G^t|}{S_{A_i}^t}$$

If  $S_G^t$  and  $S_{A_i}^t$  are empty for some post  $t$ , then  $F1 = 1$ , and otherwise  $F1 = 0$ . In final, to obtain a single score for system  $A_i$ , the  $F1$ s averaged over all the posts  $t$  of the evaluation dataset.

Method	GloVe	GPT-2	RoBERTa	RG	GoR	GoG	Ensemble
Results on dev set

Table 1: Experimental Results on Trial (dev) and Test sets. RG refers to the ensemble of RoBERTa and GPT-2 embeddings. Similarly, GoR, refers to the ensemble of GloVe and RoBERTa embeddings, and GoG refers to the ensemble of GloVe and GPT-2 embeddings

### 4.3 Results

For all experimentation, we used Google Colab free GPU<sup>1</sup> to train our models with 10 epochs. We set the batch size to 32, and we pad the comments to the 215 sequence length. We obtained 6330 OOV out of 21790 words in the vocabulary, which GloVe does not produce a representation for them. For experimentation, we used BiLSTM and BiGRU models with SAN followed by a dense layer. Also, we examined representation combinations of GloVe, GPT2, and RoBERTa and reported them in Table 1 for dev (trial) and test sets. According to the experimentations, all models perform well when multi-embedding representation is utilized.

In the first part, we took GloVe representation as our baseline representation. Regarding this representation, in most cases, GPT-2 and RoBERTa perform well (6 cases for GPT-2, and 7 cases for RoBERTa). It shows how much the contextualized representations are useful; however, it is hard to tell among GPT-2 and RoBERTa which one is performing well.

In the second part, we combined different representations that achieved a higher averaged value of F1 score in all cases. Except for one case, namely BiLSTM + Attention, the differences between representation by GPT-2 and GoR is 0.008. In general, an ensemble of embeddings achieved a higher score than single representations.

In the final, because of two reasons, we considered the BiGRU + Attention model with multi-embedding representations as the final model for this task. First, It achieved a higher averaged F1 according to the dev set, and the second higher

averaged F1 score according to the test set. The second reason is that the margin between the BiGRU+Attention model in the dev and test set was less than the others (0.009). Submitted model to the competition achieved averaged F1 score of **0.677** and place **23** of the competition among 91 teams.

We shared the implementation of the proposed model in GitHub<sup>2</sup> for the research community.

## 5 Conclusion

In this paper, we presented our approach for SemEval-2021 Task 5: Toxic Span Detection. We tried to tackle the problem by employing multi-embedding and deep learning techniques. We conducted some experiments using different models. For example, we implemented a BiLSTM model, BiLSTM with SA, BiGRU, and BiGRU with SA, but the model that gave a promising result and relied on BiGRU with SA model.

## Abstract

In this paper, we describe our system used for SemEval 2021 Task 5: Toxic Spans Detection. Our proposed system approaches the problem as a token classification task. We trained our model to find toxic words and concatenate their spans to predict the toxic spans within a sentence. We fine-tuned Pre-trained Language Models (PLMs) for identifying the toxic words. For fine-tuning, we stacked the classification layer on top of the PLM features of each word to classify if it is toxic or not. PLMs are pre-trained using different objectives and their performance may differ on downstream tasks. We, therefore, compare the performance of BERT, ELECTRA, RoBERTa, XLM-RoBERTa, T5, XLNet, and MPNet for identifying toxic spans within a sentence. Our best performing system used RoBERTa. It performed well, achieving an F1 score of 0.6841 and secured a rank of 16 on the official leaderboard.

## 1 Introduction

Internet and social networking sites have brought people together by providing a simple yet effective method of communication. Over the years people used it to exchange positive ideas but recently, there has been a rise in toxic content and hate speech over the internet (Zampieri et al., 2019, 2020). Most datasets (Fortuna et al., 2020) dealing with the problem of toxic, offensive, or hateful content aim to classify the entire text belonging to a particular class. They do not identify the parts of the text that make it toxic. Manual filtering of toxic data is tough and can cause mental and emotional stress to annotators (Zampieri et al., 2019). An automatic system with the ability to identify toxic text and highlighting toxic spans can be useful for the moderators. It will help save time and prevent stress caused by reading long texts. SemEval 2021 Task 5: Toxic Spans Detection (Pavlopoulos et al.,

2021) draws attention to the problem of identifying toxic spans present in a sentence.

Our proposed system makes use of a word-level classifier for detecting the offensive words present in a sentence. The offsets of the toxic words can then be concatenated to find the toxic spans. We made use of pre-trained language models (PLMs) for building our classifier. We experimented with BERT (Devlin et al., 2019), ELECTRA (Clark et al., 2020), RoBERTa (Liu et al., 2019b), XLNet (Yang et al., 2020), MPNet (Song et al., 2020), T5 (Raffel et al., 2020), and XLM-RoBERTa (Conneau et al., 2020) to compare their performance on the task of toxic spans detection. Owing to the increase in the number of pre-trained language models choosing the correct model is an important decision as these models contain millions of parameters and are expensive to train. So, we present a comprehensive analysis of the performance of different models, which can serve as a baseline for future work.

Our best performing system was fine-tuned using RoBERTa and attained an F1 score of **0.6841**. It was ranked **16** on the official leader board. We used different PLMs for fine-tuning and found exceedingly small variations in their performance. Further analyzing our model's performance on the test set we observed that it is essential for the model to not only detect toxic spans but also decide if it needs to predict toxic spans for that sample or not. Our code is available online<sup>1</sup> for method replicability.

## 2 Background

Identification of toxic/offensive content is an important task in natural language processing. It is essential for the moderation of harmful content over social media sites that might hurt the sentiments of individuals, groups, or communities at large. Much

<sup>1</sup><https://github.com/04mayukh/YoungSheldon-at-SemEval-2021-Task-5-Toxic-Spans-Detection>

work has been done on the identification of offensive content. OffensEval 19, 20 (Zampieri et al., 2019, 2020) provide a comprehensive analysis of methods useful for the identification of offensive content. SemEval 2020 Task 8: Memotion analysis (Sharma et al., 2020) presented with a dataset of internet memes with one sub-task to detect and quantify offensive content. Work done in (Brassard-Gourdeau and Khoury, 2019) explores different aspects of sentiment detection and their correlation to toxicity. (Pavlopoulos et al., 2020) covers the effect of context on toxicity. (D'Sa et al., 2020) uses BERT and FastText for toxicity detection. (Kurita et al., 2019) covers several attacks to by-pass toxic content filters and methods to make the filters robust to such attacks. Recent state-of-the-art systems (Wiedemann et al., 2020; Wang et al., 2020; Liu et al., 2019a; Nikolov and Radivchev, 2019) performed well in identifying offensive content. Work done in (Gröndahl et al., 2018) shows that although recent systems perform well on given datasets, very slight changes made by adversaries may fool the models. Adding words like “love” to offensive tweets may make it less offensive.

Identifying toxic content is an important NLP task. It is useful in moderating online content over the web having millions of users. Most problems deal with labeling the entire content as toxic/non-toxic. None of the previous work has tried to identify spans within a text that makes it toxic. SemEval-2021 Task 5: Toxic Spans Detection aims to bring attention to this problem via the task defined as: Given a dataset  $D$  of sentences, the objective of the task is to learn a classification function that can predict the toxic spans  $T$  present in the given sentence. The content of the provided dataset  $D$  was in English.

**Dataset statistics:** The dataset for the task consisted of character offsets for toxic spans present for each text sample. The span consisted of single words as well as a collection of words. Table 1 shows the count of samples having different number of toxic words.

From Table 1 we can infer that samples with toxic words within the range of one to three form a major component of the dataset. In the test set, samples with no toxic words were significantly more than the training and development set. Toxic words with the highest frequency of occurrence present in the training set are given in Table 2. We observed that toxic words contained stopwords (the,

a, and, of) which are generally not toxic when used independently. These stopwords can exist as part of multiword toxic spans.

### 3 System Overview

#### 3.1 Pre-trained Language Models

Natural language processing tasks are data intensive. Training deep neural networks for NLP tasks requires large amounts of training data that might not always be available. To overcome this problem researchers proposed pre-training large language models which can be fine-tuned on various downstream tasks. Pre-training involves training general representations of text to understand its syntactic and semantic relations. The main advantage of pre-training is that it can be done on unlabelled text corpus allowing training on a large amount of textual data. The pre-trained language models can then be used across various downstream tasks by fine-tuning them on task-specific datasets.

#### 3.2 Brief overview of used PLMs

**BERT:** It is a bidirectional language model based on the Transformer architecture (Vaswani et al., 2017). It uses Masked Language Modeling (MLM) and Next Sentence Prediction (NSP) as a pre-training objective.

**ELECTRA:** It is one of the most recent models and is inspired by generative adversarial networks. It introduces Replaced Token Detection (RTD) pre-training objective.

**RoBERTa:** It is a modification of BERT proposed by Facebook. It uses dynamic masking as a part of the pre-training objective. NSP was removed and the model was pre-trained on larger data for more time.

**XLNet:** It is a generalized auto-regressive pre-training method using the best of both Auto Regressive (AR) and Auto Encoding (AE) modeling techniques. It makes use of permutation language modeling (PLM) objective for pre-training.

**MPNet:** It was proposed by Microsoft. It overcomes the pre-train fine-tune discrepancy in XLNet. It makes use of both PLM and MLM to map the dependencies among predicted tokens as well as use full positional information in a sentence.

**T5:** It was proposed by Google and aimed to re-frame all NLP tasks into a single text-to-text format where both inputs and outputs are always strings. It used a masking objective similar to BERT and used teacher forcing for pre-training.

No. of Toxic words per sentence (N)	N = 0	N>0 and N<=3	N>3 and N<=7	N>7	Total
Train	486	6216	742	495	7939
Development	43	543	72	32	690
Test	394	1541	53	12	2000

Table 1: Number of samples with different frequencies of toxic words.

Toxic Word	Frequency
stupid	1237
idiot	668
the	581
idiots	428
a	383
and	350
of	288
ignorant	277
stupidity	276

Table 2: Most frequent toxic words.

**XLm-RoBERTa:** It is a multi-lingual model trained by Facebook AI on more than 100 languages. It made use of the Transformer architecture (Vaswani et al., 2017) with multilingual MLM (Devlin et al., 2019; CONNEAU and Lample, 2019) using only monolingual data as a pre-training objective.

### 3.3 Modelling as Token Classification Task

The given dataset provided spans of toxic content in a statement. Each sentence could contain multiple toxic spans. Another important thing to note was that a toxic span could comprise more than one word. We extracted all toxic words using the toxic spans. If a span contains over one word, it was further processed to extract individual words. Once we found all the toxic words, we split the original sentence to label the toxic/non-toxic words. Before splitting the original sentence, we removed extra whitespace and newline characters. We removed any punctuation before or after the word. Punctuations present within the words were not removed. Figure 1 shows an example of the process. The toxic spans have been highlighted in red in the original sentence which, we convert into an array of words labeled as toxic/non-toxic.

The next step is to prepare the data for fine-tuning on pre-trained language models. PLMs use tokenization to break the original words into sub-words. Different models use different tokenization techniques like Byte-Pair-Encoding (BPE)

(Sennrich et al., 2016), WordPiece (Schuster and Nakajima, 2012), and SentencePiece (Kudo and Richardson, 2018). One advantage of using tokenization is that it helps to reduce the vocabulary size. One challenge it poses for token classification tasks is which sub-word to use for classification. Different models also add special tokens like [CLS], [SEP], start, end tokens which are not required for the token classification task. In our approach, we used the first sub-word of the tokenized word for classification. We masked the remaining sub-words and special tokens while computing the loss. The sub-words were masked only during loss computation and not while being passed through the model. This allowed all sub-words to learn dependencies within the sentence. Figure 2 shows the tokenized words and their corresponding labels using the BERT tokenizer.

### 3.4 Fine-tuning

We used a simple approach for fine-tuning the model for token classification. We used a token classifier on top of features learned by PLMs. Our classifier consisted of three layers on top of PLM features. First was the batch normalization layer, followed by a dropout layer. The final layer was a time-distributed dense layer over features of each tokenized word containing a single neuron and a sigmoid activation to predict if the given token is toxic/non-toxic.

### 3.5 Masked Loss

As described, we reduced the problem to a token classification task where we predict the label for each word. We used binary cross-entropy loss for the fine-tuning process. In cases where the original word is broken down into multiple sub-words, we used only the first sub-word for calculating the loss. We created masks for each sentence to store the position of words/sub-words. Cross-entropy loss was calculated for required sub-words/words using the masks and then summed up over all tokens in a sentence. The summed value was the loss for a given sentence.

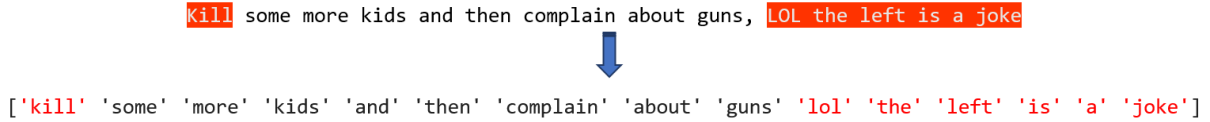

Figure 1: Converting toxic spans to toxic words.

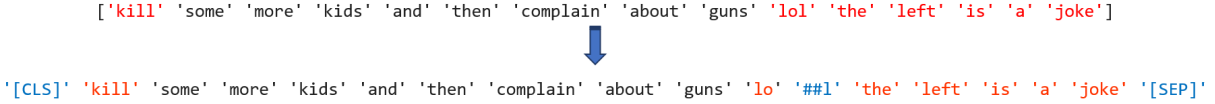

Figure 2: Tokenization for using PLMs. Sub-words(except first sub-word) and special symbols were masked.

## 4 Experimental Setup

### 4.1 Hyperparameters and Training

Our models were developed on Keras<sup>2</sup> (Chollet et al., 2015) using HuggingFace’s<sup>3</sup> implementation of transformer<sup>4</sup> (Wolf et al., 2020) models. We fine-tuned the models on TPU’s on Google Colab. We fixed the sequence length of input to 150 tokens. We padded/truncated the sequences according to their length. Our model was fine-tuned using the AdamW optimizer(Loshchilov and Hutter, 2019) with a linear learning rate decay against masked binary cross-entropy loss. We experimented with learning rates of 1e-4, 3e-5, 4e-5, 5e-5 for each PLM architecture. Fine-tuning was done for 4 epochs. Each PLM architecture with the best performance on the development set was used for making final predictions on the test set.

### 4.2 Predicting Toxic Span Offsets

Our model was trained to find the toxic words. In case the word was tokenized into sub-words, we used the first sub-word to determine the toxic nature of the entire word. We stored flag values for each sentence to find the correct label for each word during prediction. Once we found the toxic words, we searched for them in the original un-processed sentences. We concatenated the spans for all predicted toxic words which was the final expected output.

### 4.3 Evaluation Metric

The performance of the model was evaluated using the F1 score as described in (Da San Martino et al., 2019). Let system  $A_i$  return a set  $S_{A_i}^t$  of character offsets found toxic for post  $t$ . Let  $G_t$  be

Model	F1 Score	
	Dev	Test
BERT-base	0.6654	0.6812
ELECTRA-base	0.6710	0.6804
RoBERTa-base	0.6676	<b>0.6842</b>
XLM-RoBERTa-base	0.6519	0.6775
T5-large	0.6658	0.6811
XLNet-base	0.6714	0.6817
MPNet-base	<b>0.6750</b>	0.6800

Table 3: Model performance on Test set.

ground truth annotation for  $t$ . F1 score of system  $A_i$  with respect to ground truth values  $G$  for post  $t$  is calculated as follows:

$$F_1^t(A_i, G) = \frac{2 \cdot P^t(A_i, G) \cdot R^t(A_i, G)}{P^t(A_i, G) + R^t(A_i, G)}$$

$$P^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_{A_i}^t|}$$

$$R^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_G^t|}$$

where  $|\cdot|$  represents the cardinality of the set. If  $S_G^t = 0$  i.e no toxic spans are present in  $t$  then  $F_1^t(A_i, G) = 1$  if  $|S_{A_i}^t| = 0$  else  $F_1^t(A_i, G) = 0$ . Finally,  $F_1^t(A_i, G)$  was averaged over all posts  $t$  present in dataset D to obtain single score for system  $A_i$ .

## 5 Results and analysis

Table 3 shows the performance of our proposed model on different PLMs. Learning rate of 1e-4 was used for ELECTRA, 4e-5 for MPNet, and 5e-5 for the remaining PLMs to obtain the above-mentioned results. RoBERTa had the best performance on the test set while MPNet had the best

Table 5: Words predicted as toxic in Test samples containing no toxic spans.

performance on the development set. Our best performing model achieved a best F1 score of 0.6842 on the test set and was ranked 16 on the official leader board.

We further analyzed the performance of our model on the test set. We evaluated the performance of our model on samples containing any number of toxic words vs no toxic words. Table 4 shows the results of the analysis. We found that our models performed significantly well for samples having one or more toxic words present and, our best performing model had a perfect F1 score on 66.06 % of them. Our model was unable to find toxic words in only 5.97% of samples containing one or more than one toxic word.

In the case of samples that had no toxic words in a sample, our model could not perform well. Only 6.09% of samples with no toxic words were classified correctly. The dataset statistics for the test set show that samples with no toxic words constitute 19.7 % of the test set. The training and development set had only 6.12% and 6.23% samples without any toxic words. We also found the top 15 most common words which were predicted

as toxic from samples containing no toxic words in the test set. The words are given in Table 5 along with their frequency of occurrence.

We can observe that Table 2 and 5 has common words. We trained our model using token classification objective which tries to capture toxic words. The model cannot identify if the word is part of a toxic/non-toxic sentence. Sometimes these words may be part of a sentence intended to present humor or sarcasm. This may lead the model to incorrectly identify toxic words in samples containing no toxic spans.

## 6 Conclusion

In this paper, we describe our approach for SemEval 2021 Task 5: Toxic Spans Detection. We propose a word-level classifier for identifying the toxic words in a sentence. We experimented with different PLMs to provide a comprehensive analysis of their performance for identifying toxic spans. We performed well, getting a rank of 16 on the leader board. Our analysis shows that a word-level classifier performs extremely well for sentences that contain at least one toxic word. However, it cannot identify cases with no toxic spans efficiently. In the future, we would like to work on solving this problem by using a classifier to simply predict if the sentence is toxic/non-toxic along with span detection.

## Abstract

This paper presents our submission to SemEval-2021 Task 5: Toxic Spans Detection. The purpose of this task is to detect the spans that make a text toxic, which is a complex labour for several reasons. Firstly, because of the intrinsic subjectivity of toxicity, and secondly, due to toxicity not always coming from single words like insults or offends, but sometimes from whole expressions formed by words that may not be toxic individually. Following this idea of focusing on both single words and multi-word expressions, we study the impact of using a multi-depth DistilBERT model, which uses embeddings from different layers to estimate the final per-token toxicity. Our quantitative results show that using information from multiple depths boosts the performance of the model. Finally, we also analyze our best model qualitatively.

## 1 Introduction

SemEval-2021 Task 5: Toxic Spans Detection (Pavlopoulos et al., 2021) consists in detecting which spans make a text toxic. This is quite relevant for nowadays lifestyle in which, aggravated by the COVID-19 pandemic, online conversations have become key to communicate with our family, friends and job mates, or socialize through social networks and streaming chats. Being able to moderate all this digital content is crucial in order to promote healthy online conversations and discussions.

To tackle this problem, in HLE-UPC we have used a BERT-based model with a fully-connected layer on top to perform Named-Entity Recognition and Classification (NERC), with the goal of tagging each word as either toxic or not. Moreover, we have studied and proved that the use of information from different-depth layers enriches the final classification.

Our contributions to Toxic Spans Detection are:

- The proposal of an ensemble of three different multi-depth DistilBERTs, achieving an F1-score of 68.54% and being ranked 14th out of 91 teams in the challenge, just 2.29% below the best performing model.
- The study of multi-depth BERT-based models in the task of Toxic Spans Detection, showing an improvement on the performance compared to non-multi-depth architectures.
- A qualitative analysis presenting some ethical concerns regarding racial bias.

The source code for our model and pipeline is available at <https://github.com/rafelps/HLE-UPC-SemEval-2021-ToxicSpansDetection>.

## 2 Related work

**Toxicity** The task in which we are participating is not the first one to focus on text toxicity. Without going any farther, in last year's edition of SemEval we can find Task 12, also known as OffensEval 2020 (Zampieri et al., 2020), in which the goal was to identify offensive language in multilingual social media data. In the previous year's competition, SemEval 2019, Task 6 (Zampieri et al., 2019) was also tackling the identification and categorization of offensive language in social media.

Some of the models that solved these tasks involve Convolutional Neural Networks (CNN) (Mahata et al., 2019), Long Short Term Memory Networks (LSTM) (Pham-Hong and Chokshi, 2020) or attention based models (Liu et al., 2019; Wiedemann et al., 2020) branched from the BERT family (Devlin et al., 2019).

**NERC** All the mentioned models approach the task as Sequence Classification, this is, encoding a whole sentence and providing a unique prediction

for it. Toxic Spans Detection, however, goes a step further by asking participants to detect toxic spans, the exact characters or words that make a text toxic. For this reason, instead of modelling the task as sentiment analysis or document/comment classification, it seems more natural to approach it as token classification, generating an output for each token. More specifically, this task could be seen as a Named Entity Recognition and Classification (NERC) task, in which the goal would be to output the most probable sequence of labels (toxic or not) given an input sentence.

In the field of NERC, we also find some interesting models. The state-of-the-art today are attention-based models, usually stemming from transformers such as BERT (Devlin et al., 2019), which can be easily converted into a token classifier by adding a simple linear layer on top of the per-token output. However, we can also find some other attention-based models using CNNs (Baeovski et al., 2019) or even recurrent architectures such as Jiang et al. (2019); Straková et al. (2019); Peters et al. (2018), which mix BiLSTMs, CNNs or CRF layers.

### 3 Data and Methodology

#### 3.1 Data Description

For this task, the organizers provide us with the Toxic Spans Detection (TSD) dataset, also presented in Pavlopoulos et al. (2021), containing phrases and comments that may contain toxic spans. Together with each comment, there is the set of indices of the characters that are considered toxic.

The TSD dataset is split into three subsets: trial, train and test sets with approximately 700, 8000 and 2000 comments respectively. All the models presented in this work have been trained exclusively on the TSD training set, while the trial set has been used to validate our systems. Finally, the test set has served to evaluate the performance of our final models using the available limited submissions for the competition.

The TSD dataset contains very diverse comments. Some of them seem quite simple, but others may be ambiguous, require context knowledge or an understanding of tone, which makes the task extremely challenging. There are also some words that have been written in an ingenious way, to avoid naïve toxic detectors, or that are bleeped or censored. Following we present a couple of examples, where toxic characters are underlined:

- This is a stupid example, so thank you for

nothing a!@#!@.

- I bet you can't wait to see him behind bars.

#### 3.2 Data Cleaning

With a simple data exploration, it can be seen that approximately 90% of the toxic spans exactly match with word boundaries, but in the remaining cases we find strange cases such as the following ones:

1. **You are an idiot:** There is a whitespace as a toxic span boundary.
2. **You are an idiot:** A random singleton character is marked as toxic.
3. **You are an idiot:** “Y” is not marked as toxic but “ou” is.

The majority of these inconsistencies are already known by the organizers of the task and other participants. However, they should still be tackled to provide the best data possible to our models. For this reason, we have cleaned the data using three simple steps and following the idea of toxicity coming from complete words but not from single characters. For each group of consecutive annotated toxic offsets:

1. Iteratively remove the first or last toxic offset if it belongs to a whitespace. This solves the first type of inconsistencies.
2. Remove the toxic offset if it is a singleton: a single consecutive character marked as toxic. This helps in the second type of strange cases.
3. Iteratively left-expand the range of toxic offsets if the previous character is alphanumeric (so it belongs to the same word). Same for right-expansion. This solves the third problem by including the offsets of the whole word as toxic whenever more than one character is marked as so.<sup>1</sup>

After cleaning the data, almost the totality of the annotations matches word boundaries. On one side this confirms our hypothesis that toxicity comes from words or expressions but not from characters. On the other side, this enables a word by word analysis in a consistent and robust manner. Nevertheless, the task remains challenging given the subjectivity of the annotations.

<sup>1</sup>The opposite strategy, discarding words if not all their characters were marked as toxic was also studied but rejected as performed poorer.

### 3.3 Preprocessing

Once data is cleaned and before feeding it to the models, we lower case the text and tokenize it using WordPiece (Wu et al., 2016), the tokenizer used by BERT-based models, which splits text into (usually) sub-word units. Each of these units has its associated token embedding at the first layer of the respective models.

In this step, we also use the information of the already-cleaned toxic offsets to create a per-token binary label regarding its toxicity.

### 3.4 Models

**LSTM** Long Short-Term Memory was introduced in 1991 by Hochreiter and Schmidhuber (1997) as an extension of recurrent neural networks (RNNs), providing them with the ability to capture and memorize long-term dependencies and therefore help prevent the vanishing/exploding problems (Bengio et al., 1994; Pascanu et al., 2013).

We use an LSTM tagger as our baseline model to determine the lower bound performance that we should compare with. We use it as a first approach to solve the task, even though we know that the sentences of the dataset might be too long for the network to memorize and capture all long-term dependencies and the entire sentence context. As input for this model, we use pre-trained word embeddings from GloVe (Pennington et al., 2014).

**Attention-based models** In 2018, Google Research released Bidirectional Encoder Representation from Transformer (BERT) (Devlin et al., 2019) which achieved many state-of-the-art results on different NLP tasks. This success led to the creation of a lot of new models and improvements based on the BERT architecture: DistilBERT, RoBERTa, ALBERT, ... This architecture uses the same multi-head transformer structure presented by Vaswani et al. (2017), which is basically composed of several stacked Transformer blocks/encoders, including self-attention and feed-forward modules. These help the model obtain richer word representations by finding correlations with other tokens in the sentence.

For our task, we use two BERT-based models, BERT and DistilBERT, with a token classification head –a linear layer on top of the hidden state output of the last Transformer encoder–. These models are pre-trained on huge corpus from different sources and fine-tuned for our downstream task.

**Multi-depth models** Based on the previously presented BERT-like models, we implement a modification that consists in feeding the classification layer an augmented embedding for each token. This augmented embedding is formed by concatenating the hidden outputs of different Transformer blocks, instead of using the last output directly as done in common models for token classification. The empirical results show that using embeddings from different layers provides better representations and boosts the model’s performance.

### 3.5 Postprocessing

Once a model outputs its predictions, we loop through them and, for those tokens predicted as toxic, we take their offsets and add them to the final set of toxic spans for that sentence.

Additionally, we add a postprocessing step to increase the correctness of our predictions regarding white characters. These are not returned as tokens by the tokenizer but occupy a character offset. For this reason, for each pair of consecutive tokens predicted as toxic, we also include to the final set the offsets of any white characters in between.

## 4 Results

All the results presented in this section have been calculated using the official metric, the F1-score on the predicted toxic offsets. For detailed information please refer to Pavlopoulos et al. (2021).

### 4.1 Model Comparison

In Table 1 we report the results for the best configuration of each of our models both in the official trial and test sets. In these results, we can first note that all the models clearly outperform our baseline. Moreover, using the information of multiple layers is proved to be beneficial for this task, as it improves each of the respective base models, by 0.64% - 1.42%. Finally, note that although BERT is larger and more powerful than DistilBERT, it performs poorer in the test set. This might be due to the fact that we select our hyperparameters based on the F1-score on the trial set, which is relatively small and may not be representative of the test data. For this reason, our submitted model is a multi-depth DistilBERT, as it provides better generalization within this task and data.

### 4.2 Layer Selection

In this study, we have trained a multi-depth DistilBERT using the outputs of different layers or trans-

Model	F1-score (trial)	F1-score (test)
LSTM (baseline)	61.36%	62.06%
DistilBERT	69.04%	67.43%
BERT	69.22%	66.45%
Multi-depth DistilBERT	69.68%	<b>68.22%</b>
Multi-depth BERT	<b>70.01%</b>	67.87%

Table 1: Performance comparison for various architectures in the official trial (used as validation) and test sets.

former blocks to study its impact on the model’s performance.

Table 2 shows the results for different experiments in which we have concatenated the outputs of the last  $N$  layers of DistilBERT before feeding these enlarged hidden states to the fully connected layer that performs classification.

Results show that performance can be improved by adding different block’s outputs, but can also degrade when using too many. For DistilBERT, which has 6 transformer blocks, the sweet spot seems to be using the last 3 layers. Using all 6 also provides good results, which may imply that the first layer’s output is also quite informative for this task in which words themselves already help predicting their toxicity.

Last N layers	F1-score (trial)
1	69.04%
2	69.48%
3	<b>69.68%</b>
4	69.11%
5	68.94%
6	69.48%

Table 2: Performance comparison for multi-depth DistilBERT in the trial set using the concatenation of the last  $N$  layer’s outputs for the final classification.

### 4.3 Ablation Study

In these experiments, we took apart one component of our system at a time to see its effect on the system’s performance. The main components of our method are presented in Section 3, and details about our implementation can be found in Appendix A.

Table 3 shows the results for this study, in which we can easily see that all components work towards the performance of our model. Apart from the multi-depth component, which has already been studied, Dropout has been key for our giant model to generalize and prevent overfitting the small data.

Using Label Smoothing has also helped, letting the model adapt to the intrinsic subjectivity of the annotations.

Regarding data preparation, it can be seen that the cleaning step has been crucial for the good performance of our system, supporting the known quote “Garbage in, garbage out”. Finally, our simple postprocessing stage has also provided some tenths to the final performance.

Model	F1-score (trial)
Multi-depth DistilBERT	<b>69.68%</b>
(ours) – Multi-depth	69.04%
(ours) – Dropout	68.25%
(ours) – Label Smoothing	69.17%
(ours) – Data Cleaning	66.44%
(ours) – Postprocessing	69.38%

Table 3: Ablation study on the system’s components. ‘–’ means leaving that component out. Results for the official trial set.

### 4.4 Ensemble

Given the results we obtained with single models, we found it interesting to mix some of them to see if they were focusing on different parts of data and could improve the predictions while working together.

Following this idea, we created a simple majority-voting ensemble using the multi-depth models with “last  $N$  layers” for  $N = 1, 3, 6$ ; this is, a base DistilBERT, a model that concatenates the output of the last 3 transformer blocks and another one that uses all 6 layers of DistilBERT.

The final result for this ensemble is 69.34% in the trial set –used as validation– and **68.54%** in the test set, our best submission. Note that although being worse than our best single model in the trial set, it has better generalization skills and boosts the performance in the unseen test set.

## 4.5 Qualitative

Apart from the quantitative analysis done before, we analyze in a qualitative manner the performance and behaviour of our best model, to see how well it detects offensive and toxic words and in which cases it fails.

Below we present some examples of sentences in the dataset together with their ground truth spans and the detection done by the model. The ground truth toxic words appear underlined while the **prediction** is shown in red.

**Correct predictions** We observe how our system is highly capable of identifying toxic and offensive words, both when they appear alone and in multi-word expressions.

- Billy, are you a complete **idiot**, being thick headed or just not reading what people...
- People insist on being **dumb**. No other explanation.
- Could you please **kill yourself**?

**Wrong predictions** However, our system also fails in some challenging comments. As seen below with the word “poorly”, our method misses some words marked as toxic which are not very offensive or disrespectful but can become toxic due to the context.

- People don’t buy that **poorly** built Russian houses...

In other cases, our system identifies toxicity when it is not annotated, although under our perspective the prediction seems correct. This could be due to the ambiguity of the task or inconsistencies in the annotations. An example of it is the expression “freaking donkeys”:

- These **freaking donkeys** all need to be removed from office. I’m so sick and tired of...

Finally, our model fails to detect connectors such as “of” and “and” in between toxic words. In the dataset there are several annotation philosophies: some annotations tend to mark entire expressions as toxic and some others are more word-oriented, excluding connectors between words.

- Are these some of those Russian **pieces of crap** that they seem to be building all over Alaska.

**Ethical concerns** While doing the qualitative analysis we found several examples indicating that there could be racial bias in the predictions of our model, and although it is beyond the scope of the challenge, we found it important to pay attention to it. For this reason, we took some examples from the trial set containing comments about races and changed the words referring to races or origin by others. Below we show an example. The first comment belongs to the competition dataset, while the other is a modification of it, with words “black” changed for “white” and vice versa, and “Mexican” changed for “American”.

- **Black** folks built this nation and got **lynching** for the work. Heck, white folks can be so mean that when they lost their slaves they invited **illegal Mexican immigrants** to do the work black slaves use to do.
- White folks built this nation and got **lynching** for the work. Heck, black folks can be so mean that when they lost their slaves they invited **illegal American** immigrants to do the work black slaves use to do.

We observe that in both cases the system identifies the word “black” as toxic, but not “white”, even when these non-toxic adjectives are the only difference between them. Furthermore, the system only identifies “immigrants” as toxic when appearing next to “Mexican” but not with “American”.

This undesired discrimination happens because there are lots of racist comments in the dataset, which are obviously annotated as toxic. Given that it seems there are more comments against some specific ethnic groups than others, the system associates certain racial references with racism and thus with toxicity.

This is a problem that comes from the data, including the one used in the pre-training phase of BERT models. However, there are several de-bias techniques in the literature (Manzini et al., 2019; Sun et al., 2019; Liang et al., 2020) that could be applied to our model to alleviate it.

## 5 Conclusion

In this work, we have presented a solution for the SemEval-2021 Task 5: Toxic Spans Detection competition, which is a challenging task due to the subjectivity of toxicity and the requirement of context knowledge.

During the development of our solution, a multi-depth DistilBERT model, we have proved the power of pre-trained models and transfer learning to a downstream task with limited data, at the same time that we have demonstrated the benefits of combining the outputs of multiple BERT models' layers for token classification.

With an F1-score of 68.54% the presented model ranks 14 out of 91 participating teams in the competition and, although it presents some racial bias that could be corrected, from the qualitative results we conclude that it has a very good performance, hence being able to be used in real-life applications.

## Acknowledgments

We would like to thank the SemEval-2021 organizers for their effort in preparing the challenge and their help during the competition, as well as the reviewers for their constructive comments. We are also deeply grateful to Jordi Armengol-Estapé from Barcelona Supercomputing Center (BSC) for providing valuable insight into our project.

## A Implementation Details

We have developed this project using PyTorch<sup>2</sup> and the Huggingface<sup>3</sup> implementation of transformers. Specifically, we have used BertModel and DistilBertModel pre-trained models.

Although Huggingface includes models for token classification, the input dimension for their classification layer is exactly 768 (for BERT and DistilBERT), the dimension of the Transformer blocks’ output. However, in our case, we are concatenating different outputs, so these dimensions will vary from one experiment to another. To mimic their token classification models, we manually add a Dropout layer and the final classification layer with the appropriate input dimension (in our case  $768 \times \text{\#concat\_outputs}$ ).

To train the models we use Cross Entropy Loss with Label Smoothing. This type of regularization slightly changes the target vector, asking the model to predict  $1 - \epsilon$  for the correct class and  $\epsilon$  for the others instead of the usual hard assignment of 1 for the true class. As seen in Section 4.3, this technique helps the system improve as it helps modelling the intrinsic subjectivity of the data. For our best models we use  $\epsilon = 0.1$ .

We perform from 4 to 8 training epochs with Adam optimizer, learning rate  $10^{-5}$ , batch size of 8 and 25% dropout rate. Finally, we select the epoch with the best F1-score at trial set as our best checkpoint.

We keep the default values for the rest of parameters.

Each model has required approximately 15 minutes of training time on an NVIDIA Tesla V100 GPU. With the same hardware, the inference time is 430ms per sentence, so our system is able to work in Near Real Time (NRT).

# Lone Pine at SemEval-2021 Task 5: Fine-Grained Detection of Hate Speech Using BERToxic

Yakoob Khan, Weicheng Ma, Soroush Vosoughi

Department of Computer Science, Dartmouth College

{yakoob.khan.21, weicheng.ma.gr, soroush.vosoughi}@dartmouth.edu

## Abstract

This paper describes our approach to the *Toxic Spans Detection* problem (SemEval-2021 Task 5). We propose **BERToxic**, a system that fine-tunes a pre-trained BERT model to locate toxic text spans in a given text and utilizes additional post-processing steps to refine the boundaries. The post-processing steps involve (1) labeling character offsets between consecutive toxic tokens as toxic and (2) assigning a toxic label to words that have at least one token labeled as toxic. Through experiments, we show that these two post-processing steps improve the performance of our model by 4.16% on the test set. We also studied the effects of data augmentation and ensemble modeling strategies on our system. Our system significantly outperformed the provided baseline and achieved an F1-score of 0.683, placing Lone Pine in the 17<sup>th</sup> place out of 91 teams in the competition. Our code is made available at <https://github.com/Yakoob-Khan/Toxic-Spans-Detection>

## 1 Introduction

The promotion of respectful discourse has always been a core tenet of civilized societies. The Cambridge dictionary defines hate speech as “public speech that expresses hate or encourages violence towards a person or group based on something such as race, religion, sex, or sexual orientation.” Online platforms enable malicious actors to hide behind a cloak of anonymity and surreptitiously post toxic comments that are a “menace to democratic values, social stability and peace” (United Nations). To combat this problem, such platforms often employ human moderators to address offensive content that goes against community standards. However, moderators are unable to manually keep pace with the large volume of user-generated content today. This motivates the development of natural language processing systems to automatically detect hate speech

and ensure that online platforms remain healthy and inclusive for all.

There has been extensive research on hate speech detection, with the creation of large datasets (Wulczyn et al., 2017) and the use of pre-trained text representations (Devlin et al., 2019) for varied modeling approaches. Competitions on offensive language identification (Zampieri et al., 2020) have further attracted attention to this topic. Prior work has hitherto focused on classification at the document-level based on various taxonomies, such as whether a given text contains offensive language or if it is targeted towards an individual or group. This line of inquiry does not identify the toxic spans that ascribe a text as hate speech. Doing so will assist human moderators to efficiently locate offensive content in long posts and elucidate further insight into hate speech explainability.

This motivated the *Toxic Spans Detection* task (Pavlopoulos et al., 2021) where systems are asked to extract the list of toxic spans that attribute to a text’s toxicity. Consider the following example<sup>1</sup>:

<b>Text</b>	Because he’s a <b>moron</b> and <b>bigot</b> . It’s not any more complicated than that.
<b>Span</b>	[15, 16, 17, 18, 19, 27, 28, 29, 30, 31]

Table 1: A sample example from the task dataset.

As there are two toxic spans in the above text, systems are tasked to extract the character offsets (zero-indexed) corresponding to the sequence of toxic words. This is a challenging task as classification at the word-level is inherently more difficult than at the document-level. The intentional obfuscation of toxic words, use of sarcasm and the

<sup>1</sup>We caution readers that the examples included in this work contain explicit language to illustrate the severity and challenges of hate speech detection.

subjective nature of hate speech further adds complexity to the problem.

Our contributions to the task is threefold:

1. We propose **BERToxic**, a system that fine-tunes a pre-trained BERT model with additional post-processing steps to achieve an F1-score of 0.683, placing Lone Pine in the 17<sup>th</sup> place out of 91 teams in the competition.
2. We study the effects of simple data augmentation strategies on our system and find that they yield no improvement in classification performance.
3. We examine late fusion and multi-task learning neural architectures and conclude that they under-perform compared to the standalone BERT model for this task.

## 2 Our Approach

### 2.1 Baselines

To have a better sense of our final system’s performance, we initially examined two baseline models. First, we created a trivial model that randomly predicts each character offset of a text as toxic if its  $\rho > 0.5$ , drawn from a continuous uniform probability distribution.

To have a stronger baseline model, we fine-tuned the off-the-shelf spaCy NER model provided by the task organizers. This model consists of a multi-hash embedding layer (feed-forward sub-network) that uses sub-word features and an encoding layer consisting of a CNN and a layer-normalized max-out activation function. The model uses a transition-based algorithm that assumes that the “most decisive information” regarding the entities “will be close to their initial tokens”, with a loss function that optimizes for whole-entity accuracy.

### 2.2 BERToxic

We framed the toxic spans detection task as a sequence labeling problem and leverage the **B**idirectional **E**ncoder **R**epresentation from **T**ransformers (Devlin et al., 2019) model to extract rich feature representations from the input texts.

The first step in the BERToxic system pipeline (Figure 1) was to tokenize the text inputs and generate the word embeddings using BERT’s WordPiece tokenizer. This sub-word tokenization algorithm (Schuster and Nakajima, 2012) tokenizes a word like "moron" into ["mo", "##ron"] and we

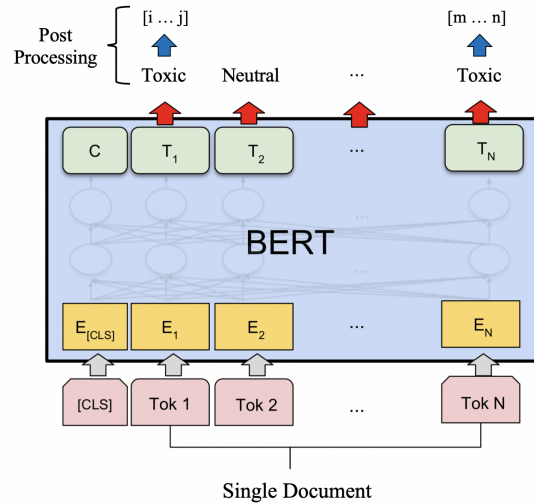

Figure 1: The BERToxic model architecture. Image modified from (Devlin et al., 2019).

ensured that the ground truth labels were preserved across all tokens of a word. As BERT uses absolute position embeddings, we padded shorter sequences with [PAD] tokens on the right side such that all tensor inputs are set to equal the maximum sequence length observed for batched parallelized training. Long sequences were truncated to 512 tokens, the maximum sequence length allowed by BERT. As the data was obtained from online comments that are generally shorter in nature, the truncation procedure was not needed in this task but nevertheless served to handle long sequences if present. We also stored the mapping

$$\mathcal{M} : t_i \mapsto (start_i, end_i)$$

of each token to its relative character offsets in the original string, used for outputting the toxic span predictions at the post-processing stage.

We performed all of our experiments using the BERT<sub>BASE</sub> model architecture that consisted of 12 layers, 768 hidden size, 12 self-attention heads and 109M parameters. The BERT<sub>LARGE</sub> model was not explored in this work due to its compute-intensive nature. Our intuition suggested that letter casing could be helpful for this task as proper nouns (e.g *Muslim*) can be used offensively, so we selected the cased model for our experiments. A token classification head containing a linear layer was applied on top of the final hidden-states output, with a label prediction of 1 denoting a toxic token, 0 otherwise. For each token  $t_i$  labeled as toxic, we utilized  $\mathcal{M}$  to output all character indices in the range of  $(start_i, end_i)$  inclusive as the toxic span

of this token.

Additionally, our system performed two post-processing steps to refine the boundary predictions. Consider the following tokenized sequence:

$$t_1, \dots, t_i, t_{i+1}, t_{i+2}, \dots, t_n$$

First, for any two consecutive tokens  $t_i$  and  $t_{i+1}$  whose prediction labels are toxic, we output the character indices in the range of  $(end_i + 1, start_{i+1} - 1)$  inclusive as toxic as well. This had the effect of including the delimiter characters between consecutive toxic words, thereby detecting toxic phrases. Second, recall that BERT’s WordPiece tokenizer could split a word into multiple tokens, say  $t_i, t_{i+1}$  and  $t_{i+2}$ . If at least one token was predicted toxic by the model, our system assigned a toxic label to all constituent tokens of this word. This achieved coherence in the prediction of toxic words and phrases, thus avoiding incomplete word piece issues.

We also attempted to vary the thresholds of the confidence scores before SoftMax for toxic token predictions but observed no improvement in performance.

### 2.3 Data Augmentation

Data augmentation is widely used to improve the generalization of models by acting as a regularizer to reduce overfitting. While various sophisticated techniques exist to artificially enhance the size and quality of the training set without collecting additional manually labeled examples, we chose to apply the set of **Easy Data Augmentation** (EDA) techniques (Wei and Zou, 2019) to generate synthetic training data for this task.

The four operations in EDA are Synonym Replacement (SR) using WordNet (Miller, 1995), Random Insertion (RI), Random Swap (RS) and Random Deletion (RD) of words in a document. Shorter documents are disproportionately more affected by these operations if a fixed number of words are modified per document. To ensure that all documents experienced the augmentation strength proportionately, the number of words  $n$  modified was varied based on the document length  $l$  using the formula  $n = \alpha \cdot l$ , where  $\alpha$  is a hyperparameter that indicates the percentage of words changed per document. Each operation was applied once per document and care was taken to ensure that the ground truth labels were preserved.

Our experiments revealed that the recommended value of  $\alpha = 0.1$  was too low for this task and

we observed small but consistent improvements as  $\alpha$  increases. Furthermore, we noted that the SR technique alone leads to better performance than using all four operations to create the augmented training set for this task.

We also attempted data augmentation using an external dataset, HateXplain (Mathew et al., 2020), that contains 20,148 documents with word-level annotations that we processed to conform to this task’s data format. Each document consisted of 2-3 annotations and we used their intersection to maximize the inter-annotator agreement in constructing the ground truth labels. HateXplain’s annotation strategy appeared to be different and included labeling pronouns, conjunctions and stop words as toxic when located between offensive words. We removed such toxic labels so that the external dataset annotation was more similar to this task. When our task dataset was augmented with the full external dataset, the model experienced underfitting, while removing all the non-toxic labeled documents from the external dataset alleviated the issue to some extent.

### 2.4 Ensemble Modeling

Ensemble modeling is an approach where multiple different models are trained and their predictions are aggregated. By adding bias to counter the variance of a single model, this line of work has been shown to improve the predictive performance of a system (Liu et al., 2019). While numerous ensemble modeling techniques like boosting, bagging, etc. exist, we investigated two techniques of interest: late fusion and multi-task learning.

We reframed the problem as a binary classification task and trained a sequence classifier to predict whether a given sentence is toxic. In the late fusion approach, we utilized NLTK’s tokenizer to split each document into sentences. If a sentence contained a ground truth toxic span, we assigned the toxic class label 1, 0 otherwise. In this way, a binary classification dataset was created to separately fine-tune a pre-trained BERT sequence classifier. We hypothesized that token labels should be predicted toxic only if the corresponding sentence was classified as toxic as well. Late fusion was performed at the prediction phase, where both the sequence and token classifiers voted in the predictions by having the former model filter toxic sentences on which the latter model made final toxic span predictions.

Rather than fine-tuning the two models separately, we also investigated if multi-task learning (MTL) improved the predictive performance of the ensemble model. We hypothesized that a training regime where the two classifiers were learned jointly could be useful as the knowledge gained in learning one task could benefit the other. To perform MTL, we fine-tuned an MT-DNN (Liu et al., 2019) model where the text encoding lower BERT layers are shared across the two tasks while the top layers are task-specific.

### 3 Experiments

The following sections describe the experimental set-up of our work.

#### 3.1 Dataset

The task data was sourced from the Civil Comments dataset (Borkan et al., 2019), which contains public comments made between 2015 - 2017 that appeared on approximately 50 English-language news sites across the world. As the original dataset contained only document-level class labels, the task organizers selected a subset of the data for crowd-sourced toxic spans annotation. For the data split, we chose to fine-tune our models using the entire provided training dataset ( $N = 7939$ ) to maximize performance, validate using the trial dataset ( $N = 690$ ), and submit our predictions using the test data ( $N = 2000$ ). The test labels were withheld during the evaluation phase of the competition and were only released afterward.

#### 3.2 Evaluation Metric

To evaluate the performance of the models, the task organizers employed a variant of the F1-score (Da San Martino et al., 2019). For a document  $d$ , define  $S_d$  as the set of toxic character offsets predicted by a system and  $G_d$  as the set of ground truth annotations. Then the F1-score of the system with respect to ground truth  $G$  for  $d$  is defined as

$$F_1^d(G) = \frac{2 \cdot P^d(G) \cdot R^d(G)}{P^d(G) + R^d(G)}$$

where

$$P^d(G) = \frac{|S_d \cap G_d|}{|S_d|}$$

$$R^d(G) = \frac{|S_d \cap G_d|}{|G_d|}$$

If a document has no ground truth annotation ( $G_d = \emptyset$ ), or the system outputs no character offset

prediction ( $S_d = \emptyset$ ), we set

$$F_1^d(G) = \begin{cases} 1 & G_d = S_d = \emptyset \\ 0 & otherwise \end{cases}$$

We finally take the arithmetic mean of  $F_1^d(G)$  over all the documents of an evaluation dataset to obtain a single F1-score for the system.

### 3.3 Implementation Details

We utilized the PyTorch framework for the development of our system, HuggingFace’s transformers library (Wolf et al., 2020) for the BERT-based models and Microsoft’s implementation of the MT-DNN model. All models were trained on Google Colab Pro’s High-RAM environment using a single NVIDIA P100 GPU. The training policy used the following hyper-parameters: batch size of 16, sequence length of 512, weight decay of 0.01. For optimization, we used Adam with a learning rate of  $5e-5$  and a linear warm-up schedule over 500 steps. Except for MT-DNN<sup>2</sup>, all our models were fine-tuned for approximately 2 epochs and we practiced early stopping by monitoring the dev F1-score to reduce overfitting. The EDA experiment was performed with  $\alpha = 0.8$  using only the SR technique. All other hyper-parameters were set to their default values according to HuggingFace’s implementation. We set a random seed for all our experiments and open-sourced the code for reproducibility.

## 4 Results

On the following page, Figure 2 visualizes the precision-recall curves<sup>3</sup> of all the models and Table 2 summarizes their performance metrics. Figure 3 shows the confusion matrix of our best performing BERToxic model and Table 3 highlights selected predictions that it made.

An interesting observation we noted from Table 2 was that the F1 scores for the test set were higher than the dev set for many of the models. We hypothesize that this is because the models have an inductive bias to predict shorter toxic spans, evidenced by the average ground truth span length of 7.2 in the test set and 14.7 in the dev set.

<sup>2</sup>MT-DNN was fine-tuned for 3 epochs with a batch size of 8.

<sup>3</sup>The curves for the spaCy and BERT multi-task model are less detailed due to the ambiguity in obtaining the probability scores from their respective implementations, necessitating the use of their predicted labels instead.

Model	Dev			Test		
	Precision	Recall	F1	Precision	Recall	F1
Random	0.143	0.463	0.175	0.089	0.413	0.122
SpaCy	0.692	0.588	0.595	0.664	0.686	0.656
BERToxic	0.781	0.678	0.681	0.683	0.732	<b>0.683</b>
+ EDA	0.787	0.683	0.684	0.681	0.725	0.678
+ HateXplain	0.792	0.674	0.681	0.683	0.721	0.678
BERT late fusion	0.733	0.636	0.639	0.675	0.709	0.669
BERT multi-task	0.744	0.629	0.634	0.665	0.694	0.656

Table 2: A summary of the performance of all our models, reporting the precision and recall scores along with the F1 evaluation metric used for the competition. The BERToxic model outperformed the strong spaCy baseline by 4.16% on the test set, placing Lone Pine in the 17<sup>th</sup> place out of 91 teams. In comparison, the top-ranked submission achieved an F1-score of 0.708. The experiments revealed that our data augmentation and ensemble modeling strategies did not outperform the standalone BERT model.

Our proposed system performed well at the toxic spans detection task, showing strength in identifying profanity and common toxic words like “idiot” and “stupid”. The model identified the obfuscation of offensive words and successfully detected hate speech from such adversarial cases (Example 1).

1. Kill this *F'n W\*ore* on site.
2. .. how I am an *ignorant fool* ..
3. *Nazi boneheads* deserve being *punched*.
4. @remoore *Shut up, racist*.
5. *Cruz is a piece of garbage a globalist fraud*

Table 3: Selected examples obtained from the test set. BERToxic’s predictions are shown in red while ground truth annotations are *italicized*.

The error analysis revealed that the system lacked nuance as it would sometimes classify toxic words used in neutral contexts (Example 2). It is also worth mentioning that there was considerable noise in the ground truth annotations. Our manual inspections concurred with the model’s predictions that some words and phrases were used in offensive contexts but the annotators thought they were neutral (Example 3 and 4). Furthermore, we observed some inconsistencies in the labeling scheme as some annotations spanned entire sentences (Example 5) while others only highlighted a few words in the sentence. These issues point to the subjective nature of hate speech and the challenges involved in its fine-grained classification.

We found through our ablation studies of data augmentation that generating synthetic data using

Figure 2: Comparison of the precision-recall curves of all the models at the token level on the test set. The area under the curve is enclosed within parentheses.

Figure 3: A confusion matrix of the BERToxic system at the token level, revealing insights about the classification performance in each category and highlighting the imbalance of the class labels in the test set.

the EDA techniques did not improve the performance of the system. This suggested that the dataset size does not appear to be the limiting factor affecting the performance of BERT in this task. Using HateXplain’s external dataset, we learned that different data sources and annotation guidelines can introduce noise that hurts the performance of models.

Finally, the ensemble modeling strategies we explored did not outperform the standalone BERT model. The late fusion technique performed slightly better than the spaCy baseline, but it seemed that the sequence classifier made errors on similar parts of the input space as the token classifier. The multi-task learning approach underperformed compared to late fusion, suggesting that the sequence labeling and classification tasks are not closely related enough to benefit their joint training.

## 5 Conclusion and Future Work

In this work, we have proposed BERToxic, an empirically powerful system that performed fine-grained detection of hate speech. We found that our exploration of data augmentation and ensemble modeling strategies did not outperform the standalone model. The error analysis revealed that BERT lacked nuance in understanding the use of offensive words in neutral contexts and encountered boundary detection issues when faced with noisy ground truth annotations.

Future avenues of work could address these limitations and explore other transformer-based models to develop more robust hate speech detectors. We hope that our findings inspire more creative approaches towards fine-grained detection of hate speech so that online discourse can remain healthy and inclusive for all.

## Abstract

This paper presents a system used for SemEval-2021 Task 5: Toxic Spans Detection. Our system is an ensemble of BERT-based models for binary word classification, trained on a dataset extended by toxic comments modified and generated by two language models. For the toxic word classification, the prediction threshold value was optimized separately for every comment, in order to maximize the expected F1 value.

## 1 Introduction

Freedom of speech is one of the most important human rights. However, because the definition of protected speech is not precise enough, it can be easily misinterpreted and misused. The problem is magnified in cyberspace, where anonymity and asynchronous communication contribute to toxic disinhibition. As a result, the Internet has become space where hatred, harsh criticism, rude language and threats may grow.

Currently, identification of such harmful content may depend mostly upon classification models that detect abusive comments or documents. However, SemEval-2021 Task 5: Toxic Spans Detection proposes detecting fragments of text that make it toxic, with the aim of supporting manual moderation of oftentimes lengthy comments. A successful solution to this problem would be a crucial step towards more constructive and inclusive online discussions. The task focuses on English, which is the most common language used on the Internet, as of January 2020 (Johnson, 2021).

In this paper we present the model we used for toxic span detection, the method we used to find optimal prediction threshold values, and two methods for producing new training examples with toxic spans annotation:

- Resampling the data: new examples are generated by substituting non-toxic words with predictions from a language model.
- Data generation: we trained a simple language model on existing examples, in order to generate new examples containing marked toxic spans.

A total of 91 teams made an official submission on the test set with the best submission achieving F1 score of 0.7083. Our approach was ranked as 11th with 0.6865 F1 score (for details see Section A of the Appendix).

## 2 Related Work

The interest in automatic identification of abusive language has increased among researchers due to the importance of public discussion in the Internet and its public impact. To our mind, the domain overlaps with other NLP tasks, such as sentiment analysis or comment classification.

In an earlier piece of work, (Yin et al., 2009) studied harassment detection on Web 2.0 datasets (i.e. Kongregate, Slashdot and MySpace) using TFIDF n-gram features and SVM models. In other research, (Sood et al., 2012a,b) analysed profanity detection in a community-based news site Yahoo!

Buzz with SVM and Levenshtein distance. In later studies, (Wulczyn et al., 2017) tried to understand personal attacks in English Wikipedia discussion comments using logistic regression and multilayer perceptron classifiers on character and word n-grams.

In the last years there were several contests focusing on various aspects of offensive language. One of them included hate speech (Bosco et al., 2018) and misogyny identification (Fersini et al., 2018) for Italian data. Another workshop concerning a similar topic was Multilingual Detection of Hate Speech Against Immigrants and Women in Twitter at SemEval-2019 (Garibo i Orts, 2019). Recently, research has focused mostly on deep learning classification of cyber hate using "accept"/"non-offensive" or "reject"/"offensive" classes, e.g. (Pavlopoulos et al., 2017). However, more and more papers concern explainability components and reasons. For example, organizers of SemEval-2019 Task 6, (Zampieri et al., 2019) required identification of the offensive content type and the target of the offensive post. In another study, carried out by (Mathew et al., 2020), aside from simple performance metrics, more complex bias and explainability factors were used to evaluate various deep neural networks models (CNN-GRU, BiRNNs and BERT). A similar idea – to clarify rationales for hate speech – comes in SemEval-2021 Task 5: Toxic Spans Detection (Pavlopoulos et al., 2021). Our solutions to this challenge are presented in this paper.

### 3 Data

There are several abusive language detection datasets available (such as (Wulczyn et al., 2017; Borkan et al., 2019)). However, their purpose is toxicity detection of the whole text, so they do not contain information about the exact spans that make a text toxic. For such a task, the SemEval-2021 Toxic Spans Detection dataset was created. It consists of 10,629 English texts and their relative lists of toxic spans' indices (7,939 train, 690 trial, and 2,000 test texts with their respective spans). Examples from the dataset are presented in Table 1.

The SemEval-2021 Task 5 annotated data turned out to be a challenging material to work on in some respects.

It results mainly from somewhat inconsistent annotation which is visible in several dimensions, see Appendix B.

## 4 System Overview

### 4.1 Resampled Data

The texts from train dataset were tokenized and the tokens that were not labeled as toxic spans were replaced with tokens suggested by a RoBERTa (Liu et al., 2019) language model. We set the limit of substituted words on 1/3 of all tokens outside the toxic span, but no more than 10. The replacement was not applied to the punctuation. Also, it was not possible to change the word to the same one, or to the word preceding the token in question. The tokens to be substituted are chosen randomly so it was possible to obtain different outcomes while processing the same text several times:

original text:

*Uh, yes he is **stupid**...as his actions have proven on countless occasions...*

generated:

*Uh, Donald Trump 's **stupid**...as recent history has shown in numerous occasions...*

*Uh, now that 's **stupid**...as my students proudly demonstrated in numerous occasions...*

*Uh, well that 's **stupid**...as Vikings fans themselves said in numerous occasions...*

### 4.2 Generated Data

The second method of expanding the original training dataset was inspired by the Ding et al. (2020) data augmentation method for the POS tagging. Firstly, the pairs of spans indices and texts from training data were encoded in linearized form, e.g. the original span and text pair:

"[9, 10, 11, 12, 13]", "One less **idiot** to worry about."

was transformed into text

"<s> One less <toxic> idiot </toxic> to worry about. </s>"

where <toxic>, </toxic> are special tokens which indicate the beginning and ending of a toxic span and <s>, </s> are special tokens indicating that this particular example is annotated. The set of such linearized training examples was extended by a dataset of the same size, containing unannotated examples from Civil Comment Dataset (Borkan et al., 2019) (with a different special starting token <u>). These examples were used to train a simple language model with 300-dimensional word embedding and two 256-dimensional LSTM layers. This language model was used to generate new sentences in linearized format, starting from the token <s> and randomly sampling next words from the

Text	Toxic span
What a pile of shit. I love Bruce and I could write a better case against Bruce than this rubbish !	[15, 16, 17, 18, 90, 91, 92, 93, 94, 95, 96]
What a jerk!	[7, 8, 9, 10]
Deep ecology madness is a sad sick religion.	[]

Table 1: SemEval-2021 Task 5 dataset examples.

model distribution until the ending token  $\langle /s \rangle$  is sampled or the generated text length exceeds 200 tokens. 10 000 of such generated examples were converted back into the format span + text and used for training the token classifier model.

### 4.3 Token Classification

To detect toxic spans within a text we use the Hugging Face (Wolf et al., 2019) implementation of the BERT model (Devlin et al., 2018). We approach the task as token classification. Therefore, there are additional layers on top of the model – a classification head (a one-dimensional linear layer on top of the hidden-states output), preceded by a 50% dropout layer.

### 4.4 Character Classification

The metric used for competition ranking was the mean value of character-level F1 score, as in (Da San Martino et al., 2019), so the token-level predicted probabilities from our model needed to be converted to character-level binary labels. The process included two stages.

- Assigning probabilities to text characters. Every character that is a part of a token is assigned the predicted probability of that token. All the other characters (e.g. whitespaces) are assigned 0.
- Choosing and applying the optimal threshold value for a given text example, based on the predicted characters probabilities. Characters with probabilities meeting this threshold are identified as being part of a toxic span.

The threshold value was optimized separately for every text example to maximize the expected value of character-level F1 score, where the F1 value for a predicted span is a random variable with respect to the distribution of golden spans.

Formally, for a given sentence composed of  $n$  letters, let's denote predicted labels (0 and 1) as  $s = (s_1, \dots, s_n)$  and golden labels as  $y = (y_1, \dots, y_n)$ .

Then the F1 measure for such prediction is

$$F_1(s, y) = \frac{2 \sum_{i=1}^n s_i y_i}{\sum_{i=1}^n s_i + \sum_{i=1}^n y_i}$$

If elements of  $s$  and  $y$  are indexed in order of decreasing probabilities of being toxic, and  $S_{i:j} = \sum_{k=i}^j y_k$ , then the expected value of  $F_1$  for the prediction with  $k$  most probable letters classified as toxic, is

$$f(k) = \sum_{k_1=0}^k \sum_{k_2=0}^{n-k} \frac{2P(S_{1:k}=k_1)P(S_{k+1:n}=k_2)k_1}{k + k_1 + k_2}$$

We approximated the distribution of the golden spans  $y$  by assuming that probabilities of characters in the golden toxic span are independent and equal to probabilities predicted by the model. This allowed us to use  $O(n^2)$  algorithm proposed by (Nan et al., 2012) to find the  $k$  which maximizes the  $f(k)$ .

### 4.5 Ensemble Models

On top of the plain prediction models we applied a selection of ensembles (Opitz and Maclin, 1999). Ensembles are aggregations of models solving the same problem, built with the hope that a panel of experts can give a better decision than a single one. In our case, the ensemble accepted character-level inputs from 2 to 9 participating models and returned a single character-level output. Among the available range, we used:

- set-theory union (i.e. at least one model declared a character as toxic),
- set-theory intersection (i.e. all models declared a character as toxic),
- majority voting (i.e. at least half of the models declared a character as toxic),
- F1-weighted voting (i.e. the vote was weighted with the model's F1 score and computed for the evaluation set),

The output of the ensemble still needed to be post-processed.

## 5 Experimental Setup

The officially released datasets (both train and trial) contained altogether 8,629 texts. From those datasets we generated nine random train/dev/test splits, with the ratio 80/10/10%.

From the train sets in each of the splits new data was generated using both methods described in 4.1: resampling data outside the span, and data augmentation. For resampling data, we used the BERT based model (uncased) model with BertTokenizerFast tokenizer or RoBERTa base model with RobertaFastTokenizer. The upper limit of changes in the text was equal to 10.

We trained the token classification model using only the train set, as well as the train set together with one or two sets of generated data. We used binary cross-entropy loss function and early stopping technique, ending the training after 3 consecutive epochs without the decrease of loss function on the dev set.

The other hyperparameters used in the training were: batch size: 8, dropout rate: 0.5, learning rate:  $1e-05$ , and max token sequence length: 340. We wanted to compare models trained on dataset with diverse sizes and, due to resampling, a lot of similar examples. To keep the evaluations for the early stopping in short and uniform intervals across all models we set a fixed number of steps per epoch: 800.

All the nine models obtained from given cross-validation splits were used for ensemble models. The best results were obtained via intersection and majority voting over models trained on cross-validation splits.

The final stage was postprocessing the spans. Whitespaces and punctuation characters that were the only characters separating two parts of toxic spans were included in the toxic span, while all the other whitespaces and punctuation characters located at the ends of spans were removed.

## 6 Results

The results of the models submitted to SemEval-2021 competition are presented in Table 2. All of the three models were trained on the official dataset and on data generated with resampling method. The results shows that adding more components of our system improves the final result. The first model is only token classifier model trained on enlarged dataset. When it comes to the second one, we used models trained on 9 different train/dev splits and

aggregated their results using ensemble. The last one was improved by the threshold optimization and additional data generated with language model.

We checked the results of token classifier trained with data obtain with the other tokenizers available, see Table 3. Our best result was obtained for XLMRobertaTokenizerFast and it exceeded our best result in the competition.

The results of the models trained on augmented datasets, either with or without optimization of the prediction threshold, are presented in Table 4. It can be observed that adding more noisy and automatically generated data to the training worsened the model results, making them more variable. The addition of the threshold that optimized the expected value of F1 metric independently on every test set example fixed both issues, producing models with higher and more stable results.

## 7 Conclusions

In many classification tasks we can observe a divergence of the objective function (e.g. F1 score), optimized loss function (e.g. cross-entropy) and applied prediction thresholds. Our results demonstrate that even when the distribution of golden classes is crudely approximated by the assumption of independent and underperforming underlying model, the F1-optimized threshold values perform better than commonly used and accuracy-optimized threshold of 0.5 in the setting with noisy and automatically augmented training data.

The implemented method of data augmentations, based on resampling non-toxic words proved to be effective by increasing the F1 score of token classifier.

Model	data augmentation	F1 on test data
BERT	resampled	0.6826
intersection ensemble over cv splits	resampled	0.6847
voting ensemble over cv splits, threshold optimization	resampled, generated	<b>0.6865</b>

## **A Our models results within SemEval-2021 Task 5 scores**

Figure 1 presents the outcome of SemEval-2021 Task 5 contest until the deadline and the green dot shows our best result at the time of publication.

## **B Original Dataset Inconsistency**

Firstly, there are words annotated as toxic in some comments, while in the other ones they are left out, despite the similar context of the utterance. The words “stupidity” or “crooked” can serve as an examples, sometimes being omitted, sometimes being treated as full toxic spans and finally, sometimes being treated as parts of toxic spans, together with their modifiers (see Table 5).

Another issue related to inconsistency is the length of the annotated span. The majority of spans consist of one to three words, but there are also cases in which spans are longer, containing not just a toxic word, but also a longer phrase including the toxic word (see Table 6). As previously, in our opinion the discrepancies are not justified by context.

Other issues we found peculiar in the provided annotation include annotating non-toxic words while omitting toxic ones (see Table 7) and beginning or ending the annotation in the middle of a word (Table 8). Such cases do not appear as often as the aforementioned discrepancies, but are also present.

Everything mentioned above might have been introduced to the dataset on purpose, as noise, in order to make the task more challenging to the models. However, we found the scale of the inconsistencies particular, the more so as it was not mentioned in the instructions for contest participants.

Figure 1: SemEval-2021 Task 5 results for models with scores  $\geq 50\%$  on the test dataset. The red dot points our model outcome until the deadline (F1=68.65%) and the green dot shows our best result at the time of publication (F1=69.09%).

Comment text (annotated spans in bold italics)
we dont need to move from anything other than left wing stupidity like yours (no annotation)
keep living in your left wing <i>stupidity</i> , there will be a market for our OIL from the SANDS for generations
oh more <i>left wing stupidity</i> ... colleges need to focus on educating and leave policy to the grown ups, like trump who is not banning anyone but suspending things
Unfortunately these people refuse to stand up to oppose the crooked self and friends rulers who don't hesitate to kill to kill them. (no annotation)
They were just <i>crooked</i> liars looking out for their own interests. Trump is way beyond that.
Now we will have endless <i>crooked honkey</i> lawyers talking unsuspecting "useful <i>idiots</i> " into filing outrageous claims.

Table 5: Examples of inconsistent annotation.

Comment text (annotated spans in bold italics)
I am watching Goodale on TV giving statements about this. <i>He is such an ass.</i> (17)
Saw him on the news. What an arrogant <i>arse!</i> (4)
<i>Trump's a liar</i> (14); <i>Trump's lawyer is a liar</i> (23). Get them outta there! Lock them up!
There is no indication that Trump will change from the <i>racist</i> (6), <i>sexist</i> (6), <i>demagogue</i> (9) that he is.
<i>The dotard almost forgot to sign it until his minder pulled him back</i> (68).
<i>Who gives a flying freak about what Kim and Park are making or not making? Really? This is what the SA chooses to write editorials about</i> (136)?
Trump simply does not care. "I am president, and to <i>hell</i> with all of you".

Table 6: Examples of inconsistency in regard to span length. The numbers in brackets indicate the number of characters within a given toxic span.

Comment text (annotated spans in bold italics)
I am totally with you on this continued stupidity that has been US policy, and now Hawaii's effort. I was a military officers wife expecting my second son, stationed in Germany at this time. As I recall, Kennedy gave Kruschev an opportunity to "save face". I doubt that Trump has the intelligence or skill, nor has he picked an intelligent UN rep. Or cabinet. This is where investigative journalism makes the difference. I am glad that Civil Beat is <i>challenging</i> the status quo mentality.
<i>Patriotism</i> : the last refuge of scoundrels..
Is this important news? Is it even <i>news</i> ? Who needs to know this <i>crap</i> ?
Yeah John, you tell all those <i>Chinese</i> and <i>Muslims</i> you hate to get the hell out of Canada.

Table 7: Examples of annotation of non-toxic words while omitting potentially toxic ones.

Comment text (annotated spans in bold italics)
It's so weird to have an actual <i>stupid narcissistic</i> childish person in the white house.
Yep you are <i>a sore loser</i>
The <i>hypocrisy</i> of the christian right is astounding.

Table 8: Examples of annotations starting or ending in the middle of a word.

Original annotation	Our re-annotation
“Watch people die from taking away their healthcare” DING DING DING! Winner of <i>stupid</i> post of the day award!	“ <i>Watch people die</i> from taking away their healthcare” DING DING DING! <i>Winner of stupid post of the day award!</i>
They’re not patriots. They’re vandals, <i>thieves</i> , and <i>bullies</i> . They’ve plastered a facade of patriotism over their outrage at being expected to obey the law.	They’re not patriots. <i>They’re vandals, thieves, and bullies.</i> They’ve plastered a facade of patriotism over their outrage at being expected to obey the law.
Rabidly <i>anti-Canadian</i> troll.	<i>Rabidly anti-Canadian troll.</i>

Table 9: Examples of differences between the original annotation and our re-annotation. The annotated spans are in bold italics.

## C Re-annotation

Because of inconsistencies in the original annotation, we decided to re-annotate the trial and test datasets and compare the differences. For this task we invited a team of 14 language experts (all of them with a master’s degree in linguistics). They received the same instruction as the one provided by the contest organizers. Each text was evaluated by three language experts, as in the original dataset creation process.

The differences between the original annotation and the one provided by our language experts are quite noticeable. Firstly, we believe our annotation is more coherent and involves fewer mistakes described earlier. Moreover, our language experts marked fragments as toxic more often: whole sentences, paragraphs or even whole comments, as well as more single words (see Table 9). The goal of our re-annotation was to evaluate the quality of the original datasets annotation and check if our understanding of toxicity is equivalent to the one of contest organizers.

# SINAI at SemEval-2021 Task 5: Combining Embeddings in a BiLSTM-CRF model for Toxic Spans Detection

## Abstract

This paper describes the participation of SINAI team at Task 5: Toxic Spans Detection which consists of identifying spans that make a text toxic. Although several resources and systems have been developed so far in the context of offensive language, both annotation and tasks have mainly focused on classifying whether a text is offensive or not. However, detecting toxic spans is crucial to identify why a text is toxic and can assist human moderators to locate this type of content on social media. In order to accomplish the task, we follow a deep learning-based approach using a Bidirectional variant of a Long Short Term Memory network along with a stacked Conditional Random Field decoding layer (BiLSTM-CRF). Specifically, we test the performance of the combination of different pre-trained word embeddings for recognizing toxic entities in text. The results show that the combination of word embeddings helps in detecting offensive content. Our team ranks 29th out of 91 participants.

## 1 Introduction

The advance of online communication has increased the use of offensive or toxic language in several websites, including social networks such as Instagram, Twitter, or YouTube. Consequently, this type of prejudiced communication could lead to negative psychological effects among Internet users, causing anxiety, harassment, and even suicide in extreme cases (Hinduja and Patchin, 2010).

Moderation is essential to promote healthy online communication. Therefore, governments, online communities, and social media platforms are continuously taking appropriate actions to implement laws and policies combating toxic language on the Web. In order to help to track this type of comments and due to the amount of data generated every day on the Web, automatic systems based

on Natural Language Processing (NLP) techniques are required. In particular, offensive language detection and analysis has become an important area of research in NLP, resulting in several studies that are contributing to combating this website phenomenon (Plaza-del Arco et al., 2019; Zampieri et al., 2019a; Ranasinghe et al., 2019; Plaza del Arco et al., 2020).

In this paper<sup>1</sup>, we present our proposal system as part of our participation in SemEval-2021 Task 5: Toxic Spans Detection (Pavlopoulos et al., 2021), which aims to identify entities that refer to a toxic language in the text. To accomplish the task, our team focused on detecting specific types of toxic entities in the text using a methodology based on the BiLSTM-CRF model showing that the combination of different pre-trained language embeddings succeeds in detecting toxic entities.

The rest of the paper is structured as follows. In Section 2 some previous related studies are introduced. In Section 3 we explain the data used in our methods and we describe the architecture of our proposed system to the Toxic Spans Detection task. In Section 4 we discuss the analysis and evaluation results for the experiments we performed. Finally, we conclude in Section 5 with remarks and future work.

## 2 Related work

Heretofore, several shared tasks have been organized in the NLP field to detect offensiveness on the Web for different languages. For instance, the well-known offensive language task OffensEval has held two editions in the International Workshop on Semantic Evaluation (SemEval) (Zampieri et al., 2019b,a) introducing as the main novelty in the second edition a multilingual dataset comprising 5

<sup>1</sup>NOTE: This paper contains examples of potentially explicit or offensive content which may be offensive to some readers. They do not represent the views of the authors.

languages. The GermEval shared task focused on the identification of offensive language in German tweets and comprised two tasks, a coarse-grained binary classification task and a fine-grained multi-class classification task (Wiegand and Siegel, 2018). For Spanish, as far as we know, the first task on offensive language appeared at the 3rd SEPLN Workshop on Evaluation of Human Language Technologies for Iberian Languages (IberEval) (Carmona et al., 2018) whose goal was to detect aggressiveness Mexican Spanish Tweets.

As a result, most of the studies and resources in offensive language research have been developed specifically for binary and multi-class classification tasks (Ranasinghe et al., 2019; Plaza-del Arco et al., 2019, 2020). However, other tasks such as Named Entity Recognition (NER) play an important role in this research and are essential to identify the entities that make a text toxic. Highlighting these toxic spans can help human moderators to interpret and identify easily this type of content on the Web instead of relying on a system that generates a score of unexplained toxicity per post. NER aims to identify and classify named entities mentioned in unstructured text into predefined categories. The earliest systems developed for addressing this task did not use training data but worked based on handcrafted features, heuristics, and a set of rules (Nadeau and Sekine, 2007; Collins and Singer, 1999; López-Ubeda et al., 2018). However, the cost of manual feature tagging and the poor obtained results lead to deep learning-based techniques as the most suitable choice to tackle the task by discovering patterns and learning the features in an end-to-end manner (López-Úbeda et al., 2020). Existing state-of-the-art approaches for sequence labeling have proven that Recurrent Neural Networks (RNNs) are capable of learning useful representations automatically as they enable the modeling of long-distance dependencies between words in a sentence (Limsopatham and Collier, 2016; Wintaka et al., 2019). Inspired by these studies, we have developed a system based on BiLSTM-CRF model along with the combination of different types of word embeddings to address the toxic spans detection task in text.

### 3 Named Entity Recognition Methodology

To address the toxic detection task, we focus on recognizing and extracting specific types of toxic enti-

ties in the text. Specifically, we follow a methodology proposed by (Huang et al., 2015) implementing a BiLSTM-CRF model for the NER task.

#### 3.1 Word Embeddings

As input layer of the BiLSTM-CRF neural network we have combined the following word embeddings:

- **Static Word Embedding.** We use GloVe embeddings which are static and word-level, i.e. each distinct word gets exactly one pre-computed embedding. This type of embeddings is context-independent (Pennington et al., 2014).
- **Contextual Word Embedding.** For our experiments, we tested two different contextual pre-trained word embeddings: BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2018) and XLM (Lample and Conneau, 2019). Unlike the previous ones, they are context-dependent which means they produce word representations that are dynamically informed by the words around them. They are based on the well-known Transformer (Vaswani et al., 2017), an attention mechanism that processes the entire text input simultaneously to learn contextual relations between words (or sub-words). Specifically, we used the *xlm-mlm-en-2048* model and the *bert-base-cased* model provided in HuggingFace (Wolf et al., 2019).

#### 3.2 BiLSTM-CRF architecture

We use the combination of bidirectional LSTM and CRF to identify the toxic spans. The context of each word in the sentence is captured by the BiLSTM and then the predictions on the entities are simultaneously performed in the CRF layer (Sutton and McCallum, 2006). The architecture of BiLSTM-CRF model is illustrated in Figure 1. This architecture follows a sequence of layers as follows:

- Embedding layer. Each word of the sentence is mapped to a vector of concatenated embeddings. As mentioned above, in our experiments, we use XLM, BERT, and GLOVE embeddings.
- BiLSTM layer. A bidirectional LSTM recurrent network takes as input the embeddings. In sequence tagging tasks, for a specific time

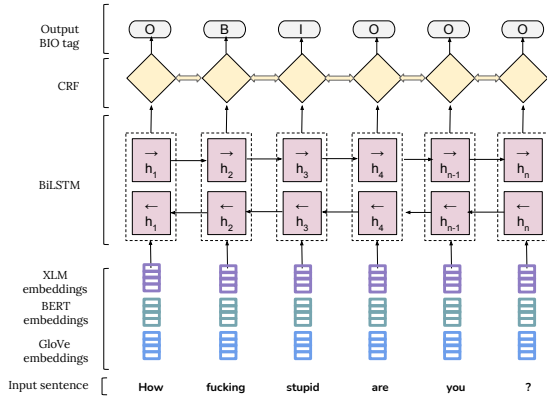

Figure 1: Proposed system architecture based on a BiLSTM-CRF neural network.

frame, this layer enables the hidden states to capture both historical and future context information and then to label a token.

- **CRF layer.** It allows to use efficiently historical and future tags to predict the current tag.

## 4 Data and Experimental Setup

### 4.1 Dataset preprocessing

We use the English dataset provided by the organizers in SemEval 2020 Task 5: Toxic Spans Detection. The dataset is split into three different subsets: train, trial, and test, consisting of 7,939, 690, and 2,000 instances, respectively.

Each instance in the dataset comprises two fields, the text and a list of toxic spans. A toxic span is defined as a sequence of characters in words that attribute to the text’s toxicity. If the text does not contain toxic spans, the span list is empty. An example of two instances in the dataset is provided in Table 1. In the first example, the word “crap” is labeled as toxic in the text, which has character offsets from 15 to 18. The second example includes the toxic span “idiot” which has character offsets from 4 to 8.

Text	Spans
What a load of <b>crap</b> .	[15, 16, 17, 18]
You <b>idiot</b> . The media went to war against truth.	[4, 5, 6, 7, 8]

Table 1: Two instances in the dataset. Toxic words are highlighted in the text.

To perform our experiments, we preprocess the subsets of the dataset in the following way. First,

we used the `nltk.tokenize` package<sup>2</sup> to tokenize the text. Then, we generated the following features for each text in the subset: the word, the position of the beginning and end of the word in the text, and the NER tag. In order to perform the NER tagging, we follow the BIO annotation scheme to label multi-token named entities (Ratinov and Roth, 2009), which represents that the label is the beginning of a span (B-Toxic), inside the span (I-Toxic), or belongs to no span (O). This scheme is the most popular in the NER task. Figure 2 shows an example of the features generated for the following example in the training set: “How fucking stupid are you?”, spans: [4, 5, 6, 7, 8, 9, 10, 12, 13, 14, 15, 16, 17].

How	0	3	O
fucking	4	11	B-Toxic
stupid	12	18	I-Toxic
are	19	22	O
you	23	26	O
?	26	27	O

Figure 2: Example of training set instance with generated features using BIO annotation scheme.

### 4.2 Experiments

During the pre-evaluation period, we trained our models on the train set and evaluated our different approaches on the trial set. During the evaluation period, we trained our models on the train and trial sets and tested the model on the test set.

Flair’s framework (Akbik et al., 2019) builds directly on Pytorch was used to design the BiLSTM-CRF network. We used the default hyperparameter setting in Flair with the following configuration: learning rate as 0.1, batch size as 32, dropout probability as 0.01, and maximum epoch as 300. All experiments (training and evaluation) were performed on a node equipped with two Intel Xeon Silver 4208 CPU at 2.10GHz, 192GB RAM, as main processors, and six GPUs NVIDIA GeForce RTX 2080Ti (with 11GB each).

Our team (SINAI) submitted 4 runs for the Toxic Spans Detection task and each run evaluates the word embeddings as an input to the BiLSTM-CRF network, as explained in Section 3.

#### Run 1. GloVe embeddings.

<sup>2</sup><https://www.nltk.org/api/nltk.tokenize.html>

**Run 2.** BERT embeddings.

**Run 3.** XLM embeddings.

**Run 4.** BERT + XLM + GloVe embeddings.

## 5 Results

In this section, we present the results obtained by our proposed system. In order to evaluate them, we use the official competition metric F1-score.

The results of our participation in the Toxic Spans Detection task during the evaluation phase are shown in Table 2. In particular, we list the performance of the four runs submitted using the BiLSTM-CRF model along with the combination of different word embeddings. If we analyze the results of the first 3 runs (each embeddings independently), we notice that they slightly differ, the best result is achieved by the contextual embedding XLM. However, training the model on the combination of static and contextual embeddings (GloVe, BERT, and XLM) leads to enhanced performance with a 0.6727 F1-score. Therefore, our results show the success of the combination of embeddings we chose to solve the task of toxic spans detection in comments using the proposed model.

Run	Word embeddings	F1-score
1	GloVe	0.6618
2	BERT	0.6606
3	XLM	0.6635
<b>4</b>	<b>BERT + XLM + GloVe</b>	<b>0.6727</b>

Table 2: Systems test results achieved by SINAI in SemEval Task 5: Toxic Spans Detection.

Table 3 shows the official rank in the competition. As we can see, we are ranked 29th out of 91 participating teams obtaining an F1-score of 0.6727 with our system. The best result was obtained by the team HITSZ-HLT with an F1-score of 0.7083, which differs from our results achieved by 3.56%. In general, low results for the task are obtained which shows the Toxic Spans Detection as a challenge to be addressed by the NLP community and, therefore, further research is needed to advance on this specific task. We also observe that the number of participants in this task is high (91) which shows the importance and interest of the NLP community in contributing to addressing this challenge.

User name (ranking)	F1-score
HITSZ-HLT (1)	0.7083
lmazxn (10)	0.6893
<b>SINAI (29)</b>	<b>0.6727</b>
UIT-ISE-NLP (63)	0.6223
ramya.akula01 (85)	0.1968
AmrHendy (91)	0.0675

Table 3: System Results per participating team in Task 5: Toxic Spans Detection.

## 6 Conclusions and Future Work

This paper presents the participation of the SINAI research group in Task 5: Toxic Spans Detection at SemEval 2021.

In this paper, we use a deep learning-based approach for NER to identify spans that make a text toxic, which focuses on the use of a BiLSTM-CRF neural network where different word embeddings are tested. The model is trained on the dataset provided by the organizers of the task (Pavlopoulos et al., 2021) and preprocessing techniques are carried out to tokenize and tagged the dataset by using the BIO scheme.

Our results show that the sophisticated BiLSTM-CRF architecture which has been successfully used for other tasks such as biomedical entity recognition or part-of-speech tagging, but also achieves remarkable results when addressing tasks related to the identification of offensive language in comments. Besides, we find that this architecture with our proposed combination of embeddings for word representation provides useful insights for the learning phase of the neural network achieving better results than training the network with a single type of word embedding.

For future work, we plan to study the performance of our proposed method using a variety of linguistic features, including emotions that are inextricably linked to offensive language.

## Acknowledgments

This work has been partially supported by a grant from the Ministry of Science, Innovation, and Universities (Scholarship FPI-PRE2019-089310), Fondo Europeo de Desarrollo Regional (FEDER), and LIVING-LANG project (RTI2018-094653-B-C21) from the Spanish Government.

## Abstract

The upsurge of prolific blogging and microblogging platforms enabled the abusers to spread negativity and threats greater than ever. Detecting the toxic portions substantially aids to moderate or exclude the abusive parts for maintaining sound online platforms. This paper describes our participation in the SemEval 2021 toxic span detection task. The task requires detecting spans that convey toxic remarks from the given text. We explore an ensemble of sequence labeling models including the BiLSTM-CRF, spaCy NER model with custom toxic tags, and fine-tuned BERT model to identify the toxic spans. Finally, a majority voting based fusion method is used to determine the unified toxic spans. Experimental results depict the competitive performance of our model among the participants.

## 1 Introduction

Social media being a key factor in the world dynamics and toxicity in user-generated contents is a real threat. Threats and hatred instigated in posts and blogs implants fear in users' minds and prevents them from sharing their creative thoughts, valuable opinions to critical information. Sometimes it leads to severe mental trauma and fatalities. Hence, it is a formidable task to precisely detect toxicity in comments and posts to be able to moderate those portions and provide the users a safe online platform to express themselves.

Toxic span detection is a process where the specific toxic segment of a text is detected instead of detecting the whole text as toxic. The goal of this task is to eradicate the vagueness that is present in simple toxic text classification models and help the moderator to precisely moderate the toxic portions instead of the whole post. To elucidate the task, two examples are presented in Table 1.

The first four authors have equal contributions.

---

**Text#1:** How fucking stupid are you?  
**Span:** [4, 5, 6, 7, 8, 9, 10, 12, 13, 14, 15, 16, 17]

---

**Text#2:** What a sociopathic and parasitic leader we have.  
**Span:** [7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 23, 24, 25, 26, 27, 28, 29, 30, 31]

---

Table 1: Example of sample texts with toxic spans.

Here, the “fucking stupid” portion of Text#1 is toxic and is attacking the personality of the second person, so the indices of this portion are included in the toxic span. In Text#2, the “sociopathic and parasitic” fragment is used as a toxic adjective to describe the leader in that context. Consequently, the indices of this fragment are incorporated in the span. We need to detect such spans accurately to remove toxicity from user content and preserve the safe and sound flow of online information.

Toxic content detection on online platforms is a state-of-the-art notion. Numerous works have been done on the binary and multi-label classification of toxic texts. For instance, Georgakopoulos et al. (Georgakopoulos et al., 2018) investigated the impact of CNN in toxic comment classification against the traditional bag-of-words approaches. A multiple word embedding-based approach was adopted by Carta et al. (Carta et al., 2019) for multi-class multi-label toxic comment classification. Besides, the effectiveness of feature extraction in hate speech detection was explored by Schmidt et al. (Schmidt and Wiegand, 2017). Multitude of datasets on toxic comments such as dataset based on Wikipedia discussion comments (Wulczyn et al., 2017), comments on online forums (Borkan et al., 2019a), and offensive language identification dataset (OLID) (Zampieri et al., 2019) were also introduced.

However, very few works detect the precise toxic span from text contents. Katsiolis et al. (Katsiolis, 2020) experimented on both unsupervised and su-

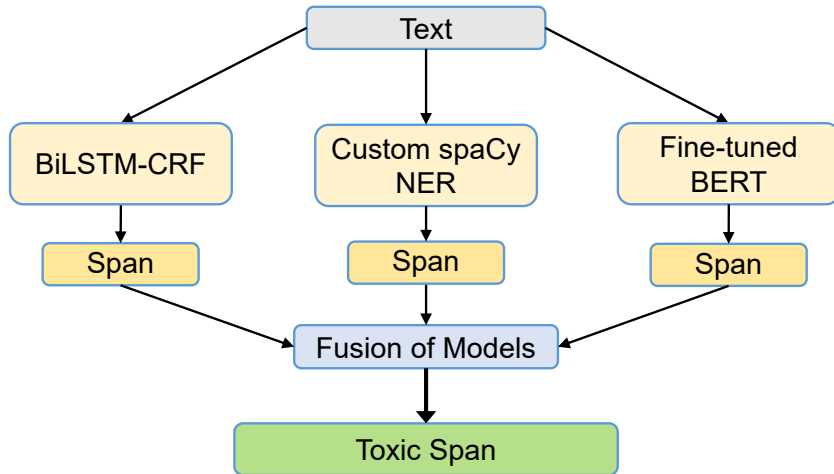

Figure 1: Overview of our proposed framework.

pervised methods to address this challenge. The unsupervised methods include the input erasure method and the LIME algorithm whereas the supervised method implements sequence labeling through a BERT model. The unintended bias created in publicly used toxicity detection models due to many reasons such as the influence of regional culture was investigated by Borkan et al. (Borkan et al., 2019a). John et al. (Pavlopoulos et al., 2017) surveyed the impact of user embeddings, user type embeddings, user biases, or user type biases on the RNN-based moderation method.

In this paper, we portray our insights acquired from experimenting on this task. We propose an approach focusing on an ensemble of sequence labeling models including the BiLSTM-CRF, spaCy NER model with custom toxic tags, and fine-tuned BERT model. We procure the spans from these models through a majority voting scheme to determine the final toxic spans.

The organization of this paper is as follows: we elucidate our proposed framework in Section 2. Section 3 encompasses the experimental details and comparative performance analysis. Finally, we conclude this paper with some future notions in Section 5.

## 2 Proposed Framework

We cast the toxic span detection as a sequence tagging task and employ an ensemble of sequence tagging models. Our proposed system comprises three individual models. The framework of our system is depicted in Figure 1. The first model is a BiLSTM-CRF model with the BIO tagging scheme. The second model is a custom spaCy named entity

recognition (NER) model. The third model is a fine-tuned BERT model for token classification. We leverage these three models as sequence tagging models. These models generate tags in token level for a text. Subsequently, we extract span based on the toxic tags. Finally, we apply a majority voting based fusion scheme on these spans and determine the final toxic spans.

### 2.1 BiLSTM-CRF

The BiLSTM-CRF model is well-known for sequence-tagging tasks such as named entity recognition (NER). We utilize the model implemented by (Reimers and Gurevych, 2017). For training purposes, the dataset needs to be in CoNLL-2003<sup>2</sup> format where two columns for tokens and BIO tags are required. Since it requires the text to be in a tokenized form, we tokenize the text using NLTK TweetTokenizer (Bird et al., 2009). After tokenization, we label the tokens with custom tags such as B-TOX(begin), I-TOX(inside), and O(outside) utilizing the toxic span from the training dataset. These tokens are then sent to the embedding layer. The embedding layer has three variants of embeddings: word embedding, casing feature or capitalization feature, and character embedding. We employ pre-trained GloVe (6B) (Pennington et al., 2014) word embedding and a CNN based character embeddings (Ma and Hovy, 2016). The embedding vectors are concatenated and the output is fed to the BiLSTM encoder which tags tokens with the BIO tagging scheme. The BiLSTM encoder is followed by a CRF classifier where the tags are optimized enforcing the intermediate logic of tags.

<sup>2</sup><https://www.clips.uantwerpen.be/conll2003/ner/>

## 2.2 Custom spaCy NER

We exploit the spaCy (Honnibal and Montani, 2017) to build an NER type sequence labeling model with the custom tag “TOXIC”. We convert the dataset to spaCy entity format and load a spaCy blank English model. We append new word vectors utilizing a pre-trained word2vec (Mikolov et al., 2013) model. Consequently, we add NER pipeline to the model and also a “TOXIC” label. We disable all the pipelines except NER and loop through the training dataset several times.

## 2.3 Fine-tuned BERT

We finetune the state-of-the-art bert-large-cased model (Devlin et al., 2019) to identify the toxic spans. We employ the BertForTokenClassification (Wolf et al., 2019) method to perform the token level tagging. This method classifies level for each tokenized word in a sentence. To generate the training data, we convert the sentence into tokens and annotate them with spans. We tag the tokens as “non-toxic” and “toxic” whereas the tokens that are tagged as “toxic” are in between the spans.

## 2.4 Fusion of Models

An ensemble approach is a simulation that constructs multiple models and then blends them to bring out improved results. To obtain a more accurate solution than a single model, we apply majority voting (Rokach, 2010) on the spans generated from three models as shown in Figure 1. The primary idea is based on the frequency of the span elements. If a span is predicted by at least two models, it is included in the final predicted span. Thus, we obtain our final toxic spans through majority voting.

# 3 Experiments and Evaluations

## 3.1 Dataset Description

For detecting toxic spans in posts, we used the Civil Comments Dataset (Borkan et al., 2019b) which consists of 10K toxic comments. The whole dataset is divided into three subsets where the train, trial, and test set comprises 7939, 690, and 2000 comments, respectively. Toxic comments are mainly divided into two portions: 1. Having no toxic spans and 2. Having toxic spans that are identified as spans with specific character positions. Analyzing the ratio of empty and toxic spans in our dataset we found that 90% of data occupies toxic spans where only 10% data have empty spans. F1-Score is used as the primary evaluation metric in this task.

## 3.2 Experimental Setup

In our CSECU-DSG system submitted to the SemEval-2021 Task 5 (Pavlopoulos et al., 2021), we make use of three sequence and entity tagging models to get better predictions. We present the configuration of our best submitted system in Table 2. Based on the predicted spans from these models, a majority voting has been applied.

System	Settings
BiLSTM-CRF	<ol style="list-style-type: none"><li>1. <i>dropout</i>: (0.25, 0.25)</li><li>2. <i>LSTM-Size</i>: [100, 100]</li><li>3. <i>maxCharLength</i>: 50</li><li>4. <i>Tokenizer</i>: TweetTokenizer</li><li>5. <i>Word embedding</i>: GloVe (6B)</li><li>6. <i>Optimizer</i>: nadam</li><li>7. <i>miniBatchSize</i>: 32</li><li>8. <i>Epochs</i>: 25</li></ol>
Custom spaCy NER	<ol style="list-style-type: none"><li>1. <i>spaCy Model</i>: blank (‘en’)</li><li>2. <i>Pipeline</i>: ner</li><li>3. <i>Word embedding</i>: word2vec</li><li>4. <i>Iteration</i>: 30</li><li>5. <i>drop</i>: 0.5</li></ol>
Fine-tuned BERT Model	<ol style="list-style-type: none"><li>1. <i>Tokenizer</i>: bert-large-cased</li><li>2. <i>Optimizer</i>: AdamW</li><li>3. <i>Batch Size</i>: 16</li><li>4. <i>Learning_rate</i>: 2e-5</li><li>5. <i>weight_decay_rate</i>: 0.01</li><li>6. <i>Epochs</i>: 25</li></ol>

Table 2: System settings.

## 3.3 Results Analysis

Now, we compare the performance of our system against other competitors’ systems. Among the 91 valid submissions, the comparative performance with top-performing teams depicted in Table 3.

Team Name	F1-Score
HITSZ-HLT9 (1st)	0.7083028253
hitmi&t (3rd)	0.6984762534
IITK@Detox (9th)	0.6895352367
<b>CSECUDSG (21st)</b>	<b>0.6795264755</b>
mnfourka (45th)	0.6581458018
ST_TSRResearch (64th)	0.6133591537

Table 3: Comparative performance analysis.

It depicts that our system achieved competitive performance compared to the participants’ systems. It only lacks by 3% from the top-performing team HITSZ-HLT.

## 4 Discussion

To estimate the impact of individual components on the overall system’s performance, we examine the performance of individual models on the test set. To do this, we make use of the test set and the findings are presented in Table 4.

Method	F1-Score
CSECU-DSG	0.6795264755
Performance of Individual Model	
–Fine-tuned BERT	0.6381618923
–Custom spaCy NER	0.6474175682
–BiLSTM-CRF	0.6404340000

Table 4: Performance analysis of individual models.

It shows that all three models obtained a similar kind of performance. However, employing the majority voting based scheme on these three models improves the overall result by almost 3% which leads to better detection of toxic spans from the text. Thus, we demonstrate the efficacy of utilizing the ensemble strategy to ameliorate the performance.

To qualitatively demonstrate the effectiveness of the ensemble approach compared to the individual models an instance is illustrated in Table 5. It clearly shows that majority voting helps to detect the accurate span.

<b>Text:</b> They are more animal than the goat, disgusting!!!!
<b>Gold:</b> [36, 37, 38, 39, 40, 41, 42, 43, 44, 45]
<b>BiLSTM-CRF:</b> [30, 31, 32, 33, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45]
<b>Custom spaCy NER:</b> [36, 37, 38, 39, 40, 41, 42, 43, 44, 45]
<b>Fine-tuned BERT:</b> [14, 15, 16, 17, 18, 19, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45]
<b>Majority voting:</b> [36, 37, 38, 39, 40, 41, 42, 43, 44, 45]

Table 5: Comparative performance analysis of models according to the predicted toxic spans.

We further investigate the reason behind the erroneous span detection by our proposed system. In this regard, we articulate some examples in Table 6.

Text	Predicted Span	Gold Span
1. See a shrink you pathetic troll.	[17, 18, 19, 20, 21, 22, 23, 24, 26, 27, 28, 29, 30]	[17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30]
2. ADN is endorsing, without officially endorsing. Bunch of cowards !!!	[58, 59, 60, 61, 62, 63, 64]	[49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64]
3. The mascot was a ridiculous pick twenty years ago, too. Did you ever see the welcome sign going into Keenesburg? "Home to 500 people and a few sore-heads."	[17, 18, 19, 20, 21, 22, 23, 24, 25, 26]	17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31]

Table 6: Examples of erroneous span detection.

We observed that our system could not detect the in-between spaces of toxic words. Such as in the first example, the predicted span is “pathetic” (17-24) and “troll” (26-30). Whereas, the gold span is “pathetic troll”(17-30). The probable reason for this can be that our models are trained with tokens of the training dataset. Another observation indicates that our system failed to detect the phrasal spans of some texts. In example #2 and #3, we see that instead of capturing the toxic phrases “Bunch of cowards” and “ridiculous pick”, it detects the toxic words only. Since two of our models are trained on token-level and only the BiLSTM-CRF model follows the BIO tags convention, the ensemble of models lacks in perceiving the context of the phrasal toxic texts and sometimes fragments the toxic sequences. Though majority voting improves the overall score, it shrinks some important features of the discrete models.

## 5 Conclusion and Future Directions

In this paper, we introduced an ensemble of three distinct models to detect the toxic spans. Among these models, BiLSTM-CRF and Custom spaCy NER models are implemented as NER type sequence and entity tagging models whereas fine-tuned BERT model is exploited as a token classification model. We also leveraged a majority voting strategy to overcome the limitations of individual models. Our model tackles the task challenge effectively and achieved a competitive performance compared to the participants’ systems.

Our future plan incorporates exploring a better sequence tagging model with an ensemble of various fine-tuned language models i.e. ALBERT, DistilBERT, RoBERTa, and GPT.

## Abstract

Detecting which parts of a sentence contribute to that sentence’s toxicity—rather than providing a sentence-level verdict of hatefulness—would increase the interpretability of models and allow human moderators to better understand the outputs of the system. This paper presents our team’s, *UTNLP*, methodology and results in the SemEval-2021 shared task 5 on toxic spans detection. We test multiple models and contextual embeddings and report the best setting out of all. The experiments start with keyword-based models and are followed by attention-based, named entity-based, transformers-based, and ensemble models. Our best approach, an ensemble model, achieves an F1 of 0.684 in the competition’s evaluation phase.

## 1 Introduction

When social media platforms were first introduced, they allowed users to post content on any topic they wished, without restricting the type of content they were allowed to put out. This absence of restrictions, along with the anonymity of users through these platforms (Pinsonneault and Heppel, 1997; Mondal et al., 2017), resulted in the spread of offensive language and hate speech online. While one might think there are only a small number of users who produce these types of hateful content, it has been shown that if social media platforms are left unmoderated, over time, the language of the community as a whole will change such that it highly correlates with the speech of hateful users rather than non-hateful ones (Mathew et al., 2020). Given the huge number of social media postings every day, manual moderation of these platforms is not a possibility. As a result, many researchers began to study automatic hate speech detection. Most studies on hate speech detection only provide labels at the sentence level, showing whether

the construct as a whole is toxic or not. But these types of models, offer little explanation as to why the class was predicted, making it hard for human moderators to interpret the results (Pavlopoulos et al.).

In an attempt to solve the aforementioned issue, we took part in SemEval-2021 shared task 5 (Pavlopoulos et al., 2021), where we aim to detect which spans of a sentence cause it to become toxic. Our contributions are as follows: We begin our experimentation by evaluating a random baseline. Next, we test keyword-based methods, trying to find if toxic spans often include words that are known as hateful or negative in available word lists. We then test attention-based models, building on the hypothesis that what the attention model learns to focus on when detecting toxic speech, are the toxic spans. Afterwards, we look at the issue as a named entity recognition problem, by considering *toxic* as a named entity category. Finally, we fine tune *T5-base* and explore the possibility of looking at the task as a text-to-text problem. We compare different neural network architectures and embeddings, and report the model with the best performance. Additionally, we experiment with some hand-crafted features and evaluate their effectiveness in detecting toxic spans. Our best result, an ensemble of named-entity-based models, achieves an F1 of 0.684.

## 2 Related Work

In this section we provide a brief overview of studies on hate and toxic speech detection, followed by work on span detection in different sub-fields.

### 2.1 Hate Speech

Hate speech is defined as “any communication that disparages a person or a group on the basis of some characteristic such as race, color, ethnicity, gender, sexual orientation, nationality, religion, or other

characteristics” (Nockleby, 2000). However, no clear distinction between toxic and hateful speech has been provided in the scientific literature (D’sa et al., 2019). There are quite a few surveys on the topic of hate speech detection. (Schmidt and Wiegand, 2017), describes available methods, features, and models for such a task. Another survey conducted in 2018 (Fortuna and Nunes, 2018), offers another view of the current state of the field, as well as suggesting ways in which hate speech detection could advance further. Other surveys on the topic published in 2020 include: (Naseem et al., 2020) which examines the impact of pre-processing on the performance of hate speech models. Corpora and resources for the task are studied in (Poletto et al., 2020). Additionally, throughout the years, many shared tasks have been organized to help propel studies in the field (Vu et al., 2020; Bosco et al., 2018; Basile et al., 2019). In addition to the classification of hate speech, significant effort has been put into the analysis of the target of hate (Silva et al., 2016; ElSherief et al., 2018).

Although numerous models have been tested, (Gröndahl et al., 2018) argues that when it comes to hate speech detection, the model is less important than the labeling criteria and the type of data. In confirmation of the importance of labeling, (Arango et al., 2019) also finds that models trained on annotations done by experts outperform systems trained on amateur annotations.

## 2.2 Span Detection

Named entity recognition (NER), code-switching detection, quotation detection, and key-phrase extraction are among many tasks that involve span identification.

(Chen et al., 2020) employs SpanBERT (Joshi et al., 2020) accompanied by a sequence tagging model to detect erroneous spans, proceeding to use detected spans to perform error correction. The combination of conditional random fields (CRF) (Lafferty et al., 2001) and attention mechanisms (Vaswani et al., 2017) are explored in (Xu et al., 2020) to explore aspect sentiment classification. The study finds that the use of multiple CRFs (to some limit) does improve performance. In (Papay et al., 2020) the authors look into systems to predict the performance of span identification tasks. To do so, BIO labels are used, and it is found that BERT (Devlin et al., 2018) helps when there is little data, while CRF is of great help in hard cases. In addition, the

frequency of spans is found to help while length hurts the performance of the model. Furthermore, LSTMs (Hochreiter and Schmidhuber, 1997) are reported to require large amounts of data to learn. (Tang et al., 2019) explores using fine-tuned BERT with attention models to extract keywords, showing how such models could enable the text classification model to be human interpretable.

## 3 Data

In this section, we will provide a brief description of the datasets utilized in this study. We will begin with our main dataset in which span-level toxicity has been labeled (3.1), next we look at other datasets that were used to better train our models, namely the hate word list that was used (3.2.1) and the sentence-level hate speech data (3.2.2).

### 3.1 Main Task Dataset: Toxic Spans

The main dataset used in this study is that of the SemEval 2021, Toxic Span detection task (Pavlopoulos et al.; Borkan et al., 2019a). In this dataset, which was built upon *Civil Comments* (Borkan et al., 2019b), toxic word sequences (for sentences in the English language) have been labeled. In other words, labels are indexes of characters that are toxic in each sentence. There are a total of 8,629 sentences in the dataset, 8,101 of which include at least one annotated toxic span, and the rest have none. Sentences are on average 35 words long. The word-length of the toxic spans varies from one to 176 words. Toxic spans are, on average, 2.29 words long.

There are some issues with regard to the quality of the annotations in the dataset. Table 1 shows some examples of annotated comments in the dataset. While the first sentence is satisfactorily annotated, the second and third examples display issues with the labels in the dataset. More concretely, in the second example we can see that the indexes result in poorly separated and broken up words. Additionally, the annotated words are not toxic. In the third example we see that some of the words which do have a toxic connotation are not included in the annotation. While these examples are not extremely common in the dataset, these types of issues make automatic detection of such spans much more difficult.

Text	Toxic Spans
what load you trump chumps just do not have any idea how to deal with reality you have terrible judgment and pick exceptionally idiotic arrogant leaders trump admitted he fired comey to stop the russia investigation man is he stupid.	['idiotic', 'man is he stupid']
except for one thing they are liars they only care about being thugs	['r one th']
what harm have you ever heard of someone getting attacked by bear while taking dump in the woods please does just owning gun make someone paranoid and pu55y at the same time	['harm']

Table 1: Examples of comments and the annotated toxic spans in the dataset

## 3.2 Datasets Used for Training

To better train our models, we made use of several auxiliary datasets.

### 3.2.1 Word-list Dataset

One of the methods tested in this study is based on word-matching. In other words, we check whether each word in the sentence is among hateful words and if so predict its label to be toxic. While this method is rather simple and we acknowledge that not all hate words are toxic and they could simply be used as a joke, we consider this method as a good first step to help us better understand the task at hand. As a result we need to use a list of hate words. For that purpose, we used a list of 1,616 unique hate words found on Kaggle (nicapotato).

### 3.2.2 Hate Speech Dataset

To be able to train our attention-based models (4.1) we needed to have sentence-level annotated data. Thus we used the *Civil Comments* dataset (Jigsaw-Conversation-AI). The fact that this dataset and our main dataset have the same domain is the reason why this specific dataset was selected. In this dataset, each sentence is labeled with a number between 0 and 1, representing how hateful the text is. We consider sentences with scores above 0.5 to be hateful, and consider the rest as non-hateful. We then create a balanced sample of 289,298 sentences to train our model. The average length of sentences in this dataset is 48.12 words which is slightly longer than the sentences in the main dataset (3.1).

## 4 Methodology

In this study we have tested and compared various models to perform toxic span detection. In this section we will go over the structure and hyperparameters of these models. The codes of all models

are publicly available on GitHub<sup>1</sup>.

### 4.1 Attention-based Methods

We begin with the intuition that if a model with an attention layer is trained to detect hate speech at the sentence-level, the words the attention layer would learn to place importance on, would be the hateful words and spans. Consequently, we create a model made up of the following three layers:

- (1) BERT-Base (Uncased) Layer which encodes our input texts.
- (2) Attention Layer which is meant to be used for the aforementioned purposes
- (3) Dense Layers which connect the attention outputs to two output nodes, detecting if the text is hateful or not.

To train this model we have two training stages:

- Sentence-level classification of hate speech
- Span-level detection of toxic spans

First we perform pre-processing by removing all punctuations (except those in the middle of words such as a\$\$hole), and lower-casing all words. Next, the aforementioned model is designed. The BERT-Base (Uncased) layer has an input size of 400 tokens (clipping the input at 400 tokens and dropping the rest). The outputs of this layer are embedding vectors with a hidden size of 768 corresponding to the 400 input tokens. The second layer is an attention layer (attention matrix size = 4096) with a Relu activation function. Our last layers are two fully connected layers (4096 nodes) with dropout of 0.1. There are two neurons in the final layer, the objective of which is to detect whether the sentence is an instance of hate speech or not. The model is trained for 10 epochs with the Adam

<sup>1</sup><https://github.com/alirezasalemi7/SemEval2021-Toxic-Spans-Detection>

optimizer and a learning rate of 0.001. We freeze the weights of the BERT layer during this training process as we find through experimentation that fine-tuning BERT in this stage results in lower performance of our model in the toxic span detection task.

Once the model has been trained, we input our sentence and if our sentence-level detector predicts the sentence to be non-hateful we move on and produce a blank output as our toxic span. If, however, the model detects the sentence to be hateful, we extract the attention values and calculate the attention score of each word. If a word is made up of multiple subwords, we average the values of all subwords. After the attention scores have been calculated we use rule-based and machine learning models to label spans as toxic. These models are explained in Table 2. We begin by rule based models, selecting a percentage of spans with attention scores above a certain threshold (shown in Figure 2). Additionally, we test different machine learning models with various sets of features. Our results are shown in Section 5.3.

## 4.2 Named Entity-based Methods

Our second intuition is to look at this problem as one similar to NER. As such, our toxic span label can be looked at as another NER label. We considered toxic, non-toxic and padding as labels and applied CRF to this NER task. The padding label was added to reduce the model bias toward the non-toxic class.

Our model is depicted in Figure 1. We train the model for 2 epochs with a learning rate of  $3 \times 10^{-5}$ . In contrast to the previous method, the embedding layer is fine-tuned during our training process. Our tests on these models are shown in Section 5.4.

## 4.3 Ensemble Models

Finally, we test two methods of combining the outputs of various models in order to achieve a better performance on the task. As previously mentioned, the expected outputs of the task are numerical indexes of the parts of the string which are believed to be toxic. Consequently, the first method of mixing could be voting, where if the majority of the models vote for one index, the index is included in the final selection. The second method is based on calculating the intersection of outputted indexes of all three models. In other words, only adding an index if it is detected by all three models. The results are shown in Section 5.6.

# 5 Results

In this section we will report the results of the models introduced in the previous section (4) on the toxic span detection task. Per the competition evaluation instructions, for all models the F1 score is reported.

## 5.1 Random Baseline

To help us better understand the complexity of the task at hand, we start with a random baseline. In this method, we first split each sentence into words (using NLTK’s functions) and then randomly label each word as toxic or not. We observe that this baseline F1-score for the task is 0.17.

## 5.2 Keyword-based

The second simple method we test is a word-matching one. Our intuition is that toxic spans will likely include hateful or negative words. Thus we begin with a list of hate words and label any word found on the list as toxic and label the rest as nontoxic. This method results in an F1-score of 0.332 which is almost twice that of the random baseline, showing that while not all hate words are toxic and not all toxic spans are hate words, there is still a considerable amount of overlap. We further test if most words in toxic spans will have a negative sentiment value. Thus we repeat the same method, this time labeling anything with a negative sentiment as toxic. To detect the sentiment score of each word we use *TextBlob* (Loria, 2018). We see that this method achieves an F1 of 0.378, outperforming the aforementioned technique. Finally we mix the two methods (labeling both hate words and words with negative sentiment as toxic), and achieve an F1-score of 0.418.

## 5.3 Attention-based

As mentioned in Section 4, the intuition behind the attention-based model is that the model which learns to detect hate speech, would learn to pay more attention to the hateful spans in the text. Consequently, we test this idea in Table 2. We can see that the rule-based attention selection method outperforms other span selection techniques. To select the best set of rules for the model, we test both the percentage of top-words (with respect to attention) which we consider for selection, and the threshold we place on the minimum value of attention which is considered. As shown in Figure 2, we can see that the top 75% of attention scores with a thresh-

Figure 1: The architecture of the named entity-based models. (a) displays a version of the model in which the two dense layers in (b) have been replaced by an LSTM layer. The results of both versions are shown in Table 3.

old of  $10^{-4}$  is the best set of hyper-parameters for the task.

Upon analysis of the results of the attention-based model, we find that the model performs well on the detection of single word spans (detecting 78% of single-word spans in the evaluation dataset) but does not detect multi-word spans well (only detecting 16% of such spans completely). This is because the distribution of attention scores are observed to be such that there is a large focus on one word and other words receive little attention values.

We further set up another experiment where we assumed that the true sentence-level labels were given. The model then predicted the toxic spans given these true labels achieving an F1 of 0.808. This shows that if the sentence-level classifier performed better, our model would have been able to get higher performance. Thus, more focus should be placed on obtaining higher accuracy in the sentence-level classification task.

#### 5.4 Named Entity-based

Table ??, displays the results of our named entity based models. We can see that LSTM layers do not improve performance, and among various embeddings, RoBERTa outperforms the others in our 5-fold cross validation testings. However, BERT achieves better results in the competition’s evaluation phase.

#### 5.5 Google’s T5

Another model we test is Google’s T5 (Raffel et al., 2019). To test the T5 model, we use hugging-face’s

T5-base model<sup>2</sup> and frame our problem as one where the context is the Tweet text and the answer is the text of the toxic spans to be detected. Our model achieves an F1 of 0.635 in the evaluation phase of the competition.

#### 5.6 Ensemble Models

As described in section 4.3, we tested intersecting and using a voting scheme for the model outputs. More precisely, we perform these methods on the outputs of the following named entity based models:

- (1) BERT + CRF
- (2) Electra + CRF
- (3) RoBERTa + CRF

We find that the competition evaluation F1 reaches 0.681 when we use voting of indexes, and 0.684 when the indexes are intersected. As can be seen both methods outperform all individual models.

### 6 Conclusion

In this study we presented and compared various methods for toxic span detection. We examined the problem from various points of views reporting our results using each model. Our best system, an ensemble model, achieved an F1 of 0.684 in the SemEval-2021 Task 5 evaluation phase. Among the named-entity-based models, BERT+CRF performs best achieving an F1 of 0.67. Our attention-based model achieved an F1 of 0.609 in the competition’s

<sup>2</sup>We were not able to test a larger version of the model due to system constraints

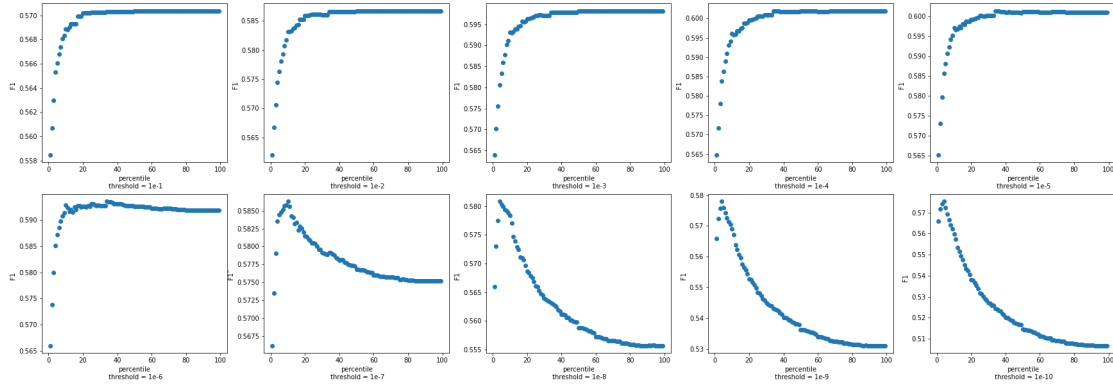

Figure 2: The effects of placing various thresholds on the minimum value of attention scores allowed to be selected and the percentage of top scores that have been selected on the F1-score of the toxic span detection task. Each plot displays one threshold value, and the x-axis in each plot is the percentile of scores we select and the y-axis is the F1 value achieved by this combination of threshold and percentile.

Model	Hate Speech Detection				Toxic Span Detection	
	Accuracy	Precision	Recall	F1	F1	F1 (Competition Evaluation)
Span Selection Rules						
R1 <sup>a</sup>	0.85	0.85	0.85	0.85	0.601	0.609
R2 <sup>b</sup>					0.601	-
R3 <sup>c</sup>					0.496	-
Decision Tree <sup>d</sup>					0.360	-
Neural Network <sup>e</sup>					0.354	-

- <sup>a</sup> **R1**: selecting words with top 75% of attention scores with threshold  $10^{-4}$  and then removing stop-words
- <sup>b</sup> **R2**: R1 + removing positive sentiment words among the top 75%
- <sup>c</sup> **R3**: R2 + adding all hate words (using the hate word list) in the sentence regardless of attention scores
- <sup>d</sup> **Decision Tree**: the input features of the model are: 1-attention score of word, 2-part of speech of the word, 3-sentiment of word 4-whether the word is a hate word or not (0/1)
- <sup>e</sup> **Neural Network**: the features inputted to the model are 1-attention score of word, 2-part of speech of the word, 3-sentiment of word, 4-whether the word is a hate word or not (0/1) - categorical features (e.g. POS) are modeled as learnable embeddings.

Table 2: Results of the attention-based models, the model structure is *BERT + Attention + Dense* and we have tested out different span selection rules

Embedding	Layers	F1 (train)	F1 (test)	F1 (Competition Evaluation)
BERT	CRF	0.702	0.648	0.67
RoBERTa	CRF	0.682	0.652	0.66
Electra	CRF	0.687	0.646	0.65
BERT	LSTM + CRF	0.668	0.62	-
RoBERTa	LSTM + CRF	0.669	0.647	-
Electra	LSTM + CRF	0.678	0.641	-

Table 3: Results of the named-entity based models evaluated using 5-fold cross-validation

evaluation phase. Future work could focus on the improvement of the sentence-level detection in our attention scheme, as we showed improvement in that regard would improve this task’s performance.

# macech at SemEval-2021 Task 5: Toxic Spans Detection

**Maggie Cech**

SAS Institute

margaret.cech98@gmail.com

## Abstract

Toxic language is often present in online forums, especially when politics and other polarizing topics arise, and can lead to people becoming discouraged from joining or continuing conversations. In this paper, I use data consisting of comments with the indices of toxic text labelled to train an RNN to determine which parts of the comments make them toxic, which could aid online moderators. I compare results using both the original dataset and an augmented set, as well as GRU versus LSTM RNN models.

## 1 Introduction

In this digital era we live in, almost everyone is communicating online. As of January 2021, Facebook, YouTube, and WhatsApp each have over 2 billion users, which means many differing viewpoints and perspectives being shared (Statista, 2021). With such a huge exchange of ideas, there is bound to be some toxicity within the comments. Aside from discouraging users to continue with or join conversations, toxic comments can also taint users' perceptions on news sites (Tenenboim et al., 2019). Thus it is important to moderate online conversations without fully censoring users.

While forums typically rely on human moderators, with such vast amounts of data coming in, it can be difficult for humans to keep up (Nobata et al., 2016). Advances in deep learning and machine learning is making text processing a viable option to replace, or at least assist, human moderators clean up comment sections (Consultants, 2019). Some methods rely on simply classifying whether a comment is toxic or not, but identifying what parts of the text are actually toxic can assist moderators and provide insight into what makes language toxic. The SemEval task 5 aims to evaluate systems that detect toxic spans within text using

datasets where spans within the comments are labelled as toxic, differing from previously released datasets where whole comments were labelled as toxic or non-toxic (Pavlopoulos et al., 2021).

This is inherently a natural language processing task, similar to text classification and sentiment analysis. This study focuses on training a recurrent neural network to determine the indices of a given string that represent the toxic portions of a comment. Recurrent neural networks are classically used for natural language and sequence labelling task, and one could view this task as a form of sequence labelling. The goal of sequence labelling is, given a sequence as input, assign a sequence of labels. Because recurrent neural networks (RNNs) are flexible in their use of context information and can recognize sequential patterns, they are an attractive and commonly used choice in sequence labelling (Graves, 2012). This paper approaches the task at hand with a sequence labelling methodology, applying an RNN and comparing the use of gated recurrent unit (GRU) and long-short term memory unit (LSTM) layers in the RNN.

## 2 Related Work

Aggression in text is complex, often clouded by sarcasm or including repeat words that cause a model to incorrectly identify words as toxic. A study by Vaidya, Mai, and Ning found that comments including identities, such as LGBTQ+, Black, Muslim, and/or Jewish identities, often resulted in false positives for toxic comments, so this was a bias we wanted to be aware of in our study (Vaidya et al., 2020).

Detecting toxic spans is not as common of a task as toxic comment detection or sentiment analysis. Many studies surrounding toxic comments have been completed largely in part due to the availability of a large corpora of data released by the

Wikimedia Foundation, as well as several Kaggle competitions hosted by Google Jigsaw. Other studies generally take a text classification approach similar to sentiment analysis, which as previously mentioned, is not exactly the task at hand (Nobata et al., 2017).

One of the comparisons made in this research is between GRU and LSTM recurrent models. Generally, LSTM units have issues with vanishing gradients when text sequences are too long, so GRUs are used instead. GRU controls the flow of information like the LSTM unit, but without the use of a memory unit (Chung et al., 2014). Previous research has shown GRU outperforms LSTM for all depths in speech recognition. The same study determined that bi-directional RNN models consistently outperform uni-directional models and found that models with 5 or more recurrent layers did not improve the results (Khandelwal et al., 2016). As a result, in our research, we compare GRU and LSTM models to find if GRU will consistently outperform LSTM in a sequence labelling task, as opposed to speech recognition, and use bi-directional RNN models with fewer recurrent layers, as they were not shown to have any benefit. This paper will also compare the results of augmented and non-augmented datasets to determine if the use of synonyms will improve the performance after training.

### 3 Methodology

#### 3.1 Pre-Processing

Quite a bit of pre-processing was required to prepare this data for training. First, we label the comments using the given indices representing the toxic spans within the comments. A word labelled with a "/1" is toxic and with "/0" is not toxic. The comments are then run through a function that goes through the following text preprocessing steps:

1. Text to lowercase
2. Remove URLs
3. Remove numbers
4. Remove extra whitespace
5. Expand contractions ("it's" to "it is", "they're" to "they are", etc.)
6. Remove punctuation

7. Tokenize the strings - here one token is one word in the comment
8. Lemmatize the tokens
9. Remove stop words (list of stop words from nltk.corpus package)

After this text processing is completed, we use SAS DLPy<sup>1</sup> and SAS SWAT Python<sup>2</sup> packages to continue with the processing. From the SAS SWAT package, we are able to connect to a server where we can upload the cleaned text data into a CASTable (similar to a Pandas DataFrame). Then the text data needs to be converted to embeddings. To do this, we use GLOVE 100-dimension trained word vectors and apply the vectors to the CASTable containing the comments. Because text data from human sources is so varied and can often include unknown words or misspellings, we remove any comments that could not be converted to numeric embeddings and place them in a separate table. Instead of using these unknown embeddings in training and scoring using a neural network, we will make simple predictions based on if any common toxic words are present in the comments. This is not ideal but only about 2-5% of data ends up in this separate table and saves us the trouble of dealing with finding all of the words that could not be converted to embeddings.

Ideally we would not be removing observations from the dataset and further experimentation with different embedding sets could lead to better outcomes. This does affect the final results slightly as there is both less data being used in training and worse prediction accuracy from the comments not used in the main prediction set contributing to the final score, but because the percentage of data actually removed is so low, we decided it would not make a big enough difference to focus on. The comments removed from the main set are predicted using common toxic words gathered from the training set. Although misspellings are often a cause for the embeddings failing on a comment, the misspelled word may not have been part of the toxic span, so the comment could still be predicted using common toxic words and have a fairly acceptable accuracy.

After the comments are converted to embeddings, we find the maximum column count of a

<sup>1</sup><https://sassoftware.github.io/python-dlpy/>

<sup>2</sup><https://sassoftware.github.io/python-swat/>

single embedding and pad all other embeddings to this maximum value. We then create output columns - one column for each 100-D word vector - and fill the columns with the toxicity labels from earlier. The final table used for training and scoring contains columns for the original comment, the labelled comment, the cleaned comment, 100 dimension embeddings for each word in the comment and the rest of the columns zero-padded to the longest value, and toxicity labels for each word in the comment, also zero-padded to the longest value.

We can then build an RNN using SAS' deepLearn actionset<sup>3</sup>, train the model using the dlTrain action, and score using the dlScore action. When training, the embeddings columns are used as input columns to the model, where each token is 100 columns for each 100 dimension embedding, and the target columns are the label columns that contain either a 1 for a toxic word or a 0 for a non-toxic word, where each token is one column.

### 3.2 Augmented Data

The goal of using augmented data was to increase the amount of data being used in training the models. To do this, we found every comment with only one toxic word and created up to five new comments with the toxic word replaced with a different synonym. We were able to do this by using wordnet from the nltk Python package that finds a list of synonyms for a given word. Figure 1 shows

	original comment
0	Another violent and aggressive immigrant killi...
1	I am 56 years old, I am not your fucking junio...
2	<b>Damn, a whole family. Sad indeed.</b>
3	What a knucklehead. How can anyone not know th...
4	"who do you think should do the killing?"\n\nA...

Figure 1: Original toxic comments

the original comments, with comment 2 being the example that is augmented, and figure 2 shows the new comments created using synonyms of the

	original comment
6	<b>damn,</b> a whole family. Sad indeed.
7	<b>dam,</b> a whole family. Sad indeed.
8	<b>hoot,</b> a whole family. Sad indeed.
9	<b>red_cent,</b> a whole family. Sad indeed.
10	<b>shit,</b> a whole family. Sad indeed.

Figure 2: Augmented toxic comments

word "damn". By augmenting only comments that contain a single toxic comment, we are able to increase the size of the data set from 7,939 comments to 21,822 comments - almost three times as many comments to be used in training. The idea here was to increase the size of the training data set to improve performance.

### 3.3 GRU vs LSTM

As mentioned in the introduction, we trained a bi-directional RNN model. After comparing performance, we found that a model with more than one bi-directional RNN layer was not improving the accuracy of the predictions, so we used a smaller model with only one bi-directional layer. The input layer connects to a fully connected layer, which goes into the bi-directional layer, into another fully connected layer, and finally to the output layer. Figure 3 shows the model architecture. We trained our data on two different models, one with a GRU cell used in the bi-directional layer and one that uses an LSTM cell in the bi-directional layer.

## 4 Experimental Results

In this section, we discuss the results from the two experiments - GRU vs LSTM models and augmented vs original data used in training. We use F1 scores to compare the two different models and types of data sets. The F1 scores, discussed later on, are a combination of both the predictions from the trained models and the comments that are predicted using common toxic words (which will henceforth be referenced as "guessed comments" for lack of better terms). The guessed comments do have a slight effect on the final results which will be described in this section

<sup>3</sup>[https://go.documentation.sas.com/doc/en/pgmsascdc/9.4\\_3/casdlpg/cas-deeplearn-TblOfActions.htm](https://go.documentation.sas.com/doc/en/pgmsascdc/9.4_3/casdlpg/cas-deeplearn-TblOfActions.htm)

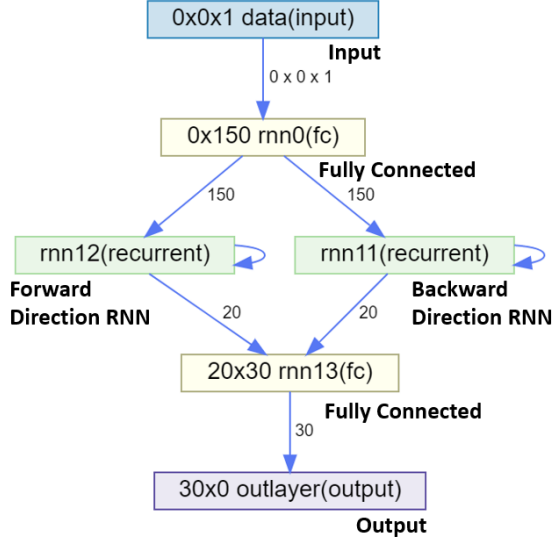

Figure 3: RNN model architecture showing layer dimensions

#### 4.1 Evaluation Metric

Each model’s performance was evaluated using an F1 score, as described in (Martino et al., 2019). If the system is represented by  $A_i$ , the return set from the system is  $S_{A_i}^t$ ,  $t$  represents a post or comment, and  $G$  represents the ground truth annotations for post  $t$ , then F1 score of a system is defined as:

$$F_1^t(A_i, G) = \frac{2 \cdot P^t(A_i, G) \cdot R^t(A_i, G)}{P^t(A_i, G) + R^t(A_i, G)} \quad (1)$$

$$P^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{S_{A_i}^t} \quad (2)$$

$$R^t(A_i, G) = \frac{|S_{A_i}^t \cup S_G^t|}{S_{A_i}^t} \quad (3)$$

If  $S_G^t = 0$ , an instance where there are no toxic spans present, then  $F_1^t(A_i, G) = 1$  if no toxic spans are predicted, and  $F_1^t(A_i, G) = 0$  otherwise. To obtain the final F1 score for a particular system, the F1 scores are averaged over all posts  $t$ .

#### 4.2 Augmented Data

Table 1 shows comparisons between the use of augmented and non-augmented data when training both the GRU and LSTM. We can see in the various hyperparameter settings, the augmented data actually performs worse than the original data. This is interesting considering generally the more data points used, the better the model. It is possible that

the method in which we augmented the data, only changing one word within a comment, did not help the model learn any of the connections between the text but rather memorize more toxic words, many of which are often repeated.

Table 1 also shows that the learning rate does not affect the augmented data quite as drastically as it does the non-augmented data, with the non-augmented data showing much lower F1 scores when a lower learning rate is used, such as 0.001. It may be interesting to further explore if larger datasets are less affected by changes to the learning rate. The augmented dataset is almost three times larger than the original dataset, so it is also much more time consuming to train. With much longer training times and worse performance, the original dataset proves to be the more effective option. Table 3 shows that across both dev and test datasets, results from augmented dataset training were worse than their non-augmented counterparts.

We also compared results from only comments with a single toxic word present to find if these performed better for the augmented data, since only comments with a single toxic word were augmented. Again, the original dataset outperformed the augmented data. The differences between the single toxic word scores and scores when all comments are factored in are also very similar between augmented and non-augmented data results, showing the augmented data did not make much of a difference in predicting single toxic word comments. Table 2 shows these results.

#### 4.3 GRU vs LSTM

After tuning the hyperparameters for both models, we found that the GRU model performs slightly better than LSTM across most hyperparameter settings. We were able to get the highest F1 score using GRU as well. Even between the scores using augmented data, GRU still performs slightly better than LSTM. Table 1 shows these results.

#### 4.4 Results and analysis

Table 3 shows F1 scores using the best hyperparameter settings across the four methods - GRU, GRU trained with augmented data, LSTM, and LSTM trained with augmented data. The F1 test column shows scores for the evaluation data given, which was to be used for submitting a team’s results. Our team submitted results for each of these methods in hopes of securing a better spot on the leaderboard, but ultimately ended up with a very low score, the

Method	F1 Dev	F1 Test
GRU	0.519	0.602
GRU Augmented	0.504	0.551
LSTM	0.514	0.600
LSTM Augmented	0.501	0.550

Table 3: Best F1 scores for dev and test sets

reasoning for which is described in the note below. We were able to later calculate the F1 scores for the evaluation data when the entire dataset was released, after the competition ended, and those are the scores shown in Table 3.

It is interesting to note that the test data outperforms the dev data for every method used. This may be due to some kind of overfitting occurring. This is peculiar but is also likely due to the evaluation data containing fewer guessed comments, or comments predicted using common toxic words instead of predicted by the model. Because both the predicted comments and the guessed comments are used in calculating the F1 score, the portion

of the entire dataset that is guessed would have an impact on the final score. The dev set had 2.5% of guessed comments and the test set had slightly fewer, with 2% of the entire dataset being comprised of guessed comments, which would explain the better results shown.

One can also see in Table 3 that the GRU model outperforms the LSTM model, even if just slightly, for both the original and augmented datasets and across both dev and test data. Other research has noted that GRU cells may be better for specificity, or finding true negatives, and focusing on less prevalent content, whereas LSTM cells are better for detecting true positives and focusing on highly prevalent content. (Gruber and Jockisch, 2020). Looking into the dev dataset, only 6% of the observations contain no toxic spans, but this model is not predicting whether an entire comment contains any toxic spans, it is predicting if each word is toxic. Out of all of the text, 93% of the words are non-toxic words, or in this case, words to be labelled negative for toxicity. A model that can better predict true negative outcomes would have

the best performance with this data.

#### 4.5 Note on Official Results Discrepancy

The official results in task 5 for the SemEval conference show this team to have an F1 score of 0.070. This score is much lower than the values we are presenting here because after adding the ground-truth values for the evaluation data it was found that the best F1 score we achieved was 0.602, as shown in Table 3, and the results were submitted to the competition out of order or formatted incorrectly, producing a very low F1 score.

#### 5 Conclusion

We experimented with several different RNN models and ultimately utilized the results from bi-directional GRU and LSTM models. It was found that the GRU model slightly outperforms the LSTM model for this test case. As was found by Gruber and Jockisch, GRU cells can be better for detecting true negatives and since 93% of the words in the training dataset we used were non-toxic words, it follows that GRU cells may outperform LSTM cells in cases where there are more negative instances than positive in the datasets. It would be interesting to explore if using both a GRU cell and an LSTM cell in a model would further increase performance, with GRU focusing on less prevalent content and true negatives, and LSTM focusing on high prevalent content and true positives.

In the exploration of the use of augmented data, we found that not only did the models trained on augmented data perform worse than those trained on the original dataset, but they were also much slower to train. We compared if the F1 scores for observations with a single toxic word were higher for the models trained with augmented data, since only comments with a single toxic word present were augmented, but still the original datasets outperformed the augmented datasets. Because the augmented data does not improve results, we can continue to use the original dataset to cut down on computation time. We also found that the F1 scores resulting from the augmented data training did not react as greatly to changes in the learning rates as the original datasets did, which may be interesting to explore further.

## Abstract

Recurrent Neural Networks (RNN) have been widely used in various Natural Language Processing (NLP) tasks such as text classification, sequence tagging, and machine translation. Long Short Term Memory (LSTM), a special unit of RNN, has the advantage of memorizing past and even future information in a sentence (especially for bidirectional LSTM). In the shared task of detecting toxic spans in texts, we first apply pretrained word embedding (GloVe) to generate the word vectors after tokenization. Then we construct Bidirectional Long Short Term Memory-Conditional Random Field (Bi-LSTM-CRF) model by Baidu research to predict whether each word in the sentence is toxic or not. We tune hyperparameters of dropout rate, number of LSTM units, embedding size with 10 epochs and choose the epoch with best validation recall. Our model achieves an F1 score of 66.99% on test dataset.

## 1 Introduction

Detecting toxic words plays a critical role in social media to ensure healthy online discussions. In previous study, some tasks (Liu et al., 2019; Borkan et al., 2019a) only identify offensive language based on the whole sentence or post. Most of them do not detect specific spans of words that make the sentence or post offensive.

In SemEval-2021 Task 5: Toxic Spans Detection (Pavlopoulos et al., 2021), the data was collected from civil comments (Borkan et al., 2019b). Each post is in string format, and a word is marked as toxic span in the form of its characters' offsets in the string. The goal of the task is to classify whether each word in a sentence is toxic or not. If so, the indices of characters in the word should be returned. The task is evaluated by F1 score based on the character offsets among all posts.

The challenges of this task include:

- The small dataset makes it very difficult to train complicated models like deep neural networks, since it may cause overfitting.
- We need to predict which word or phrase is toxic given a text (many-to-many) rather than whether the entire sentence is offensive or not (many-to-one). This creates restrictions on feature engineering and modeling:
  - Feature Engineering: We cannot delete or add words in the sentence.
  - Modeling: Models need to be specific on each word instead of sentiment classification on whole sentence.
- Most of the words and phrases in sentences are not toxic. This indicates our dataset is imbalanced.

The models we explore in this task include word-based Conditional Random Field (CRF), word-based Bidirectional Long Short Term Memory (Bi-LSTM) with and without pretrained word embedding, Bidirectional LSTM-CRF with pretrained word embedding. We choose Bi-LSTM-CRF as final submission, since it performs the best during our experiments.

The structure of this paper is organized as follows:

- In section 2, we review related work of applications of different models in Sequence Tagging, Name Entity Recognition, and Sentiment Analysis.
- In section 3, we present the summary statistics of data and how we build models with performance evaluation.
- In section 4, we discuss our model results on validation dataset with key findings.

Figure 1: System Flowchart

- In section 5 and 6, we present our conclusion based on experiment results and future work.

## 2 Related Work

Toxic Span Detection is a type of sequence labeling tasks and is similar to name entity recognition tasks with only two categories. (Xing et al., 2010) surveyed various sequence labeling tasks in terms of methodologies and applications. They also reviewed a few extensions of sequence classification including early classification and semi-supervised learning on sequences. (Nguyen and Guo, 2007) compared different learning algorithms such as Conditional Random Fields (CRF), Support Vector Machine (SVM), and Perceptron for sequence labeling tasks. (Akbik et al., 2018) proposed a new type of embedding called contextual string embedding for sequence labeling tasks. A Comparison between multiple word embedding methods were conducted by (Lauren et al., 2018) for sentiment classification and sequence labeling tasks.

For name entity recognition (NER), (Mansouri et al., 2008) presented a machine learning based approach called Fuzzy Support Vector Machine. Recent advanced deep learning models were summarized by (Yadav and Bethard, 2019) in various shared tasks.

Currently, models that are widely used in various NLP tasks include CRF, LSTM, RNN, and transformers. Also, word embedding such as Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al.,

2014), and ELMo (Peters et al., 2018) are preferred before model training.

## 3 Data and Methodology

### 3.1 Data Description

Toxic Spans Detection Dataset includes trial and training data. The training data contains 7939 records, and trial data contains 690 records. The sentences and indices of characters in toxic span are provided separately. To obtain if a word is toxic or not after tokenization, we split the text by space and punctuation and map the indices of toxicity to corresponding words. As a result, the word sequences in text will be marked as toxic (1) or non-toxic (0).

The distribution of the length of text (in word count) is summarized in Table 1. It shows that training and trial data follow a similar distribution in percentile, mean, and standard deviation (std).

The count of toxic and non-toxic words in texts are concluded in Table 2. It shows the dataset is highly imbalanced that most of words are non toxic.

### 3.2 Methodology

**CRF** Conditional Random Field (CRF) was developed in 2001 (Lafferty et al., 2001) for sequence prediction. Given the observable sequence  $X$  and labeling sequence  $Y$ , the objective of CRF is to construct model for conditional probability  $P(Y | X)$ . An advantage of using CRF compared with other sequential models such as Hidden Markov Model (Rabiner and Juang, 1986) is that it does not rely on the assumption of label independence.

Model	Precision	Recall	F1
CRF	0.686	0.341	0.4556
Bi-LSTM	0.6277	0.3664	0.4627
Bi-LSTM (glove-twitter-50)	0.8571	0.4884	0.6222
Bi-LSTM (glove-twitter-100)	0.8113	0.5	0.6187
Bi-LSTM-CRF (glove-twitter-100)	0.8333	0.5233	0.6429

Table 3: Model evaluations on validation data

Before fitting the model, for each word we create binary features to check whether the word is uppercase, lowercase, titlecase, and digit. We also append the same features of previous and next words. Next, we use “crfsuite” package to build CRF model. We choose “lbfgs” as optimization algorithm, and we set c1 and c2 equal to 0.1, max iteration equal to 100.

**Bi-LSTM** Long Short Term Memory (LSTM) is one of the most commonly used recurrent neural networks in many natural language processing tasks (Hochreiter and Schmidhuber, 1997). It consists of input gate, output gate, forget gate, and cell. Its gate structure enables the model to memorize long-term dependency and to prevent gradient vanishing issues.

In the experiments, we use Bidirectional LSTM (Bi-LSTM) in tensorflow.keras as second baseline. We configure number of LSTM units to be 200, embedding size equal to 50, and max sequence length to be 240, which is the max sentence length in training dataset. Thus, sentences with length of less than 240 will be padded. To reduce overfitting of neural networks, we set dropout rate as 0.2. Our final output layer uses sigmoid activation function with adam optimizer for gradient descent (Kingma and Ba, 2014).

We set number of epochs equal to 10 and record checkpoints. Since tensorflow package does not contain built-in F1 score, the final model parameters are loaded from the checkpoint with highest validation recall.

#### Bi-LSTM with pretrained word embedding

To further improve model performance, we adopt pretrained word embedding to generate word representation before training Bi-LSTM. The word embedding we use includes glove-twitter-50 and glove-twitter-100 in gensim (Řehůřek and Sojka, 2010). This means we need to modify our embedding size to 50 and 100 respectively. All other hyperparameters are consistent with Bi-LSTM above.

#### Bi-LSTM-CRF with pretrained word embedding

Our final model is Bidirectional LSTM-CRF created by Baidu Research (Huang et al., 2015). Compared with previous Bi-LSTM architecture, we add an extra output layer of CRF to make final predictions (as shown in Figure 1). Accordingly, we replace the loss function of binary cross entropy by CRF loss. We use glove-twitter-100 as pretrained embedding layer. All other hyperparameters of LSTM remain the same.

## 4 Experiment Results

We split proportion of training and validation dataset into 9:1. The evaluation results on validation set are summarized in Table 3. For each model discussed above, we list its precision, recall, and F1 score with default threshold. Since the dataset is highly imbalanced, we only focus on the evaluation metrics of toxic words. There are several key findings:

- Models with pretrained word embedding perform better than those without pretrained word embedding, since it produces higher precision and recall (thus higher F1 score).
- The performances of pretrained word embedding are close to each other regardless of embedding size. We do not want to further increase the embedding size, since it will increase the training time but not boost the performance significantly.
- As a final output layer, CRF can further improve recall for Bi-LSTM while keeping the precision in the same level. Therefore, it can increase F1 score.

Based on the model evaluation table, we choose Bi-LSTM-CRF with pretrained glove-twitter-100 embedding as our final model. The model achieves an F1 score of 0.6699 in final submission.

The confusion matrix for test data can be found in Table 5. We first flatten the sequence to a list of

Texts	Predictions	Error Type
Chris Birch is a mean, self-centered, contrary <u>ass</u> .		
... always <u>sucks</u> up to Big Oil.	[ass, sucks]	False Positive
I wish this <u>moron</u> would have been shot to death by the US soldier instead of the other way around.	[moron]	False Positive
Lord have Mercy on us, Trump is running <b>amok</b> .	[]	False Negative
... They're <b>vandals</b> , <b>thieves</b> , and bullies.	[]	False Negative

Table 4: Examples of False Positive / Negative

	Actual Pos	Actual Neg
Pred Pos	1747	1504
Pred Neg	736	73892

Table 5: Confusion matrix on test data

words before calculation. We define toxic words as positive (Pos) examples and non toxic words as negative (Neg) examples in the matrix. The table shows there are a lot of false positives (1504) in our model, this implies our model may be over-sensitive to the toxic words.

To deep dive into the model performance with specific examples, we collect a few sentences from test data in Table 4. In false positive examples marked as underline, the words “ass”, “sucks”, and “moron” are predicted as toxic words where there exists no toxicity in these sentences. In false negative examples marked as bold, the model fails to identify toxic words like “amok”, “vandals”, and “thieves”. The errors may come from the following reasons:

- Incorrect labels by ground-truth spans. These errors are unavoidable from the model due to human mistake.
- The pre-trained word embedding from GloVe does not reflect sentiment for those words. In other words, these words are not marked as positive or negative but neutral in word embedding.
- The position of words in sentence was not detected as toxicity by our Bi-LSTM-CRF model. For example, one word could be marked as toxic spans when it is in the beginning of the sentence but not the case when it is at the end. This will cause difficulty for model training to detect toxicity.

## 5 Conclusion

Detecting toxic words in texts is critical to furnish a healthy environment on social media. Sequence labeling task for finding specific offensive words is more difficult than sentiment classification on sentence level, since it requires models to locate the positions or indices of words in sentences. In addition, the task also places restrictions on feature engineering, because we cannot delete or add words in sentences.

Our experiment shows pretrained word embedding can improve model performance compared with randomized embedding weights. This verifies the concept of transfer learning where we can borrow the outputs from other resources and use them as inputs to achieve specific goals. Another finding is the benefit of model stacking where we add an extra layer of CRF after Bi-LSTM that further enhances predictability. In such case, when a single model does not work well in NLP tasks, combining different models with pretrained word embedding can be a good option to explore. However, there are still a lot of false positive examples in test set where the model predicts toxic words that in fact are not toxic.

## 6 Future Work

Further improvements can focus on feature engineering and model implementation. For feature engineering, we can conduct data augmentation for false negative examples: We first collect the words that are predicted as non-toxic but actually toxic, and reconstruct sentences using those toxic words as more training samples. This method can increase the weights of words that were originally omitted by the model, so that it may return better results. Similarly, we can also collect false positive examples and perform data augmentation to reduce false positive rates.

In addition to data augmentation, one can perform word-level text normalization to transform

words of different tenses to the same, even though each word cannot be deleted or added in a sentence.

From the model perspective, we may consider using more advanced classifiers with complicated structures. Due to resource limitations, we cannot design any large neural networks models such as deep neural networks (DNN) or transformers. Most of our experiments are done locally or via Google Colab. Training large neural networks will be very time-consuming and expensive when using tremendous amount of computing resources including multiple GPUs, TPUs.

If we have more time and available resources, we can experiment with more complex models such as BERT (Devlin et al., 2018), GPT (Radford et al., 2018), and so forth. In addition, we can deploy larger LSTM-related architecture including Bi-LSTM-CNN-CRF for sequence labeling (Ma and Hovy, 2016).

# LIIR at SemEval-2021 task 6: Detection of Persuasion Techniques In Texts and Images using CLIP features

Erfan Ghadery , Damien Sileo , and Marie-Francine Moens

Department of Computer Science (CS)

KU Leuven

{erfan.ghadery, damien.sileo, sien.moens}@kuleuven.be

## Abstract

We describe our approach for SemEval-2021 task 6 on detection of persuasion techniques in multimodal content (memes). Our system combines pretrained multimodal models (CLIP) and chained classifiers. Also, we propose to enrich the data by a data augmentation technique. Our submission achieves a rank of 8/16 in terms of F1-micro and 9/16 with F1-macro on the test set.

## 1 Introduction

Online propaganda is potentially harmful to society, and the task of automated propaganda detection has been suggested to alleviate its risks (Martino et al., 2020b). In particular, providing a justification when performing propaganda detection is important for acceptability and application of the decisions. Previous challenges have focused on the detection of propaganda techniques (Martino et al., 2020a), based on news articles. However, many use cases do not solely involve text, but can also involve other modalities, notably images. Task 6 of SemEval-2021 proposes a shared task on the detection of persuasion techniques detection in memes, where both images and text are involved. Subtasks 1 and 2 deal with text in isolation, but we focus on subtask 3: visuolinguistic persuasion technique detection.

This article presents the system behind our submission for subtask 3 (Dimitrov et al., 2021). To handle this problem, we use a model containing three components: data augmentation, image and text feature extraction, and chain classifier components. First, given a paired image-text as the input, we paraphrase the text part using back-translation and pair it again with the corresponding image to enrich the data. Then, we extract visual and textual features using the CLIP (Radford et al., 2021) image encoder and text encoder, respectively. Finally, we use a chain classifier to model the relation between labels for the final prediction. Our proposed

method, named LIIR, has achieved a competitive performance with the best performing methods in the competition. Also, empirical results show that the augmentation approach is effective in improving the results.

The rest of the article is organized as follows. The next section reviews related works. Section 3 describes the methodology of our proposed method. We will discuss experiments and evaluation results in Sections 4 and 5, respectively. Finally, the last section contains the conclusion of our work.

## 2 Related work

This work is related to computational techniques for automated propaganda detection (Martino et al., 2020b) and is the continuation of a previous shared task (Martino et al., 2020a).

Taks 11 of SemEval-2020 proposes a more fine-grained analysis by also identifying the underlying techniques behind propaganda in news text, with annotations derived from previously proposed propaganda techniques typologies (Miller, 1939; Robinson, 2019).

This current iteration of the task tackles a more challenging domain, by including multimodal content, notably memes. The subtle interaction between text and image is an open challenge for state of the art multimodal models. For instance, the Hateful Memes challenge (Kiela et al., 2020) was recently proposed, as a binary task for detection of hateful content. The recent advances in pretraining of visuolinguistic representations (Chen et al., 2020) lead the model closer to human accuracy (Sandulescu, 2020).

More generally, propaganda detection is at the crossroad of many tasks, since it can be helped by many subtasks. Fact-checking (Aho and Ullman, 1972; Dale, 2017) can be involved with propaganda detection, alongside various social, emotional and discursive aspects (Sileo et al., 2019a),

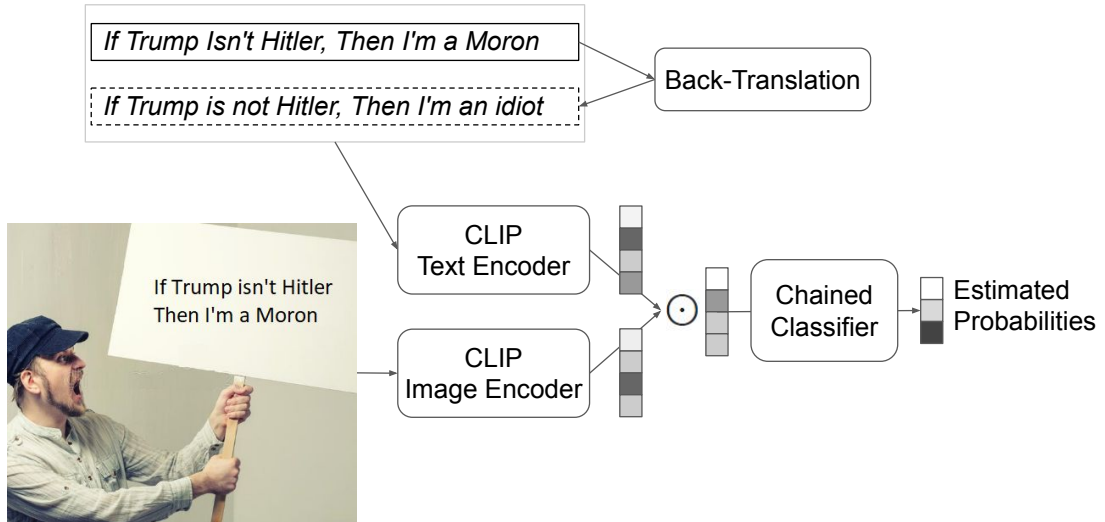

Figure 1: The overall architecture of our proposed model. For each example, use Back-Translation to derive augmentations of the text, and we compute persuasion techniques probabilities separately. Then, we average the estimated probabilities from augmented and original examples.

including offensive language detection (Pradhan et al., 2020; Ghadery and Moens, 2020) emotion analysis (Dolan, 2002), computational study of persuasiveness (Guerini et al., 2008; Carlile et al., 2018) and argumentation (Palau and Moens, 2009; Habernal and Gurevych, 2016).

### 3 Methodology

In this section, we introduce the design of our proposed method. The overall architecture of our method is depicted in figure 1. Our model consists of several components: a data augmentation component (Back-translation), a feature extraction component (CLIP), and a chained classifier. Details of each component are described in the following subsections.

#### 3.1 Augmentation Method

One of the challenges in this subtask is the low number of training data where the organizers have provided just 200 training samples. To enrich the training set we propose to use the back-translation technique (Sennrich et al., 2016) for paraphrasing a given sentence by translating it to a specific target language and translating back to the original language. To this end, we use four translation models, English-to-German, German-to-English, English-to-Russian, and Russian-to-English provided by (Ng et al., 2019). Therefore, for each training sentence, we obtain two paraphrased version of it. In

the test time, we average the probability distributions over the original and paraphrased sentence-image pairs.

#### 3.2 Feature Extraction

Our system isProbabilities of a combination of pre-trained visuolinguistic and linguistic models.

We use CLIP (Radford et al., 2021) as a pre-trained visuolinguistic model. CLIP provides an image encoder  $f_i$  and a text encoder  $f_t$ . They were pretrained on a prediction of matching image/text pairs. The training objective incentivizes high values of  $f_i(I) \cdot f_t(T)$  if  $I$  and  $T$  are matching in the training corpus, and low values of they are not matching<sup>1</sup>. Instead of using a dot product, we create features with element-wise product  $f_i(I) \odot f_t(T)$  of image and text encoding. This enables aspect-based representations of the matching between image and text. We experimented with other compositions (Sileo et al., 2019b) which did not lead to significant improvement.

We then use a classifier  $C$  on top of  $f_i(I) \odot f_t(T)$  to predict the labels.

#### 3.3 Chained Classifier

In this task, we are dealing with a multilabel classification problem, which means we need to predict a subset of labels for a given paired image-text sample as the input. We noticed that label

<sup>1</sup>They assign each image to the text associated to other images in the current batch to generate negative examples

Figure 2: Probabilities of label co-occurrence in the training set. Some label pairs, for instance (SMEARS and LOADED LANGUAGE) are frequently associated.

co-occurrences were not uniformly distributed, as shown in figure 2. To further address the data sparsity, we use another inductive bias at the classifier-level with a chained classifier (Read et al., 2009) using scikit-learn implementation (Pedregosa et al., 2011).

Instead of considering each classification task independently, a chained classifier begins with the training of one classifier for each of the  $L$  labels. But we also sequentially train  $L$  other classifier instances thereafter, each of them using the outputs of the previous classifier as input. This allows our model to model the correlations between labels. We use a Logistic Regression with default parameter as our base classifier.

Our chain classifier uses combined image and text features as the input. We transfer the predicted probabilities of the classifier via the sigmoid activation function to make the probability values more discriminating (Ghadery et al., 2018). Then we apply thresholding on the  $L$  labels probabilities since the task requires a discrete set of labels as output. We predict a label when the associated probability is above a given threshold. We optimize the threshold on the validation set by a simple grid search using values between 0.0 and 0.9 with a step of 0.005.

## 4 Experiments

### 4.1 Datasets

We use the dataset provided by SemEval-2021 organizers for task 6. The dataset consists of 687(290) samples as the training set, 63 samples as the dev set, and 200 samples as the test set. Each sample

Label	Count
Smears	199
Loaded Language	134
Name calling/Labeling	118

is an image and its corresponding text. We use 10% of the training set as the validation set for hyperparameter tuning.

## 5 Evaluation and Results

### 5.1 Results

In this section, we present the results obtained by our model on the test sets for Subtask 3. Table 2 shows the results obtained by the submitted final model on the test set. All the results are provided in terms of macro-F1 and Micro-F1. Furthermore, we provide the results obtained by the random baseline, the best performing method in the competition, and median result for the sake of comparison. Note that, we used the first released training set at the time of final submission which contained just 290 training samples. Therefore, we also provide results obtained by our model after using all the provided 687 training samples. Results show that LIIR has achieved a good performance compared to the majority class baseline and the median result which demonstrates that our model can effectively identify persuasion techniques in text and images. Also, we can observe LIIR has achieved a competitive performance compared to the best result obtained by the best team in the competition when it uses all the training samples.

System	Macro-F1	Micro-F1
Majority class	0.05152	0.07062
Median	0.18842	0.4896
LIIR(290 examples)	0.18807	0.49835
LIIR(687 examples)	0.21796	0.51122
Best system	<b>0.27315</b>	<b>0.58109</b>

Table 2: The results obtained by LIIR compared to the baselines on the Test set for Subtask 3. Numbers in parentheses show the total number of train samples used by our model.

## 5.2 Ablation Analysis

In this part, we provide an ablation study on the effect of different components of our proposed method on the dev set. First, we show the effect of using just visual features, just textual features, and both. Furthermore, we examine how well the final results of our model was influenced by the augmentation method. Table 3 shows the ablation study on the effect of using different features. The first observation is that image features contain more information compared to the textual features. Also, we can observe that the best Micro-F1 score is obtained when we combine both visual and textual features. These results show the effectiveness of our method in making use of both visual and textual information.

System	Macro-F1	Micro-F1
LIIR – textual features	0.32275	0.53237
LIIR – visual features	<b>0.33347</b>	0.52954
LIIR	0.29972	<b>0.58312</b>

Table 3: Ablation analysis for the effect of using different features by our model on the dev set.

In Table 4, the effect of the augmentation technique is shown. As the results show, the augmentation approach is quite effective in improving the model performance by a high margin.

System	Macro-F1	Micro-F1
LIIR w/o Augmentation	0.25090	0.54952
LIIR w Augmentation	<b>0.29972</b>	<b>0.58312</b>

Table 4: Ablation analysis for the effect of augmentation method on the dev set.

## 6 Negative Results

We also tried to use CLIP as a zero-shot classifier for propaganda technique detection. To do so, we constructed prompts such as :

(1) *This image is committing [LABEL] fallacy.*

or

(2) *Saying that [TEXT] is [LABEL] fallacy.*

For each input image/text, we generated a prompt for each labels, and used CLIP to estimate the estimate an affinity score between the prompt and the image. CLIP is designed to predict relatedness between the input image and text, and we expected that an input text mentioning the relevant propaganda technique should be associated with higher probabilities that the others.

However, this method did not seem to perform better than chance. This suggests that propaganda detection technique task might be too abstract for CLIP in zero-shot settings.

## 7 Conclusion

We described our submission for the shared task of multimodal propaganda technique detection at SemEval-2021. Our system performances that are competitive with other systems even though we used a simple architecture with no ensemble, by leveraging non-supervised learning. We believe that further work on zero-shot learning would be a valuable way to improve propaganda detection techniques for the least frequent labels.

# AIMH at SemEval-2021 Task 6: Multimodal Classification Using an Ensemble of Transformer Models

Nicola Messina   Fabrizio Falchi   Claudio Gennaro   Giuseppe Amato  
ISTI-CNR, via G. Moruzzi 1, 56124 Pisa, Italy  
{name.surname}@isti.cnr.it

## Abstract

This paper describes the system used by the AIMH Team to approach the SemEval Task 6. We propose an approach that relies on an architecture based on the transformer model to process multimodal content (text and images) in memes. Our architecture, called DVTT (Double Visual Textual Transformer), approaches Subtasks 1 and 3 of Task 6 as multi-label classification problems, where the text and/or images of the meme are processed, and the probabilities of the presence of each possible persuasion technique are returned as a result. DVTT uses two complete networks of transformers that work on text and images that are mutually conditioned. One of the two modalities acts as the main one and the second one intervenes to enrich the first one, thus obtaining two distinct ways of operation. The two transformers outputs are merged by averaging the inferred probabilities for each possible label, and the overall network is trained end-to-end with a binary cross-entropy loss.

## 1 Introduction

Social networks play a critical role in our society. Nowadays, most of the ideas, thoughts, and political beliefs are shared through the internet using social platforms like Twitter, Facebook, or Instagram. Although these online services enable information to be spread efficiently and effectively, it is non-trivial to understand if the shared contents are free of subtle meanings altering people’s judgment abilities.

Among all the types of content living in a social network, memes acquire a significant role. Memes are small yet effective units of information able to spread cultural ideas, symbols, or practices and usually exist under the form of pictures, possibly with overlaid text. Memes are created so that they can propagate rapidly and reach a large number of users; for this reason, they are one of the most

popular types of content used in an online disinformation campaign, influencing the users through several rhetorical and psychological techniques, such as causal oversimplification, name-calling, or smear. The automatic detection of these memes and the disinformation techniques they are possibly employing is a challenging yet crucial task for the proper management of a social network.

In the last few years, machine learning and deep learning have defined remarkable milestones in automatic content extraction and reasoning from multimedia data. All these breakthroughs acquire a fundamental role in large-scale analysis of multimedia content from social networks.

In this work, we tackle the problem of recognizing which kind of disinformation technique is used to forge memes for a disinformation campaign. In particular, we propose an architecture based on the well-established transformer architecture model (Vaswani et al., 2017) for processing both the textual and visual inputs from the meme. This architecture, which we call DVTT (Double Visual Textual Transformer), comprises two full transformer networks working respectively on images and texts; however, each of these transformers is conditioned on the other modality. We consider this task as a multi-label classification problem, where text and/or images from the meme are processed, and probabilities of presence of each possible persuasion technique are returned as a result.

In this paper, we tackle subtasks 1 and 3 of the *SemEval 2021 Task 6* challenge<sup>1</sup> (Dimitrov et al., 2021). Subtask 1 consists of identifying which of 20 possible persuasion techniques are used in it given only the textual content; subtask 3 is very similar to subtask 1, but both textual and visual contents of the meme are used, and there are 22 possible persuasion techniques. Our proposed models

<sup>1</sup><https://propaganda.math.unipd.it/semEval2021task6/index.html>

could reach the 5th position for subtask 1 and the 4th position for subtask 3 on the publicly available leaderboard. The code for replicating our results is available on GitHub<sup>2</sup>.

## 2 Background

Recently, machine learning, and deep learning in particular, defined astonishing milestones in automatic content extraction and reasoning from multimedia data. In particular, concerning joint visual and textual analysis, many state-of-the-art approaches succeeded in tasks like visual question answering (Hu et al., 2017; Anderson et al., 2018; Teney et al., 2017), image captioning (Zhou et al., 2020; Rennie et al., 2017; Huang et al., 2019; Cornia et al., 2019), and image-text matching (Chen et al., 2019; Lu et al., 2019; Faghri et al., 2018; Lee et al., 2018; Messina et al., 2020), often using structured reasoning using graph networks and graph convolutions.

In the last few years, a graph-network related model, the transformer network (Vaswani et al., 2017), acquired increasing attention on the joint processing of images and texts. Many works, inspired by the BERT model (Devlin et al., 2019), obtained remarkable results on word region alignments, visual-question answering, and image-text matching using transformer encoders (Lu et al., 2019; Qi et al., 2020; Su et al., 2020).

Recently, the authors in (Carion et al., 2020) used the full transformer stack to construct a powerful object detector, demonstrating these models' potential in pure visual contexts.

Given the enormous flexibility of the transformer architecture, in this work, we consider images and texts respectively as sets and sequences of vectors, and we ask the transformer to process them to produce probabilities of presence of each possible persuasion technique.

## 3 System Overview

In this section, we first give a brief overview of the Transformer architecture on which our proposal is based; then, we present in detail our system proposals for solving subtasks 1 and 3.

### 3.1 Review of the Transformer Architecture

In the original transformer formulation for language translation, the source sequence is processed

<sup>2</sup><https://github.com/mesnico/MemePersuasionDetection>

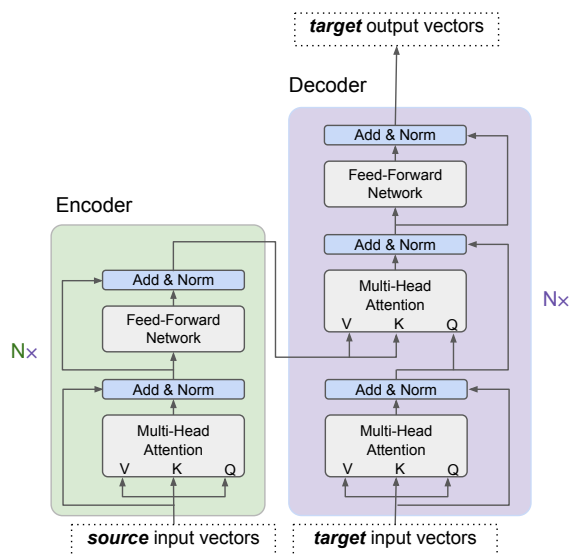

Figure 1: The transformer network. Encoder and Decoder modules are replicated N times.

using the *transformer encoder* model, which creates a suitable set of contextualized vectors encoding the input sequence. Using the representations created by the encoder, the *transformer decoder* module is trained to predict the words for the target sentence one at a time. During the decoding process, the decoder is conditioned, at each time step, by the vectors generated by the encoder.

Both the encoder and the decoder modules leverage the power of the multi-head attention mechanism. This mechanism transforms every word representation from a target sentence to a new representation space conditioned on the words from a source sentence.

The multi-head attention associates to the source sequence vectors  $\{s_i\}$  a key  $K_i$  and to the target vectors  $\{t_j\}$  a query  $Q_j$  and a value  $V_j$ ; the target values are transformed using the scaled dot-product attention as follows:

$$\text{Att}(Q, K, V) = \text{softmax} \left( \frac{QK^T}{\sqrt{d_k}} \right) V. \quad (1)$$

This is the core of the multi-head attention mechanism, which is the fundamental building block in the transformer architecture for both the encoder and the decoder modules (Figure 1).

### 3.2 A Transformer Encoder Baseline

Although the transformer architecture was originally designed to handle sentences (sequences of words), the model in itself can effectively process an arbitrary set of vectors possibly coming from

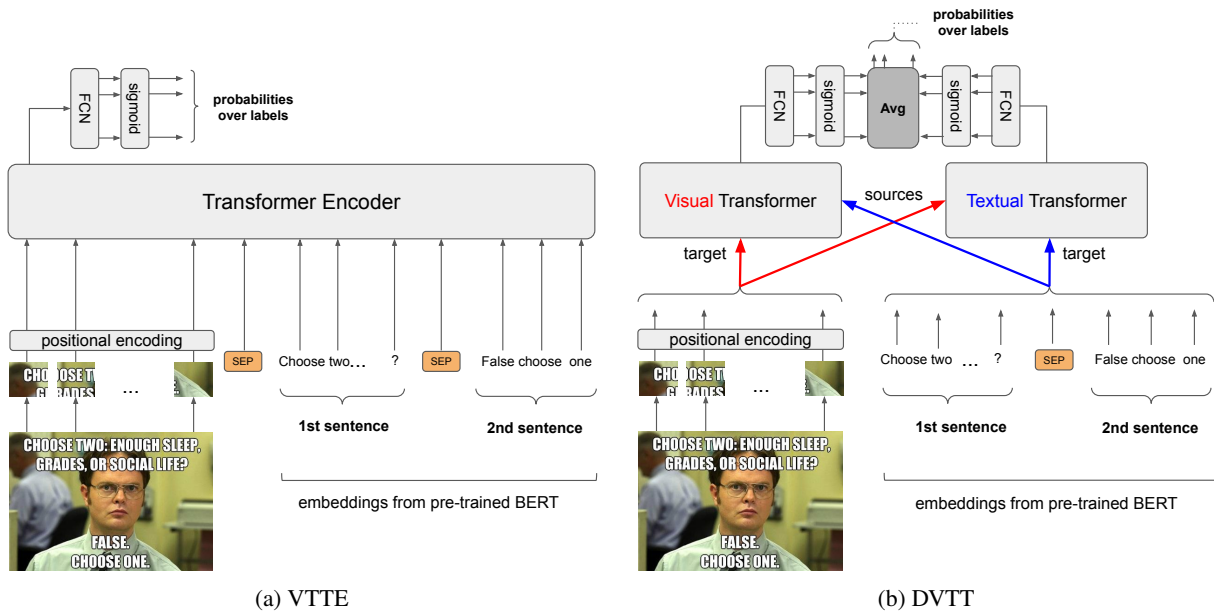

Figure 2: The proposed architectures: (a) the Visual-Textual Transformer Encoder model (VTTE) used as a baseline, and (b) the novel Double Visual Textual Transformer model (DVTT). The shown meme is taken from <https://engineermemes.blogspot.com>, and it is licensed under the Creative Common license.

other modalities (e.g., different chunks of an image).

For this reason, many works (Lu et al., 2019; Qi et al., 2020; Su et al., 2020) recently proposed architectures based on the transformer encoder model to jointly reason on images and texts for solving tasks like visual question answering or image-text matching.

Inspired by these works, we defined a baseline for inferring probabilities over the possible persuasion techniques by feeding images and texts to a transformer encoder, using the first output token as the input to the multi-label classifier head. The transformer encoder visual and textual input features are pre-extracted respectively from a CNN and a pre-trained BERT model, as explained in Section 4. Like in BERT, where different sentences are encoded by separating them using a special token, the textual and the visual inputs are separated by the SEP embedding. An overview of this approach is presented in Figure 2a. We refer to this baseline as *VTTE* (Visual-Textual Transformer Encoder).

### 3.3 Double Visual-Textual Transformer

In this work, instead, we propose an architecture that can exploit the full Transformer architecture to jointly reason on visual and texts and producing label probabilities as output. We call this model *DVTT* (Double Visual Textual Transformer), and it is outlined in Figure 2b. DVTT is composed of two

different transformer networks able to process visual and textual inputs concurrently; the important aspect of DVTT is that each transformer is conditioned on the other modality so that it is possible for the whole architecture to jointly reason on the two modalities following two different paths: in the first, the text is the key aspect, and images integrate the reasoning performed on the text; conversely, in the second, the images are the primary modality and the text intervene to enrich the visual features.

For each of the two transformers, the final head is a multi-classification head constructed on the first token of the output sequence. In particular, a linear layer outputs the logits over each possible persuasion technique, and the final softmax operator converts logits into probabilities, exactly like in the VTTE baseline model. The two transformers outputs are merged by averaging the inferred probabilities for each possible label, and the overall network is trained end-to-end with a binary cross-entropy loss.

## 4 Experiments

We used the data provided by the *SemEval 2021 Task 6* challenge organizers to train and validate our model. Although we mainly concentrated on subtask 3 (images + texts), we also tackled subtask 1, which is essentially equivalent to subtask 3, except that only the text is available.

**Dataset** The provided dataset comprises 687 memes for training, 63 memes for validating on the so-called development set, and 200 memes for the final testing. All the memes carry textual captions written in English. Note that, in the end, we were allowed to use the annotations for the development set, so we had at our disposal a total of 750 annotated memes to use for the training and validation phases. The annotations consist of a list of persuasion techniques for every meme. In subtask 1 there are 20 possible persuasion techniques and 22 in subtask 3.

**Metrics** The official metrics for computing the model performance are the Micro- $F_1$  and Macro- $F_1$  scores;

The  $F_1$ -score is defined as the harmonic mean of precision and recall:

$$F_1 = \frac{2}{\text{recall}^{-1} + \text{precision}^{-1}} \quad (2)$$

The  $F_1$ -score gives values in the interval  $[0, 1]$ , hence it is often a good way of summarizing the performance of binary classifiers.

The difference between Micro- $F_1$  and Macro- $F_1$  scores lies in the way *precision* and *recall* are computed: in Micro- $F_1$ , they are computed from all the true positives, false positives, and false negatives over all the labels; for this reason, Micro- $F_1$  gives each sample the same weight, thus giving more emphasis to the most frequent labels. On the other hand, Macro- $F_1$  is computed as the mean value among the  $F_1$ -scores computed on the different labels:  $\text{Macro-}F_1 = \frac{1}{N} \sum_1^N F_1^i$ , where  $N$  is the number of labels and  $F_1^i$  is the  $F_1$ -score computed among the samples having label  $i$ . In this case, all the classes contribute equally regardless of how often they appear in the dataset.

**Model Setup** For subtask 3, we used the proposed DVTT model (Figure 2b). We used a learning rate of  $5 \cdot 10^{-5}$  and a batch size of 8. We trained the models for 40 epochs in all the experiments, decreasing the learning rate after 30 epochs to  $5 \cdot 10^{-6}$ . The transformer is composed of 4 encoder layers and 4 decoder layers, with 1024-dimensional feed-forward networks for producing queries, keys, and values.

As a baseline for subtask 3, we used the VTTE architecture (shown in Figure 2a), composed of a 4-layer transformer encoder module, with a multi-label classification head on top, exactly like the one

in DVTT. For subtask 1, instead, we used the VTTE architecture (Figure 2a) with the same setup used for the subtask 3 baseline, except that the visual input is not fed to the network.

**Features Extraction** For all the conducted experiments, we obtained suitable visual and textual features from pre-trained state-of-the-art networks. Concerning images, we re-scaled them to  $256 \times 256$ , and we took a  $224 \times 224$  crop (a random crop during training and a center crop during inference). We also normalized the images using the pixels mean and standard deviation computed on the whole dataset.

In order to input an image to the transformer, we had to encode it as a set of features. We used a ResNet50 pre-trained on image classification, as it is characterized by a good performance at low computational costs compared to deeper backbones; we down-sampled the features maps from the last convolutional layer to a  $7 \times 7$  spatial grid of 2048-dimensional features. The resulting flattened 49 visual features were then augmented with their spatial positions by appending the normalized coordinates of the chunk to the 2048-dimensional visual feature. Another possibility consisted of using visual features extracted from state-of-the-art object detectors, like Faster-RCNN. However, images carried in memes are not homogeneous: they show possible stacked scenes and overlaid text, making it very difficult for an object detector to identify the most critical regions.

Concerning text processing, we used a pre-trained BERT model (Devlin et al., 2019) for extracting word embeddings. BERT embeddings are trained on some generic language processing tasks such as sentence prediction or sentence classification and demonstrated state-of-the-art results in many downstream tasks. Every meme can carry one or more sentences, encoded in the same string and separated by “\n\n”. For this reason, during the string tokenization phase, we simply replaced “\n\n” with the SEP token. In the basic DVTT model, we trained only the transformer models, leaving the feature extractor fixed. In the Experiments section, we also report the results from a fine-tuning of the feature extractors.

**Validation** The test-set annotations were hidden to the participants, so the model should be validated using a split of the available annotated data. Given that the available annotated memes are relatively

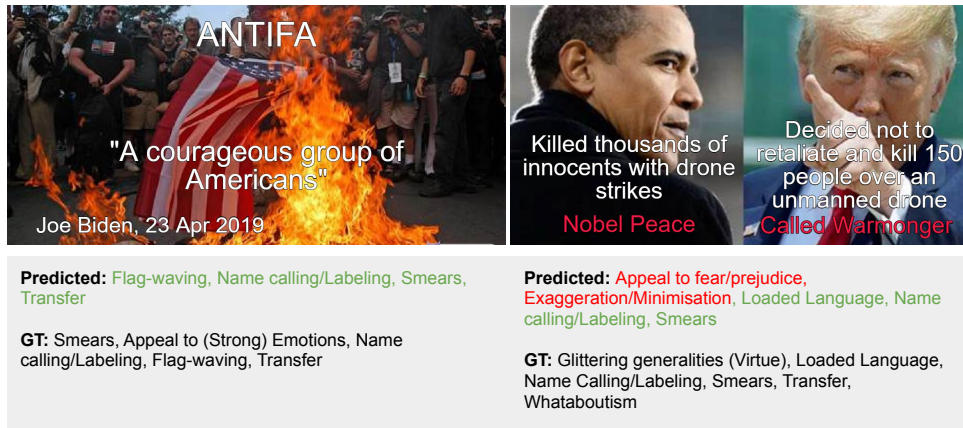

Figure 3: Example of predictions from the DVTT model for subtask 3. In green, the true positives labels; in red, the false positives labels. Images obey to the Creative Common license and they are searched on the Bing image-search engine using "free to modify, share and use" license filtering.

Model	Macro- $F_1$	Micro- $F_1$
VTTE (Baseline)	0.327	0.596
DVTT	0.336	<b>0.601</b>
DVTT - Balanced	0.300	0.489
DVTT - Finetuned	<b>0.341</b>	0.592
DVTT - 2 layers	0.310	0.596
DVTT - 6 layers	0.325	0.583

Table 1: Ablation results on subtask 3

Model	Macro- $F_1$	Micro- $F_1$
VTTE	0.372	0.566
VTTE - Balanced	0.361	0.490
VTTE - Finetuned	0.386	<b>0.581</b>
VTTE - 2 layers	0.365	0.565
VTTE - 6 layers	<b>0.389</b>	0.569

Table 2: Ablation results on subtask 1. Note that VTTE in this case does not receive the images in input.

few, we validated our model using cross-validation. In particular, we split the training data into six different folds, training six different models by using five out of six data folds and validating them using the remaining fold. We selected the model having the best sum of Micro- $F_1$  and Macro- $F_1$  scores on the validation fold. All the performance measures reported in the Results section are an average of the metrics from this 6-fold validation procedure.

For participating in the final competition on the test set, we prepared an ensemble model composed of all the six trained models, and we produced the final probabilities by soft-voting.

We used a final binary-classification threshold of 0.3 over the label probabilities.

## 5 Results

Concerning subtask 3, we studied the performance of our DVTT model by comparing the  $F_1$ -scores against the VTTE baseline; furthermore, we tried also to train the model using a balanced sampling of the labels and to fine-tune the feature extractors (BERT and the ResNet-50), using a learning rate of 1/10 with respect to the one used for training the transformer models. Using a lower learning rate during the fine-tuning process is a common procedure to avoid model overfitting. We also report the results of slightly different variants of the DVTT model obtained by increasing and decreasing the number of the transformer's encoder / decoder layers: the base architecture contains four layers; we also experimented with two and six. The results of these experiments are reported in Table 1.

For subtask 1, instead, we used the VTTE model without visual input, trying out the same experiments performed for subtask 3. In this case, when varying the number of layers, we only considered the transformer encoder ones (there is no decoder in the VTTE model). The ablation results on subtask 1 are reported in Table 2.

## 6 Discussion

Looking at the subtask 3 results in Table 1, we can notice that the proposed DVTT model can achieve slightly better results than the VTTE baseline. In particular, the DVTT with fine-tuned BERT and ResNet50 modules achieve the best results on the Macro- $F_1$  metric. Also, the choice of using four encoder and decoder layers seems to lead to the best compromise on both the metrics. Concerning the results of subtask 1 in Table 2, fine-tuning the BERT model is even in this case a good choice. Fine-tuning the feature extractors, in fact, enables the model to slightly adjust the weights of the backbones pre-trained on generic tasks to align them to the specific domain.

Figure 3 reports some examples of predictions from our model for subtask 3. We evidenced in green the true positives and in red the false positives. The model can correctly identify most of the persuasion techniques. However, there are cases where it is probably necessary to access more contextual information to solve the most complex labels. For example, in the second meme from the left, the model outputs the label *Exaggeration/Minimisation* probably due to the presence of vague quantities (*Killed thousands of innocents*). It would be necessary to access external data to effectively reason on the complex common sense and historical facts hidden behind these complex memes.

## 7 Conclusions

In this work, we proposed transformer-based models for tackling subtasks 1 and 3 of the SemEval-2021 Task 6, concerning the identification of persuasion techniques in memes. In particular, for subtask 3 which involves both images and texts from the meme, we proposed a Double Visual Textual Transformer (DVTT) model. This model uses the full power of the transformer architecture; it demonstrated better results than the baseline, which is composed of a single transformer encoder module fed with both images and text. On the public leaderboard, we reached 4th place on subtask 3. Using the baseline model, which can process text alone without images, we also tackled subtask 1, reaching 5th place on the public leaderboard.

In the future, we plan to improve our visual feature extraction pipeline, using face expression detection and classification and possibly employing ad-hoc trained object detectors suitable for meme

images. Also, it would be interesting to study the effective reasoning abilities of the proposed models, by leveraging the attention mechanisms of the transformer, possibly integrating the data with a knowledge base of historical facts that helps to create a more suitable context.

<sup>2</sup>Faculty of Economic Sciences, University of Warsaw

{konrad.kaczynski, piotr.przybyla}@ipipan.waw.pl

## Abstract

Among the tasks motivated by the proliferation of misinformation, propaganda detection is particularly challenging due to the deficit of fine-grained manual annotations required to train machine learning models. Here we show how data from other related tasks, including credibility assessment, can be leveraged in multi-task learning (MTL) framework to accelerate the training process. To that end, we design a BERT-based model with multiple output layers, train it in several MTL scenarios and perform evaluation against the SemEval gold standard.

## 1 Introduction

Fine-grained propaganda detection is a new approach to tackling online misinformation, highlighting instances of propaganda techniques on the word level. These techniques are used in textual communication in order to encourage certain beliefs, but instead of straightforward presentation of arguments, they rely on psychological manipulation, logical fallacies or emotion elicitation.

There are general-purpose natural language processing (NLP) methods that could be used for automatic detection of such text fragments. The challenge here is that they require large amounts of training data, which are laborious to produce. However, propaganda techniques are often related to other misinformation challenges, for which large datasets do exist, e.g. credibility assessment or fake news detection.

In the present study we aim to investigate how this connection can be used in the multi-task learning (MTL) framework. We show how the performance of multi-label token-level propaganda detection within shared task 6 at SemEval-2021 can be improved by building neural architectures that are also trained to solve other tasks: single-label propaganda detection from SemEval-2020

and document-level credibility assessment based on a fake news corpus. We check different MTL scenarios (parallel and sequential) and show which aspects of the model benefit the most from this approach.

## 2 Problem Statement

We participate in SemEval-2021 Task 6 („Detection of Persuasion Techniques in Texts and Images”), subtask 2 (Dimitrov et al., 2021), where the goal is to identify all propaganda techniques within a provided fragment of text. Specifically, given a character sequence  $\langle c_0, c_1, \dots, c_N \rangle$ , we aim to produce a set of annotations  $\{(b_0, e_0, t_0), (b_1, e_1, t_1), \dots, (b_k, e_k, t_k)\}$ , where each triple consists of the character offsets of the span it covers ( $0 \leq b_i < e_i \leq N$ ) and an indication which one from the set of 20 known techniques is detected there ( $t_i \in T$ ). We can see it as a multi-label sequence classification task (Read et al., 2009), where each character (or token) can be assigned from 0 to 20 labels.

## 3 Related Work

Propaganda has been observed in text for a long time, but the problem of automatic detection of such techniques was posed just recently. Initially, a lack of word-level datasets confined the analysis to document-level classification, e.g. based on stylometric features (Rashkin et al., 2017; Barrón-Cedeño et al., 2019). Classification on the word level became possible with the dataset (Da San Martino et al., 2019b) released for the „Fine-Grained Propaganda Detection” shared task at the NLP4IF 2019 workshop (Da San Martino et al., 2019a). The corpus includes 550 news articles annotated with propaganda techniques on the word level. Among the submissions, the best performing models were based on word embeddings and pretrained lan-

guage models, such as BERT (Devlin et al., 2018). To tackle the data sparsity problem, participants employed various over-sampling methods or trained their models on auxiliary data. Similar objectives were pursued at SemEval 2020 Task 11, consisting of two subtasks: binary sequence tagging task and multi-class classification task. The majority of tasks’ participants based their solutions on the Transformers architecture (Vaswani et al., 2017) and word embeddings, combining them with other neural architectures (e.g. CNNs or LSTMs) or models such as CRF and logistic regression. Ensemble models were able to achieve satisfactory results when performing both tasks jointly.

## 4 Methods

### 4.1 Data Description

We make use of three datasets in English. In all the following approaches, the main focus is on the corpus released for SemEval-2021 Task 6 (Dimitrov et al., 2021) (S21). Additionally, we utilise the corpora from SemEval-2020 Task 11 (S20) (Da San Martino et al., 2020) and news credibility research (FN) (Przybyła, 2020).

S21 consists of text of 870 memes (607, 63 and 200 in the training, development and test subsets, respectively) annotated with 1550 spans a few words long (40 characters on average), each from one of 20 propaganda techniques. Most commonly occurring techniques are *Loaded language* (35%), *Name Calling/Labelling* (19%) and *Smears* (12%).

S20 corpus consists of 446 press articles (371 and 75 in the training and development subsets, respectively) annotated with 14 propaganda categories on a word level. Among the 7192 annotated spans, *Loaded language* (34%), *Name Calling/Labelling* (17%) and *Repetition* (12%) are most common categories. Given that very few spans overlap (8%), we represent the task as single-label classification by merging these spans according to their order in corresponding label files. Finally, we exclude sentences that do not contain any propaganda annotations.

To obtain the FN data, from the original corpus of 103,219 news articles classified as either credible or non-credible based on their source, we randomly select a sample of fifty thousand sentences with a binary credibility label.

### 4.2 Multi-Task Architecture

Figure 1 shows the architecture designed to fulfil the MTL objectives. A text document (usually one sentence) is first processed by BERT, resulting in 768-dimensional vectors:  $h_i$  for the  $i$ -th token and  $h_0$  for the whole document, using the [CLS] token. These vectors are processed by classification modules  $D_x$ , each consisting of a linear dense layer and a softmax activation function. Three types of such operations are considered:

- $d_0 = D_d(h_0)$ : document-level representation is used to produce 2-dimensional score vector ( $d_0$ ), indicating class probabilities in binary single-label classification,
- $s_i = D_s(h_i)$ : token-level representation is used to produce  $k$ -dimensional score vector ( $s_i$ ), indicating class probabilities in multi-class single-label classification,
- $m_i = D_m(h_i)$ : token-level representation is used to produce  $l \times 2$ -dimensional score vector ( $m_i$ ), indicating class probabilities in multi-class multi-label classification.

The following subsections describe several scenarios of using these three output types to improve the accuracy of propaganda detection.

### 4.3 Single Task

In the primary method we use BERT-Base-Uncased with the token-level multi-label classification layer, trained using only S21 data (SINGLE S21). The output for the  $i$ -token, denoted by  $m_i$ , is a  $20 \times 2$  matrix, in which the  $j$ -th row reflects the probability of the  $j$ -th propaganda technique being present in this token. If the token does not participate in any propaganda techniques, the first column of the matrix will be filled with ones and the second one with zeros. Since the S21 corpus is annotated at the character level, during preprocessing we map the initial annotation into tokens obtained via Word-Piece tokenisation.

### 4.4 Sequential Multi-Task Learning

In case of sequential MTL, the main training described in previous section is preceded with training for one of two auxiliary tasks:

- single-label classification task on S20 corpus (MULTI-S S20-S21).
- document-level classification task with FN corpus (MULTI-S FN-S21).

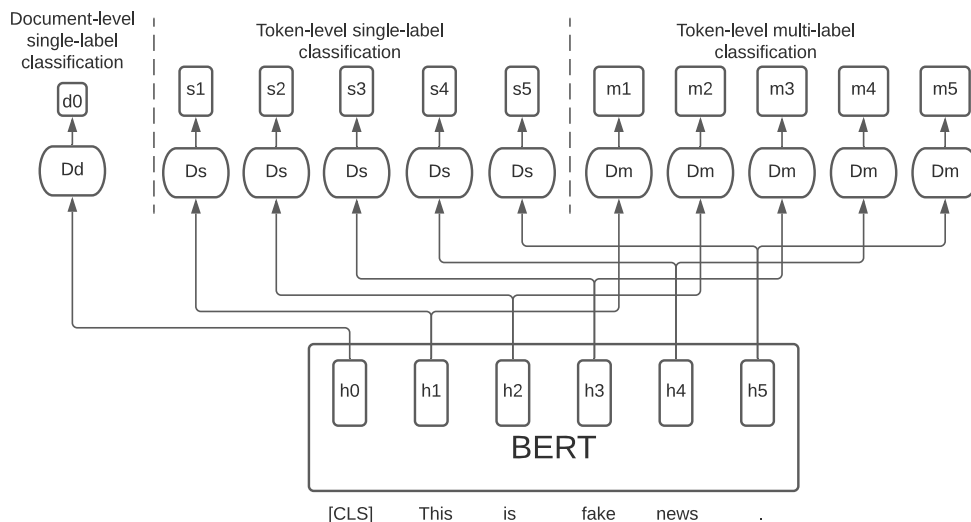

Figure 1: Multi-task architecture of our solution

For MULTI-S S20-S21, we involve the token-level single-label classification layer to produce 16-dimensional  $s_i$  vector. This allows to classify each token in S20 corpus into one of 16 categories (14 propaganda + non-propaganda + padding). MULTI-S FN-S21 uses the document-level single-label classification output ( $d_0$ ) layer for classifying sentences from FN corpus as coming from credible ( $d_0 = (0, 1)$ ) or non-credible ( $d_0 = (1, 0)$ ) articles.

For each model the learning procedure is the same: first, during an auxiliary task, only the additional classification layer is trained using cross-entropy loss and the auxiliary data. In the second phase, the training continues as a regular task on S21 data, as described in the previous section. Weights of all trainable variables are being updated in both phases.

#### 4.5 Parallel Multi-Task Learning

In the parallel MTL objective, the auxiliary task and the target task are learnt jointly. Similarly to sequential MTL, we devise two models, each consisting of BERT with two separate classification layers on top:

- single-label and multi-label classification on S20 and S21 corpora (MULTI-P S20-S21),
- document-level and multi-label classification tasks on FN and S21 corpora (MULTI-P FN-S21).

Every batch of data consists of sentences coming from both datasets: four sentences from S20 or FN and four sentences from S21 are sent through their corresponding classification layers to produce

outputs, and then count losses and update weights based on appropriate losses.

## 5 Evaluation

### 5.1 Experimental setup

We train our models according to multi-task scenarios, and use development subset of S21 to choose optimal number of training epochs of the final phase. The model trained up to this point is applied to test data to produce final predictions. In case of sequential MTL scenarios, this is preceded by training on additional corpora: on S20 for 10 epochs or on FN for 1 epoch. In case of parallel multi-task scenarios, the difference of training set sizes requires a special approach. For S20-S21, one epoch of training covers the whole S21 and 1/9 of S20. For FN-S21, we choose a balanced sub-sample of 18 thousand sentences and each training epoch covers the whole S21 and 1/30 of this sub-sample.

We use cross-entropy as the loss function, and compute it only for non-padding tokens. For all experiments we use a maximum sequence length of 210 tokens, Adam optimizer (Kingma and Ba, 2015) with the learning rate of  $3 \times 10^{-5}$  and batch size of four sentences. We use the L1 regularisation (Ng, 2004) with  $\alpha = 0.01$ . During fine-tuning of the model, weights of all trainable variables, including those in BERT, are being updated. During inference, we translate token-level labels back to character-level labels, including spaces and punctuation marks between adjacent tokens with identical labels. All experiments are conducted within the *TensorFlow* framework.

Approach	Dev			Test		
	F1	Precision	Recall	F1	Precision	Recall
SINGLE S21	0.5412	0.5798	0.5075	<b>0.4571</b>	0.4752	0.4403
MULTI-S S20-S21	0.5084	0.5181	0.4990	0.4444	0.4500	0.4390
MULTI-S FN-S21	0.4581	0.4836	0.4351	0.4185	0.4778	0.3723
MULTI-M S20-S21	<b>0.5455</b>	0.5747	0.5191	<u>0.4074</u>	<u>0.4121</u>	<u>0.4028</u>
MULTI-M FN-S21	0.5291	0.6429	0.4496	0.4381	0.5307	0.3730

Table 1: Propaganda detection performance on the development and test set for different evaluated approaches. The best F1 scores are highlighted. The run submitted to the shared task is underlined.

## 5.2 Evaluation measures

To evaluate our results we use character-level F1 measure prepared for the shared task (Dimitrov et al., 2021). It compares model’s results with the golden annotations, accounting for the imbalance of categories and partial overlaps between fragments with the same label.

## 6 Results

Table 1 shows the performance of the considered approaches on the development and test set. The highest F1 score on the development set was obtained by the MULTI-P S20-S21 model. Hence, this model was used to generate the predictions on the test set submitted to the shared task (underlined). However, we can see that the single task approach is not far behind on the development set and actually provides the best performance on the test set. The differences between approaches are relatively modest and no single model outperforms others on each set and metric. This is mostly due to the small size of the propaganda datasets. Specifically, choosing the approach and number of training epochs based on the development set, which contains just 63 documents, may lead to overfitting.

In order to better understand how the introduction of MTL influences the models, we perform additional experiments. Firstly, in Table 2 we show F1 score for the recognition of each technique in single task and sequential MTL scenarios using both auxiliary datasets. One could expect the usage of S20, annotated with a similar set of propaganda techniques, to improve performance for overlapping labels, but the data do not confirm this. For example, the performance for the relatively large (12.7%) *Smears* (Smr) category improves noticeably, even though it was not present in S20. At the same time, we see F1 drop in case of some techniques present in both datasets, such as *Appeal to authority* (AtA) or *Slogans* (Slg). Clearly, the

Technique	S21	M-S S20	M-S FN
AtA	0.6316	0.0000	0.7273
Atfp	0.0000	0.3966	0.0000
Bwf\D	0.6292	0.5824	0.0000
CO	0.0000	0.1667	0.0000

Gg	0.2222	0.0000	0.0000
LL	0.7038	0.6385	0.7135
NC-L	0.6136	0.6159	0.6830
Slg	0.3448	0.0000	0.3750
Smr	0.3839	0.5756	0.4743
Whbt	0.3830	0.0000	0.2222

Table 2: Per-technique F1 score on test set for different auxiliary datasets: S20 propaganda (S20) and fake news (FN) used in sequential multi-task scenario (techniques with no performance differences omitted for brevity).

language constructions covered by these labels in case of press articles and memes are too different to offer clear advantage of MTL. The relationship with fake news detection is even weaker, resulting in many techniques not being recognised.

Secondly, in Figure 2 we show how F1 on test set changes during training on S21 for the single task configuration and two scenarios based on S20 data: sequential and parallel. As expected, we see that pre-training allows our model to obtain good performance much faster, e.g. reaching F1=0.4 after 7 epochs instead of 14. But after longer training, the single-task approach catches up and beyond 20th epoch, when all version reach stable results, it outperforms the MTL variants.

## 7 Conclusion

In this work we explore how detection of propaganda techniques in text of memes can be facil-

Figure 2: F1 scores during training for single task approach and multi-task learning using S20 data.

itated using external data in multi-task learning framework. The results show that the auxiliary tasks indeed influence the results, both in terms of accelerating the learning process and changing the set of recognised techniques. Nevertheless, these modifications do not offer clear advantages over the basic BERT-based solution.

We hypothesise this is because the link between main and auxiliary tasks is not strong enough to deliver benefits through multi-task learning. Additionally, propaganda is rarely a straightforward phenomenon and different techniques may require tailored approaches. We treat this effort as a preliminary study and aim to further investigate MTL’s relevance in detecting propaganda by extending the auxiliary tasks portfolio with corpora reflecting other related issues, such as hate speech or hyper-partisan language.

## Abstract

This paper presents the solution proposed by the 1213Li team for subtask 3 in SemEval-2021 Task 6: identifying the multiple persuasion techniques used in the multi-modal content of the meme. We explored various approaches in feature extraction and the detection of persuasion labels. Our final model employs pre-trained models including RoBERTa and ResNet-50 as a feature extractor for texts and images, respectively, and adopts a label embedding layer with multi-modal attention mechanism to measure the similarity of labels with the multi-modal information and fuse features for label prediction. Our proposed method outperforms the provided baseline method and achieves 3rd out of 16 participants with 0.54860/0.22830 for Micro/Macro F1 scores.

## 1 Introduction

The development of the Internet and Information Technology promotes the generation and dissemination of information, but also fuels the proliferation of disinformation. As one of the most popular types of content in disinformation, memes attract readers easily and brought further challenges to the detection of disinformation (Martino et al., 2020; Dimitrov et al., 2021).

Specifically, memes employ a number of techniques to influence users, which can be divided into the use of logical fallacies and appealing to the emotions of the audience (Dimitrov et al., 2021). In practice, the former misuses logical rules to disguise wrong conclusions as correct and objective,

Figure 1: Examples of multi-modal samples, we rewrite the sentences on our own and collect the images from<sup>‡</sup>, <sup>§</sup>, <sup>¶</sup>, respectively. The first two rows illustrate the visual and the textual content, and in the last row, each line reveals the label (techniques) of the sample.

while the latter utilizes emotional language to induce the audience to agree with the speaker emotionally and prevent their rational analysis of the argumentation.

Identifying the techniques used in memes contributes to the understanding of user-generated content and further helps to the detection of disinformation. The subtask 3 of SemEval-2021 Task 6 (Dimitrov et al., 2021) is organized to stimulate the study of computational methods to detect persuasion techniques in memes that inhere in texts and images.

As shown in Figure 1, each sample consists of a set of textual sentences and an attached image. According to the task description (Dimitrov et al., 2021), the image and the sentence could convey the modality-specific persuasion techniques, respectively, and at the same time, images can be combined with sentence to express some techniques, which we named global techniques. Based on the understanding of the task, we attribute the main challenges of subtask 3 to the following three as-

Figure 2: Overview of our proposed method. Our method takes the textual sentences and image as inputs and predicts a binary result for each label. Notably, “LE” in the figure denotes the label embedding module, and this figure illustrates the prediction for the label highlighted in red.

pects: 1) extracting essential features from each modality to predict modality-specific labels, 2) fusing multi-modal features to understand the content fully for predicting global labels, and 3) capturing the connections among multi labels.

Correspondingly, we present the methods to handle these challenges. Specifically, our method employs the powerful feature extractor including the pre-trained RoBERTa (Liu et al., 2019) and ResNet-50 (He et al., 2016) to extract textual and visual features, respectively. Besides, inspired by the work Augenstein et al. (2019), our method adopts a label embedding layer to learn how semantically close the labels are to one another implicitly, and the embedding layer maps each label to a learnable fixed-size vector. Before the label prediction, multi-modal features are fused according to their relevance with each label using attention mechanism (Bahdanau et al., 2015), and the final prediction is based on the fused features.

## 2 Related Work

Subtask 3 is a multi-label classification task based on multi-modal data. As for the multi-label classification tasks, it was earlier handled by many machine learning methods. Zhang et al. (Zhang and Zhou, 2005) used a k-nearest neighbor-based algorithm to conduct experiments on real-world multi-label bioinformatic data. Vens et al. (Vens et al., 2008) proposed a hierarchical multi-label classification method based on Decision trees. With the rapid development of deep learning, multi-label classification methods based on deep neural networks have become mainstream. Wang et al. (Wang et al., 2016) introduced and multi-label image classification network with the fusion of CNN and RNN.

Chernyavskiy et al. (Chernyavskiy et al., 2020) used a RoBERTa-based network combined with additional CRF (Lafferty et al., 2001) layers and transfer learning mechanism (Pan and Yang, 2010) to address a multi-label classification task in SemEval-2020. However, these previous multi-label classification tasks were often based on single modality data. These approaches fall short when the task requires the use of multiple modal data.

Moreover, in the field of multi-modal tasks, we focus on task of multi-modal fake news detection. Recent work (Jin et al., 2017; Wang et al., 2018; Khattar et al., 2019) mainly concern the fusion of multi-modal features and adopt a binary classifier, which is not applicable to current multi-label classification scenarios.

## 3 Methodology

### 3.1 Task Formulation

The task of identifying the techniques used in memes is defined as a multi-label classification problem of given multi-modal sample. We refer the textual sentences as  $\mathbf{S}$  and the attached image as  $\mathbf{I}$ , and use  $\mathcal{M}$  to denote the multi-modal model which map inputs  $\mathbf{S}$  and  $\mathbf{I}$  into a set of  $N$  binary values that represent the corresponding label. The task is formulated as follows:

$$\mathcal{M}(\mathcal{F}(\phi(\mathbf{S}), \phi(\mathbf{I}))) \longrightarrow \{0, 1, \dots, 1\} \quad (1)$$

In the Equation 1,  $\phi$  denotes the multi-modal feature extractor for textual and visual content, respectively, and  $\mathcal{F}$  denotes the fusion of the multi-modal features. The length of predicted results is the same as the number of labels and 1 indicates the corresponding label is predicted.

## 3.2 Method

In this section, we demonstrate the method used by our team for subtask 3. As shown in Figure 2, our method consists of three main layers: Extraction Layer, Fusion Layer, and the final Classifier. In the rest of this subsection, we describe each layer in detail.

### 3.2.1 Extraction Layer

In the Extraction Layer, the pre-trained RoBERTa is used to extract textual features. Specifically, given that RoBERTa receives at most two sentences as input while some samples may contain multiple pieces of sentences, we splice all sentences into a single sentence and retain the character “\n\n” as the separator. As for the outputs of RoBERTa, we merely reserve the representation of each token as sequential features  $\mathbf{T}$  for the post-processing.

For the image input, we use the ResNet-50 pre-trained on ImageNet to extract visual features. Before the image is input to the ResNet-50 network, it needs to be normalized and cropped into  $3*224*224$ . Afterward, we select the last convolution layer’s feature maps with size  $2048*7*7$  as visual features and transform it into a sequential features  $\mathbf{V}$  with size of  $49 * 2048$ .

### 3.2.2 Fusion Layer

The Fusion Layer aims to select the features for the label prediction. As mentioned earlier, the labels implied in the memes include both modality-specific labels and global labels. To promote the prediction of modality-specific labels, we perform the average-pooling on both textual and visual features to extract the modality-specific features  $\mathbf{T}_{avg}$  and  $\mathbf{V}_{avg}$  (“avg” in Figure 2).

$$\mathbf{T}_{avg} = \text{AvgPooling}(\mathbf{T}) \quad (2)$$

$$\mathbf{V}_{avg} = \text{AvgPooling}(\mathbf{V}) \quad (3)$$

Meanwhile, to promote global labels’ prediction, we adopt the attention mechanism to fuse multi-modal features. Particularly, As depicted in Equation 4-6, we first calculate the similarity between  $i$ th label embeddings and textual features. We then weighted-sum the textual features according to the similarity scores and obtain label-related representation  $\mathbf{T}_{i,att}$  (“att” in Figure 2). The similar operation is applied to the Visual and produce  $\mathbf{V}_{i,att}$ .

$$S_{i,j} = \mathbf{L}_i \cdot \mathbf{T}_j^T, \forall j \in [1, \dots, \ell_T] \quad (4)$$

$$\alpha_i = \text{Softmax}[S_{i,1}, \dots, S_{i,n}] \quad (5)$$

$$\mathbf{T}_{i,att} = \sum_{j=1}^{\ell_T} \alpha_{i,j} \mathbf{T}_j \quad (6)$$

Finally, we concatenate the features obtained above as the final representation of the input and pass it into the Classifier.

$$\mathbf{R}_i = [\mathbf{T}_{avg}; \mathbf{V}_{avg}; \mathbf{T}_{i,att}; \mathbf{V}_{i,att}] \quad (7)$$

### 3.2.3 Classifier

We adopt a three-layers fully connected network as the classifier, which maps the final representation  $\mathbf{R}_i$  obtained ahead into a scalar. Then we employ a sigmoid function to squeeze the scalar to the interval of 0-1. Notably, for each label, the process mentioned above is required and performed synchronously. Hence our model finally outputs a vector whose length is consistent with the number of labels.

## 4 Experimental Setup

### 4.1 Dataset

The dataset was provided by SemEval2021 Task6 subtask3, and the training set, development set, and test set contain 687, 63, and 200 samples, respectively. Each sample is combined with an image-text pair, id, and labels.

### 4.2 Evaluation Measures

The official evaluation measure for this technique classification is Micro-F1. The Macro-F1 is also reported, and we will consider both the performance of Micro-F1 and Macro-F1 during the experiment.

### 4.3 Parameter Settings

To train the model, we adopt the binary cross-entropy loss as the objective function and employ the Adam method(Kingma and Ba, 2015) with a learning rate of 0.0001 to optimize it. We set the minibatch size at 64 and the dimensions of label embeddings at 256. Based on experimental verification, we fixed the parameters of ResNet-50 while fine-tuning the parameters of RoBERTa during the training. Our methods are implemented with PyTorch and run on a single Nvidia 1080ti graphic card.

Model	Macro F1	Micro F1
RoBERTa+ ResNet-50	0.0812	0.1333
+ visual_att	0.1155	0.4140
+ textual_att	0.0814	0.5256
+ full_att	0.2040	0.5680

Table 1: Ablation results on validation set.

Rank	Team	Macro F1	Micro F1
1	Alpha	0.27315	0.58109
2	MinD	0.24389	0.56623
3	<b>1213Li</b>	<b>0.22830</b>	<b>0.54860</b>
4	AIMH	0.20729	0.53994
5	Volta	0.18877	0.52070
...	...	...	...
16	Baseline	0.05152	0.07062

Table 2: Evaluation results of top 5 teams on blind test set that reported on the official website.

#### 4.4 Ensemble

We use an ensemble of 5 models with different development set to predict the training set. Among the five ensembled models, one model uses the original training set and development set, and the remaining four models use the 64 samples randomly divided from the combined data of the training set and development set as the new development set, and use the rest as the training set.

### 5 Results and Discussion

The result of the ablation study is shown in Table 1. As we can see, the baseline method is very ineffective since it utilizes only the average-pooling features of visual and textual information, indicating that the lack of the interaction between modality-specific features and label information hinder the model to select vital features for prediction and leads to poor performance.

So we introduce the attention mechanism to selectively choose valid information from visual features and textual features, respectively. As shown in the second group of Table 1, the use of the attention mechanism significantly improves the model’s performance, especially the Micro F1 score.

Finally, the model that uses both visual features and textual features in combination with the attention mechanism has the optimal performance. During the test stage, we chose the model that performed best on the development set and got the

final result through the ensemble. The final evaluation results are reported in Table 2.

## 6 Conclusion

This paper demonstrates the method that we proposed for subtask 3 in SemEval-2021 Task 6, which aims to identify which of 22 persuasion techniques are used in the textual and visual content of the specific meme. Our method uses RoBERTa and ResNet-50 to extract multi-modal features, introduces the attention mechanism to fuse multi-modal features, and adopts the label embeddings to learn the representation of labels. Our proposed model achieves noticeable improvements over the baseline method, and the official evaluation ranked our submission 3rd out of 16 teams.

# NLyticsFKIE at SemEval-2021 Task 6: Detection of Persuasion Techniques In Texts And Images

**Albert Pritzkau**

Fraunhofer FKIE / Wachtberg, Germany  
albert.pritzkau@fkie.fraunhofer.de

## Abstract

The following system description presents our approach to the detection of persuasion techniques in texts and images. The given task has been framed as a multi-label classification problem with the different techniques serving as class labels. The multi-label classification problem is one in which a list of target variables such as our class labels is associated with every input chunk and assumes that a document can simultaneously and independently be assigned to multiple labels or classes.

In order to assign class labels to the given memes, we opted for RoBERTa (A Robustly Optimized BERT Pretraining Approach) as a neural network architecture for token and sequence classification. Starting off with a pre-trained model for language representation we fine-tuned this model on the given classification task with the provided annotated data in supervised training steps. To incorporate image features in the multi-modal setting, we rely on the pre-trained VGG-16 model architecture.

## 1 Introduction

Social networks provide opportunities to conduct disinformation campaigns for organizations as well as individual actors. The proliferation of disinformation online, has given rise to a lot of research on automatic fake news detection. SemEval-2021 Task 6 considers disinformation as a communication phenomenon. By detecting the use of various persuasion techniques in communication, it takes into account not only the content but also how a subject matter is communicated.

The goal of the shared task is to build models for identifying such techniques in the textual content of a meme only (two subtasks) and in a multimodal setting in which both the textual and the visual content are to be analysed together (one subtask).

The shared task defines the following subtasks:

### Subtask 1

Given only the “textual content” of a meme, identify which of the 20 techniques are used in it. This is a multi-label classification problem.

### Subtask 2

Given only the “textual content” of a meme, identify which of the 20 techniques are used in it together with the span(s) of text covered by each technique. This is a multilabel sequence tagging task. The task is the combination of the two subtasks of the SemEval 2020 task 11 on “detecting propaganda techniques in news articles”. Note that subtask 1 is a simplified version of subtask 2 in which the spans covered by each technique is not supposed to be provided.

### Subtask 3

Given a meme, identify which of the 22 techniques are used both in the textual and visual content of the meme (multi-modal task). This is a multilabel classification problem.

In this work, we covered our approach on both technique classification (TC) tasks (Subtask 1 and Subtask 3) detecting the type of communication technique used in a given message. To build models, the first subtask assumes purely textual content as inputs, whereas the third is designed in multi-modal setting in which both the textual and the visual content are to be analysed together. Below, we describe the systems built for these two subtasks. At the core of our systems is RoBERTa (Liu et al., 2019), a pre-trained model based on the Transformer architecture (Vaswani et al., 2017).

Although we did not manage to participate in

the second subtask, we will describe our solution below for the sake of completeness.

Finally, we will address some limitation of the general settings of this shared task.

## 2 Related Work

The goal of the shared task is to investigate automatic techniques for identifying various rhetorical and psychological techniques in online disinformation campaigns. A comprehensive survey on fake news has been presented by [Zhou and Zafarani \(2018\)](#). Based on the structure of data reflecting different aspects of communication, they identified four different perspectives on fake news: (1) the false knowledge it carries, (2) its writing style, (3) its propagation patterns, and (4) the credibility of its creators and spreaders.

The shared task emphasizes communicative styles that systematically co-occur with persuasive intentions of (political) media actors. Similar to [de Vreese et al. \(2018\)](#), propaganda and persuasion is considered as an expression of political communication content and style. Hence, beyond the actual subject of communication, the way it is communicated is gaining importance.

We build our work on top of this foundation by first investigating content-based approaches for information discovery and then open up our focus to dissemination mechanisms. Traditional information discovery methods are based on content: documents, terms, and the relationships between them ([Leskovec and Lang, 2008](#)). They can be considered as a general Information Extraction (IE) methods, automatically deriving structured information from unstructured and/or semi-structured machine-readable documents. Communities of researchers contributed various techniques from machine learning, information retrieval, and computational linguistics to the different aspects of the information extraction problem. From a computer science perspective, existing approaches can be roughly divided into the following categories: rule-based, supervised, and semi-supervised. In our case, we followed the supervised approach by reframing the complex language understanding task as a simple classification problem. Text classification also known as text tagging or text categorization is the process of categorizing text into organized groups. By using Natural Language Processing (NLP), text classifiers can automatically analyze human language texts and then assign a set

of predefined tags or categories based on their content. Historically, the evolution of text classifiers can be divided into three stages: (1) simple lexicon- or keyword-based classifiers, (2) classifiers using distributed semantics, and (3) deep learning classifiers with advanced linguistic features.

### 2.1 Deep Learning for IE

Recent work on text classification uses neural networks, particularly Deep Learning (DL). [Badjatiya et al. \(2017\)](#) demonstrated that these architectures, including variants of recurrent neural networks (RNN) ([Gao and Huang, 2017](#); [Pavlopoulos et al., 2017](#); [Pitsilis et al., 2018](#)), convolutional neural networks (CNN) [Zhang et al. \(2018\)](#), or their combination (CharCNN, WordCNN, and HybridCNN), produce state-of-the-art results and outperform baseline methods (character n-grams, TF-IDF or bag-of-words representations).

### 2.2 Deep Learning architectures

Until recently, the dominant paradigm in approaching NLP tasks has been focused on the design of neural architectures, using only task-specific data and word embeddings such as those mentioned above. This led to the development of models, such as Long Short Term Memory (LSTM) networks or Convolution Neural Networks (CNN), that achieve significantly better results in a range of NLP tasks than less complex classifiers, such as Support Vector Machines, Logistic Regression or Decision Tree Models. [Badjatiya et al. \(2017\)](#) demonstrated that these approaches outperform models based on char and word n-gram representations. In the same paradigm of pre-trained models, methods like BERT ([Devlin et al., 2018](#)) and XLNet ([Yang et al., 2019](#)) have been shown to achieve the state of the art in a variety of tasks.

### 2.3 Pre-trained Deep Language Representation Model

Indeed, the usage of a pre-trained word embedding layer to map the text into vector space which is then passed through a neural network, marked a significant step forward in text classification. The potential of pre-trained language models, as e.g. Word2Vec ([Mikolov et al., 2013](#)), GloVe ([Pennington et al., 2014](#)), fastText ([Joulin et al., 2017](#)), or ELMo ([Peters et al., 2018](#)) to capture the local patterns of features to benefit text classification, has been described by [Castelle \(2019\)](#). Modern pre-trained language models use unsupervised learning

techniques such as creating RNNs embeddings on large texts corpora to gain some primal “knowledge” of the language structures before a more specific supervised training steps in.

## 2.4 About BERT and RoBERTa

BERT stands for Bidirectional Encoder Representations from Transformers. It is based on the Transformer model architectures introduced by Vaswani et al. (2017). The general approach consists of two stages: first, BERT is pre-trained on vast amounts of text, with an unsupervised objective of masked language modeling and next-sentence prediction. Second, this pre-trained network is then fine-tuned on task specific, labeled data. The Transformer architecture is composed of two parts, an Encoder and a Decoder, for each of the two stages. The Encoder used in BERT is an attention-based architecture for NLP. It works by performing a small, constant number of steps. In each step, it applies an attention mechanism to understand relationships between all words in a sentence, regardless of their respective position. By pre-training language representations, the Encoder yields models that can either be used to extract high quality language features from text data, or fine-tune these models on specific NLP tasks (classification, entity recognition, question answering, etc.). We rely on RoBERTa (Liu et al., 2019), a pre-trained Encoder model which builds on BERT’s language masking strategy. However, it modifies key hyperparameters in BERT such as removing BERT’s next-sentence pre-training objective, and training with much larger mini-batches and learning rates. Furthermore, RoBERTa was also trained on an order of magnitude more data than BERT, for a longer amount of time. This allows RoBERTa representations to generalize even better to downstream tasks compared to BERT. In this study, RoBERTa is at the core of each solution of the given subtasks.

## 2.5 Image Feature Extraction using Pre-trained Models

Convolutional neural network (CNN) visual features have demonstrated their powerful ability as a universal representation for various recognition tasks. In this study we rely on the extraction of visual features on state of the art convolutional neural network architectures. From the most popular architectures such as VGG (Simonyan and Zisserman, 2015), ResNet (He et al., 2016), AlexNet (Krizhevsky et al., 2017), GoogLeNet (Szegedy

et al., 2015) we initially generated the image features using a pre-trained VGG-16 model architecture.

## 2.6 Multimodal Deep Learning

Multimodal deep learning involves multiple modalities used together to predict some output. The different modalities present in a particular piece of content are extracted and fused early in the classification process. In this study, we concatenated the features extracted from images and text sequences using a Convolutional Neural Network (CNN) and RoBERTa encodings (Liu et al., 2019), respectively. These features were used to try and predict persuasive techniques.

## 3 Dataset

The dataset to this task is provided by Dimitrov et al. (2021). Furthermore, there is a related shared task “SemEval 2020 task 11 on Detecting propaganda techniques in news articles” (Martino et al., 2020) since it serves as the basis for the second sub-task. In particular, the second subtask is the combination of the two subtasks of the previous task. Finally, there is a recent survey on computational propaganda detection by da San Martino et al. (2019).

## 4 Our approach

In this section, we provide a general overview of our approaches to the three subtasks. Subtasks 1 and 3 are both given as multilabel classification problems, whereas subtasks 2 is given as a multilabel sequence tagging task.

### 4.1 Experimental setup: Subtask 1

**Model Architecture** This subtask is a multi-class multi-label problem, as one or more labels have to be assigned to each sample. Our model for this subtask is based on RoBERTa.

**Input Embeddings** The input embedding layer converts the inputs (memes text) into sequences of features: word-level sentence embeddings. These embedding features will be further processed by the latter encoding layers.

**Word-Level Sentence Embeddings** A sentence is split into words  $w_1, \dots, w_n$  with length of  $n$  by the WordPiece tokenizer (Wu et al., 2016). The word  $w_i$  and its index  $i$  ( $w_i$ ’s absolute position in the sentence) are projected to vectors by embedding

sub-layers, and then added to the index-aware word embeddings:

$$\hat{w}_i = \text{WordEmbed}(w_i)$$

$$\hat{u}_i = \text{IdxEmbed}(i)$$

$$h_i = \text{LayerNorm}(\hat{w}_i + \hat{u}_i)$$

**Target Encoding** We encode the target labels using a multi-label binarizer as an analog of one-hot aka one-of-K scheme to multiple labels.

## 4.2 Experimental setup: Subtask 2

This subtask is given as a multilabel sequence tagging problem.

**Tagging format** We transformed the initial span markup into a IOB tagging format (Inside, Outside, Begin). As we have 20 possible entity classes, each token can be assigned one of the 41 tags given by an O-tag, and the I-tag and B-tag of the various techniques, respectively.

**Model Architecture** We fine-tuned a RoBERTa model to predict the above IOB tags for each token in the input sentence. One problem with the above setup is that each token is classified independently of the surrounding tokens: while these surrounding tokens are taken into account in the contextualized embeddings that RoBERTa produces, there is no modeling of the dependency between the predicted labels: for example, logically an I-tag should not follow O. Since RoBERTa does not model the dependencies between the predicted token, we further added a linear-chain Conditional Random Field (CRF) model (Lafferty et al., 2001) as an additional layer, in order to model the dependency between the predicted labels of individual tokens. Since the sequence of an O-tag following an I-tag does not appear in the training set, it assigns by observation a very low probability to the transition from an O-tag to an I-tag. We trained the resulting RoBERTa-CRF model as shown in Figure 1. The CRF receives the logits for each input token, and makes a prediction for the entire input sequence, taking into account the dependencies between the labels, similarly to (Lample et al., 2016). Note that RoBERTa works with byte pair encoding (BPE) units, while for the CRF it makes more sense to work with complete words. Thus, only head tokens were used as input to the CRF, and skipping any word continuation tokens.

Figure 1: RoBERTa-CRF model with IOB-encoded target. The CRF model ignores non-starting word pieces such as the depicted ##ing token.

## 4.3 Experimental setup: Subtask 3

**Model Architecture** We build our cross-modality model with self-attention and cross-attention layers following the recent progress in designing natural language processing models (e.g., transformers (Vaswani et al., 2017)). Our model takes two inputs as part of a meme: an image and its related text. Each image is represented as a feature vector, and each sentence is represented as a sequence of words. As depicted in Figure 2, via design and combination of the self-attention and cross-attention layers, our model is able to generate language representations, image representations, and cross-modality representations from the inputs. Next, we describe the components of this model in detail.

**Input Embeddings** The input embedding layers convert the inputs (i.e., an image and a short text) into two sequences of features: word-level sentence embeddings and image embeddings. These embedding features will be further processed by the latter encoding layers.

**Word-Level Sentence Embeddings** A sentence is split into words  $w_1, \dots, w_n$  with length of  $n$  by the WordPiece tokenizer (Wu et al., 2016). The word  $w_i$  and its index  $i$  ( $w_i$ 's absolute position in the sentence) are projected to vectors by embedding sub-layers, and then added to the index-aware word embeddings:

$$\hat{w}_i = \text{WordEmbed}(w_i)$$

$$\hat{u}_i = \text{IdxEmbed}(i)$$

$$h_i = \text{LayerNorm}(\hat{w}_i + \hat{u}_i)$$

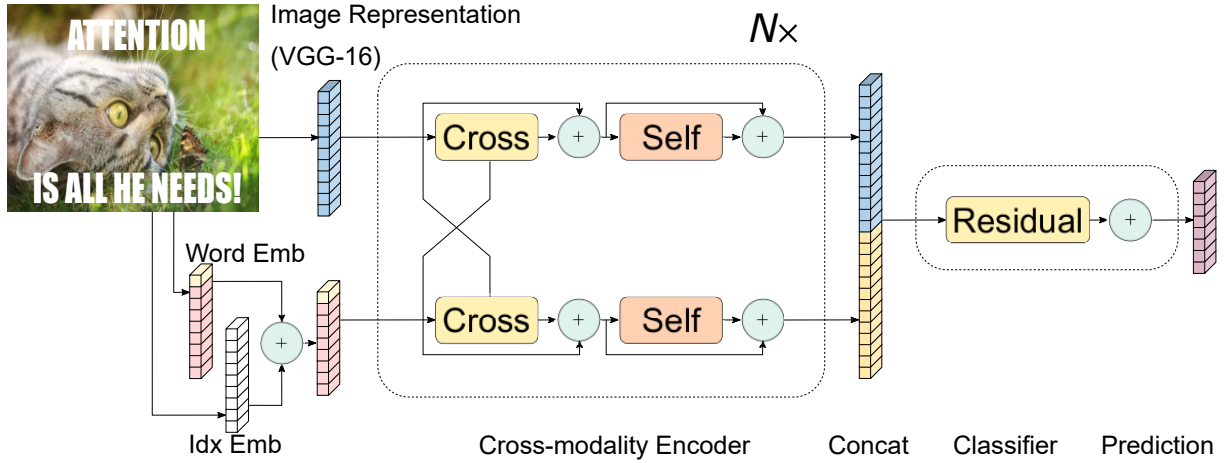

Figure 2: Multimodal model configuration for learning image-and-text cross-modality representations. ‘Self’ and ‘Cross’ are abbreviations for self-attention sublayers and cross-attention sublayers, respectively.

**Visual features** In this study we rely on the extraction of visual features on state of the art convolutional neural network architectures by generating the image features using a pre-trained VGG-16 model.

**Encoders** We build our encoders, i.e., the language encoder, and the cross-modality encoder, on the basis of two kinds of attention layers: self-attention layers and crossattention layers. We first review the definition and notations of attention layers and then discuss how they form our encoders.

**Attention Layers** Attention layers (Bahdanau et al., 2015; Xu et al., 2015) aim to retrieve information from a set of context vectors  $y_j$  related to a query vector  $x$ . An attention layer first calculates the matching score  $a_j$  between the query vector  $x$  and each context vector  $y_j$ . Scores are then normalized by softmax:

$$a_j = \text{score}(x, y_j)$$

$$\alpha_j = \exp(a_j) / \sum_k \exp(a_k)$$

The output of an attention layer is the weighted sum of the context vectors w.r.t. the softmax normalized score:  $Att_{X \rightarrow Y}(x, \{y_j\}) = \sum_j \alpha_j y_j$ . An attention layer is called self-attention when the query vector  $x$  is in the set of context vectors  $y_j$ . Specifically, we use the multi-head attention following Transformer (Vaswani et al., 2017).

**Single-Modality Encoders** After the embedding layers, we apply a temporal convolutional layer to each single modality. The result of this projection is a uniform feature space with defined

dimensions as the input to the cross-modality encoder.

**Cross-Modality Encoder** Each cross-modality layer in the cross-modality encoder consists of two self-attention sub-layers, one bi-directional cross-attention sub-layer, and a feed-forward sub-layer. We stack (i.e., using the output of  $k$ -th layer as the input of  $(k+1)$ -th layer)  $N \times$  these cross-modality layers in our encoder implementation. Inside the  $k$ -th layer, the bi-directional cross-attention sub-layer (‘Cross’) is first applied, which contains two unidirectional cross-attention sub-layers: one from text to image and one from image to text. The query and context vectors are the outputs of the  $(k-1)$ -th layer (i.e., text features  $\{t_i^{k-1}\}$  and image features  $\{i_j^{k-1}\}$ ):

$$\hat{t}_i^k = \text{CrossAtt}_{T \rightarrow I}(t_i^{k-1}, \{i_1^{k-1}, \dots, i_m^{k-1}\})$$

$$\hat{i}_j^k = \text{CrossAtt}_{I \rightarrow T}(i_j^{k-1}, \{t_1^{k-1}, \dots, t_n^{k-1}\})$$

The cross-attention sub-layer is used to exchange the information and align the entities between the two modalities in order to learn joint cross-modality representations. For further building internal connections, the self-attention sub-layers (‘Self’) are then applied to the output of the crossattention sub-layer:

$$\tilde{t}_i^k = \text{SelfAtt}_{T \rightarrow T}(\hat{t}_i^k, \{\hat{t}_1^k, \dots, \hat{t}_m^k\})$$

$$\tilde{i}_j^k = \text{SelfAtt}_{I \rightarrow I}(\hat{i}_j^k, \{\hat{i}_1^k, \dots, \hat{i}_n^k\})$$

We add a residual connection and layer normalization (annotated by the ‘+’ sign in Fig. 1) after each sublayer as in Vaswani et al. (2017).

**Classification** At the core of the classifier we use a residual block as introduced by He et al. (2016). The input to the residual block is given by concatenation of the output of the cross-modality encoder. The input and output size of the residual block corresponds to the sum of the output size of the cross-modality encoder. Lastly, in order to obtain the desired one-hot encoding as the output of the classifier, a linear transformation is applied.

**Target Encoding** We encode the target labels using a multi-label binarizer as an analog of one-hot aka one-of-K scheme to multiple labels.

#### 4.4 Results and Discussion

We participated in both techniques classification tasks (subtask 1 and 3). The official evaluation ranked our system 9th and 13th out of 16 and 15 teams, respectively. In this study, we focused on suitable combinations deep learning methods as well as their hyperparameter settings. Finetuning pre-trained language models like RoBERTa on downstream tasks has become ubiquitous in NLP research and applied NLP. Even without extensive pre-processing of the training data, we already achieve competitive results and can serve as strong baseline models which, when fine-tuned, significantly outperform training models from scratch. When improving on these baseline models, data scarcity appears to be an immense challenge. This is especially evident in the ratio of the given training samples to the number of possible target classes. We expected better results with the multimodal solution. The causes of the problem will be investigated in more detail in the future.

## 5 Conclusion and Future work

We described our approach for the SemEval-2021 Task 6 on Detection of Persuasion Techniques in Text and Images. We employed RoBERTa-based neural architectures, additional CRF layers, and a cross-modality framework for learning the connections between image and text in a multi-modal transformer architecture.

In future work, we plan to investigate more recent neural architectures for language representation such as T5 (Raffel et al., 2019) and GPT-3 (Brown et al., 2020). In case of the multimodal setting, it might also be useful to evaluate alternative model architectures such as ResNet (He et al., 2016) to improve image representation.

Furthermore, we expect great opportunities for transfer learning from the areas such as argumentation mining (Stede, 2020) and offensive language detection (Zampieri et al., 2019). To deal with data scarcity as a general challenge in natural language processing, we examine the application of concepts such as active learning, semi-supervised learning (Ruder and Plank, 2018) as well as weak supervision (Ratner et al., 2020).

## Abstract

In recent years, memes combining image and text have been widely used in social media, and memes are one of the most popular types of content used in online disinformation campaigns. In this paper, our study on the detection of persuasion techniques in texts and images in SemEval-2021 Task 6 is summarized. For propaganda technology detection in text, we propose a combination model of both ALBERT and Text-CNN for text classification, as well as a BERT-based multi-task sequence labeling model for propaganda technology coverage span detection. For the meme classification task involved in text understanding and visual feature extraction, we designed a parallel channel model divided into text and image channels. Our method<sup>1</sup> achieved a good performance on subtasks 1 and 3. The micro  $F_1$ -scores of 0.492, 0.091, and 0.446 achieved on the test sets of the three subtasks ranked 12th, 7th, and 11th, respectively, and all are higher than the baseline model.

## 1 Introduction

The intentional shaping of information to promote a predetermined agenda is called propaganda. Propaganda uses psychological and rhetorical techniques to achieve its purpose. Propaganda techniques generally include the use of logical fallacies and appeal to the emotions of the audience. In recent years, memes combining images and text have been widely used in social media, and the use of memes can easily and effectively attract a large number of users on social platforms. Memes are one of the most popular types of content used in online disinformation campaigns (Martino et al., 2020), and memes applied in a disinformation campaign achieve their purpose of influencing users through

rhetorical and psychological techniques. Therefore, it is meaningful to research computational techniques for automatically detecting propaganda in particular content.

The SemEval 2021 Task 6 (Dimitrov et al., 2021) consists of three subtasks:

- Subtask 1 - Given only the “textual content” of a meme, identify which of the 20 techniques are used. The 20 techniques include appeal to authority, loaded language, and name calling or labeling.
- Subtask 2: Given only the “textual content” of a meme, identify which of the 20 techniques are used along with the span(s) of the text covered by each technique.
- Subtask 3: Given a meme, identify which of the 22 techniques are used for both the textual and visual content of the meme. These 22 technologies include the 20 technologies in subtasks 1 and 2, and 2 technologies, i.e., transfer and appeal to (strong) emotions, are added.

The detection of propaganda techniques in texts is similar to a text sentiment analysis, and both can be attributed to text classification tasks. In a previous study, Peng et al. (2020) used the adversarial learning of sentiment word representations for a sentiment analysis. A tree-structured regional CNN-LSTM (Wang et al., 2020) and dynamic routing in a tree-structured LSTM (Wang et al., 2019) were used for a dimensional sentiment analysis. In previous SemEval competitions, Dao et al. (2020) used GloVe-LSTM and BERT-LSTM models, and Paraschiv et al. (2020) used an ensemble model containing BERT and BiLSTM to detect both spans and categories of propaganda techniques in news articles (Da San Martino et al., 2020). In addition, in multimodal analysis combining images and

<sup>1</sup>The code of this paper is available at: <https://github.com/zxyqjuring/SemEval-2021-task6>

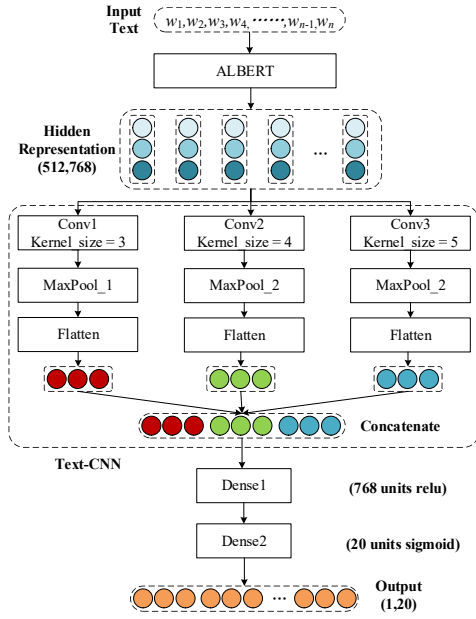

Figure 1: ALBERT-Text-CNN model architecture.

text, Yuan et al. (2020) proposed a parallel channel ensemble model combining BERT embedding, BiLSTM, attention and CNN, and ResNet for a sentiment analysis of memes. Li et al. (2019) proposed a Visual BERT model that aligns and fuses text and image information using transformers (Vaswani et al., 2017).

In this paper, we propose three different systems for the three subtasks in SemEval-2021 Task 6. For subtask 1, we added a Text-CNN layer after the pre-trained model ALBERT to fine-tune it for a multi-label classification of text. For subtask 2, we used the idea of partitioning to transform the problem into the detection of 20 techniques for each text separately. BERT was used in the model for text feature extraction followed by multi-task sequence labeling, and the results of each task were combined to obtain the final results. For subtask 3, we built the system using a parallel channel model containing text and image channels. The text channel used both the ALBERT and Text-CNN models to extract features of text in the meme, and the image channel used ResNet and VGGNet for image feature extraction. The information extracted by the two parallel channels was then combined through a fully connected layer after concatenation. Using micro  $F_1$ -scores as metrics, the results of the proposed model in subtasks 1, 2, and 3 were 0.625, 0.215, and 0.636, respectively, on the dev set.

The remainder of this paper is organized as follows. First, section 2 describes the details of the

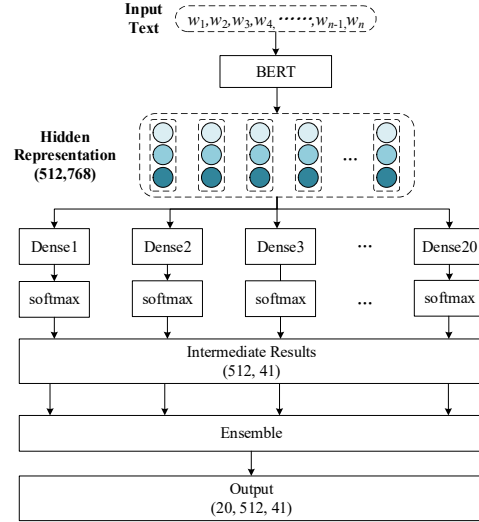

Figure 2: Architecture of multi-task sequence labeling model.

ALBERT and Text-CNN used in our system. Section 3 then presents the experimental results. Finally, some concluding remarks are presented in section 4.

## 2 System Overview

### 2.1 Subtask 1

Subtask 1 requires a detection model that uses only the textual features of the meme content and detects which of the 20 propaganda techniques were used. This is a multi-label classification problem for text, based on the pre-trained ALBERT model and added a Text-CNN layer. As illustrated in Figure 2, the proposed model includes an ALBERT layer, a Text-CNN layer, a fully connected layer, and an output layer.

- ALBERT (Lan et al., 2020) is a lite BERT for self-supervised learning of language representations, which uses layer-to-layer parameter sharing to reduce the number of parameters of the model, which not only speeds up the model training but also outperforms BERT on certain datasets. With our model, the pre-trained ALBERT model is fine-tuned to obtain a  $512 \times 768$  hidden representation matrix for subsequent multi-label classification of text.
- Text-CNN (Kim, 2014) is a convolutional neural network applied to a text classification task, using multiple kernels of different sizes to extract key information in sentences, and is thus able to better capture the local relevance. In

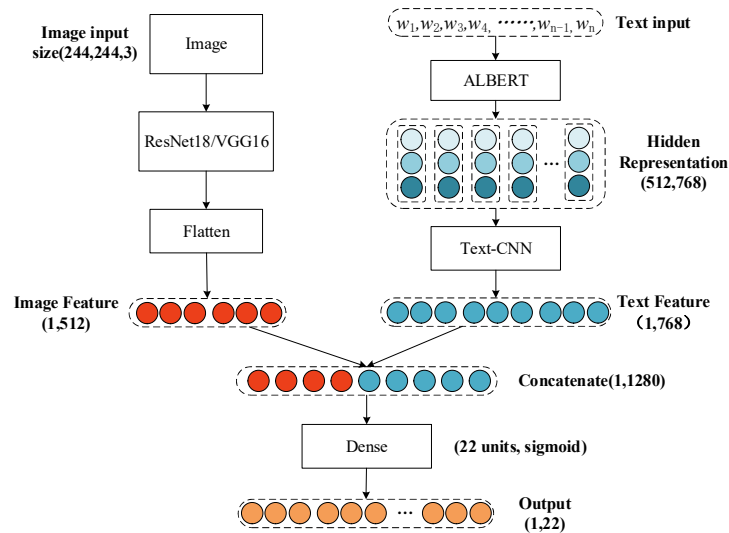

Figure 3: Architecture of parallel channel model.

this layer, we used three different sizes of one-dimensional convolution kernels, i.e., 3, 4, and 5, to extract information from the hidden representation matrix output from the ALBERT layer for the final multi-label text classification.

## 2.2 Subtask 2

Subtask 2 was a multi-label sequence-labeling task. We built the model by converting the problem to detect the coverage of each propagation technique separately for the input sequence, and built a multi-task sequence labeling model based on a fine-tuning of BERT.

As illustrated in Figure 3, the input sequence was first obtained using the pre-trained BERT (Devlin et al., 2019) model with a hidden representation matrix with dimensions of  $512 \times 768$ . Subsequently, 20 parallel fully connected layers were input separately for the detection of each propaganda technique coverage span (For each propagation technique, the sequence labeling task is performed separately for the input text). For each technique, the intermediate result of each parallel channel output is a  $512 \times 41$  matrix, and the ensemble layer represents the stacking of 20 matrices from 20 parallel channels, the dimensions of the final output were  $20 \times 512 \times 41$ , which denote the propaganda technique category, maximum sentence length, and code corresponding to each technique, respectively.

## 2.3 Subtask 3

For subtask 3, we modeled the problem as a multi-label classification task of the meme text and image content. We used a parallel channel model of text and image channels, and then concatenated the text and image features extracted by the two parallel channels to apply multi-label meme classification. The architecture of the proposed model is shown in Figure 4.

**Text Channel.** In the text channel, we used the ALBERT-Text-CNN model used in subtask 1, taking the text part of the meme content as an input to obtain a 768-dimensional text feature vector as the output.

**Image Channel.** In the image channel, we used ResNet and VGGNet, taking the image part of the meme content as input to obtain a 512-dimensional image feature vector as the output. The ResNet model (He et al., 2016) is a deep residual learning model for image recognition, and presents the inter-layer residual jump connection and solves the deep vanishing gradient problem. VGGNet (Simonyan and Zisserman, 2015) is a deep convolutional neural network with small-sized convolutional kernels and a regular network structure, in which the size of the convolution kernels used in VGG16 in our experiment is  $3 \times 3$ , and the pooling kernels is  $2 \times 2$ . Furthermore, only the structures of the ResNet and VGGNet were used in our experiment, and the pre-training weights were not applied.

### 3 Experimental Results

#### 3.1 Dataset

The organizer provided a dataset containing 687 memes for the training set, 63 memes for the development set, and 200 memes for the test set. The dataset of subtask 1 provides the ID, text of the meme, and the corresponding propaganda techniques used, and the dataset of subtask 3 also contains the corresponding meme image. The dataset of subtask 2 provides the ID, text of the meme, and the corresponding propaganda techniques used in a certain text fragment, in which the scope covered by the propaganda technology in the text is marked as “start,” “end,” and “text fragment,” respectively.

The datasets were preprocessed using the following procedures before model training:

- In subtasks 1 and 3, we first used one-hot encoding to encode the label into a vector whose length is the total number of technology categories.
- In subtask 2, we labeled each token in the text as “I-technique” and “O-technique” based on the 20 propaganda technology terms. “I-technique” indicates that the publicity technique was used and “O-technique” indicates that it was not, e.g., O-Smears and I-Smears. For 20 different propaganda techniques there are 40 different codes, and then add another padding code, so the label code length is 41.
- In subtask 3, we normalized the meme image size to  $224 \times 224 \times 3$ .

#### 3.2 Evaluation Metrics

The official evaluation measure for all subtasks is the micro  $F_1$ -score, which is defined as follows:

$$F_1 - score = 2 * \frac{Prec * Rec}{Prec + Rec} \quad (1)$$

where  $Prec$  and  $Rec$  denote the precision and recall scores of all samples, respectively. For subtask 2, the standard micro  $F_1$ -score was slightly modified to account for partial matching between spans (Dimitrov et al., 2021). In addition, the macro  $F_1$ -score was also reported for each type of propaganda.

#### 3.3 Implementation Details

All models used the TensorFlow2 backend, and all BERT-based models were implemented using

the HuggingFace Transformers toolkit(Wolf et al., 2020). The Adam optimizer (Ba and Kingma, 2015) was used to update all trainable parameters. The loss functions in subtasks 1 and 3 were binary cross-entropy, and subtask 2 was categorical cross-entropy. The hyper-parameters in the model training process were obtained using a grid-search strategy, as shown in Table 1. Once the optimal settings of the parameters were obtained, they were used for classification on the test sets of different corpora.

Hyper-parameter	Values
Learning rate	5e-6
Adam epsilon	1e-8
Text-CNN dropout	0.3
Text-CNN filters	64
Classifier dropout	0.3
Batch size	16

Table 1: Hyper-parameters in our models.

#### 3.4 Results

Table 2 presents the results of Subtask 1. We conducted experiments on several pre-trained models including BERT, RoBERTa(Liu et al., 2019), and ALBERT combined with the Text-CNN layer, and observed that the ALBERT and Text-CNN models achieved the best performance, the reason for which may be that the training datasets are small, and a serious overfitting will occur by directly fine-tuning BERT. Furthermore, the experiments show that the ALBERT model has fewer parameters and performs better on small datasets. Adding a Text-CNN layer after the BERT-based model can better extract the local relevance information of the text, which not only effectively alleviates the overfitting phenomenon it also effectively improves the model performance.

In subtask 2, the results of our proposed multi-task sequence labeling model on the dev set are  $F_1$ -score of 0.215,  $Precision$  of 0.378, and  $Recall$  of 0.151. The results on the test set are  $F_1$ -score of 0.091,  $Precision$  of 0.186, and  $Recall$  of 0.061.

Table 3 shows the results of Subtask 3. It can be observed that ResNet18 works better than VGG16 when using both ALBERT and ALBERT-Text-CNN models. The performance was improved by adding a Text-CNN layer to the text channel. Considering that the micro  $F_1$ -scores are relatively close, we selected the models with the top-three  $F_1$ -

Model	$F_1$ -Macro	$F_1$ -Micro
BERT	0.302	0.509
RoBERTa-Text-CNN	0.385	0.500
BERT-Text-CNN	0.414	0.560
ALBERT-Text-CNN	<b>0.472</b>	<b>0.625</b>

Table 2: Scores of different models for subtask 1 on dev set.

Model	$F_1$ -Macro	$F_1$ -Micro
ALBERT-VGG16	0.240	0.577
ALBERT-ResNet18	0.272	0.605
ALBERT-Text-CNN+VGG16	<b>0.346</b>	0.606
ALBERT-Text-CNN+ResNet18	0.247	<b>0.636</b>
Hard Voting	0.245	0.625

Table 3: Experimental results of different models for subtask 3 on dev set.

scores and used hard voting to generate the results for comparison.

For all three subtasks, the proposed systems achieved micro  $F_1$ -scores of 0.492, 0.091, and 0.446 on the test set, respectively. The results of all models exceeded the baseline. However, there is a considerable decrease compared to the scores of 0.625, 0.215, and 0.636 achieved on the dev set.

## 4 Conclusions

In this paper, we presented our system for the SemEval-2021 Task 6, the experimental results in subtasks 1 and 3 show that our proposed ALBERT-Text-CNN model and the parallel channel model achieved a good performance in the detection of persuasion techniques in texts and images.

We participated in all three subtasks and achieved the 12th, 7th, and 11th places in the test set, respectively. In a future study, to improve the generalization ability of the model, we will focus on how to deal with the problems caused by unbalanced training data.

## Abstract

Internet memes have become ubiquitous in social media networks today. Due to their popularity, they are also a widely used mode of expression to spread disinformation online. As memes consist of a mixture of text and image, they require a multi-modal approach for automatic analysis. In this paper, we describe our contribution to the SemEval-2021 Detection of Persuasion Techniques in Texts and Images Task. We propose a Multi-Modal learning system, which incorporates “memebeddings”, viz. joint text and vision features by combining them with compact bilinear pooling, to automatically identify rhetorical and psychological disinformation techniques. The experimental results show that the proposed system constantly outperforms the competition’s baseline, and achieves the 2nd best Macro F1-score and 14th best Micro F1-score out of all participants.

## 1 Introduction

Propaganda is a mode of communication by which the interested party pursues the aim of influencing public opinion in favour of a specific agenda or ideas. This is achieved by disseminating one-sided, biased or even fake news. With the advent of social media networks, propagandist text can reach an enormous audience. Given the overload of online text produced on a daily basis, it is not feasible to monitor this manually and researchers have started to investigate automatic methods to detect propaganda in text.

In the SemEval-2020 Task 11 on Detection of Propaganda Techniques in News Articles (Da San Martino et al., 2020), participants were asked to identify 14 different propagandist techniques in news articles. The task attracted a large interest, with 44 teams participating in the task. The best systems all used pre-trained transformers and ensemble techniques. We further refer

to Da San Martino et al. (2020b) for a comprehensive review of computational propaganda detection techniques.

More recently, internet memes have emerged as a very popular mode of expression on social networks. While memes initially seemed to be used by users of specific online communities, they have gained popularity very rapidly and are today used by a very large and varied user base. Memes can be used for very different purposes: they can be used as a form of visual rhetoric (Huntington, 2013), for online bullying or trolling (Leaver, 2013), but they can also function as a kind of persuasive device, while the intended message is wrapped in humour (Shifman, 2013). As a result, they form an interesting object of study for automatically detecting propaganda techniques.

The goal of the SemEval-2021 shared task on the detection of persuasion techniques (Dimitrov et al., 2021) is to build models for identifying rhetorical and psychological techniques that are used to influence social media users in online disinformation campaigns. This paper reports on our participation in Subtask 3, which is a multi-modal task conceived as a multi-label classification problem: given a meme, the system has to identify which of the 22 techniques are used both in the textual and visual content of the meme. To solve subtask 3, we propose a multi-modal multi-task learning system, which incorporates “memebeddings”, viz. joint text and vision features combined by means of compact bilinear pooling, to automatically identify rhetorical and psychological disinformation techniques in memes.

## 2 System Architecture

### 2.1 Task Overview

The SemEval 2021 Task 6 for detection of persuasion techniques in texts and images revolved

(a)

**Actual picture of  
the media trying to  
heal the divide in America**

(b)

Figure 1: Examples of memes where the analysis of only the text (a) or both the text and image (b) are required to automatically detect the correct persuasion technique.

around identifying 22 rhetorical and psychological disinformation techniques in internet memes. These techniques cover a wide array of phenomena like *Causal Oversimplification*, *Exaggeration/Minimisation*, *Name Calling/labeling* or *Presenting irrelevant data (red herring)*. For a full list of all categories, we refer to the task description paper (Dimitrov et al., 2021).

While some techniques in certain contexts may be accurately found just by processing the textual modality, it is very difficult to consistently identify all of the techniques without complete visual and textual context. Figure 1 shows examples of the two different cases, where in the first image, it is fairly obvious that the text contains all necessary information to predict the propaganda techniques accurately, whereas in the second meme, the textual modality is not sufficient to provide all information required to correctly predict the label. To tackle the task at hand, our approach incorporates information from both domain-related text and visual pre-training, and finally combines the two modalities using Multi-modal Compact Bilinear (MCB) Pooling (Fukui et al., 2016).

## 2.2 Proposed Models

Our multi-modal system is composed of three sub-modules:

1. **The visual pre-processor:** the visual module uses a ResNet-51 architecture (He et al., 2016) which is pre-trained to identify sub-reddits (E.g. */r/motivation*, */r/pets* */r/politics*) from around 6200 Reddit memes.
2. **The text pre-processor:** the text module uses a pre-trained BERT-large-uncased model (De-

vlin et al., 2019), fine-tuned on the PTC Corpus (Martino et al., 2020a) from the SemEval 2020 Shared Task.

3. **Integration Network:** the two sets of embeddings from the first two modules are combined with MCB pooling.

### 2.2.1 Visual Embeddings

We decided to use the Resnet-51 architecture for the Visual pre-processor. This model was trained to predict one of the 18 sub-reddits the memes were scraped from. We hypothesized that the learned embeddings are able to distinguish certain elements of the meme, since the model is forced to encode the sub-reddit it comes from, and the sub-reddits represent the genre (E.g. */r/politics*, */r/sports*) or the emotion associated with the meme (E.g. */r/motivation*, */r/dankmemes*).

### 2.2.2 Textual Embeddings

For the text pre-processor we used a pre-trained bert-large-uncased model from the HuggingFace transformers package<sup>1</sup>. We fine-tuned the model with additional linear layers for the multi-label task of predicting propaganda techniques in the PTC Corpus. BERT based fine-tuned models are often used for a lot of text classification tasks and obtain state-of-the-art performances in a large number of NLP tasks like GLUE (Wang et al., 2018) and SQuAD (Rajpurkar et al., 2016).

### 2.2.3 Combined Embeddings

We train the final model with the combined embeddings from the visual and text pre-processor,

<sup>1</sup><https://huggingface.co/transformers/>

for the final task of multi-label prediction of the 22 propaganda techniques. While the visual pre-processor and textual pre-processor become excellent feature generators individually, combining the embeddings from two modalities with different dimensions (768d for text and 1024d for images) becomes very complicated.

While a dot product will be simple and efficient to compute, it will only encode a linear mapping of features, i.e first order interactions where every visual feature only interacts with just one textual feature and not multiple features. In addition, a dot product cannot be computed with two vectors having different dimensions. A cross product on the other hand, computes the relation of every feature from one modality to every feature from the second modality. While this is closer to the representation we need, the cross product of two vectors, with 768 and 1024 dimensions respectively, will be 786,432 dimensional. To use this large a vector, the classification model would need billions of parameters, making it almost impossible to train such a model in practice.

MCB Pooling combines the computation efficiency of the dot product with the higher order representation of the cross product. It was first implemented for the task of Visual Question Answering (Antol et al., 2015), which also focuses on jointly encoding textual and visual content. It centers around constructing count sketch projections of the vectors by means of the Fast Fourier Transform (FFT) to reduce them to lower-dimensional vectors without losing a lot of information. Once the vectors are projected to lower-dimensions, computing the cross-product becomes feasible again. Pham et al. (2013) demonstrated, though, that the count sketch of the outer product of two count sketch projections is the same as the convolution of the two count sketch projections, as shown in Equation 1:

$$\Psi(x \otimes q, h, s) = \Psi(x, h, s) * \Psi(q, h, s) \quad (1)$$

where  $x$  and  $q$  are the embeddings from the textual and visual modality respectively,  $\Psi(x, h, s)$  represents the count sketch projection of a vector  $x$ , and  $*$  represents the convolution operator. Figure 2 summarizes the proposed system architecture.

### 2.3 Experimental Setup

The ResNet-51 model for the visual pre-processor was trained with Stochastic Gradient Descent and

penalized with the cross-entropy loss. For the initial state we used the model pre-trained on ImageNet, and fine-tuned by replacing the classification layer.

The BERT model for the text embeddings was fine-tuned by freezing the pre-trained model and adding a linear layer as well as a classification layer. The model was trained with the AdamW optimizer, with a rate decay of 0.01, and penalized with cross-entropy as well.

The final MCB model uses embeddings from both models and combines them into a single vector of 8000 dimensions with MCB, then passes them through two linear layers of sizes 2048 and 1024 respectively, followed by a classification layer for the multi-label output for the 22 techniques. This final model is optimized with Adam and penalized with cross-entropy as well. We used the train set released by the task organizers for training, and the development set as a validation set for optimizing hyper-parameters.

## 3 Results

Table 1 summarizes the key results of our multimodal approach. While combining the visual and textual embeddings with a simple weighted averaging consistently beats the task baselines by a significant margin, using MCB Pooling results in a considerable performance increase over weighted averaging, both for Macro and Micro F1-scores. In addition, when analyzing samples that are misclassified by the weighted averaging approach, but correctly predicted by MCB Pooling, we noticed around 40 percent of the examples required combining information from both the visual and textual modalities like Figure 1(b).

While the MCB model is able to better pool the understanding of both modalities, it still fails when a complex concept or inference is involved. Figure 3a represents a common meme format frequently found in the memes we were able to obtain from Reddit. Consequently, we expect the model has sufficiently learnt the corresponding visual features to come to a correct prediction. Figure 3b, however, requires some complex visual ideas the model has to infer in combination with the text, which it fails to do frequently. We believe that jointly training visual and textual embeddings (making the learning more coherent and not disjointed between the two modalities), instead of simply attempting to combine independent vi-

sual and textual information, would solve this issue. However, joint training can get computationally expensive and would require a much larger dataset.

#### 4 Conclusion and Future Work

This paper presents the multi-modal approach we proposed for automatically detecting persuasion techniques in memes. As memes combine text and images to obtain the desired effect, we built a system where visual and textual embeddings are combined to classify 22 different propaganda techniques. The experimental results show that combining textual and visual embeddings by weighted averaging already beats the baseline. These results, however, are considerably improved by combining both embedding sets by means of MCB Pooling.

In future work, we will investigate how we can incorporate additional semantic information in our model. A first step could consist of integrating more explicit argumentation information into our

model. As these propaganda techniques use psychological and rhetorical techniques, we believe it might be interesting to include argumentation structures such as logical fallacies, where the reasoning is flawed, and by consequence the conclusion cannot be drawn from the premise(s) in the text. To this end, we will build on recent work on automatic fallacy detection (Habernal et al., 2017). In addition, we also aim to include automatic emotion detection features, as writers of propagandist text often use emotional language to convince their readers. Finally, we will investigate an approach to jointly train visual and textual embeddings, rather than combining separate embedding sets, as our error analysis showed that efficient analysis of memes often requires a combined approach.

## Abstract

The objective of subtask 2 of SemEval-2021 Task 6 is to identify techniques used together with the span(s) of text covered by each technique. This paper describes the system and model we developed for the task. We first propose a pipeline system to identify spans, then to classify the technique in the input sequence. But it severely suffers from handling the overlapping in nested span. Then we propose to formalize the task as a question answering task by machine reading comprehension (MRC) framework which achieves a better result compared to the pipeline method. Moreover, data augmentation and loss design techniques are also explored to alleviate the problem of data sparsity and imbalance. Finally, we attain the 3<sup>rd</sup> place in the final evaluation phase.

## 1 Introduction

Fake news detection has attracted the attention of many researchers. But most of the conventional fake news detection methods focus on long-form journalism, and little attention has been paid to the propaganda techniques. Memes have become the most popular type of content on social media platforms, and it can easily mislead the audience to agree with the speaker through propaganda techniques. The SemEval-2021 Task 6 focuses on detecting the use of rhetorical and psychological techniques in memes without (subtask 1, subtask 2) and with (subtask 3) visual content.

We first adopted a model to identify the span and techniques sequentially, and made many attempts to optimize the model, but the results were not satisfactory. Then we tried some end-to-end method, e.g. MRC framework.

These authors contributed equally to this work This work is licensed under a Creative Commons Attribution 4.0 International License. License details: <http://creativecommons.org/licenses/by/4.0/>

We found that the pipeline model can't handle the span overlapping issue effectively, but the MRC framework with an informative query is well performing in this scenario. In addition, the data augmentation and a carefully designed loss can alleviate the impact of data sparsity and imbalance. We attain an F1 score of 0.3974 and the 3<sup>rd</sup> place in the final evaluation phase

## 2 Related Work

There was also a related previous task on fine-grained propaganda detection (Da San Martino et al., 2019), where the participants used Transformer-style models, LSTMs and ensembles (Fadel et al., 2019; Hou and Chen, 2019; Hua, 2019). Some approaches further used non-contextualized word embeddings, e.g., based on FastText and GloVe (Gupta et al., 2019; Al-Omari et al., 2019), or handcrafted features such as LIWC, quotes and questions (Alhindi et al., 2019). Moreover, Martino et al. 2020 analysed computational propaganda detection from Text Perspective and Network Perspective, argued for the need of combined efforts blending Natural Language Processing, Network Analysis, and Machine Learning.

## 3 System Description

### 3.1 Pipeline model for Span and Technique Detection

Inspired by the method (Chernyavskiy et al., 2020) proposed for NER task, we construct a pipeline model with RoBERTa (Liu et al., 2019) as the backbone to identify spans and techniques in input sequence. Figure 1 depicts our proposed pipeline model.

#### 3.1.1 Span Identification

We treat the span identification as a binary sequence tagging task. The span identification model

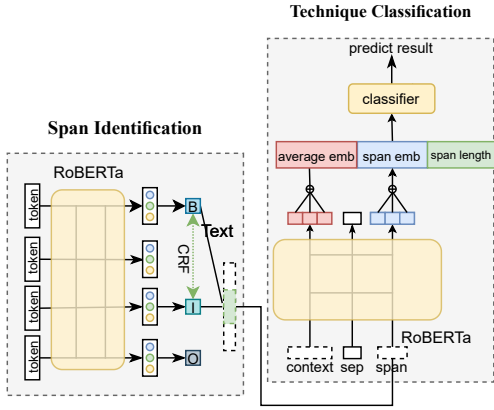

Figure 1: Pipeline Model for Span and Technique Detection

is fed with chunks of sentences encoded by Byte-Pair-Encoding (BPE) and the Conditional Random Field (CRF) layer (Lafferty et al., 2001) receives the logits for each input token, and makes a BIO prediction for the entire input sequence, finally got the spans in input sequence.

### 3.1.2 Technique Classification

We take the result of span identification model as a part of the input:  $[CLS] \langle context \rangle [SEP] \langle span \rangle$ , where  $\langle context \rangle$  is the sentence from which the span is extracted. The input of softmax layer includes three parts, (i) context embedding, is extracted from the last two layers of RoBERTa model; (ii) span embedding, is the average of span tokens embedding; (iii) span length embedding, is constructed with the length of the span, as different propaganda techniques have significant differences in span length. Finally, the model output the technique category for the given input sequence.

As the pipeline model suffers from incapable of handling overlapping issue in nested span, significantly inspired by (Li et al., 2019), we proposed to utilize the MRC framework to identify the span and corresponding techniques.

## 3.2 Span Detection as MRC

We formalize the task as a question answering task. Each span is characterized by a query, and span are extracted by answering these queries given the context. For example, the task of assigning the Name calling/Labeling to "CALM DOWN [LITTLE TRUMP HATER]\n FOUND YOUR BINKY\n" is formalized as answering the question "Find the words and phrases with strong emotional implications (either positive or negative) that in-

fluence an audience". This strategy naturally tackles the span overlapping issue in nested span: the detection of different spans that overlap requires answering different independent questions.

Figure 2: BERT-MRC Span Detection Model

### 3.2.1 BERT Encoder

Given the question  $q_y$ , we need to extract the text span  $x_{start,end}$  from input text sequence  $X = \{x_1, x_2, \dots, x_n\}$  given  $q_y$  using MRC frameworks. We use BERT as encoder with the concatenated informative query  $q_y$  and input sequence  $X$  as input by adding special token [CLS] and [SEP], and get the whole representation matrix  $H$  from BERT.

$$H = BERT([q_y, X]) \quad (1)$$

### 3.2.2 START-Predictor

The START-Predictor output the probability of each token being a start token of a span, and  $E_{start}$  is the parameter to learn:

$$P_{start} = softmax(H \cdot E_{start}) \quad (2)$$

### 3.2.3 END-Predictor

The END-Predictor output the probability of each token being an end token of a span,  $E_{end}$  is the parameter to learn:

$$P_{end} = softmax(H \cdot E_{end}) \quad (3)$$

### 3.2.4 SPAN-Predictor

As there could exist more than one span in given input sequence, we need to predict multiple start token and end token. Deciding which start-end pair that consist of continuous token sequence between start token and end token. We get the possible start token indexes  $I_{start}$  and end token indexes  $I_{end}$  by applying  $argmax$  on  $P_{start}$  and  $P_{end}$ . Each  $i$  in

$I_{start}$  and  $j$  in  $I_{end}$  construct a continuous token sequences  $x_{i,j}$  with constriction  $i \leq j$ . A binary classifier is used to compute the probability of  $x_{i,j}$  as a valid span, and  $E_{span}$  is the parameter to learn:

$$I_{start} = \operatorname{argmax}(P_{start}) \quad (4)$$

$$I_{end} = \operatorname{argmax}(P_{end}) \quad (5)$$

$$p_{i,j} = \operatorname{sigmoid}(E_{span} \cdot [E_i; E_j]) \quad (6)$$

### 3.2.5 Train

During the training stage, input sequence  $X$  is with two label sequence  $Y_{start}$  and  $Y_{end}$ , representing the ground-truth label of each token  $x_i$  being the start index and end index.  $Y_{start,end}$  the ground-truth span. And the loss for each predictor as follows:

$$L_{start} = \operatorname{CrossEntropy}(P_{start}, Y_{start}) \quad (7)$$

$$L_{end} = \operatorname{CrossEntropy}(P_{end}, Y_{end}) \quad (8)$$

$$L_{span} = \operatorname{CrossEntropy}(P_{span}, Y_{span}) \quad (9)$$

The model is end-to-end fine-tuned by minimizing the loss as follows:

$$L = L_{start} + L_{end} + L_{span} \quad (10)$$

### 3.2.6 Predict

For every example to be predicted, we duplicate the example 20 times and pair each example with one technique description as model input. The model output spans detected for each example, and techniques can be mapped from those examples with spans detected.

## 4 Experiment and Result

We use the provided training dataset for training, and evaluate the model on the development dataset during evaluation phase. We implemented several experiments to explore the effect of different methods. The following is the detail for each experiment.

### 4.1 Data augmentation

As there are only 290 records in the training dataset, we explored two data augmentation methods to increase the amount of relevant data. We did the data augmentation based on PTC corpus<sup>1</sup>. And Enlarge Training Dataset get a better result.

<sup>1</sup><https://propaganda.qcri.org/semEval2020-task11/>

Data augmentation	F1
Two-Stage Fine-Tune	0.19322
Enlarge Training Dataset	<b>0.21053</b>
Train Dataset	0.19073

Table 1: Result for Data Augmentation.

#### 4.1.1 Two-Stage Fine-Tune

Train a best-performing model using BERT as backbone with PTC corpus, then finetune the trained model on the training dataset. Table 1 shows the result of this method.

#### 4.1.2 Enlarge Training Dataset

Train a best-performing model using BERT as backbone with training dataset and annotate PTC corpus automatically. After that we train the second model using the filtered samples according to annotated labels and training dataset. Table 1 shows the result of this method.

### 4.2 Loss setup

This task is faced with serve data imbalance issue: the top 6 technique category examples account for 78%, which is significantly outnumber the reset of 14 technique category examples, leading to huge number of top 6 examples overwhelms training. In order to remit the impact of imbalance issue, we tried different loss functions. Table 2 shows the result of different loss function. From the result we can see that Asymmetric Loss improved the result over other loss function.

#### 4.2.1 Focal Loss

By setting  $\gamma \geq 0$  in Eq.12, the contribution of easy samples can be down-weighted in the loss function, enabling to focus more on harder samples during training(Lin et al., 2018).

$$L = -yL_+ - (1 - y)L_- \quad (11)$$

$$\begin{cases} L_+ = (1 - p)^\gamma \log p \\ L_- = p^\gamma \log (1 - p) \end{cases} \quad (12)$$

#### 4.2.2 Asymmetric Loss

Asymmetric loss can perform hard thresholding of very easy samples, meaning fully discard negative samples when their probability is low enough(Ben-

Loss Function	F1
CrossEntropy	0.19073
Focal Loss	0.20453
Asymmetric Loss	<b>0.20817</b>

Table 2: Result for Different Loss.

Model	F1
BERT-MRC <sub>neg=2</sub>	0.2986
BERT-MRC <sub>neg=4</sub>	0.3665
BERT-MRC <sub>neg=10</sub>	0.3463
BERT-MRC <sub>neg=4.DA</sub>	<b>0.3779</b>
BERT-MRC	0.2815

Table 3: Results for MRC-BERT.

Baruch et al., 2020).

$$L = -yL_+ - (1 - y)L_- \quad (13)$$

$$p_m = \max(p - m, 0) \quad (14)$$

$$ASL = \begin{cases} L_+ = (1 - p)^{\gamma_+} \log p \\ L_- = p_m^{\gamma_-} \log(1 - p_m) \end{cases} \quad (15)$$

Where the probability margin  $m \geq 0$  is a tunable hyperparameter.

### 4.3 BERT-MRC Span Detection

In the training dataset, some examples do not contain any technique. We duplicate each example 20 times and pair same example with different technique description as model input. The example paired with the technique it contained is treated as positive examples and others as negative examples. We also tried to sample different number of negative examples. Table 3 shows the result of different sampling strategy. When sample 4 negative examples, the model BERT-MRC<sub>neg=4.DA</sub> achieve the best result. The performance decrease when sample more negative examples, which may be caused by introducing too much noise into the model. The model is trained with hyperparameter learning rate  $5e-5$ , batch size 8, max sequence length 128, and bert-base-cased as the backbone.

## 5 Conclusion

We create a pipeline model and an end-to-end MRC model to identify the span and techniques. We attain an F1 score of 0.3974 and the 3<sup>rd</sup> place at in final evaluation phase with BERT-MRC<sub>neg=4.DA</sub> model. Our implementation shows that 1) reformulating the task into an MRC task to detect the

overlapping span is effective; 2) data augmentation is about to increase model generalization ; 3) careful loss design can alleviate the effect of data imbalance.

## Abstract

This paper describes and examines different systems to address Task 6 of SemEval-2021: *Detection of Persuasion Techniques In Texts And Images, Subtask 1*. The task aims to build a model for identifying rhetorical and psychological techniques (such as causal oversimplification, name-calling, smear) in the textual content of a meme which is often used in a disinformation campaign to influence the users. The paper provides an extensive comparison among various machine learning systems as a solution to the task. We elaborate on the pre-processing of the text data in favor of the task and present ways to overcome the class imbalance. The results show that fine-tuning a RoBERTa model gave the best results with an F1-Micro score of 0.51 on the development set.

## 1 Introduction

The purpose of this task was to identify propaganda in electoral campaigns where memes are one of the most popular types of content used to carry out disinformation campaigns. They are most effective on social media platforms since they can easily reach many users. SemEval-2021 task 6 (Dimitrov et al., 2021) refers to propaganda whenever information is purposefully shaped to foster a predetermined plan. Propaganda uses psychological and rhetorical techniques to achieve its objectives. Such techniques include the use of logical fallacies and appealing to the emotions of the audience. Logical fallacies are usually hard to spot since the argumentation, at first sight, might seem correct and objective. However, a careful analysis shows that the conclusion cannot be drawn from the premise without the misuse of logical rules. Another set of techniques uses emotional language to induce the audience to agree with the speaker only based on the emotional bond that is being created, provok-

ing the suspension of any rational analysis of the argumentation.

The Oxford dictionary defines a meme as ‘An image, video, piece of text, etc., typically humorous in nature, that is copied and spread rapidly by internet users, often with slight variations’. They generally consist of an image superimposed with text. The role of the image in a deceptive meme is either to reinforce/complement a technique in the text or to convey one or more persuasion techniques. A total of 3 subtasks were defined: For subtasks 1 and 2, only the meme’s textual content was given. The former was a multilabel classification problem while the latter was a multilabel sequence tagging problem, each with 20 labels of techniques. For subtask 3, both textual and visual content of the memes were given. The goal was to identify which of the techniques are used for a given text/image. In this paper, we describe a system to address the subtask 1 for which, a training dataset of 600 sentences with their labels was given. The test set consists of over 200 sentences. We evaluated the performance of all the models using the Micro and Macro F1 scores.

We make use of 13 different models to approach the problem at hand, experimenting with different data preprocessing techniques to finally document 23 sets of results. We found that strong results can be achieved by fine-tuning a pre-trained RoBERTa language model. However, we also discovered that some other models, when used as part of a voting classifier, gave decent results without requiring resources and time needed to train a RoBERTa model.

The rest of the paper is organized as follows. Section 2 discusses the related work. Section 3 talks about the methodology. Section 4 describes the dataset for the task. Section 5 provides the experimental setup. Section 6 presents the systems implemented to address the task. Section 7 shows

the results and Section 8 concludes the paper.

## 2 Related Work

The closest research to persuasion detection in Computer Science is perspective detection. Lin et al., (2006) discussed different types of machine-learning classifiers such as Naïve Bayes and Support Vector Machines for the perspective detection. Another topic, closely knitted with the detection of persuasion techniques is hate speech detection. Sood et al., (2012) worked on detecting personal insults, profanity, and user posts characterized by malicious intent. Xiang et al., (2012) focused on vulgar language and profanity-related offensive content. Xu et al., (2012) further look into jokingly formulated teasing in messages that represent bullying episodes.

Burnap and Williams, (2014) specifically looked into othering language, characterized by an ‘us’ and ‘them’ dichotomy in racist communication. Approaches to detecting hate speech on Twitter using convolutional neural networks and convolution-GRU-based deep neural networks are discussed in Gamback and Sikdar, (2017) and Zhang et al., (2018) respectively.

Persuasion technique detection is a multi-label classification problem. Many attempts have been made in the literature to make a multi-label classification system (Spyromitros et al., 2008; Elisseeff et al., 2001; Zhang and Zhou, 2006; Curram and Mingers, 1994; Huang, 1988; Crammer and Singer, 2003).

## 3 Method

In this paper, we make use of a one-versus-rest strategy to split a multi-label classification dataset into binary classification problems, splitting the data into one binary dataset for each class (Hastie et al., 1998), called ‘pairwise coupling’. We present results with various approaches for the persuasion techniques detection in the text data. We make use of pre-defined language models and tune the hyperparameter for best performance on the dataset. Soft voting classifier and hard voting classifier (Zhou et al., 2002) are deployed to use traditional machine learning models for the task. A soft voting classifier uses the average of probabilities for each class to classify the test instance, whereas, in hard voting, the classifier assigns the class that was voted by a majority of the classifiers. In our case, since we implemented our own voting classifier, we did not

always go with the majority but experimented with different threshold values. In some cases, we gave more weightage to the models which gave more promising results. Various models, such as Logistic Regression, Naive Bayes, SVM, RNN, BiLSTM, BERT, naming a few, were implemented, which are discussed in the later sections. RoBERTa model performed the best for the persuasion techniques detection task on the text data (Section 7).

## 4 Dataset

In this paper, we provide systems to address subtask-1. The input data for subtask-1 is the text extracted from the memes. The training, the development, and the test sets for subtask-1 were distributed as JSON files.

An object of the JSON has the following type:

```
{
  "id": "125"
  "labels": [
    "Loaded Language",
    "Name calling/Labeling"
  ]
  "text": "I HATE TRUMP \n\nMOST TERROR-IST DO"
}
```

where

- id is the unique identifier of the example across all three tasks
- text is the textual content of the meme, as a single UTF-8 string.
- labels is a list of techniques used in the text (Written below). In this case, two techniques were spotted: Loaded Language and Name calling/Labeling.

Below are the technique names with their frequency in the training dataset.

- Appeal to authority: 13
- Appeal to fear/prejudice: 43
- Black-and-white Fallacy/Dictatorship: 18
- Causal Oversimplification: 27
- Doubt: 34
- Exaggeration/Minimisation: 52
- Flag-waving: 27
- Glittering generalities (Virtue): 32
- Loaded Language: 313
- Misrepresentation of Someone’s Position: 3
- Name calling/Labeling: 188

Number of labels	Number of sentences
0	161
2	119
3	90
4	47
5	11
6	2
8	1

Table 1: Number of labels for number of sentences

- Obfuscation, Intentional Vagueness, Confusion: 4
- Presenting Irrelevant Data (Red Herring): 3
- Reductio ad hitlerum: 9
- Repetition: 8
- Slogans: 84
- Smears: 168
- Thought-terminating cliché: 20
- Whataboutism: 40
- Bandwagon: 2

Table 1 reports the number of sentences with multiple (or no) labels. For example, the first row suggests that there were 161 sentences in the dataset with no labels.

## 5 Experimental Setup

We train a wide range of different models for the task. As discussed in Section 3, we used both a soft voting classifier and a hard voting classifier on the traditional machine learning models for better performance. However, it should be noted that a soft voting classifier cannot be used in all the models, and accordingly, models were categorized. In order to assign different weights to different models, as per the individual performance, we used our own version of the hard voting classifier by scikit-learn (Pedregosa et al., 2011). Most of the models that we implemented support a multi-class classification where one assumes that each sample is assigned to one and only one label. However, since we were in a multi-label classification scenario, where we were required to assign a set of target labels, we wrapped these models in a OneVsRestClassifier. We converted the multi-label classification problem into a series of binary classification problems assuming that there was not any underlying correlation between any two labels and they were mutually

exclusive. Below is the list of the machine learning and deep learning approaches that we implemented to build the systems to identify persuasive techniques.

- Logistic Regression (LR), a meta-model trained using the stochastic average gradient solver.
- Standard Naive Bayes (NB) and **Support Vector Machine (SVM)** from scikit-learn library in python.
- Linear Support Vector Classification (SVC) to return a *best fit* hyperplane that divides, or categorizes the data.
- Bernoulli Naive Bayes, a variant of Naive Bayes, using learning rate of 0.12.
- Ridge classifier with 0.01 as the tolerance for the stopping criteria.
- SGDClassifier (SDGC) with added *L2* regularization to prevent overfitting and the hinge loss function.
- Passive Aggressive Classifier (PAC) with 50 as the cap for the number of iterations the model makes over the data.
- Random Forest Classifier (RFC) which creates a set of decision trees from a randomly selected subset of the training set.
- Multi-layer Perceptron (MLP) regressor with 1 hidden layer of size 8, followed by 2 of size 16 and finally another of size 4.
- Long Short-Term Memory Network (LSTM) (Hochreiter and Schmidhuber, 1997).
- Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018).
- A Robustly Optimized BERT Pretraining Approach (RoBERTa) (Liu et al., 2019).
- A Deep Neural Network model that used a vocabulary size of 10,000; a batch size of 32; and was trained over 6 epochs. The system consisted of an embedding layer of size 128, followed by a 1D Convolution layer with 32 filters and *same* padding. Further, we used a max pooling layer of pool size 2 and an LSTM layer with 64 units and Dropout regularization of 0.2. Finally, 2 dense layers with 64 units and 1 unit respectively and activations *ReLU* and *sigmoid* were used.

**Evaluation Measures:** The given evaluation measure for the task was Micro-F1. We also report Macro-F1 in this paper as it is more favorable for multi-class classification problems.

F1-score is the harmonic mean of Precision and Recall

**Precision:** It is the fraction of relevant instances among all retrieved instances

**Recall:** It is the fraction of retrieved instances among all relevant instances

First, we independently find the F1 Score for each label, and then, to aggregate these F1-scores into a single F1-score, two ways can be used.

- **Macro F1-Score:** Simply average all the F1-Scores and calculate a mean F1-Score.
- **Micro F1-Score:** Instead of calculating each label's F1-Score, derive the F1-Score by calculating Precision and Recall by summing all the true positives, false positives, and false negatives of the system for different labels.

## 6 System Description

We split the training data into a training and validation set in the ratio 9 : 1, *i.e.*, 90% of the corpus was used for training while the remaining 10% was part of the validation set. The preprocessing (Section 6.3) for all the models was the same and once the best model was found, it was retrained including the validation set for training as well. The trained model was then used to predict labels for the Development set. The model yielding the best accuracy on the earlier chosen validation set was used for the submission of the Development set. We followed a similar approach for the submission of the results in the task on the test set using RoBERTa model. We secured 15<sup>th</sup> rank in the task.

### 6.1 Initial Setup

The labels were in the form of a string under the column 'labels'. For easier manipulation, these were first one hot encoded into multiple labels using ',' as a separator. It should be noted that multiple columns for the same label (Owing to white space before the comma in a few cases) had to be merged.

### 6.2 Data Augmentation

We observed a lack of data along with an internal data bias. To overcome this issue, we incorporated different data augmentation techniques. While a few of the techniques we employed for data augmentation boosted the performance, many of them

just confused the model and decreased the validation set accuracy. The techniques which were discarded for making no significant improvement on the results are as follows:

- **Random Swap:** Choose two words in the sentence at random, and swap their positions.
- **Synonym Replacement:** Choose a few words from the sentence at random, and replace them with their synonyms.
- **Random Deletion:** Randomly delete a word if a uniformly generated number between 0 and 1 is smaller than a pre-defined threshold.
- **Random Insertion:** Find a synonym of a word chosen at random from the sentence and insert it into a random position in the sentence.

However, *Back Translation* which is a classic data augmentation technique gave positive results. This method translates the text data to some language and then translates it back to the original language. This can help to generate textual data with different words while preserving the context of the text data. In our model, we made use of the Language translation API provided by Google Translate. We ran each text sentence through 5 different translations. Each series consisted of translation from English to another language of the similar scripts followed by another language that required transliteration and then back to English. We used this with 10 different languages (other than English) to create maximum diversity in the corpus. After we had generated a much larger corpus than before, there was still a serious problem of data bias in most labels since there were more zeroes (in one hot encoding) than ones. For that, apart from the original corpus, we only took those text samples out of the augmented data, in which that label was present. Compared to the previous training dataset, upon using this dataset, the performance (Micro F1 score) of the model on the development set rose for a few models while it fell for others. For the latter, we believe that the decrease in data-size was under-compensated by the decrease in the problem of bias.

### 6.3 Preprocessing

Since the corpus sentences were texts extracted from memes, we expected them to contain some patois and other contractions. Consequently, we started our preprocessing by substituting conjunctions with the complete words, and some of the more commonly used lingos with their literal and

Table 2: Results with various systems

legal English counterparts.

After that, we proceeded by using custom made functions for subjecting the sentences to lowercasing and removing most punctuation marks or any kind of special character which do not include any valuable information for text classification.

Next, we take care of the stopwords, which are a set of frequently used words (often short) and their removal is critical because, in their absence, we can focus on the essential words to the context of the sentence more. Therefore, we remove all the stop-words present in the text sentences using the default set of stop-words that can be downloaded from the NLTK library (Bird et al., 2009).

Next, we moved to Lemmatization. Stemming is another widely used technique for a similar purpose where one chops off its inflections and keeps what hopefully represents the main essence of the word. However, we observed that lemmatization gave better results on the provided data. Instead of chopping words off (truncating the word), lemmatization relies on a linguistic knowledge base like

*WordNet* (An extensive database of English which superficially resembles a thesaurus, in that it groups words based on their meanings) to obtain the correct base forms of words.

## 7 Results and Analysis

Table 2 presents the F1-Micro and F1-Macro obtained with various systems on the test data for the subtask-1 of Task-6 after training on both the augmented data and just the original base data. The scores for the models trained on the augmented data use the prefix *Aug* in the column name. The models with the *Drop* column marked *X*, were trained on the complete augmented data. In contrast, while training the ones containing a *✓*, we took only those augmented sentences that contained the label we were training the model for. This was done to cope with the data bias problem as discussed in Section 6. In the machine learning models, the *Threshold* column contains an integer value which is the threshold for the hard voting classifier *i.e.*, the minimum number of models predicting a technique

to be associated with a sentence. However, in the case of the Deep Neural Network, the *Threshold* column contains the probability of the prediction of a particular technique.

The system ‘All models together’ deployed an ensemble of traditional machine learning models, as listed in the Section 5. From table 2, we unsurprisingly infer that *RoBERTa* gave the best results for the persuasion techniques classification on the text data. Even so, there are quite a few takeaway points one can conclude from the same.

Firstly, even though there is a visible gap between RoBERTa and the rest of the models, the ensemble of models was almost 200 times faster on a CPU compared to RoBERTa, which was trained on a GPU. This indicates that the former is a superior choice when quick NLP predictions are required using low-end systems.

Next, we observe the effect of tackling the data bias technique by choosing some specific augmented sentences for the training corpus. In ‘All models together’, even though a better result was reported by the system without the drop and the threshold value 0, overall, dropping the sentences gave better performance for different threshold values. One can note that the latter system even gave better F1-Macro score universally for all thresholds.

Finally, we adjudge a rather interesting observation. Most of the systems comprehensively work far better with the augmented data, but the Deep Neural Network, which contained 1.5 Million trainable parameters, showed a startling outcome. The score obtained after training on the base corpus was better than the one obtained after training on much larger augmented data. Repeated back-translation might be the reason that we fed the similar type of data instances to the system. Thus, the model was not able to learn enough, giving poor accuracy and faulty predictions. We didn’t see the similar observation in traditional machine learning models or even MLP regressors because these models use fewer parameters.

## 8 Conclusion

Persuasion techniques detection is a multi-label classification problem. This paper presents and analyzes 13 machine learning and deep learning-based systems for persuasion techniques detection in the text data. Persuasion data has an extensive range of techniques as labels (20 in our case) with

high-class imbalance. We observe that the data augmentation technique, *i.e.*, Back Translation, helps overcome class imbalance and produces more robust systems. Besides, we present the essential data preprocessing for the task. Results show that RoBERTa, a deep neural language model, outperformed other systems by a significant margin. Fine tuning the RoBERTa model on the training data captures the sensitive features for persuasion techniques identification.

## Abstract

This paper presents one of the top systems for the SemEval-2021 task 6 (Dimitrov et al., 2021), “detection of persuasion techniques in text and images”. The proposed system, LeCun, targets subtask-1 for detecting propaganda techniques based on the textual content of a meme. We have used an external dataset from a previous relevant SemEval competition (Martino et al., 2020). We also have articulated another dataset using data-augmentation techniques. The final proposed model consisted of 5 ensemble transformers (four RoBERTa models and one DeBERTa), each trained on either a different dataset or pre-processing. Apparently, ensembling models trained on different datasets improve performance more than ensembling models trained on the same dataset/preprocessing. Also, it is obvious, fine-tuning the model on the Competition dataset after training it for a few epochs on the other datasets would improve the f1-micro up to 0.1 additional scores. The final model achieved an f1-micro score of 0.512 on the test dataset and an f1-micro of 0.647 on the development dataset.

## 1 Introduction

The definition of Memes was constantly changing since it was first conceived. But, Memes eventually got an academic definition, called an “Internet Meme”. As Davison (2012) Internet Meme can roughly be defined as “a piece of culture, typically a joke, which gains influence through online transmission”. But what makes Internet memes unique is the speed of their transmission and the fidelity of their form. Therefore the Internet meme can act as a powerful medium for persuasion techniques that preach an ideology or way of thinking. (Moody-Ramirez and Church, 2019)

On the other hand, the term “propaganda” is defined as a form of communication that employs

persuasive strategies and attempts to achieve a response that furthers the desired intent of the propagandist (Jowett and O’donnell, 2018). With the rise of social media, a new form of propaganda rises called “Computational Propaganda.” The author in (Woolley and Howard, 2017) defined Computational Propaganda as “The use of algorithms, automation, and human curation to purposefully distribute misleading information over social media networks”.

Task 6 at SemEval-2021 (Dimitrov et al., 2021), detection of persuasion techniques in text and images, defined three subtasks. The first two subtasks deal with the textual contents of memes that ask the participants to identify which of the 20 propaganda techniques are in the text. While the third subtask encourages the participants to determine which of the 22 techniques are in the meme’s textual and visual content. This paper proposes a solution for subtask1 that uses pre-trained language models to detect propaganda and possibly even identify the persuasion strategy that the propaganda sample employs.

The rest of the paper is broken down as follows. Section 2 discusses related-work to the task of propaganda identification. Section 3 provides a description of the data and the pre-processing techniques used. Section 4 describes the proposed system and architecture. Section 5 presents system analysis. Finally, the conclusion and future work are provided in Section 6.

## 2 Related Work

There have been efforts in persuasion techniques identification and classification using machine and deep learning-based approaches. The authors in (Al-Omari et al., 2019) used word embeddings with BERT (Devlin et al., 2019) and BiLSTM (Schuster

---

\* Equal Contribution

and Paliwal, 1997) for binary detection of propaganda spans. Authors in (Altitı et al., 2020) experimented with a CNN (LeCun et al., 1999), BiLSTM and BERT and showed BERT to have the best accuracy on classifying persuasion techniques in propaganda spans. Also, the authors in (Jurkiewicz et al., 2020) used a RoBERTa model (Liu et al., 2019), a class-dependent re-weighting method and used a semi-supervised learning technique of self-training and demonstrated the effects of these techniques in an ablation study. A group of researchers (Morio et al., 2020) experimented with a variety of PLMs (pre-trained language models), including BERT, GPT-2 (Radford et al., 2019), RoBERTa, XLM-RoBERTa (Conneau et al., 2019), XLNet (Yang et al., 2019) and XLM (CONNEAU and Lample, 2019). And have demonstrated that RoBERTa and XLNet generally perform better for propaganda detection.

### 3 Data Description

In this section, we describe the data and the task and the preprocessing step

#### 3.1 Data

The dataset used during our experiments has been provided by the SemEval-2021 Task 6 (Dimitrov et al., 2021). The dataset, “Competition dataset”, consists of short text samples that were extracted from Memes. We have also resorted to using an external dataset (Da San Martino et al., 2019) that is comprised of news articles with propaganda spans, “External Dataset”. To use the External dataset effectively, we needed to chop down the news articles closer to the text’s length in the current dataset and take only the text fragment that contained the propaganda and the corresponding label representing the propaganda technique in that text fragment.

#### 3.2 Data Preprocessing

Our data preprocessing pipeline consists of two components, 1) Data cleaning 2) Data augmentation. In this section, we will describe the techniques we used in each component.

##### 3.2.1 Data Cleaning

To increase performance accuracy, some data preprocessing techniques have been tested. We have

---

See [https://github.com/jasonwei20/eda\\_nlp](https://github.com/jasonwei20/eda_nlp) for the data augmentation code

experimented with typical pre-processing techniques, such as “Stop-Words Removal”, which refers to removing commonly used words (such as “the”, “a”, “an”, “in”) to eliminate noise that may otherwise hinder the model’s ability to learn and predict sequences. We have also experimented with “Stemming” which refers to the process of reducing inflection in words (e.g., connect, connected, connection) to their root form (e.g., connect). The specific Stemming algorithm that was used is Porters Algorithm (Porter, 1980).

##### 3.2.2 Data Augmentation

We experimented with Data Augmentation (Wei and Zou, 2019). This is the process of using the original given data to produce more data to increase the given dataset size. Data Augmentation has been proved to be useful when dealing with small datasets. Although this technique is more prevalent in computer vision tasks, there are some versions of the technique that are specifically tailored to work with text data as described at (Wei and Zou, 2019). These techniques include Synonym Replacement, Random Insertion, Random Swap, Random Deletion, Back-translation. Table 1 shows examples on generating data using data-augmentation. This was done by using the “Easy Data Augmentation” library (Wei and Zou, 2019).

Back-translation was only applied on the Competition dataset and the other four techniques on the External dataset. For each sentence in the External dataset, 0.1 percent of Synonym Replacement, Random Insertion, Random Swap, and Random deletion was applied. We did that nine times per sentence for each sample. In the Back-translation, AWS API was used to translate the text from English to Dutch back to English. Also, from English to Dutch to Russian, back to English. For each sample, we generate two additional samples. The Competition dataset has a size of 487. After merging the External dataset and the Competition dataset, we ended up with a dataset of size 18,571. This data will be referred to as the “Competition + External Dataset”. After applying data augmentation on the Competition + External dataset, we ended up with a dataset of size 52,966. This data will be referred to as the “Augmented Dataset.”

### 4 System Description

Different model architectures have experimented with different pre-processing techniques. The final system ended up ensembling five models, each

<b>Back-translation</b>	<i>This document describes our Memorandum Propaganda Detection System</i>

Table 1: Generated Samples using Data-augmentation

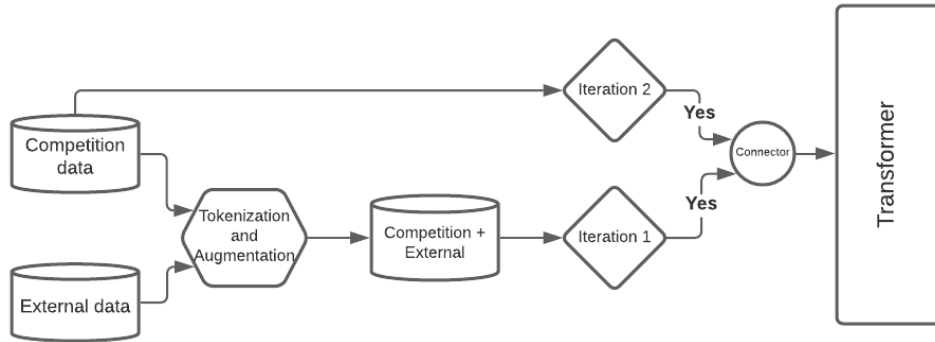

Figure 1: Approach 2 Training Schema

trained on a different approach. The ensemble model consists of 1 DeBERTa (He et al., 2021) model and 4 RoBERTa models each trained in a different approach or data pre-processing technique. We have two training approaches we used in training our models. The first one is a typical fine-tuning. The second approach consists of two iterations. In the first iteration, the model is trained on the pre-processed dataset. In the second iteration, the model from the first iteration is fine-tuned on the Competition dataset exclusively. Figure 1 demonstrates the second approach.

#### 4.1 Proposed System

The system is an ensemble model of 5 classifiers. One of them is using the DeBERTa large classifier, and the rest are RoBERTa large classifiers. Each classifier is trained on a different approach/pre-processing. For the DeBERTa large classifier, the Augmented dataset was used with the stop words removed and lowered text case. Then we trained it on the first approach for six epochs. It achieved F1 micro of 0.554 on the development set. As mentioned earlier, there are 4 RoBERTa large classifiers; the first classifier is trained on the Competition dataset and the External dataset without augmentation. We dropped samples that do not have any propaganda technique and trained the model on the first approach for four epochs. It achieved an F1 micro score of 0.550. The second RoBERTa classifier

has the same pre-processing as the first RoBERTa classifier but is trained on the second approach. It achieved an F1 micro score of 0.602 on the development set. The third RoBERTa classifier is trained on the Augmented dataset with the stop words and trained using the first approach with four epochs. It achieved F1 micro of 0.54. The fourth RoBERTa classifier is the same as the third model but fine-tuned on the Competition dataset and achieved an f1 score of 0.62. Table 2 summarizes the performance of the classifiers of LeCun’s ensemble model.

## 5 System Analysis

### 5.1 Ensemble Analysis

This section will be analyzing different combinations of the models that lead to the final proposed system. In the second approach, we noticed that fine-tuning the classifiers from the first iteration on the Competition dataset will always boost the performance up to 0.1 additional f1 micro scores on the development set. However, when it came to the ensemble model, it turned out that the ensemble model with classifiers from the second training approach doesn’t increase the overall performance, and sometimes it decreased it. Table 3 demonstrates the performance of different classifiers combinations. Ensemble (A) consists of classifier (3) with f1 micro of 0.602 and classifier (5) with f1 micro of 0.62. After the ensemble, the overall score

#	Model Type	Epochs	LR	SQM	BS	Dataset	Approach	F1-Macro	F1-Micro
1	DeBERTa Large	3	2e-06	164	8	Augmented	1	0.430	0.554
2	RoBERTa Large	2	2e-05	64	8	Competition + External	1	0.340	0.550
3	RoBERTa Large	3	2e-05	64	8	Competition + External	2	0.388	0.602
4	RoBERTa Large	4	2e-05	128	16	Augmented	1	0.358	0.540
5	RoBERTa Large	2	2e-05	128	16	Augmented	2	0.430	0.622

Table 2: Models Hyper-parameters. LR (Learning Rate), SQM (Sequence Max Length), BS (Batch Size)

	Ensemble Combination	F1 Micro	F1 Macro
A	(3)(5)	0.58	0.40
B	(4)(5)	0.59	0.40
C	(3)(4)(5)	0.62	0.41
D	(2)(3)(4)(5)	0.60	0.37
E	(1)(2)(3)	0.56	0.39
F	(1)(2)(3)(4)	0.59	0.40
G	(1)(2)(3)(4)(5)	0.64	0.44

Table 3: Performance on Different Ensemble Combinations

dropped to 0.58. However, Ensemble (A) suggests that ensembling classifier (3) and classifier (5) isn't optimal. In the final ensemble model (G), we noticed that the overall score would decrease if we removed one of these models. For example, in ensemble (F), classifier (5) was dropped, and both f1 micro and macro decreased.

## 5.2 Error Analysis

This section examines the ensemble model weaknesses to give insight on what to do next to improve the model performance. We have generated the confusion matrix and scores for each class for the test set (see Appendix). In the confusion matrices, the "None" class indicates that either the model predicted an incorrect class (not in the ground-truth labels set) or it didn't predict the correct class (in the ground-truth labels set but not in the predicted labels set). It is worth noting that the correctly classified "None" (not in the predicted labels set and not in the ground-truth labels set) is not provided in the model evaluation confusion matrix. We noticed that the model performs poorly at detecting the classes (last column) in the input test (see Figure A2). One possible explanation for this is that the model is trained on data that has a lot of samples without propaganda (count of labels = 0) (see Figure A1). In addition to that, the label matrix is sparse (zero is the dominant label in a one-hot vector). One possible solution is to remove samples with zero labels and rely on the

sparsity of vectors in detecting samples without propaganda. Another possible solution is to train a Two-Stage model, where the first stage filters out non-propaganda samples and the second stage classify the propaganda samples.

## 6 Conclusion and Future Work

In this paper, we presented our proposed system, LeCun, for detecting propaganda in contextual content. We have used an external dataset from a previous SemEval competition and performed a data-augmentation on the external dataset to expand the dataset size. We have also investigated different ensemble combinations for state-of-the-art pre-trained language models. However, there are many questions we got throughout our participation in this competition which made us curious to investigate. These questions are:- What is the influence of the data augmentation on the model performance? What is the influence of using an external dataset? How can the model weaknesses be improved? How can span identification help in improving the score of technique classification?

For future work, we will be working on answering these questions. We plan to do more in-depth experimenting with different augmentation techniques and different model architectures. We will also investigate the influence of the external dataset by training models on the competition dataset, external dataset separately and compare the final results of each.

## Abstract

Memes are one of the most popular types of content used to spread information online. They can influence a large number of people through rhetorical and psychological techniques. The task, *Detection of Persuasion Techniques in Texts and Images*, is to detect these persuasive techniques in memes. It consists of three subtasks: (A) Multi-label classification using textual content, (B) Multi-label classification and span identification using textual content, and (C) Multi-label classification using visual and textual content. In this paper, we propose a transfer learning approach to fine-tune BERT-based models in different modalities. We also explore the effectiveness of ensembles of models trained in different modalities. We achieve an F1-score of 57.0, 48.2, and 52.1 in the corresponding subtasks.

## 1 Introduction

Memes are text superimposed on graphics that convey messages in the form of jokes, sarcasm, etc. In the current era of the internet and social media, they are very quick to spread. If used as a part of a disinformation campaign, it can be quite tricky to notice the agenda behind them and has the potential to influence a large mass of people without them realizing it (Muller, 2018; Tardáguila et al., 2018; Glowacki et al., 2018).

To this end, SemEval 2021 Task 6 (Dimitrov et al., 2021) focuses on identifying such persuasive techniques (Miller, 1939) in a multimodal (visual-linguistic) setting. It consists of three subtasks that enable the participants to study the problem in each modality. Only the English textual cues are used in tasks A and B, while the visual cues are also used in task C. Task B is a modification of task A which further requires predicting the spans for each identified technique as well.

\*The authors have contributed equally.

Figure 1: Sample memes demonstrating the multimodal setting

Meme classification is a multimodal problem that often requires visual and textual cues to convey a message. Memes can convey very different meanings if either of the cues is removed. A few samples are shown in figure 1 to demonstrate the importance of visual and textual cues for classification.

We experiment with BERT (Devlin et al., 2019) based unimodal models for tasks A and B. Since they are state-of-the-art models for natural language understanding, they are a good choice for understanding the complex propaganda techniques in texts. Transformers (Vaswani et al., 2017) have limited sequence length, which limits their performance on longer data, but in the case of memes, the textual content is also very limited.

For task C, we experiment with Visual-Linguistic (VL) models like UNITER (Chen et al., 2020), VisualBERT (Li et al., 2019), LXMERT (Tan and Bansal, 2019) for the cross-modal understanding of memes. We further explore the effectiveness of ensembling models trained in

different modalities.

The code for all subtasks is available at <http://github.com/kshiti98/multimodal-propaganda.git>

## 2 Background

Propaganda aims to push biased agendas to influence people’s mindsets. It is successful in achieving its goal by hiding its way through any of the numerous media platforms available in the current world. A major factor behind the success of such campaigns is the boom of the internet and social media in recent years. Another factor being the difficulty to spot such techniques manually because of the high volume of text produced and the unnoticeable nature of such content. With the recent interest of the research community in “fake news,” the detection of persuasive techniques or highly biased texts has emerged as an active research area. Some of the previous work in this direction analyzes the general pattern of propaganda (Garimella et al., 2018; Chatfield et al., 2015), performs analysis at a document level (Rashkin et al., 2017; Barrón-Cedeño et al., 2019) and a fine-grained analysis of the text (Da San Martino et al., 2019, 2020). However, most previous work analyses the techniques in a textual unimodal setting only. This work studies propaganda techniques in a new age domain like memes.

Meme classification task can be considered a combined VL multimodal problem. It is similar to the currently popular VL problems like Visual Question Answering (Antol et al., 2015), Visual Commonsense Reasoning (Zellers et al., 2019) and Visual Entailment (Xie et al., 2019), as we have to classify semantically correlated text with that of the visual content in the image. Hence a cross-modal approach under vision and text should perform better than unimodal architectures. Basic VL approaches are based on simple fusion techniques in the form of early or late fusion to correlate unimodally trained visual and textual models. However, in an ideal scenario, a multimodally trained model should be more effective in detecting persuasive techniques in memes. With the rising interest in VL problems, recent work attempts to study similar problems in a VL multimodal setting (Gomez et al., 2020; Kiela et al., 2020; Suryawanshi et al., 2020).

**Data Description** The dataset consists of 951 memes in total, which is further divided into train/

Figure 2: Data Distribution of the labels in the training set

dev/ test splits. All the tasks have the same set of memes in their training sets, but the labeling differs for each of them. For task A, only the textual cues were used to identify the techniques. For task B, the spans of each technique were further detected. For task C, more techniques were identified using visual cues.

The distribution of the labels is illustrated in figure 2. Detailed information of the dataset can be found in the task description paper (Dimitrov et al., 2021).

## 3 System Overview

Systems proposed for all the tasks use BERT-based models with task-specific modifications.

The proposed systems are explained in detail below:

### 3.1 Task A - Text Classification

We use transfer learning to fine-tune BERT-based models for this task. To fine-tune the models, we experiment with BASE and LARGE variants of BERT and RoBERTa. We attach a feed-forward network on the [CLS] token embedding with two linear layers having the model’s default dropout and *Tanh* activation layer in between. The model architecture is illustrated in figure 3a. We apply a standard Binary Cross Entropy loss to train this model with the hyperparameters mentioned in table 1. Since there is a substantial class imbalance in the dataset, we add weights to the positive samples in

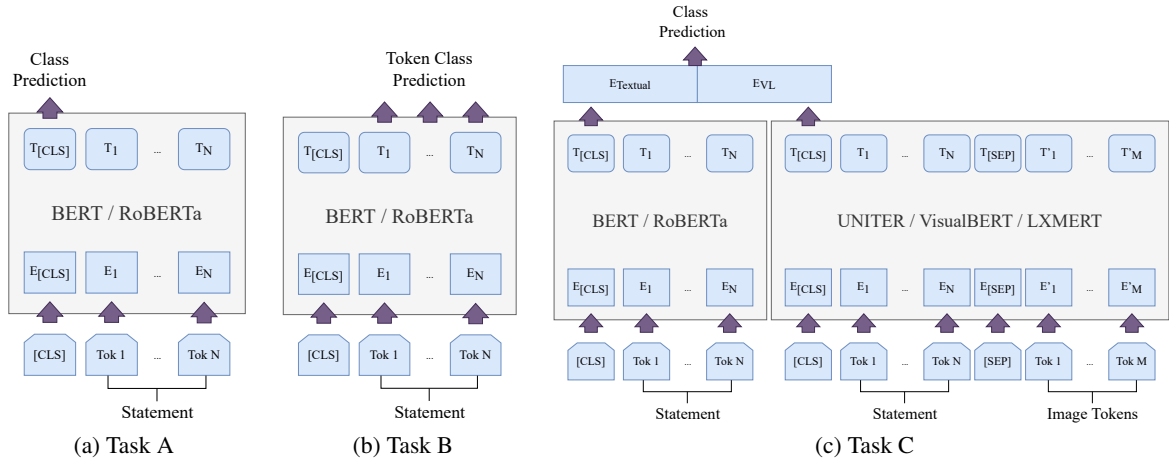

Figure 3: Proposed architectures for the given subtasks

the loss function by using the following equation:

$$\ell(\mathbf{x}, \mathbf{y}) = -\frac{1}{Nd} \sum_{n=1}^N \sum_{k=1}^d [p^k y_n^k \log x_n^k + (1 - y_n^k) \log(1 - x_n^k)]$$

$$p^k = \frac{1}{f^k} (|K| - f^k)$$

(1)

Where  $N$  is the batch size,  $n$  index denotes  $n^{th}$  batch element,  $d$  is the number of classes,  $f$  stands for a vector of class absolute frequencies calculated on the train set,  $\mathbf{x}$  is the output vector from the last Sigmoid layer,  $\mathbf{y}$  is a vector of multi-hot encoded ground truth labels and  $|K|$  is the size of the train set.

We finally use the standard Sigmoid activation function to compute probabilities for each label.

### 3.2 Task B - Span Identification and Text Classification

We experiment with the same BERT-based encoders for this task.

**Pre Processing** Since the spans are given on character-level in the dataset and the transformer models run on token-level, we transform all the spans to token-level by taking the intersection with the tokenized input. Further, we train the model with the obtained token-level labels as targets.

**Model** We model the problem statement as a token-level *multi-label* classification problem for span identification. The model architecture is illustrated in figure 3b. We use the same classifier to classify all token embeddings. To handle class imbalance, we apply weighted Binary Cross-Entropy loss with class weights as mentioned in equation 1

**Post Processing** Since all tokens of a word should belong to the same set of classes, we merge all the tokens of each word and assign a union of those classes to the chosen word.

Finally, all the words are classified using the following equation where  $W_i$  is the set of labels of the  $i^{th}$  word,  $L_{i,j}$  is the set of labels of the  $j^{th}$  token of the  $i^{th}$  word and  $N_i$  is the number of tokens of the  $i^{th}$  word:

$$W_i = \bigcup_{j=1}^{N_i} L_{i,j}$$

We do not apply loss on special tokens so that the classifier is not misled while training.

### 3.3 Task C - Visual-Linguistic Classification

We experiment with Visual-Linguistic (VL) models for this task. Since meme classification is a multi-modal task, a multimodal transformer architecture should be a good choice.

**Pre Processing** The image tokens used in the VL models are extracted using Faster R-CNN (Ren et al., 2015) and a fixed number of image tokens are created by extracting the features of the top 36 regions of interest.

**Model** We first experiment with training the VL models directly. Although the VL models should perform better in the presence of extra cues for classification, poor performance is observed compared to the powerful textual-only models.

On further analyzing the problem, we observe that propaganda detection is a complex semantic problem, and often the classes can be detected by

Parameter	Task A	Task B	Task C	
			VL	Ensemble
Dropout	0.1	-	-	-
Max Sequence Length	128	512	128	128
Batch Size	8	8	16	32
warmup	-	-	0.1	0.1
Learning Rate	1e-05	1e-05	1e-05	1e-05
patience	50	50	50	50
Weight Decay	-	0.01	0.01	0.01
Optimizer	Adam	AdamW	BertAdam	BertAdam

Table 1: Hyperparameters

using just the text. So, we experiment with the textual models and ignore the visual cues in the data. Surprisingly, the textual model outperforms the VL model when trained to learn multimodal labels using just the textual cues. We further study both models to better understand the learnings of each of them (see Section 5) and continue experimentation with ensembling both models.

We propose an ensemble of multimodal transformers like UNITER, VisualBERT, LXMERT with unimodal transformers like BERT and RoBERTa to help the classification model as each architecture can focus on their domains and later merge those embeddings. Rather than using a naive average ensembling method, we propose our own model, illustrated in figure 3c. Our model concatenates the [CLS] token embeddings from transformers in each modality and then applies classification on top of the concatenated vector. The base encoders are fine-tuned unimodally and then frozen while training the ensemble classifier. To train the textual model unimodally, we train the textual model with textual labels only to learn relevant features.

## 4 Experimental Setup

### 4.1 Implementation

We use HuggingFace<sup>1</sup> library (Wolf et al., 2020) to experiment with textual models, and use the official implementations of the multimodal transformers in PyTorch<sup>2</sup> (Paszke et al., 2019). The models were trained with the default hyperparameters with an exception for the parameters mentioned in table 1. All experiments were conducted using Nvidia GeForce RTX 2080 Ti GPU.

For training the models, we use the same train/dev/ test split as mentioned in the task, which is

<sup>1</sup> 🤗 Transformers, v4.2.0, <https://huggingface.co/transformers/>

<sup>2</sup> PyTorch, v1.7.1, <https://pytorch.org/>

in the ratio 10:1:3 with 951 samples in total. We use the best-performing model by comparing the F1-micro scores on the validation set for all our experiments.

### 4.2 Evaluation Metrics

For tasks A and C, the F1-micro score is used as the main performance metric. Due to various low resource classes in the dataset, F1-macro was also used to give weight to the smaller classes in the performance metric, but it was revealed to be highly impacted by small variations in the model.

For task B, we use the official evaluation metric as defined in the task. As the task is a multi-label sequence tagging task, the standard micro-averaged F1 is modified to account for partial matching between the spans.

## 5 Results

We conduct several experiments to compare the performance of models on each of the tasks. Detailed information can be seen in table 2.

For task A, RoBERTa<sub>LARGE</sub> is the best performing model on the task. Although the average performance of the model is worse than BERT<sub>LARGE</sub> on the test set, the maximum performance is still better.

Similarly, for task B, RoBERTa<sub>LARGE</sub> outperforms other models by a large margin.

For task C, we trained the textual models on visual-linguistic labels for a fair comparison with the other VL models. Unexpectedly, they also show decent performance and surprisingly perform better than the multimodal transformers. Finally, the ensemble models are trained with their textual model trained on textual labels and the VL model trained on VL labels. They outperform their unimodal components and end up with a fair performance increase in each of the cases.

During the post-evaluation phase, we conduct more experiments and report the corresponding performances on the test set for the best-validated models on the dev set. We realize that our submitted model performed worse on the test set in task C because the checkpoint used for test set predictions was different from the best validation checkpoint.

The final values we achieve on the test set by using the best validation set checkpoints are 57.56, 48.23, and 55.68 by using RoBERTa<sub>LARGE</sub>, RoBERTa<sub>LARGE</sub> and RoBERTa<sub>LARGE</sub> + UNITER, respectively on all the subtasks.

Model	Task A		Task B		Task C	
	Dev Set	Test Set	Dev Set	Test Set	Dev Set	Test Set
BERT <sub>BASE</sub>	64 ±0.7	52.2 ±2.5	53.1 ±1	45.6 ±1.5	63.3 ±1.2	51.9 ±1
BERT <sub>LARGE</sub>	62.8 ±0.8	<b>54.8</b> ±1.5	53.5 ±2.1	44.7 ±2.5	62.7 ±1.4	52.5 ±0.9
RoBERTa <sub>BASE</sub>	61 ±0.8	51.2 ±1.2	53.2 ±0.6	43.9 ±0.9	61.5 ±1.1	49.8 ±1.2
RoBERTa <sub>LARGE</sub>	<b>64.7</b> ±1.1	53.2 ±3.9	<b>58.5</b> ±2.1	<b>47.6</b> ±1.5	63.9 ±1.1	54.2 ±1
UNITER					64.9 ±0.2	49.2 ±0.6
VisualBERT					57.8 ±0.6	45.8 ±0.7
LXMERT					54.5 ±0.3	44.4 ±0.0
BERT <sub>BASE</sub> + UNITER					66.1 ±0.2	52.9 ±0.8
RoBERTa <sub>LARGE</sub> + UNITER					<b>67.3</b> ±0.9	<b>54.9</b> ±0.6
BERT <sub>BASE</sub> + VisualBERT					63.1 ±0.3	53.1 ±0.5
RoBERTa <sub>LARGE</sub> + VisualBERT					64.4 ±0.5	52.7 ±1.9

Table 2: Mean and std of F1-micro scores computed from 10 runs of the mentioned models. Test set values are reported after choosing the best model for the dev set using early stopping.

Figure 4: Comparison of different models in the 3 most occurring classes. F1-micro scores of 10 runs are computed on the dev set.

We observe that all BERT-based models give a decent performance for all tasks. An interesting insight we get from the visual-linguistic task is that the problem is not completely multimodal. Several of the persuasive techniques can be identified by using just the textual cues, which is evident from figure 2 as well. While textual models like RoBERTa are pretrained on a much larger textual dataset and are able to learn more complex semantics from the data, VL models suffer when used in textual-only domains. We carry out experiments to further study the differences in these models with different types of labels and propose an architecture that benefits from both models.

A class-wise comparison is carried out for all models. Since several of the classes have very low positive samples, it is difficult to draw conclusions

because of the high variance in performance due to different model initializations, so we compare the most frequently occurring labels only. The difference in the performance of different models is illustrated in figure 4. For this comparison, we train the textual model on multimodal and textual labels to compare the capability of the models. Ideally, the textual models should be trained on textual labels only to learn more relevant features. The ensemble is trained with a textual model trained on textual labels and a VL model trained on VL labels. The comparison shows that the multimodal models are performing much better for detecting *Smears*, which has various samples which require visual cues as well. Another observation is that RoBERTa is performing better on *Loaded Language* and *Name calling / Labelling*. Training an ensemble of the textual model and the multimodal is helping the model perform better in all classes.

To further study the models, we report the performance for each of them in different modalities. To measure the textual performance of the models, we compare the sets of labels in task A and C to shortlist labels which were identified only after the presence of visual cues. We do not consider those predictions and calculate the F1-micro score for the remaining subset of the predictions. Similarly, for measuring the visual performance, we do not consider the labels which were identified by just using the textual cues. The performance of several runs of the models is compared in figure 5. The comparison also supports the claim that ensembling models trained in different modalities help to learn from

Figure 5: Comparison of different models in different modes. F1-micro scores of 10 runs are computed on the dev set.

the best of both worlds.

## 6 Conclusion

Although detecting persuasive techniques in memes is a multimodal problem, often, most of the techniques can be identified by just using the textual cues from the meme. Since VL models are still in their nascent stages, powerful textual models help with solving the problem at hand. Future work can be done to improve these kinds of problems that are not multimodal in the truest sense. The ensembling method used in our model is very basic; better architectures can be explored to continue this line of work.

## Acknowledgments

We thank the organisers of the shared task for their effort, and the anonymous reviewers for their comments.

# MinD at SemEval-2021 Task 6: Propaganda Detection using Transfer Learning and Multimodal Fusion

Junfeng Tian, Min Gui, Chenliang Li, Ming Yan, Wenming Xiao

Alibaba Group, China

{tjf141457, guimin.gm, lcl193798, ym119608, wenming.xiaowm}@alibaba-inc.com

## Abstract

We describe our systems of subtask1 and subtask3 for SemEval-2021 Task 6 on *Detection of Persuasion Techniques in Texts and Images*. The purpose of subtask1 is to identify propaganda techniques given textual content, and the goal of subtask3 is to detect them given both textual and visual content. For subtask1, we investigate transfer learning based on pre-trained language models (PLMs) such as BERT, RoBERTa to solve data sparsity problems. For subtask3, we extract heterogeneous visual representations (i.e., face features, OCR features, and multimodal representations) and explore various multimodal fusion strategies to combine the textual and visual representations. The official evaluation shows our ensemble model ranks 1st for subtask1 and 2nd for subtask3.

## 1 Introduction

With the recent interest in “fake news”, the detection of propaganda or highly biased texts has emerged as an active research area (Da San Martino et al., 2020, 2019; Chernyavskiy et al., 2020).

SemEval-2021 Task 6 (Dimitrov et al., 2021) provides three subtasks aiming to detect persuasion techniques in texts and images. We participate in subtask1 and subtask3, which are defined as follows:

- **subtask1:** Given only the “textual content” of a meme, identify which of the 20 techniques are used in it. This is a multilabel classification problem.
- **subtask3:** Given a meme, identify which of the 22 techniques are used both in the textual and visual content of the meme (multimodal task).

For subtask1, we focus on using transfer learning to tackle problems related to the scarcity of data

since deep learning models require a whole lot of data while it is difficult to obtain vast amount of the labeled data. Especially, we first fine-tune the pre-trained language models on an external dataset from SemEval-2020 Task 11 (Da San Martino et al., 2020) and then continue to fine-tune them on the training dataset of SemEval-2021 Task 6. The probabilities of these tuned models are averaged to make the final prediction.

For subtask3, we concentrate on multimodal fusion to combine textual and visual representation. Heterogeneous visual representations are extracted, including face, OCR and multimodal representations. Face representation consists of recognized human faces and facial expressions. OCR representation can capture the relations among snippets in an image. Multimodal pre-trained model is capable of simultaneously processing multimodality inputs for joint visual and textual understanding. After that, we explore three multimodal fusion strategies (i.e., Average, Concat and MLP) to combine the textual and visual representations.

The experimental results show that transfer learning can leverage knowledge from source data to tackle problems related to the scarcity of data, and heterogeneous visual representation (i.e., face, OCR, and multimodal representation) can be used as complementary features to better detect persuasion techniques. Our ensemble model ranks 1st for subtask1 and 2nd for subtask3.

## 2 System Overview

In this section, we provide a general overview of our systems for the two subtasks. We consider the propaganda detection task as multimodal multi-class multi-label classification task, predicting one or more labels given an input text and an input image.

## 2.1 Model

Various pre-trained models are explored to extract textual and visual features, and these textual and visual features are fused to predict labels.

**Textual Representation** In this paper, five pre-trained language models (PLMs) are used. Representations of the special token [CLS] are passed to the classification layer. We briefly describe each PLM:

- **BERT** (Devlin et al., 2019) is a powerful transformer-based PLM and enables bidirectional training using a “masked language model” (MLM) pre-training objective. The masked language model randomly masks some input tokens and aims to predict the masked tokens. BERT also use next sentence prediction (NSP) objective during pretraining, which is a binary classification loss for predicting whether two segments follow each other in the original text. With tailored finetune objectives, BERT can improve performance on downstream tasks such as classification tasks.
- **RoBERTa** (Liu et al., 2019) proposes an improved recipe for training BERT models and boosts the performance on GLUE(Wang et al., 2019), RACE(Lai et al., 2017) and SQuAD(Rajpurkar et al., 2016). It shares the same model architecture with BERT, and mainly improves BERT by dynamic masking and a larger byte-level Byte-Pair Encoding (BPE)(Sennrich et al., 2016).
- **XLNet** (Yang et al., 2019) integrates the segment recurrence mechanism and relative encoding scheme of Transformer-XL(Dai et al., 2019) into pretraining with reparameterizing. It can capture the dependency between the masked positions and alleviate a pretrain-finetune discrepancy.
- **DeBERTa** (He et al., 2020) disentangles attention mechanism and encodes each word with two vectors representing content and position, respectively. An enhanced mask decoder is also used to incorporate absolute positions in the decoding layer to predict the masked tokens in model pre-training. These methods enables DeBERTa to obtain competitive performance of both natural language understand (NLU) and natural language generation (NLG) downstream tasks.
- **ALBERT** (Lan et al., 2019) replaces the next sentence prediction (NSP) loss with a sentence order prediction (SOP) loss to better model inter-sentence coherence. Besides, it equips two parameter reduction techniques to lower memory consumption and increase the training speed of BERT. With fewer parameters compared to BERT-large, ALBERT establishes new state-of-the-art results on the GLUE, RACE, and SQuAD benchmarks.

**Visual Representation** Three visual representations are adopted, including face representation, OCR representation and single-stream multimodal representation.

- **Face Representation** It is important to recognize faces and facial expressions for propaganda detection. We use a state-of-the-art *face recognition* model, which is a ResNet-34 network (He et al., 2016) with 29 conv layers. In an image, each face is encoded as a 128 dimensional vector using the published toolkit<sup>1</sup> and adopt mean pooling for the final face representation.
- **OCR Representation** For text in an image, the 2-D position of the text can capture the font size and the relationship among tokens within the image. Therefore, we use a 2-D position embedding to jointly model interactions between text and layout information across the image. We extract the bounding box 2-D position using the Microsoft OCR<sup>2</sup>.
- **Multimodal Representation** Recent studies on vision-language pre-training have pushed the limits of a variety of Vision-and-Language (V+L) tasks, and both the image and text content can help understand the semantics of the meme for propaganda detection. Therefore, we also extract a region-based image features with Faster R-CNN (Ren et al., 2015) to represent the image. Then, we follow (Li et al., 2021) and use a pre-trained multi-modality model SemVLP to better learn the multimodal fusion between the image and text.

**Multimodal Fusion** For multimodal propaganda detection, we employ 3 fusing methods to combine the textual and visual features.

<sup>1</sup>[https://github.com/ageitgey/face\\_recognition](https://github.com/ageitgey/face_recognition)

<sup>2</sup><https://docs.microsoft.com/en-us/azure/cognitive-services/computer-vision/concept-recognizing-text>

- **Average** The predicted probabilities of text and image features are averaged for prediction:

$$\hat{y}_c = (\text{sigmoid}(W_1(\tanh(W^t h^t) + b_1)) + \text{sigmoid}(W_2(\tanh(W^v h^v) + b_2)))/2$$

where  $h_t$  and  $h_v$  stand for textual and visual representations, respectively.

- **Concat** The text and image features is concatenated to predict probabilities:

$$\hat{y}_c = \text{sigmoid}(W[h^t, h^v] + b)$$

- **MLP** Before making prediction, we map text and image features to the same semantic space:

$$\hat{y}_c = \text{sigmoid}(W(\tanh(W^t h^t + W^v h^v) + b))$$

## 2.2 Training

**Multilabel Classifier** We provide an additional label-wise feed-forward network (FFN) and a linear layer to extract label. At training time, we propose to minimize the binary cross-entropy (BCE) objective  $\mathcal{L}$  as follows:  $\mathcal{L}_{\text{BCE}}(\hat{y}_c, y_c) = -y_c \log \hat{y}_c - (1 - y_c) \log (1 - \hat{y}_c)$  where  $y_c$  is the ground truth of class  $c$  and  $\hat{y}_c$  is the predicted value. At test time, we predict the label as  $\tilde{y}_c = \mathbb{I}(\hat{y}_c > T)$  where  $T$  is a probability threshold and  $\mathbb{I}$  is the indicator function.

As for label imbalance problem, focal loss (FL) (Lin et al., 2017), which down-weights easy examples and focus training on hard negatives, is adopted during training.

**Transfer Learning** It is difficult to get vast amounts of labeled data for supervised models. Transfer Learning enables us to utilize knowledge from previously learned tasks and apply them to newer, related ones. We use transfer learning from the news articles domain: we first train the model using the news data, and then we continue training for this task. In preliminary experiments, we find that fine-tuning layers in the process is better than freezing them as feature extractors.

## 3 Experimental Setup

### 3.1 Dataset

We conduct experiments with the train, the dev and the test datasets provided by SemEval-2021 Task 6 (Dimitrov et al., 2021), which contains 687, 63 and 200 memes for subtask1 and subtask3, respectively.

**External Resources** We use the annotations of the PTC corpus (more than 20,000 sentences) from SemEval-2020 task 11 (Da San Martino et al., 2020) as external resource. Although its domain is news articles and fewer techniques are considered, the annotations are made using the same guidelines as SemEval-2021 task 6.

### 3.2 Evaluation Measures

Subtask1 and subtask3 are multi-label classification tasks. The official evaluation measure for both tasks is micro-F1. We also report macro-F1.

### 3.3 Parameter Settings

We adopt the large models and select hyper-parameters using validation on a subsample of the training data. The cased models are used because that upper cases contain strong emotion signals in this task. We use adamW optimizer (Loshchilov and Hutter, 2019) with 500 warm-up steps and train for 10 epochs with a  $2e-5$  learning rate and a 8 batch size. The last checkpoint is used for evaluation.

### 3.4 Submitted Systems

**Post-processing** *Repetition* means repeating the same message over and over again so that the audience will eventually accept it. Therefore, we assign a *Repetition* label in case if there exists a bigram appears more than 3 times.

**Ensemble** We use model ensemble for final submission. In particular, for subtask1 we explore 5 pre-trained models (using BCE Loss, Focal Loss and Transfer Learning, respectively), and for subtask3 we additionally explore face, OCR, multimodal representations and the fusion strategies. We take the probabilities of these settings and average them to make the final prediction.

### 3.5 Test Results

Table 1 and Table 2 list the results of the top-performing teams for subtask1 and subtask3. We can see that our proposed model is ranked 1st for subtask1 and 2nd for subtask3 among all teams.

## 4 Discussion

More thorough studies and analyses are conducted in this section, trying to answer two questions: (1) How is the performance of transfer learning on less data? (2) How is the performance of multimodal fusion on multimodal data? Moreover, we give

Rank	Team	F1-Macro	F1-Micro
1	<b>MinD</b>	<b>0.28993</b>	<b>0.59331</b>
2	Alpha	0.26218	0.57187
3	Volta	0.26621	0.56958
	Baseline	0.04427	0.06439

Table 1: Results of top 3 teams for **subtask1 (test)**.

Rank	Team	F1-Macro	F1-Micro
1	Alpha	<b>0.27315</b>	<b>0.58109</b>
2	<b>MinD</b>	0.24389	0.56623
3	1213Li	0.22830	0.54860
	Baseline	0.05152	0.07062

Table 2: Results of top 3 teams for **subtask3 (test)**.

error analyses on the test dataset to provide an overview of problematic labels.

#### 4.1 Transfer Learning

We perform ablation study for each PLM (row) and each learning method (column) in Table 3 for subtask1. It shows that:

First, RoBERTa and DeBERTa were generally the best performing models. Given that RoBERTa and DeBERTa are carefully tuned models base on BERT, this result is reasonable.

Second, both Focal Loss and Transfer Learning help to alleviate data sparsity problems. Focal Loss help DeBERTa and ALBERT improve 0.7 and 0.6 points. Because Focal Loss assigns higher weights to sparse samples and reduces the weights to frequent samples. Transfer Learning helps BERT, RoBERTa, XLNet improve 1.0, 4.0, 5.7 points, respectively. RoBERTa with Transfer Learning achieves the best single model score. Transfer Learning help transfer the parameters trained on related data or task to the newer model. Instead of learning from scratch, the newer model can leverage knowledge to tackle problems related to the scarcity of data.

#### 4.2 Multimodal Fusion

For subtask3, we compare different multimodal representations in Table 4 and fusion strategies in Table 5. We find that:

(1) both OCR Representation and Multimodal Representation models outperform the Text Representation model. OCR Representation can additionally capture the relative space relationship instead of sequential information among texts in an image.

Training PLM	BCE	FL	Transfer
BERT	0.5833	0.5552	<b>0.5941</b>
RoBERTa	0.6070	0.5950	<b>0.6478</b>
XLNet	0.5573	0.5418	<b>0.6148</b>
DeBERTa	0.6307	<b>0.6378</b>	0.6230
ALBERT	0.5251	0.5319	<b>0.5081</b>

Table 3: Results (**F1-Micro**) for **subtask1 (dev)**. **BCE**, **FL**, **Transfer** stand for models training using BCE Loss, Focal Loss and Transfer Learning, respectively.

Model	F1-Macro	F1-Micro
Text Representation	0.2481	0.5012
Face Representation	0.1956	0.2332
OCR Representation	<b>0.2722</b>	0.5208
Multimodal Representation	0.2355	<b>0.5876</b>

Table 4: Results for **subtask3 (dev)**. We explore various multimodal representations.

(2) Multimodal Representation model achieves the best single model performance since it jointly aligns the semantics between image and text and thus is effective for the vision-language understanding task.

(3) Table 5 lists the results of different fusion strategy. We combine the text and face representations since they are the minimal semantic elements in the image. *Concat* obtains the best result on both Macro-F1 and Micro-F1 metrics, though it is the simplest strategy for fusion.

#### 4.3 Error Analysis

To provide an overview of problematic labels, We give error analysis in Table 6 and Table 7. We find that: (1) *Loaded Language and Name Calling*, which are the most frequent labels, show reasonably good performance (0.8190 and 0.6667 F1 score).

(2) On the other hand, as to labels with fewer training samples (less than 20), the system tends not to predict. Additionally, we find rules for *Repetition* do not work and all the predicted label are wrongly classified.

(3) *Slogans, Glittering generalities and Smears* are relative hard to identify. Meanwhile, Recall values of *Transfer and Strong Emotions* for subtask3 are less than 0.1. It lacks enough training samples to well fit the network parameters.

Fusion	F1-Macro	F1-Micro
Average	0.3673	<b>0.6114</b>
MLP	0.3947	0.6094
Concat	<b>0.4218</b>	<b>0.6114</b>

Table 5: Results for **subtask3 (dev)**. We explore various multimodal representations.

## 5 Conclusion

In this paper, we adopt transfer learning to handle data sparsity problems for subtask1, and fuse heterogeneous multimodal representation for subtask3. The experimental results show that transfer learning can leverage knowledge from source data to tackle problems related to the scarcity of data, and heterogeneous visual representation (i.e., face, OCR, and multimodal representation) can extract complementary features.

In future work, we plan to explore fine-grained multimodal fusion with token representations in text and object features in images.

## Abstract

Inscribing persuasion techniques in memes is the most impactful way to influence peoples' mindsets. People are more inclined to memes as they are more stimulating and convincing and hence memes are often exploited by tactfully engraving propaganda in its context with the intent of attaining specific agenda. This paper describes our participation in the three subtasks featured by SemEval 2021 task 6 on the detection of persuasion techniques in texts and images. We utilize a fusion of logistic regression, decision tree, and fine-tuned DistilBERT for tackling subtask 1. As for subtask 2, we propose a system that consolidates a span identification model and a multi-label classification model based on pre-trained BERT. We address the multi-modal multi-label classification of memes defined in subtask 3 by utilizing a ResNet50 based image model, DistilBERT based text model, and a multi-modal architecture based on multikernel CNN+LSTM and MLP model. The outcomes illustrated the competitive performance of our systems.

*Keywords:* persuasion techniques, transfer learning, multimodal neural architecture.

## 1 Introduction

Persuasion techniques are quite recurrent in social media contents as it reaches a vast community. Proselytizing contents are adroitly implanted in posts and blogs which influence people's thoughts unconsciously. Nowadays such techniques are also being instilled in memes as people's attention is easily captured through illustration rather than narration. Manipulators often use this as a tool to promote their own deceitful agenda which can be political or anything else. Fake news is also spread through these disguised duplicitous contents which

cause a lot of casualties. Therefore, it is an indispensable task to detect these techniques in multimodal contents to protect the users from deception.

The objective of SemEval 2021 task 6 (Dimitrov et al., 2021) is to detect the persuasion techniques in textual and multi-modal contents. This task includes three subtasks where the first two are based on textual contents only. More precisely, the first subtask requires us to detect which persuasion techniques among the given 20 techniques are inscribed in the textual content whereas the second subtask requires us to not only find which techniques are used but also to find the specific span of the text each technique corresponds to. The third subtask is a multi-modal multi-label classification problem where we need to identify which of the given 22 techniques are engraved both in the textual and visual content of the meme. An example from the provided dataset along with the desired output for three subtasks is depicted in Figure 1.

Numerous works have been done on the multi-label classification of text contents. (Chalkidis et al., 2019) depicted the pre-eminent impact of bidirectional GRU with label-wise attention in the legal domain. A consolidation of latent emotion memory (LEM) network and Bi-GRU was exploited for multilabel emotion classification (Fei et al., 2020). Besides, SemEval 2020 task 11 (Da San Martino et al., 2020) introduced two subtasks including span identification of propagandistic fragments in text content and technique classification of propagandistic fragments. The top-performing team (Morio et al., 2020) in the span identification subtask utilized several pre-trained language models for both subtasks. They also proposed an effective ensemble method with stacked generalization. The winning team (Jurkiewicz et al., 2020) of the technique classification subtask approached with an ensemble of RoBERTa based models and utilized RoBERTa-CRF archi-

---

The first four authors have equal contributions.

Tasks	Input	Output (Persuasion Techniques)
Subtask #1	ELEGANT AT LYING BRUTAL WITH THE TRUTH	<ul style="list-style-type: none"> <li>Loaded Language</li> <li>Exaggeration / Minimisation</li> </ul>
Subtask #2		<i>BRUTAL</i> : Loaded Language <i>BRUTAL WITH THE TRUTH</i> : Exaggeration / Minimisation
Subtask #3	ELEGANT AT LYING BRUTAL WITH THE TRUTH + Meme:113_image.png	<ul style="list-style-type: none"> <li>Exaggeration / Minimisation</li> <li>Glittering Generalities (Virtue)</li> <li>Loaded Language</li> <li>Smears</li> </ul>

Figure 1: An illustration of the different subtasks.

texture for the span identification subtask. (Wen et al., 2020) addressed a multi-label image classification problem by following human behavior pattern where labels and image features extracted by the ConvNet were projected to a common latent vector space to capture label correlation. (Song et al., 2018) used a deep multi-modal CNN method for multi-instance multi-label image classification.

In this paper, we present our approaches to address the challenges of identifying persuasion techniques in the textual and multimodal contents as defined in SemEval 2021 task 6. We exploit various kinds of approaches ranging from traditional statistical classifiers to the state-of-the-art deep learning architecture (e.g. multi-kernel CNN+LSTM, MLP, and ResNet50) and transformer models (e.g. BERT, DistilBERT, and FastBERT) in our proposed unified architecture.

We arrange the rest of the paper as follows: we explicate our proposed framework in Section 2. Section 3 unfolds the experimental details and comparative performance analysis. We analyze the performance of our models and also portray an analysis of erroneous detection in Section 3.4. Finally, we conclude this paper with some future prospects in Section 4.

## 2 Proposed Architecture

### 2.1 Subtask 1: Multi-label Persuasion Techniques Classification

In subtask 1, we need to design a method to identify the persuasive techniques used in textual content of a meme. The overview of our proposed system is depicted in Figure 2. In our proposed system, we combine three different models: 1) Logistic regression classifier, 2) Decision tree classifier, and 3)

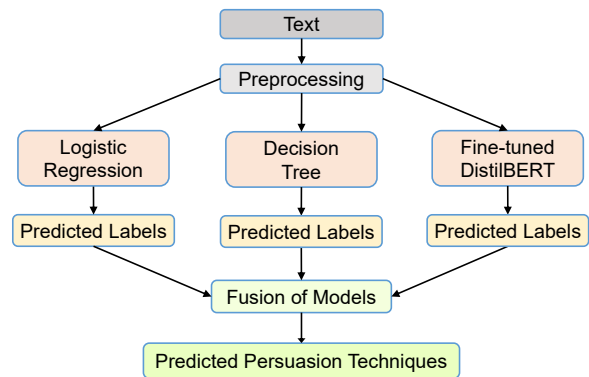

Figure 2: Proposed framework of Subtask 1.

Fine-tuned DistilBERT model. We apply some pre-processing techniques including removing punctuations, numbers, special and single characters, multi-space, text lower-casing, word contradiction, and lemmatizing (Loper and Bird, 2002). Using our proposed models, we get different probability values for corresponding labels. Comparing our threshold score against the probability values, we find multi-label predictions from the individual models and employ the majority voting scheme to obtain our final multi-label predictions.

#### 2.1.1 Logistic Regression

Logistic regression (Cheng and Hüllermeier, 2009) is a machine learning model using probability concepts. It exploits some set of discrete values and the result is converted into a probability score by using a logistic sigmoid function. In our system, we employ a Tf-Idf vectorizer scheme for effective feature representation. We fix our threshold score to 0.05 for converting the probability score into a specific label category. If the probability score is greater than threshold values, it returns 1 as a true value for a specific label and vice versa.

### 2.1.2 Decision Tree

The decision tree (Safavian and Landgrebe, 1991) is a supervised learning classifier where values are divided ceaselessly following some specific parameters. We divide the decision tree into two sub-components, one is decision nodes which split our values and another is leaves which are considered as final decided outcomes. For multi-label classification, we get different probabilities for all the class labels and set the threshold value to select labels following the same process as employed in the logistic regression.

### 2.1.3 Fine-tuned DistilBERT

DistilBERT (Sanh et al., 2019) is a transformer model that has 40% fewer parameters than BERT-base and works 60% faster. We fine-tuned DistilBERT model using the training dataset. For training purposes, we format the pre-processed data into two columns. One column contains the pre-processed text, and the other column carries labels. We convert the labels using scikit-learn (Pedregosa et al., 2011) MultiLabelBinarizer. We construct a neural network named DistilBERTClass involving the DistilBERT model along with the dropout and linear layer on top of it. The dimension of the linear layer is 20 which is the number of labels given in our subtask. We train the model a couple of times by feeding our dataset and we get the probability of each label. We use a random threshold to select the final labels.

### 2.1.4 Fusion of Models

We assemble our three individual models through a majority voting scheme. In majority voting, we count the occurrences of labels from three distinct models. We append the labels with the frequency of 2 or more to the final list of labels. Therefore, we obtain our final list of persuasive techniques for a given meme text.

## 2.2 Subtask 2: Span Identification of Persuasive Techniques

We propose a system that integrates a span identification model and a multi-label classification model for this subtask. We exploit an approach based on pre-trained BERT (bert-base-uncased). We employ SemEval 2020 Task 11’s (Da San Martino et al., 2020) propaganda dataset as an external corpus. The overview of our proposed model is depicted in Figure 3.

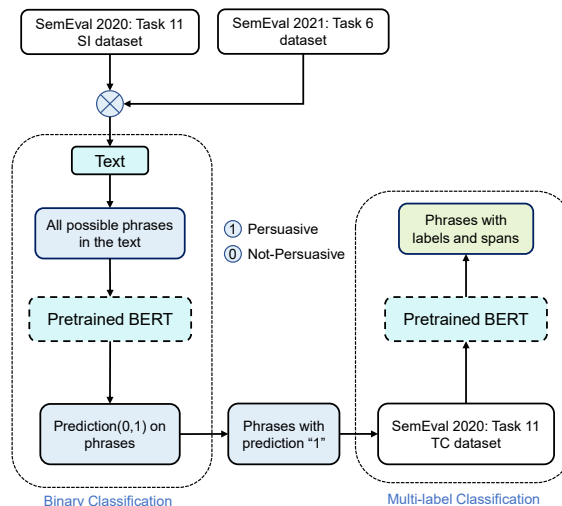

Figure 3: Proposed framework of Subtask 2.

### 2.2.1 Span Identification

We accumulate the sentences extracted from the articles of SemEval 2020 Task 11’s SI dataset, SemEval 2021 Task 6’s train, and development dataset. We derive all possible phrases from these sentences. Phrases with their indices included in span are labeled as 1 (Persuasive) while others are labeled as 0 (Not persuasive). This customized dataset is then sent to the pre-trained BERT model (Devlin et al., 2019) for training. We also extract all possible phrases from the test dataset. The pre-trained BERT model conducts binary classification on this test set. Here, the phrases are considered as sentences, so this process can be comprehended as a binary sentence classification task. After classifying the phrases derived from the test dataset, the indices of the phrases classified as 1 (Persuasive) are included in the spans and further processed for technique classification.

### 2.2.2 Technique Classification

The phrases of the test data that are predicted as persuasive in the previous segment are used as the test dataset of this segment. In this portion, we congregate SemEval 2020 Task 11’s technique classification dataset, SemEval 2021 Task 6’s train, and development dataset. In the case of the last two of them, we only include the text fragments, the indices of which are included in the provided spans instead of the whole text. We then send this contrived trainset to another pretrained BERT model with the same configuration as before and operate multi-label classification on the test set which generates predicted labels among the given 20 labels

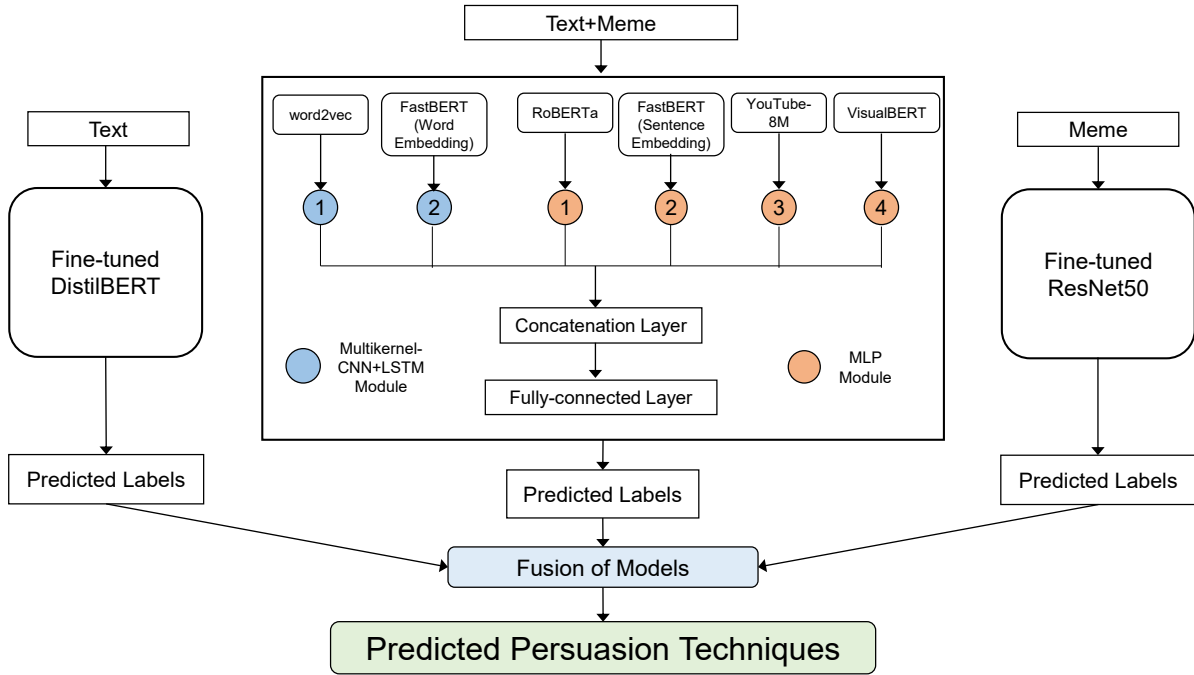

Figure 4: Proposed framework of Subtask 3.

per phrase. The phrases, their start index, end index, and their corresponding labels are then reintegrated as text fragments, start index, end index, and technique accordingly with their original text and converted into a suitable format for submission.

### 2.3 Subtask 3: Multi-modal Multi-label Classification

For this multi-modal subtask, we propose a majority voting based architecture as illustrated in Figure 4. We exploit a fine-tuned DistilBERT model, an ensemble of multi-kernel CNN with LSTM module and MLP module, and a fine-tuned ResNet50 model. These three models produce a list of persuasive techniques singularly and these lists are passed to the majority voting module to obtain the final list of persuasive techniques.

#### 2.3.1 Fine-tuned DistilBERT

We use the same process of training described in Section 2.1.3. We accumulate the training and development dataset in a single corpus. Later, we use the 90% percent of the data for training and the rest of used as the validation set for finetuning.

#### 2.3.2 Fine-tuned ResNet50

We perform fine-tuning on the residual neural network (He et al., 2016) having 50 layers. We convert our meme dataset as the format of the iMet Collection 2019 - FGVC6 dataset (Zhang et al., 2019).

For training purposes, we include an additional label for the memes which have no labels assigned. We utilize the “ResNet50” pre-trained model, having “imagenet” as weights and 1000 classes. We interchange the Average pool layer with the AdaptiveAvgPool2d layer. We attach some batch normalization layers, dropout, and a linear layer. In the linear layer, the BatchNorm1d takes 2048 features as input. In the output layer, we return 23 output features where we add one additional label with the number of labels given in our problem. We train two layers such as layer4 and the last linear layer with the corresponding learning rate  $1e-5$  and  $5e-3$ . We train the model numerous times and then get the model predictions. Finally, we set a random threshold to get the final predicted labels.

#### 2.3.3 Ensemble of Multi-kernel CNN + LSTM and MLP Model

To address the challenge of the multimodal subtask, a combination of high-level features in a neural architecture is conventional. Our proposed model suggests a fusion of features extracted from multi-kernel CNN on top of the LSTM model and MLP (multi-layer perceptron) model. We exploit two kinds of word embeddings including word2vec (Mikolov et al., 2013) and fine-tuned FastBERT (Liu et al., 2020) models which are sent to the convolutional model of kernel size (2, 3) and subsequently to the LSTM model.

Besides, we also explore a multi-layer perceptron model for one-dimensional image features, sentence embeddings, and multi-modal features.

- **Image Features:** The image features are extracted from YouTube-8M (Abu-El-Haija et al., 2016) image feature extractor model(1024-dimension).
- **Sentence Embeddings:** These are extracted from the fine-tuned FastBERT (768-dimension) model and pre-trained RoBERTa (768-dimension) (Liu et al., 2019) model.
- **Multi-modal Features:** VisualBERT (Li et al., 2019) is exploited to blend image features along with text features. We implement the model proposed by (Li et al., 2020). We extract the image features utilizing Detectron2 (Wu et al., 2019) and the text features are encoded from a pre-trained BERT model. Both features are then merged inside VisualBERT. The dimension of the features is (164,768) and we flatten these features for our MLP module.

The output from two multi-kernel CNN+LSTM (MKCNN+LSTM) modules and four MLP modules are concatenated and further transmitted to the fully connected layer.

### 2.3.4 Fusion of Models

The list of predicted labels from the above three models are subsequently passed to a majority voting module. The primary idea behind majority voting is based on the frequency of the labels. If a label exists in the majority of the models, it is appended in the final list of labels.

## 3 Experiments and Evaluations

### 3.1 Dataset Description

In SemEval-2021 task 6 (Dimitrov et al., 2021), overall 950 data has been provided for subtask 1, 2, and 3. In the case of subtask 1 and 2, training, development, and test set contain 687, 63, and 200 textual data respectively. For subtask 3, the same amount of textual and meme data has been accommodated since it is a multi-modal subtask. Dataset for subtask 1 and 3 is annotated with 20 and 22 persuasive techniques correspondingly while subtask 2 dataset provides spans of 20 techniques used all together in the text.

### 3.2 Experimental Setup

In this section, we illustrate our submitted systems in SemEval-2021 Task 6. In case of subtask 1, we use three different models i.e. logistic regression, decision tree classifier, and fine-tuned DistilBERT model. The system configuration of these three individual models are given in Table 1.

System	Settings
Logistic Regression	<ol style="list-style-type: none"> <li>1. <i>max_iter</i>: 2000</li> <li>2. <i>C</i>: 20</li> <li>3. <i>penalty</i>: l2</li> <li>4. <i>tol</i>: 0.001</li> </ol>
Decision Tree	<ol style="list-style-type: none"> <li>1. <i>min_samples_split</i>: 2</li> <li>2. <i>min_samples_leaf</i>: 1</li> <li>3. <i>criterion</i>: gini</li> <li>4. <i>splitter</i>: best</li> </ol>
Fine-tuned DistilBERT	<ol style="list-style-type: none"> <li>1. <i>Tokenizer</i>: distilbert-base-uncased</li> <li>2. <i>Dropout</i>: 0.2</li> <li>3. <i>Learning rate</i>: 2e-5</li> <li>4. <i>Batch size</i>: 16</li> <li>5. <i>num_workers</i>: 4</li> <li>6. <i>Maximum length</i>: 60</li> <li>7. <i>Epochs</i>: 10</li> </ol>

Table 1: System settings for Subtask 1.

We used the same system configuration of pre-trained BERT model for two segments i.e. span identification and multi-label technique classification in the subtask 2. The system settings are depicted in Table 2.

System	Settings
Pre-trained BERT	<ol style="list-style-type: none"> <li>1. <i>max_seq_length</i>: 128</li> <li>2. <i>Epochs</i>: 1</li> <li>3. <i>train_batch_size</i>: 8</li> <li>4. <i>eval_batch_size</i>: 8</li> <li>5. <i>Weight decay</i>: 0.5</li> <li>6. <i>Learning rate</i>: 4e-5</li> <li>7. <i>adam_epsilon</i>: 1e-8</li> <li>8. <i>warmup_ratio</i>: 0.06</li> <li>9. <i>max_grad_norm</i>: 1.0</li> <li>10. <i>gradient_accumulation_steps</i>: 1</li> <li>11. <i>logging_steps</i>: 50</li> <li>12. <i>save_steps</i>: 2000</li> </ol>

Table 2: System settings for Subtask 2.

For subtask 3, we used three types of models. One is a fine-tuned DistilBERT model which is trained using the text written in a meme. The other model is a fine-tuned ResNet50 model, and the last one is multi-kernel CNN+LSTM and MLP model. These three models trained with the given dataset using different parameter settings. The system settings for each model are represented in Table 3. As meme is a combination of text and image, therefore we consider the majority voting based predictions as the final predictions for subtask 3.

System	Settings
MultiKernel LSTM with MLP	<ol style="list-style-type: none"> <li>1. <i>nb_filters</i>: 200</li> <li>2. <i>nb_rnnoutdim</i>: 600</li> <li>3. <i>rnn_dropout</i>: 0.5</li> <li>4. <i>optimizer</i>: adam</li> <li>5. <i>Threshold</i>: 0.3</li> <li>6. <i>Epochs</i>: 600</li> </ol>
Fine-tuned DistilBERT	<ol style="list-style-type: none"> <li>1. <i>Tokenizer</i>: distilbert-base-uncased</li> <li>2. <i>Dropout</i>: 0.25</li> <li>3. <i>Learning rate</i>: 1e-4</li> <li>4. <i>Batch size</i>: 16</li> <li>5. <i>maximum length</i>: 60</li> <li>6. <i>Epochs</i>: 30</li> </ol>
Fine-tuned ResNet50	<ol style="list-style-type: none"> <li>1. <i>Image Size</i>: (224,224,3)</li> <li>2. <i>Train Batch Size</i>: 32</li> <li>3. <i>Test Batch Size</i>: 16</li> <li>4. <i>Optimizer</i>: Adam</li> <li>5. <i>Optimizer Learning rate</i>: 2e-4</li> <li>6. <i>Epochs</i>: 900</li> </ol>

Table 3: System settings for Subtask 3.

### 3.3 Results and Analysis

We now compare our proposed CSECUDSG system’s performance with other participants systems in three subtasks as shown in Table 4, Table 5, and Table 6, respectively. In all the subtasks, the baseline system is set to random. The organizers used the F1-Micro as the primary evaluation measure for all the subtasks.

The overall scores of the three subtasks portray that our system acquired competitive performance. However, in all the subtasks, our system has some shortcomings with respect to the top performing teams. MinD, Volta, and Alpha are the top-performing teams in corresponding subtasks. We further analyze the performance of our systems in the subsequent section.

Team_Name	F1-Macro	F1-Micro
MinD	0.28993	0.59331
Alpha	0.26218	0.57187
Volta	0.26621	0.56958
<b>CSECUDSG</b>	<b>0.18454</b>	<b>0.48894</b>
NLPITR	0.12590	0.37917
TriHeadAttention	0.02397	0.18373
Baseline	0.04427	0.06439

Table 4: Comparative performance analysis on test set for Subtask 1.

Baseline	0.05152	0.07062

Table 6: Comparative performance analysis on test set for Subtask 3.

### 3.4 Discussion

In this section, we discuss the contribution of each model’s performance against the combined system. For subtask 1, we showed the individual model’s performance on the test set in Table 7. From the table, we can see that the decision tree classifier achieved a score of 0.335 where the score is 0.426 and 0.480 in the case of the logistic regression classifier and DistilBERT model respectively. Analyzing this individual model’s score, we can say that we achieved the highest score from the DistilBERT model. After applying majority voting, our score increased to 0.008% and the final score is 0.48894 which means that the ensemble of three individual models can detect better than individual models.

In subtask 3, from the Table 8 we observe that the fine-tuned DistilBERT model provides a little better score than the majority voting based model. However, for the multi-modal task, both text and image contexts are important, therefore we consider the majority voting based model.

Tasks	Text/Image	Predicted labels	Gold labels
Subtask #1	AMERICAN EXPERIENCE\nTHE GREAT WAR\n	<ul style="list-style-type: none"> <li>❖ Flag-waving</li> <li>❖ Slogans</li> <li>❖ Loaded Language</li> </ul>	[ ]

Method	F1-Score
CSECUDSG	0.51312
Performance of Individual Models	
–MKCNN+LSTM and MLP model	0.36836
–Fine-tuned ResNet50 model	0.46449
–Fine-tuned DistilBERT model	0.52899

Table 8: Individual model’s performance for Subtask 3.

Further, we look into the reason behind the inaccuracy of multiple labels detected by our systems in all the subtasks. For this purpose, we have shown some examples in Figure 5. We noticed that due to the imbalance of labels in the dataset, our systems could not detect the labels which are present in less amount. As the percentage of these three labels i.e. ‘Loaded Language’, ‘Smears’, and ‘Name calling/Labeling’ are higher than the other labels, our system detects these three labels considerably but overlooks other labels.

#### 4 Conclusion and Future Directions

In this paper, we traversed different classification approaches along with a rich set of transfer learning features to tackle the challenges of the task. To predict the multiple labels in subtask 1 and 3, we exploited a unified architecture based on three different models. However, for span and technique classification in subtask 2, we used the pre-trained BERT model where the SemEval-2020 task 11 dataset is used to ameliorate the performance.

In the future, for subtask 1 and subtask 2, we have a plan to employ more pre-processing techniques and to conduct our experiment on efficient classifiers. Besides, we want to use deep learning models as well as other transfer learning fine-tuned models i.e. RoBERTa, BERT, GPT. For subtask 3, we plan to incorporate various image datasets to get more efficacious features.

## Abstract

In writing, humor is mainly based on figurative language in which words and expressions change their conventional meaning to refer to something without saying it directly. This flip in the meaning of the words prevents Natural Language Processing from revealing the real intention of a communication and, therefore, reduces the effectiveness of tasks such as Sentiment Analysis or Emotion Detection. In this manuscript we describe the participation of the UMuTeam in HaHackathon 2021, whose objective is to detect and rate humorous and controversial content. Our proposal is based on the combination of linguistic features with contextual and non-contextual word embeddings. We participate in all the proposed subtasks achieving our best result in the controversial humor subtask.

## 1 Introduction

In this manuscript we describe our participation in the shared task *HaHackathon 2021* (Meaney et al., 2021), proposed in the Forum for Information Retrieval Evaluation (IberEval'2021) whose objective is the identification and evaluation of humorous and offensive texts written in English. Humor allows you to present the reality by highlighting the comic and ridiculous side of life. Humor is hard to identify, even for humans (Vrticka et al., 2013). On the one hand, there are many forms of humor: from mild forms, such as jokes or puns, that result in better and safer social environments, to biting forms, like sarcasm, which is used as a rhetorical device. Humor can also have a constructive end, as happens in satire, where irony, double meaning, and sharp analogies are used to ridicule someone or something. On the other hand, the sharper the humor, the more effort it takes to understand it. When humor is misunderstood, or when humor itself has a transgressive purpose, it can lead to controversies and confrontations. Furthermore, an added

difficulty is that humor is highly subjective and context dependent, making it even more difficult to understand (Jiang et al., 2019). Nevertheless, the benefits of endowing to a machine basic notions about humor and figurative language understanding outweigh the challenges they pose, because they lead to natural language-based interfaces to feel more naturally, such as chat-bots and virtual assistants (Ritschel et al., 2019) and more reliable results in tasks such as opinion mining.

We participate in all the proposed subtasks of HaHackathon'2021 with two systems that combines linguistic features (LF) extracted with a tool developed by our research group with (1) pre-trained word embeddings (PWE) from fastText (Mikolov et al., 2017) and GloVe (Pennington et al., 2014), and (2) contextual word embeddings from BERT (Devlin et al., 2018) (CWE). Our best result was achieved in task 1c (controversial humor), in which we trained a classification neural network that distinguishes between *non-humor*, *humor*, and *offensive* but outputs a binary prediction which indicates whether a text is controversial or not. The code is available at <https://github.com/Smolky/hahackathon-2021>.

## 2 Background

The HaHackathon 2021 challenge consists in two binary classification problems of humorous content and controversial tweets and two regression problems to identify how humorous and controversial the annotators considered the texts. We only used the dataset given by the organizers, two pretrained word embeddings models, and the contextual word embeddings from BERT.

The dataset provided consisted in 10k tweets written in English and posted in three subsets, namely training, development, and testing, with a ratio of 80-10-10. All tweets were annotated by

US English-speaking annotators of different genders and age groups with the following questions: (1) *Is the intention of this text to be funny?*, (2) *[If so] How humorous do you find the text? (on a scale of 1 to 5)*, (3) *Is this text generally offensive?*, and (4) *[If so] How generally offensive is the text? (on a scale of 1 to 5)*. Based on the data we had during the competition, we observed that the training dataset was imbalanced for subtask 1a, with a predominance of humorous tweets (61.65%) and almost balanced for subtask 2a. For regression subtasks, the average rating was 2.26 ( $\sigma$  of 0.5670) for subtask 1b and 0.58 ( $\sigma$  of 0.98) for subtask 2a.

Most of the literature found on the detection of humor highlights the importance of figurative language in which, contrary to the literal sense of language, words and expressions change their conventional meaning to refer to something without saying it directly (del Pilar Salas-Zárate et al., 2020). The reader can find in that work a compendium of works that analyze sarcasm, irony, and satire in English. Modern approaches rely on novel deep-learning transformers, such as the work described in Javdan et al. (2020), focused on sarcasm from a figurative language perspective, and in which the authors used BERT to build an aspect-based sentiment analysis system to determine whether the response is sarcastic. Other works, such as the one described in del Pilar Salas-Zárate et al. (2017), explores the differences and similarities in how satire is perceived in countries that share the language, but not the cultural background. To do this, they compare the use of linguistic characteristics with a corpus of satirical news written in Spanish from Spain and another written in Spanish from Mexico.

### 3 System overview

Our proposal is based on the usage of LF, PWE, and CWE to detect humor and controversial content. CWE have outperformed previously state of the art results regarding text classification tasks. However, we state that both PWE and CWE ignore relevant clues that are present in writings. For example, we observed in the dataset provided, the presence of capital letters (commonly used when shutting or to raise the voice), quoted sentences or dialogues that reproduce real or figurative conversations that are not captured with any of the above techniques.

To obtain the LF, we use a subset of the features extracted with UMUTextStats (García-Díaz et al., 2020, 2021). This tool is inspired in LIWC

(Tausczik and Pennebaker, 2010) but designed by our research group from scratch for the Spanish language. As the HaHackathon 2021 dataset only deals with English, we only extract statistical features discarding all features that we had that work with Spanish lexicons. Specifically, we select:

- **Expressive lengthening**, drawing out or emphasizing a verbalized word, giving it character.
- **Common typing mistakes**, such as starting sentences in lowercase, numbers, consecutive repetitions of the same word, and incorrect use of punctuation.
- **Corpus statistics**, such as the standard type/token ratio (TTR), the number of words, syllables, sentences, quoted sentences, interrogative and exclamatory sentences, and the average length of the words.
- **Punctuation symbols and emoticons**.
- **Common traits used in social media communication**, such as the presence of hyperlinks, hashtags or jargon.

The next step was to obtain the best deep-learning architecture for each subtask. We evaluate two main approaches. On the one hand, we combine the LF with PWE and different deep-learning architectures. On the other, we combine the LF with CWE from BERT (*bert-base-uncased*) using HuggingFace<sup>1</sup>. After performing these two models, we sent our results to the platform to evaluate them with the development dataset, achieving our best result with BERT for subtask 1a and RNNs for subtasks 1b, 1c, and 2a. After performing these two models, we sent our results to the platform to evaluate them with the development dataset, achieving our best result with BERT for subtask 1a and RNNs for subtasks 1b, 1c, and 2a.

### 4 Experimental setup

Our experimental setup is depicted in Figure 1 and, in a nutshell, we can described as follows.

First, we perform a preprocessing stage that consist of:

1. Removing social media language, such as hyperlinks or mentions.

<sup>1</sup><https://huggingface.co/> (v3.4.0)

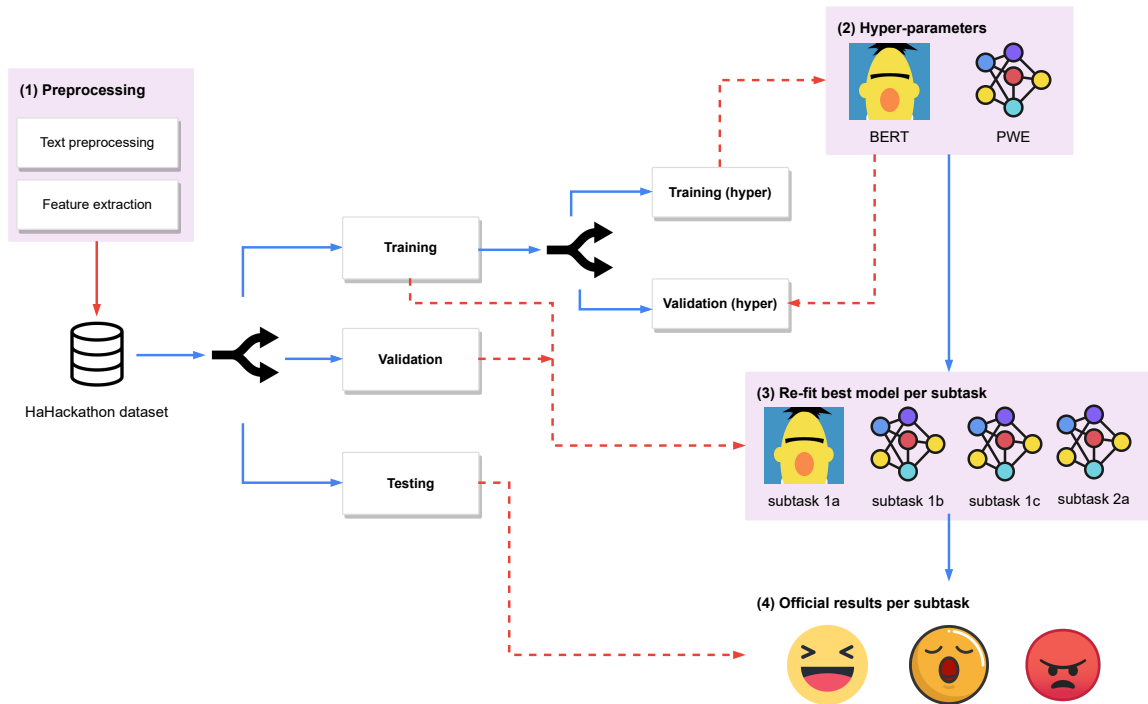

Figure 1: Pipeline of the participation of UMUTeam at HaHackathon'2021.

2. Removing digits.
3. Removing word elongations.
4. Transforming the tweets into their lowercase form.
5. Removing punctuation symbols.

Second, as the organizers of the shared task released the labels of the development dataset in the last stage of the competition, we begun the competition by dividing the 8K tweets of the training data into two folds in a ratio of 80-20. Third, two main approaches were evaluated. On the one hand, we use Talos<sup>2</sup> to evaluate different pretrained word embeddings models (FastText, GloVe, and word2vec) and several neural networks architectures (MLP, CNN, LSTM, BiLSTM, GRU, and BiGRU). On the other, we evaluate contextual word embeddings from BERT. These two processes are described in detail in the next paragraph. Finally, the classification subtasks (1a and 1c), the results are evaluated with the Accuracy and the F1-measure whereas the regression subtasks (1b and 2a) are evaluated with the Root Mean Squared Error (RMSE).

In case of BERT, we proceed as follows: we fine tune BERT with the training split of the Ha-

<sup>2</sup><https://github.com/autonomio/talos> (v0.6.6)

hackathon 2021 dataset for 2 epochs and a batch size of 64. Then, we freeze the resulting model and concatenate it to the LF in a new model composed of two hidden layers of 32 and 16 neurons respectively and trained for 10 epochs. In case of PWE, we evaluate word embeddings from fastText and GloVe but also we evaluate that the weights of the embeddings were learned from scratch in the embedding layer. Next, the LF and the word embeddings are concatenated, and used as input to a MLP, in which we evaluated (1) the number of hidden layers (between 1 and 8), (2) the number of neurons (8, 16, 48, 64, 128, 256), and (3) the shape of the network (*funnel*, *rhombus*, *long\_funnel*, *brick*, *diamond*, and *triangle*). We also evaluate the dropout rate to avoid overfitting (0, 0.2, 0.5, and 0.8), the activation function of the hidden layers (*relu*, *sigmoid*, *tanh*, *selu*, and *elu*), the learning rate, and the batch size (16, 32, and 64). Each combination of parameters was evaluated during 1000 epochs with an early stopping mechanism. Due to time constraints, we evaluated only 1000 combinations of these hyperparameters randomly selected.

## 5 Results

First, the best hyper-parameter combinations (validation set) are shown in Table 1.

Subtask 1a							
ACC	architecture	features	shape	# layers	1st neuron	dropout	PWE
83.926	MLP	lf+we	triangle	7	48	-	none

Subtask 2a							
RMSE	architecture	features	shape	# layers	1st neuron	dropout	PWE
0.68037	CNN	we	triangle	4	128	0.5	fastText
0.68085	BIGRU	we	triangle	7	48	-	fastText
0.68399	LSTM	we	triangle	4	128	0.5	fastText
0.70100	CNN	lf+we	diamond	8	48	-	gloVe
0.70353	CNN	lf+we	funnel	2	256	-	gloVe

Table 1: Results of the best five hyperparameter combination for each subtask trained and evaluated with the training dataset with a ratio of 80-20.

We can observe that MLP and CNN perform better for subtask 1a, whereas recurrent neural networks achieve better results in subtasks 1b, 1c, and 2a. Regarding the feature sets, we observe that for subtasks 1a, 1b, and 1c, the combination of LF and WE achieved better results whereas only word embeddings achieved better results in subtask 2a. It draw our attention that the shape of the neural network (*shape*, *# layers*, and *1st neuron*) and the dropout rate vary according to the subtask. For example, in subtask 1a, four of the fifth best results were achieved without dropout, whereas for subtask 1b and 2a, a high dropout (0.5) resulted in better results.

Next, we compare our results with the rest of the participants and the baselines (see Table 2) with the test dataset. The organizers of the task provided two baselines based on a Naive Bayes for the classification subtasks (1a, 1c) and a Support Vector Regression for the regression subtasks (1b, 2a); both trained with a bag of words. In subtask 1a we achieve an F1-score of 91.6% and an accuracy of 93.25% reaching position 45. The best result is for *PALI* with an F1-score of 98.54% and an accuracy of 98.2%. In subtask 1b, we achieve an RMSE of 0.8847, reaching position 47 and falling below the baseline. The best result is for *abcbpc*, with an RMSE of 0.4959. For subtask 1c, we achieve an F1-score of 57.22% and an accuracy of 46.5%, reaching position 14. The best result is for *PALI*, with an F1-Score of 63.02% and an accuracy of 49.43%. In subtask 2a we achieved an RMSE of 0.8740, reaching position 46 and falling below the baseline. The best result was for *DeepBlueAI* with an RMSE of 0.412.

During the hyper parameter tuning stage, we evaluated the reliability of the PWE without the LF with our custom training and evaluating splits. The results in our development dataset were slightly better with the combination of both feature sets in three subtasks: 83.516% (LF+PWE) vs 83.379% (PWE) of accuracy in subtask 1a, 0.79820 vs 0.81958 of RMSE in subtask 1b, and 61.125% (LF+PWE) vs 60.688% (PWE) of accuracy in subtask 1c. However, in subtask 2a, PWE performed better without LF: 0.68037 (PWE) vs 0.70100 (LF+PWE).

## 6 Conclusions

Table 2: Comparison of our results with other participants and the baseline for each subtask

niques and to improve our methods, we consider our results to be far from competitive. It should be noted that, for reasons unrelated to this competition, we did not have time to do all the tests we wanted. On the one hand, the final labels of the development dataset were published before the final stage, but we did not fit the models with this new information. On the other hand, we only submit one run in the final stage. Compared with the rest of the participants, we observe they submitted an average of 7.5737 runs ( $\sigma$  of 8.1720). However, although we believe that our results could have been somewhat better, there is still a long way to go. First, it caught our attention that BERT does not outperform the results achieved with dense,

recurrent, and convolutional neural networks for subtasks 1b, 1c, and 2a. At this respect, we will review our pipeline to detect weakness. It also draw our attention that our results did not beat the baselines in the regression tasks which indicates some kind of implementation or conceptualization error. Second, we only evaluated a subset of the LF that we had for Spanish. Accordingly, we will adapt UMUTextStats to English and compare their reliability with de-facto tools like LIWC. Third, we will focus on the interpretability of the models, as we believe that LF result in more interpretable models. Finally, we will evaluate machine learning ensembles as a mean of combining the LF.

## Abstract

This research presents the work of the team's ES-JUST at semEval-2021 task 7 for detecting and rating humor and offensive text using deep learning. The team evaluates several approaches (*i.e.* BERT (Devlin et al., 2018), Roberta (Liu et al., 2019), XLM-Roberta (Conneau et al., 2019), and BERT embedding + Bi-LSTM) that employ in four sub-tasks. The first sub-task deal with whether the text is humorous or not. The second sub-task is the degree of humor in the text if the first sub-task is humorous. The third sub-task represents the text is controversial or not if it is humorous. While in the last task is the degree of an offensive in the text. However, Roberta pre-trained model outperforms other approaches and score the highest in all sub-tasks. We rank on the leader board at the evaluation phase are 26, 26, 25, and 9 through 0.9564 F-score, 0.5709 RMSE, 0.4888 F-score, and 0.4467 RMSE results, respectively, for each of the first, second, third, and fourth sub-task, respectively.

## 1 Introduction

Dealing with natural languages has long been a challenge and an interesting topic for researchers (Chowdhury, 2003). Understanding and generating languages is part of natural language processing (NLP) (Nadkarni et al., 2011). Recently, the language model is able to deal with sequence-to-sequence problems such as question and answer, translation, multiple choice. In addition, it is able to capture complex relationships, semantic meaning, word meaning disambiguation, and word aspect-based (Deng and Liu, 2018). Humorous text is one of the important things we watched every day. It is commonly used to express an opinion on issues (societal, political, sports, and economic), whether in posts on social media platforms, or as advertising for a specific product (Kramer, 2011). In addition, the humor in the text makes the text complex in

terms of interpretation and understanding of the text. Because of the manipulation of the meaning of words and the way the text is written to express the sense of humor in the words. On the other hand, understanding the humorous in the text varies according to the age or gender of the person, or even according to the culture, social status and mentality of the person (Goel and Dolan, 2007). In this task, a dataset was collected in the English language that represents humor and joke in the text and words. We participated in this task to build an approach capable of distinguishing a text that is humorous or not. Here we have explicitly used pre-trained models that deal with the concept of contextual text such as Bert (Devlin et al., 2018), Roberta (Liu et al., 2019), and XLM-Roberta (Conneau et al., 2019). In addition, as a baseline we worked on training the dataset by the Bert embedding layer and extracting weights to feed it into the Bi-LSTM and Dense layers.

In all sub-tasks we used as a baseline BiLSTM (Graves and Schmidhuber, 2005) layer with a BERT embedding layer, as well as, pre-trained models such as Bert (Devlin et al., 2018), Roberta (Liu et al., 2019), and XLM-Roberta (Conneau et al., 2019).

In all sub-tasks, Roberta model showed superiority compared to other approaches. We ordered according to the official results among 36 participating teams. In the first sub-task, we achieved 26th rank with an 0.9564 F-score result. On the second sub-task, ranked 26th with a score of 0.5709 RMSE. A third sub-task placed 25th with 0.4888 F-score (Sokolova et al., 2006). The last sub-mission we took the 9th rank with a score of 0.4467 RMSR (Chai and Draxler, 2014). The remainder of this paper is organized as follows: Background in Section 2. The properties of the dataset and the system in section 3. Section 4 explains the experiment and analyzing results. The last section 5 shows

conclusions and future work.

## 2 Background

In (Hossain et al., 2019) developed a new humor corpus, which consist of 15,095 news headlines in English. They substituted the headlines with few words to be funny. Also, (Li et al., 2020) used attention-based with bi-directional long short-term memory (AttBiLSTM) to classify slang language into negative humor or positive humor. In (Anamoradnejad, 2020) utilized a BERT embedding layer with several parallel hidden layer to categorize 200K humorous sentences whether (positive or negative). While (Fan et al., 2020) used two kinds of attention mechanisms (internal and external) to capture sense of humor in words. Most of the previous works came to predict the humor polarity (positive, negative) or the humor rating (range values) in the text. However, this research addressing the humor and offensive score detection.

## 3 Methodology

### 3.1 Task Description

We worked with four sub-tasks provided by SemEval-2021 <sup>1</sup>, in task-1 divided into (a, b and c sub-tasks). Each sub-task related to the other. Moreover in task-2 has one sub-task (a). In general, Sub-task-1a will predict whether the text expresses a humorous or not (binary classification problem 1, 0). Sub-task-1b if the text is considered a humorous, will predict how humorous it is from 0 to 5 values (regression problem). Sub-task-1c If the text is a humorous, we would predict if it is controversial or not (binary classification problem 1, 0). Sub-task-2a will predict the offense.

### 3.2 Data-set

A dataset consists of a set of texts and each text has four categories (is-humor, humor-rating, humor-controversy, offense-rating) in English language (Meaney et al., 2021). Each text asked by 20 annotators to label each category of the text. As well as, the annotators come from different gender and age groups. For is-humor and humor-controversy categories were taken the majority of the classes by 20 annotators as label for each text. Whereas, humor-rating and offense-rating categories take the average of rating classes between range 1 and 5 over 20 annotators as a label for each text. Table 2

<sup>1</sup>[https://competitions.codalab.org/competitions/27446#learn\\_the\\_details](https://competitions.codalab.org/competitions/27446#learn_the_details)

shows examples of the training dataset per text with the four classifications for each category. Moreover, in humor-rating and humor-controversy, we noted the categories have many NaN values, because if is-humor the majority of the classes were not classified as humor which means 0 label, so the remaining categories of humor are NaN values. Therefore, we need to remove the NaN values from each category as pre-processing the dataset before training the models. Table 1 shows the total number in the training, development and testing dataset for each category.

Dataset	Is-H	H-R	H-C	O-R
Training	8000	4932	4932	8000
Development	1000	632	632	1000
Testing	1000	615	615	1000

Table 1: The total number for each category (is-humor, humor-rating, humor-controversy, offense-rating) after removing NaN values.

### 3.3 System overview

The proposed system focused on pre-trained transformer models, we Moreover applied some techniques that represent embedding words and feeding them into long short-term memory (LSTM) layers to train the data-set. Through all of the sub-tasks, the highest score was via the Roberta model. It is one of the powerful models pre-trained on a huge data-set and complex architecture. As well, it was released by Facebook and designed base on the BERT model that was released by Google. All pre-trained models are capable of handling long text dependencies and capturing features and relationships. Furthermore, the structure of pre-trained models that involve encoder-decoder (Cho et al., 2014) is enabled to deal with sequence-to-sequence (Sutskever et al., 2014) tasks. In addition, BERT-Large (Devlin et al., 2018) and Roberta-Large (Liu et al., 2019) models consisted of 24 layers, 1024 hidden units of output word embedding, and 16 head attention layers, where both models have the same layered structure but differ in the method of approach to training and the volume of data used to train each model.

There are two approaches used to train a BERT model 1- Masked Language Model (MLM) is masking some tokens of the training dataset with a [mask] symbol and try to predict the token. 2 - Next Sentence Prediction (NSP) is training the dataset by assigning 1's for neighboring sentences

Text	Is-H	H-R	H-C	O-R
TENNESSEE: We're the best state. Nobody even comes close.	1	2.42	1	0.2
*Elevennessee walks into the room* TENNESSEE: Oh shit				
I got REALLY angry today and it wasn't about nothing, but you're going to have to take my word for that.	0	Nan	Nan	0.15
Told my mom I hit 1200 Twitter followers. She pointed out how my brother owns a house and I'm wanted by several collection agencies. Oh ma!	1	2.11	1	0

Table 2: An example illustrating the features of a training dataset whether a humor or offense. If Is-humor class is 0 then the Humor-rating and Humor-controversy classes are Nan values.

and 0's for randomly chosen sentences. In contrast, Roberta used the MLM model approach for the training phase, as well as trained on a huge dataset compared to the BERT model.

Moreover, we tried the XLM-Roberta-Large pre-trained model (Conneau et al., 2019), which has 550M parameters with 24-layers of architecture. In addition, it consists of 1024 of the output hidden-state embedding, 4096 of feed-forward hidden-state, and 16 of head attentions. The model has Trained on 2.5 TB of newly created clean CommonCrawl data that supports 100 languages.

On the other hand, this research exploits BERT embedding to represent text. Where the weights were extracted by training the dataset on the BERT embedding layer and then feeding them into a BiLSTM layer of 128 units (Graves and Schmidhuber, 2005). Moreover, We used the dropout layer with 0.3 ratios, the max-pool layer, then passing the information into a dense layer with 64 units. In the last layer for classification tasks, the final dense layer is 2 hidden output units with a sigmoid activation function, and for regression, one unit output in the final dense layer. The Figure 1 shows the model architecture used for prediction label on classification and regression tasks.

## 4 Experimental and Results

In the experimental phase, the dataset was divided into three parts (training, development, and testing). We used the training dataset to train the model, and the development dataset to fine-tune the model to capture the best hyper-parameters without occurring over-fitting or under-fitting the model. Moreover, we used the test data set to check the performance of the model with an unseen dataset and to ensure the generalizability of the model. However, to perform the experiments we used collaborative google Colab as a platform, which provides a num-

Figure 1: An illustration of the proposed model architecture.

ber of GPUs available for use with modest memory size<sup>2</sup>. In addition, in our experiments with pre-trained models, we used the transformers library that is based on the PyTorch language and allows you to fine-tune the models and train them on your own dataset<sup>3</sup>. In training the model, we did not use any pre-processing technique in the entered dataset. Although, there are some symbols, upper and lower case letters, misspellings, and some abbreviations in the dataset. However, We did not treat these issues in dataset, where the dataset is trained as it is. In order, for the model to be more realistic and robust in dealing with the real dataset. As well as, the model might deal with those cases as features for each case in the dataset for the model learning phase. Just in pre-processing phase, we needed to remove NaN values in both sub-task (1B and 1C). In order to test the performance of the approaches used in this task, where each sub-task has a metric that meets the type of output of each sub-task such as regression metric or classification metric. Accuracy and F-score metrics were a measure of the

<sup>2</sup><https://colab.research.google.com>

<sup>3</sup><https://huggingface.co/transformers/>

performance in sub-task-1a and sub-task-1c. Likewise, the RMSE metric was a measure of outcome performance in both sub-task-1b and sub-task-2c. In the process of model tuning, we tried several hyper-parameters, where the batch size was fixed 8, and the Adam optimizer function was used on all experiments. Furthermore, we applied several learning-rates in the range 1e-5, 4e-5, 1e-6, 3e-6 and a different number of epoch 2, 4, 8, 12 epochs. The table 3 shows the main experiments among many models with different LRs and Epochs for each sub-task.

Sub-task	Model	Epoch	LR
1-A	Roberta-Large	4	1e-6

Table 3: The models applied and hyper-parameters used. (ES denotes to early-stopping technique)

## 4.1 Result

Roberta achieved high-performance results compared to other approaches, that exhibit his ability to capture traits and distinguish between labels. The table 4 presents the best results for both development and evaluation level results, as well as the best hyper-parameters selected based on the experimental phase for each sub-task. In sub-task-1A Roberta-

Large achieved high scores in a binary classification problem compared to the other models, where we scored 26 at F-score metrics in the evaluation phase for our ranking on the leader-board. While in the sub-task-2B also Roberta achieved acceptable results in the regression problem and outperformed the other models, as we ranked on the Leader Board 26 at RMSR metric. For the rest of the other sub-tasks, sub-task -3C is treated as a binary classification, which we achieved 25 rank in evaluation phase by F-score. In the last sub-task, our rank was 9 for an RMSR metric at the evaluation phase on the leader board.

### 4.1.1 Error Analysis

This section presents some analyzes to clarify the outcomes and limitations model of each sub-task. Figure 2 represents the confusion matrix for each label is given in sub-task-1A which is a classification problem. The figure shows the number of cases which the actual label matches the predicted label ( $y = \hat{y}$ ) which is 946 in total. While the number of labels that differ ( $y \neq \hat{y}$ ) that the model could not predict the label, it is 54. In the square that represents 31 false positives, we can see that it is a little more than the square that represents 23 false positives. This is because the training dataset is slightly biased towards label 1, which is 4,932 out of 8,000, while label 0 makes up 3,068 of the training data set.

Figure 2: An illustration of the confusion matrix for sub-task-1A.

Moreover, the sub-task-1B represented in figure 3. We applied the round function to obtain integer numbers and categories of labels to display, which shows four values existing in this task as continuous labels in range 0 - 4. In the figure, the label shows a label 2 obtained the highest match in the model between the actual labels and the predicted

Sub-task	Model	Epoch	LR	Development result	Evaluation result
1-A	Roberta-L	8	1e-6	0.9426-F1 & 0.9270-Acc.	0.9564-F1 & 0.9460-Acc.
1-B	Roberta-L	2	3e-5	0.518-RMSE	0.5709-RMSE
1-C	Roberta-L	8	8e-5	0.5493-F1 & 0.5585-Acc.	0.4888-F1 & 0.5545-Acc.
2-A	Roberta-L	12	1e-5	0.5209-RMSE	0.4467-RMSE

Table 4: The best results gained for both development and evaluation level with hyper-parameters chosen.

labels, while the labels 0, 1, 4, the model could not recognize them in the prediction phase. This is due to the size of the training dataset is a little for each label compared to 2, 3 labels. The size of the dataset in 0, 1, and 4 labels in the training dataset are 16, 410, and 47 respectively. On the other hand, label 2 is repeated 2835 times and 3 is repeated 1624 times in the training dataset.

Figure 3: An illustration of the discretization confusion matrix for sub-task-1B.

A third sub-task, which is a binary classification problem. The figure 4 shows the model is able to recognize label 0 a little more than label 1, but in general, the model is not learned well (high biased). The number of cases for both (0 and 1) labels in the training dataset were 2467 and 2465 almost equal, respectively.

Finally, in the last sub-task-2C, we needed to use a round function to approximate continuous values to discrete values. However, the diameter of the figure 5 clearly shows the highest label to the lowest label distinguished by the model. Where the values are logically acceptable compared to the number of cases for each label in the training dataset, which are 5737, 1043, 623, 364, 214, and 19 frequency for each of 0, 1, 2, 3, 4, 5 labels respectively.

## 5 Conclusion

In this paper, we presented several approaches that addressed four sub-tasks. We obtained high scores

Figure 4: An illustration of the confusion matrix for sub-task-1C.

Figure 5: An illustration of the discretization confusion matrix for sub-task-2A.

using a pre-trained Roberta model for each sub-task. In the first sub-task, predicting if the text is humorous or not, we gained a 0.9564 F-score. While in the second sub-task, finding a humorous text representation rate from 0 to 5, that was got a 0.5709 RMSE. A third sub-task, verification of the text is controversial or not, obtained a 0.4888 F-score. The last sub-task is to find the offensive rate in the text for the range of 0 to 5, which achieved 0.4467 RMSE. For future works, we are going to do more experiments and using ensemble technique to enhance the results. Moreover, adding more dataset with the original to treat the biased label.

## Abstract

This paper describes our contribution to SemEval-2021 Task 7: Detecting and Rating Humor and Offense. This task contains two sub-tasks, sub-task 1 and sub-task 2. Among them, sub-task 1 contains three sub-tasks, sub-task 1a, sub-task 1b and sub-task 1c. Sub-task 1a is to predict if the text would be considered humorous. Sub-task 1c is described as follows: if the text is classed as humorous, predict if the humor rating would be considered controversial, i.e. the variance of the rating between annotators is higher than the median. We combined three pre-trained models with CNN to complete these two classification sub-tasks. Sub-task 1b is to judge the degree of humor. Sub-task 2 aims to predict how offensive a text would be with values between 0 and 5. We use the idea of regression to deal with these two sub-tasks. We analyze the performance of our method and demonstrate the contribution of each component of our architecture. We have achieved good results under the combination of multiple pre-training models and optimization methods.

## 1 Introduction

Humor is an intellectual activity that can cause certain emotions in human thinking. Humor is not only very important but also very common in daily life. People's research on humor has involved many fields such as psychology, sociology, linguistics and so on. Of course, it also has special value for the research of computing languages. Because of its complexity and inherent subjectivity, the development of automatic humor recognition and assessment poses a great challenge in Computational Linguistics, and therefore is a popular subject in various shared task competitions. (Dick et al., 2020) However, we must also recognize the difficulties of humor research. First of all, although humans can easily judge whether a sentence is humorous

in daily life, but due to humor is restricted by geography, environment, social background and other aspects, we usually not only pay attention to this sentence or whether the matter is humorous, We have to figure out how humorous or funny this context is? In other words, we pay more attention to its degree of humor which is not so easy for computers. And because humor is affected by the environment, different people have different understanding of humor. Just like sometimes your humor is based on the suffering of others. Things you find funny, but others don't necessarily find them funny. In other words, humor is controversial. So we have to determine the specific humor rate. This task is to take a median as the criterion for humor. It is also difficult to judge the humor of this dispute by computer language.

More recently, some humorous sentences can also have derogatory and offensive elements. Whether humor can cause offense is also one of the researches in this thesis. I believe that the study of humor not only helps to improve the computer's understanding of humor in certain aspects, but also purifies our network environment.

The four sub-tasks of SemEval-2021 task7 are designed to solve the above problems. For deep learning, the computer must not only judge whether a sentence is humorous. It is more important to understand this humorous sentence. In our paper, we designed two effective systems to solve the above four sub-tasks. For Sub-task 1a and Sub-task 1c, We take them as a binary classification task. We designed an efficient system using the idea of BERT-CNN. This is not a new idea because people have tried in the past. We also use the other popular pre-training models, including the derived ALBERT and RoBERTa. For sub-task 1a, we need to judge whether a sentence is humorous. We predict a Label L: where  $L \in \{is\_humor - 1, not\_is\_humor - 0\}$ . For sub-task 1c, we also need to judge whether a sentence is controversial and predict a Label L: where  $L \in \{humor\_controversy - 1, not\_humor\_controversy - 0\}$ . For sub-task 1b,

we combined regression ideas with the current popular pre-training model to complete these two sub-tasks. The two input sentences were split into two lists and fed into the Regression Model, which made a prediction about the funniness of each sentence. Then we compared the results of the prediction to determine the funnier of the two sentences. We compare the humor between each sentence and finally return a humor value. (Ammer and Grüner, 2020) Finally, the humor rate and the level of controversy are mapped to the range from 0 to 5. We use mean square error to measure these two tasks.

## 2 Background

The judgment of humor is the same as other text classification problems in natural language processing. The most important thing is to find suitable features to represent sentences. The task is to assign predefined categories to a given text sequence. Many works have shown that pre-trained models on large corpora are beneficial for text classification and other NLP tasks, which can avoid training new models from scratch. Since 2013, people have proposed some word embedding approaches such as word2vec (Mikolov et al., 2013) and glove (Pennington et al., 2014). However, because their word embeddings are all in the same space, they cannot express the role of polysemy. In other words, they are non-contextual embeddings, they cannot capture the high-level concepts of sentences, such as semantics and context (Sun et al., 2020). Later, someone proposed the ELMo model to solve this problem. Compared with word2vec and glove, ELMo captures contextual information and not just individual information of words. In word2vec, the vector representations of words are completely consistent in different contexts, and ELMo is optimized for this (Zhang et al., 2017). More recently, pre-trained language models have shown to be useful in learning common language representations by utilizing a large amount of unlabeled data: such as OpenAI GPT (Brown et al., 2020) and BERT (Devlin et al., 2018). BERT is based on a multi-layer bidirectional Transformer (Vaswani et al., 2017) and is trained on plain text for masked word prediction and next sentence prediction tasks. This paper tried other two new pre-training models of ALBERT (Lan et al., 2019) and RoBERTa (Liu et al., 2019) based on BERT. And we fine-tuned down-

stream tasks for a variety of pre-trained models. Finally, we completed these four sub-tasks effectively.

## 3 System overview

### 3.1 Data

The data of the four sub-tasks are all provided by SemEval (Meaney et al., 2021). The official organizer provides the same training set and test set for all sub-tasks. We split the training set into a new training set and a test set by using the stratified 5-fold cross-validation. BERT uses the wordpiece tool for word segmentation and inserts special separators (`[CLS]` which are used to separate each sample) and separator (`[SEP]` which are used to separate different sentences in the sample). For each fold of the data set, the input data format is as follows: `[CLS]+[sentence]+[SEP]` (Bai and Zhou, 2020). There are a total of 8000 data in the training set and 1000 data in the test set. In addition, the training set was split into 85% and 15% for training and development set respectively (Note: We did not include the use of the development dataset which was given by the task organizers). They are all English sentences. Each sentence of the data in the training set can be regarded as a combination of `{id,text}` and one of `{is_humor,humor_rating,humor_controversy,offense_rating}`. For the data we did a simple pre-processing. We first remove the characters specified at the beginning and end of the string. (the default is a space or a newline.)

### 3.2 Methodology

Text classification technology is an efficient information retrieval and data mining information technology. The classification method based on machine learning trains a classification model by learning a given training set, and then uses the training model to classify text. Traditional machine learning classification methods include: random forest (RF), naive Bayes (NB), logic Regression (LR) and Support Vector Machine (SVM), etc. However, with the development of deep learning, many NLP tasks can adopt a pre-training + fine-tuning structure. The most typical is the BERT pre-training model. We propose two architectures to solve four sub-tasks.

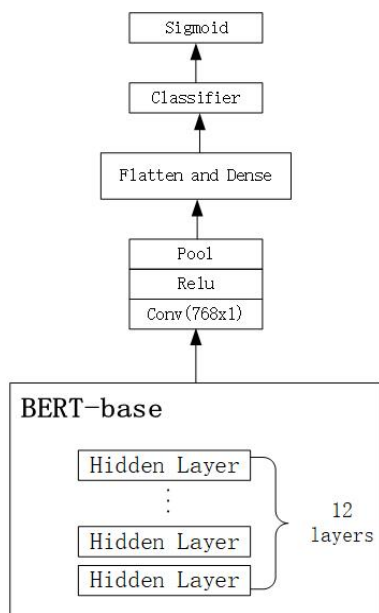

Figure 1: Model for Sub-task 1a and Sub-task 1c

### 3.2.1 Method A

Method A is designed to solve sub-task 1a and sub-task 1c. CNN for textual tasks by Kim (Kim, 2014) showed superiority in text classification tasks. CNN can be used with learned vector representations of the text (embeddings). These embeddings may either be initialized randomly and trained along with the model, or can be pre-trained vectors.

The proposed model maximizes the utilization of knowledge embedded in pre-trained BERT language models by feeding the outputted contextualized embeddings of its last four hidden layers into a several filters and convolution layers of the CNN. Finally, the output of the CNN was passed to a dense layer and the predictions were obtained (Safaya et al., 2020).

As shown in Figure 1, we use BERT-base as a pre-training model to build the model and other pre-training models are similar. BERT is a model built based on Transformer Encoder. Its entire architecture is actually based on DAE (Denoising Autoencoder). This part is called Masked Language Model (MLM) in the BERT (Devlin et al., 2018) article. MLM is not strictly a language model, because the entire training process is not trained using a language model. BERT randomly replaces some words with the MASK tag, and then predicts the word masked. The process is actually the process of DAE. BERT has two main trained models, namely BERT-Small and BERT-large. BERT-large uses a 12-layer encoder structure, that is, twelve

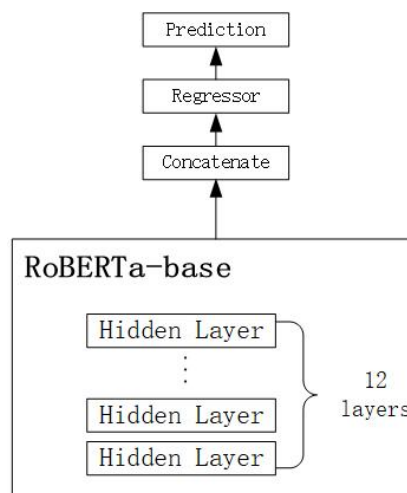

Figure 2: Model for Sub-task 1b and Sub-task 2

hidden layers. The whole model has a lot of parameters. For sub-task 1a and sub-task 1c, we tried a variety of methods based on BERT-base, including BERT+LSTM and other pre-trained models ALBERT and RoBERTa (add a linear layer). The last method to try is after BERT pre-training model, we use one or two layers of CNN to perform feature extraction. Finally, we input into a linear classifier to classify English sentences (humorous or controversial).

### 3.2.2 Method B

Method B is used to solve sub-task 1b and sub-task 2 (Regression tasks). Since the values we want to output (values between 0 and 5) are continuous. We pre-trained through the input of two English sentences and then made a humorous (controversial) comparison. Since the effect of CNN on the regression task is not very useful, we mainly tried and improved on the pre-training model. We mainly use BERT, ALBERT and RoBERTa for word embedding. As shown in Figure 2, RoBERTa works best. BERT has the worst effect. Because RoBERTa is trained with dynamic masking, FULL SENTENCES without NSP loss, large mini-batches and a larger byte-level BPE (Liu et al., 2019). In addition, it adjusted the parameters of the Adam algorithm. From 16G data to 160G. RoBERTa uses a larger batch size, and the number of training is more. The network structure is complex, so the fitting effect is better. Finally, we throw the trained model into a regression model to calculate the humor rate and controversial rate.

## 4 Experimental setup

The code this time is mainly based on [Transformers](#) under Hugging Face. The neural network tool we use is PyTorch. For sub-task 1a and sub-task 1c, we use the same method A (the same structure). We just read different id of training set. Sub-task 1b and sub-task 2 used the other method B.

### 4.1 Hyper-parameters

In this work, because our models are implemented based on PyTorch. We use the BERT-base+CNN as our sub-task 1a and sub-task 1c’s pre-trained model. For all models, in order to save GPU memory, the batch size parameter of GPU in fine-tuning is set to 8 and the gradient accumulation steps (gas) is set to 1, so that each time a sample is an input, the gradient is accumulated 1 times, and then the back-propagation update parameters are performed. The memory is saved by sacrificing a certain training speed; learning rate is  $5e-5$ . we use the triangular learning rate. First, the learning rate is gradually increased through warm up, and then the linear learning rate is gradually reduced through linear learn rete decay, which effectively improves the training effect. (Bai and Zhou, 2020) The hyper-parameters of each model and the results on the test set are shown in Table 1.

Tasks	Hyperparameters
Sub-task 1a and sub-task 1c	lr= $5e-5$ output hidden states=True epoches=5 per gpu train batch size=8 gas=1 filt size=(3,4,5) num filter=(3,4,5) hidden size=68 dropout=0.2
Sub-task 1b and sub-task 2	output hidden states =True dropout=0.1 lr= $5e-5$ epoches=10 per gpu train batch size=8 gas=1

Table 1: Hyperparameters of the used model

### 4.2 Prediction module

For sub-task 1a and sub-task 1c, we mainly use Precision and F1-score to evaluate our model A. The

criteria evaluation of F1-score is as follows:

$$Precision = \frac{TP}{TP + FP}$$

$$Recall = \frac{TP}{TP + FN}$$

$$F1 = \frac{Precision * Recall * 2}{Precision + Recall}$$

For task 1b and task 2, we use RMSE to evaluate our model. RMSE is as follows:

$$RMSE = \sqrt{\frac{\sum_{i=1}^N (y_i - \hat{y}_i)^2}{N}}$$

## 5 Results

For sub-task 1a and sub-task 1c, we first tried [BERT-base](#) as our word embedding model. On this basis, we added LSTM (Wang et al., 2018) to further extract the features of words. Long-term short-term memory (LSTM) network has the ability to maintain long-term memory. The ability of has proven to be particularly useful for learning sequences containing long-term patterns of unknown length. We also tried two other pre-training models (ALBERT and RoBERTa) as a comparative experiment. These two new language models have made some improvements on the basis of BERT, but they have different effects on different data sets. RoBERTa is suitable for complex neural network architecture, ALBERT architecture is relatively streamlined. From the data in Table 2, it can be seen that they are almost the same as BERT in extracting word features. Finally, we chose to add CNN on the basis of BERT to extract the features of words, and found that the effect is better than LSTM and other pre-training models.

Since CNN is not very effective in dealing with regression problems, we mainly use RoBERTa as our system architecture. From Table 3, we can find that compared to BERT, RoBERTa’s RMSE is far better than BERT-base under the same training epochs.

## 6 Conclusion

In this paper, we gave a description of the BERT+CNN architecture and the popular RoBERTa pre-training model architecture, and finally solved four sub-tasks. The best F1 for Sub-task 1a is 0.9206 and the best F1 for Sub-task

1c is 0.6744. The best root mean square errors of Sub-task 1b and Sub-task 2 are 0.6510 and 0.5588. Our four sub-tasks all appeared on the leaderboard (Note: The data from our computer is a little different from the official evaluation results. The results of the final four sub-tasks in the leadboard are shown in Table 4.). Experiments have shown that CNN has a certain effect on text classification, but this time only one layer of CNN was added to the Classifier. In addition, the experiment also shows that RoBERTa has a better effect than BERT in dealing with regression problems. In the future, we will try to integrate and distill the model and process the data. We consider to introduce external knowledge to model headlines and improve the humor recognition performance.

Method	Task 1a		Task 1c	
	F1	Acc	F1	Acc
BERT	0.9175	0.9310	0.6659	0.6835
ALBERT	0.9162	0.9210	0.6576	0.6911
RoBERTa	0.9176	0.9320	0.6488	0.7300
BERT+LSTM	0.9054	0.9120	0.6519	0.6806
BERT+CNN	<b>0.9206</b>	0.9250	<b>0.6744</b>	0.7025

Table 2: the Table for Sub-task 1a and Sub-task 1c

Method	Sub-task 1b	Sub-task 2
	RMSE	RMSE
BERT	1.7161	1.826
ALBERT	0.6700	0.6576
RoBERTa	<b>0.6510</b>	<b>0.5588</b>

Table 3: the Table for Sub-task 1b and Sub-task 2

Task	Best Result
sub-task 1a	0.9205(F1)
sub-task 1b	0.7010(RMSE)
sub-task 1c	0.4271(F1)
sub-task 2	0.5419(RMSE)

## Abstract

Humor detection and rating poses interesting linguistic challenges to NLP; it is highly subjective depending on the perceptions of a joke and the context in which it is used. This paper utilizes and compares transformers models; BERT base and Large, BERTweet, RoBERTa base and Large, and RoBERTa base irony, for detecting and rating humor and offense. The proposed models, where given a text in cased and uncased type obtained from SemEval-2021 Task7: HaHackathon: Linking Humor and Offense Across Different Age Groups. The highest scored model for the first subtask: Humor Detection, is BERTweet base cased model with 0.9540 F1-score, for the second subtask: Average Humor Rating Score, it is BERT Large cased with the minimum RMSE of 0.5555, for the fourth subtask: Average Offensiveness Rating Score, it is BERTweet base cased model with minimum RMSE of 0.4822.

## 1 Introduction

SemEval 2021 Task7 is constructed to detect and rate the humor and offense inside jokes in the English language (Meaney et al., 2021). Humor is an essential aspect of strengthening human communication and relations. However, the interpretation of humor differs based on the perceptions of a joke and the context in which it is used. In 2012, the Human Rights Commission found the most commonly reported form of harassment in Australia was sexist or offensive jokes (the, 2012), humor appreciation; is a highly subjective phenomenon as a sense of humor varies from person to person depending on factors such as age, gender, and socio-economic status. In this task, data labels and ratings were collected from a balanced set of age groups from 18-70. Moreover, annotators represent a variety of genders, political stances, and income levels. The automatic detection of linguistic elements

in natural language texts such as aggression, humor, irony, and sarcasm has drawn attention to research communities (Davidov et al., 2010). Several studies and experiments have been performed to develop and improve humor detection systems (Annamoradnejad, 2021) (Winters and Delobelle, 2020) (Sane et al., 2019) (Mao and Liu, 2019) (Chen and Soo, 2018). BERT language model (Annamoradnejad, 2021) (Devlin et al., 2019) showcase the highest results compared to all other works. This paper aims to utilize the Transformers models; BERT base and Large (Devlin et al., 2019), BERTweet (Nguyen et al., 2020), RoBERTa base and Large (Liu et al., 2019), and RoBERTa base irony (Barbieri et al., 2020) for humor detection, humor rating, and offense rating using the dataset obtained from SemEval-2021 Task7 that contains training, development, and test data. Our contributions are: Preprocessing text techniques for text tokenization, word segmentation, spell correction, removing the punctuation, encoding, and extracting embeddings. Furthermore, training six state-of-the-art Transformers Models and compare its results against the Base-line Model. We have achieved a 0.9540 F1-score for Subtask1-A Humor Detection using BERTweet cased model compared to the first place score, which is 0.9820 F1-score. For Subtask1-B Average Humor Score, our RMSE result is 0.5555 using BERT Large cased model, the first place RMSE is 0.4959. Finally, for Subtask2 Average Offensiveness Score, our RMSE results is 0.4822 using BERTweet cased model, while the first place RMSE is 0.4120.

This paper's structure is as follows: Section 2 reviews related works focused on Humor detection in SemEval-2020. Section 3 presents data exploration, preprocessing, training models, and evaluation metrics. Section 4 introduces the experiments and results. Section 5 remarks the conclusion and proposes future works.

## 2 Related Work

The previous Humor Detection task on SemEval2020 Task7 was focused on humor rating only without considering if it is offensive or not. However, in SemEval2021 Task7, the task requires detecting the hidden offense inside jokes. Rozen et al., 2020 (Rozen et al., 2020) presented a novel L2-Regularization approach with freezing the weights for the first epoch to train and fine-tune the word embedding model, ensemble different language models - BERT, XL-NET, and Roberta, and duplication from each language models, with a weighted average between them. Their approach ranked second place in SemEval-2020 Task 7: "Assessing Humor in Edited News Headlines", subtasks 1 and 2.

Shatnawi et al., 2020 (Shatnawi et al., 2020) also proposed the BERT-Flair-based Humor Detection Model (BFHumor) that combined the BERT regressor and Flair library to predict the funniest values of edited headlines for the same Task 7 of SemEval 2020; the mode ranked 4th in subtask1 and 12th in the subtask2. Meanwhile, Pramodith Ballapuram 2020 (Ballapuram, 2020) participated in the same task using a non-ensemble model; he proposed a Siamese Transformer based approach, coupled with an Attention mechanism to make use of contextual embeddings and focus words and their impact against other tokens on generating important features and rating the funniness of the edited headline, he scored fifth place in subtask1 and fourth place in subtask2.

## 3 Methodology

Our methodology of tackling the humor detection problem consists of four phases: Data exploration and Visualization, Data Pre-Processing, Learning Models, and Evaluation Criteria.

### 3.1 Data Exploration

The dataset from SemEval-2021 Task7: Ha-Hackathon: Detecting and Rating Humor and Offense, consists of five columns as table 1 shows; col-1 is the id of the text, col-2 "text" is the raw text for a joke to process, col-3 "is-humor" is a binary classification for the text, 1 means it is humor and 0 means it is not humor, col-4 "humor-rating" is a numerical representation for how much humorous is the text if it is labeled as humor from col-2, col-5 "humor-controversy" is binary classification to represent the subjectivity of humor appreciation

with a controversy score, 1 means the humor of the text is controversial and 0 is not, col-6 "offense-rating" is a numerical representation for how much offensive is the text. The competition consists of two subtasks: subtask1 is divided into three parts A,B and C and predicts is-humor, humor-rating, and humor-controversy respectively. Subtask2 is to predict the offense-rating.

Data sections are described separately, starting with subtask1-A; it is a binary classification problem to detect whether the text is humor or not. The distribution between its classes is balanced, so no need for data upsampling or downsampling. Subtask1-B is dependent on subtask1-A; if the text is labeled as humorous, a value will be provided to humor rating, and if it is not, the rating will be none. For this task, we dropped records that are labeled as not humorous. Humor rating is a regression problem since the rating is a continuous value between zero and five, the values are distributed normally which helps the model to generalize better. Subtask1-C also depends on subtask1-A; if the text is classified as humorous, then predict if the humor rating would be considered controversial. It is a binary classification task, and the distribution between its classes is balanced. Table 2 shows the number of instances per each class for both "is\_humor" and "humor\_controversy". Subtask2 is a regression problem to predict how offensive a text would be, the target value is between zero and five. After checking the target distribution, it is skewed to the left, which indicates the model will have difficulty in training, reducing the chances of predicting the values above 3.

We explored the number of the words distribution per instance and the number of unique words; where we do not count the same words. Both distributions were similar in density, that indicated most of the text content are unique and non-repetitive words. the maximum number of words within instances is 70 words for the whole data set and the average number of words is around 20 words. We choose to define the input sequence length equal to 128 as through tokenization, some words will be divided to multiple tokens. To check odd or very long words that need to be handled, we visualize the mean word length for each instance in the data set, and the word length is in the average mean. Finally, we checked the number of punctuations in the text since it affects the model as it affects the text in the encoding phase, especially when it is

attached with a word (e.g., animals do not encode the same as animal's). We handle the punctuation in the preprocessing part, which will be described in the next section.

### 3.2 Data Pre-Processing

In this phase, we apply enhancement techniques to the text. Removing duplicate sentences, repetitive characters, spilling mistakes, and stop words. Also, it includes encoding methodology to transform text from its original form to a vector that makes the computer understands it. We used Ekphrasis (Baziotis et al., 2017) for spell correction, remove contraction words, and annotate caps text as it is crucial to know the speaker's tone, capital letters indicate a level of aggression. We used GloVe (Pennington et al., 2014) vocabulary to find the out of vocabulary words that Ekphrasis did not fix, applied some spell correction manually, and removed the punctuation that has been attached to some words using regular expressions. We applied the tokenization technique. For GloVe embeddings, using Keras tokenization tool that splits the tokens based on the space. For example ["We went to Aqaba."] will be tokenized as the following: ['We', 'went', 'to', 'Aqaba.'], and each token gets encoded. On the other hand, the BERT model uses a WordPiece tokenizer that depends on its own vocabulary, and if it faces an out-of-vocabulary word, it will be split into sub tokens that starts with ##token. For example, ['tokenization'] become ['token', '##ization'], and for the RoBERTa model, it uses byte pair encoding (BPE) word pieces. RoBERTa handles the out-of-vocabulary words the same way as the BERT model but with some modification on the algorithm. For example: ['tokenization'] become ['token', ' ization']. We encoded the text using GloVe and transformers; Glove considers frequency when building

the embeddings, unlike word2vec.

### 3.3 Learning Models

This section will describe the models we have used; it will be divided into two sub-sections: Baseline Model, and Transformers Models.

#### 3.3.1 Base Line Model

The baseline model is BiLSTM model. It takes an encoded sentence with 100 token sequence size as input, each encoded using GloVe embeddings that have been fed into the embedding layer; which considered to be as a lookup table which consists of 300-dimensional pretrained GloVe embeddings, and each row in the table is considered a representation of the word. Next is two BiLSTM models that consist of 128 nodes, 0.2 dropouts to avoid overfitting, and He uniforms weight initializer (He et al., 2015). Output passes through a feed-forward network which consist of four hidden layers of 512, 256, 128 and 64 neurons respectively, for each layer we use ReLU activation function, 0.4 dropouts, and He uniforms weight initializer. Finally, the output layer consists of the Sigmoid activation function in binary classification and linear layer for the Regression task. We used Stochastic Gradient Descent (SGD) with a 0.01 learning rate, 0.99 momentum, and Nesterov implementation (Nesterov, 2003). It is worth mentioning that we used the early stopping technique to avoid overfitting with five patience.

#### 3.3.2 Transformers Models

We have applied different type of pretrained models using Simple Transformers library (Rajapakse) which is an API built above Hugging Face library (Wolf et al., 2019). In this section, we generally describe the models that we used. Bidirectional Encoder Representation from Transformers (BERT) is a pretrained model which uses attention models to learn the contextual relation between the words in the sentence, consisting of two main parts: an encoder and a decoder: an encoder that encodes the text, and a decoder for the output result based on the task. We used Bert cased and uncased models, which both have been trained on BookCoupus (Zhu et al., 2015) with 800 million words and En-

English Wikipedia with 2,500 million words. We trained the model using this hyperparameter: 128 sequence length, three epochs, 32 batch size, 4e-5 learning rate, and AdamW as an optimizer. Then we used the BERTweet model trained on BERT architecture using 850 million English tweets. We trained this model using almost the same hyperparameters, except that we used eight as batch size. We have used, too, Robustly Optimized BERT pre-trained approach (RoBERTa). It is a fine-tuned version of the BERT model with some changes on the data size and input representation. Training the model on larger data set significantly improves the model performance using BookCorpus, English Wikipedia, CC-news with 63 million English news articles, OpenWebText, and Stories; which is a subset of CommonCrawl data. Model developers use dynamic masking instead of static masking that has been used in the BERT model, this technique allows to improve the model performance. Furthermore, they have used the full sentence without using the next sentence prediction loss. We trained both RoBERTa base and large models using the following hyperparameters: for the base three 128 sequence length, three epochs, 32 batch size, 4e-5 learning rate, and AdamW optimizer, and the large model, we kept everything the same as the base model but change the batch size to 16. Moreover, we have used the RoBERTa irony model that has been fine-tuned using 58 million tweets for irony detection on TweetEval benchmark; also, we used everything as the base and large model. We have also used XLM-RoBERTa (Conneau et al., 2020), and XLNet (Yang et al., 2019) as a black box, we did not go into the model’s detail, but in general, it is an improved version model from BERT. We applied them using the following hyperparameters: 128 sequence length, three epochs, 16 batch size, 4e-5 learning rate, and AdamW optimizer.

### 3.4 Evaluation Criteria

F1 score criteria was used for the binary classification task and the second criteria is RMSE for the regression task. We used the 8-Fold Cross-validation method to determine the best model since we only have an 8k data instances for training. We trained our models using seven folds, kept the last fold unseen for validation in each iteration, and used every model from each iteration to predict the development and testing data and combine all the results to obtain the final result.

## 4 Experimentation and Results

### 4.0.1 Task 1-A Is-Humor:

We constructed a baseline model and fine-tuned it using different approaches and preprocessing techniques. We tested our model using four types of preprocessing techniques (None, Ekphrasis, Ekphrasis with removing stop words, and Ekphrasis with applying Custom Spell Correction). After that, we tested Adam and SGD as optimizers, SGD performs better on this model. After comparison, the best parameters for the models are described in the fifth row of table 3; we applied the early stopping technique to reduce the overfitting with 0.4 dropout. We test Transformers models, refer to the table 4. In general, we fine-tuned all the models in two ways, the Cased model, which means that the text is kept in its original form without lowering the characters’ case. Uncased means that lower-case all the characters in the text. By experiment, cased models performed better than uncased since it captures more aggressive behaviors from the writer. Moreover, BERTweet performs well using the Cased model on this task. Since the model has already been trained on Twitter data, it captures all the slang, acronyms, and abbreviations.

### 4.0.2 Task 1-B: Humor Rating

We used the experiments from the previous task since they are dependent if humor equals zero; we do not need to predict the humor rating. If it is one, we have to predict the humor rating value between zero and five. We first used the best model from the baseline by changing the last layer to a linear layer to predict continuous values since it is a regression task. Same hyperparameters from model 5 from table 3 we got 0.8651 RMSE, and we consider it as our baseline. After that, we tested the best transformer models from the previous task, refer to table 5. We found out that the best model is the BERT large case model, which seems unexpected since most of the other models perform almost the same, around 0.54.

### 4.0.3 Task 2 Offensiveness Score:

We have used the same methodology from the Subtask1-B; we first constructed a baseline for this task, which is the best model from the Subtask 1-A hyperparameters model 5 from table 3, and we got 0.86783 RMSE. After that, we tested the best models from the previous task’s transformers, refer to table 6. We found out that the best model is BERT

	Pre-Processing	learning rate	# epochs	dropout	batch size	optimizer	features	Accuracy	Precision	Recall	F1-score
1	None	0.0001	50	.4	128	Adam	GloVe	0.8594	0.8778	0.8968	0.8872

RoBERTa irony	Cased	3	16	0.54585

Table 5: Transformers models on humor rating

Large model and it performs well on regression tasks since it performs well on the two tasks related to regression. All the previous experiments applied the cross-validation method on the training data. Since we decided that we do not want to overfit the development and test dataset, we will use the best models that perform well on the cross-validation phase to predict the development and test dataset’s output. We changed the threshold point for the is-humor task; using the ROC curve, and the best split is 0.233357 since it improves the model by 0.04 percent on the development phase, so we apply it to the testing phase. The best model for the is humor task is BERTweet cased base model that scored a 0.9540 F1 score on the testing phase; for the humor rating task, we used BERT large cased model that scored 0.5555 RMSE on the testing phase, and for

the offensive score, we used BERTweet large cased model that scored 0.4822 RMSE on testing phase.

Model	Text Type	# epochs	batchsize	RMSE
BERTweet	Uncased	3	8	0.5304
RoBERTa base	Uncased	3	32	0.5734
RoBERTa Large	Uncased	3	32	0.5494

RoBERTa Large	Cased	3	32	0.7190
RoBERTa irony	Cased	3	16	0.8501

Table 6: Transformers models on offensiveness score

## 5 Conclusion and Future Work

In this paper, we experimented with a set of state-of-the-art Transformers and contextual models for detecting and rating humor and offense in text. Our experimental results show that the BERTweet Large model is the best model for humor binary classification task with a 0.9540 F1 score and offensive rating with 0.4822 RMSE, and BERT Large cased model is the best for humor rating task scored 0.5555 RMSE. We plan to enhance the top models using ensemble learning methodology and test out more novel methods.

# Gulu at SemEval-2021 Task 7: Detecting and Rating Humor and Offense

**Maoqin Yang**

School of Information, Yunnan University, Yunnan, P.R. China

maomaoq33@gmail.com

## Abstract

Humor recognition is a challenging task in natural language processing. This document presents my approaches to detect and rate humor and offense from the given English text. This task includes 2 tasks: task 1 which contains 3 subtasks (1a, 1b, and 1c), and task 2. Subtask 1a and 1c can be regarded as classification problems and take ALBERT as the basic model. Subtask 1b and 2 can be viewed as regression issues and take RoBERTa as the basic model. And finally, team-Gulu scores in subtask 1a with a weighted average F1 score of 0.9190, in subtask 1b with an RMSE score of 0.7405, in subtask 1c with a weighted average F1 score of 0.5561, and in subtask 2 with an RMSE score of 0.5807 on the private leader board.

## 1 Introduction

For social animals like humans, humor is an effective bonus. From the perspective of evolutionary psychology, “humorous” often means superior creativity, in other words, a smarter mind. Therefore, it is important to recognize whether a sentence is humorous and how humorous the sentence is. It is a bit impractical to recognize such a huge data set by humans, so it becomes necessary for us to develop a system to automatically detect humor. In this task, the organizer collects labels and ratings from a balanced age group of 18-70. Annotators also represent various genders, political positions, and income levels. Therefore, for some texts classified as humorous, we should once again prove whether they are controversial and predict the offensiveness of the text. For more specific content, please refer to the official website of the competition<sup>1</sup>.

<sup>1</sup><https://competitions.codalab.org/competitions/27446>

Because the pre-trained and deep learning models have shown excellent performance in many NLP problems such as classification and topic extraction(Zampieri et al., 2019), so I use deep learning methods to deal with those four tasks. According to the latest related research progress, the transformer-based language model has become my favorite model. In order to facilitate the understanding of the corresponding model of each subtask, I made it into a table shown as Table 1. I choose A Lite BERT (ALBERT)(Lan et al., 2019) as my basic model in subtask 1a. In subtask 1b and subtask 2, I choose Bidirectional Encoder Representations for Transformers (BERT)(Devlin et al., 2018) model as my basic model. In subtask 1c, A Robustly Optimized BERT (RoBERTa)(Liu et al., 2019) has been chosen. To get a more effective and higher accuracy model in subtask 1a, BiGRU combined with attention. To prove the effectiveness of this model, there are also comparative experiments with other neural networks for task 1c. To obtain as much effective information as possible from the limited data, the 5-fold cross-validation method has been used.

## 2 Related Work

Automatic humor recognition is a very challenging research topic in natural language processing. A person’s degree of humor is largely determined by his educational knowledge and common sense of life. In addition, many types of humor require a lot of external knowledge, such as irony, metaphor and satire.

Yang et al. (2015) first determined the semantic structure behind each structure of the humor and design feature set, and then used a calculation method to identify the humor and their humor recognizer was very effective in automatic distinction humorous and non-humorous text.

subtask	1a	1b	1c	2
category	classification	reg	classification	reg
model	ALBERT+BiGRU	BERT	RoBERTa+BiLSTM+BiGRU	BERT

Table 1: The category and model used for each subtask, where the *reg* stands for *regression*

Morales and Zhai (2017) proposed a generative language model based on the inconsistency theory to model humorous text, so that they can use background text sources such as Wikipedia item descriptions, and can build multiple functions for recognizing humorous comments. Using supervised learning to classify reviews into humorous reviews and non-humorous reviews, these functions showed that the features constructed based on the proposed generative model were more effective than the main features proposed in the existing literature.

Liu et al. (2018) found that certain grammatical structural features are consistently related to humor. Both experimental results and analysis showed that humor can be regarded as a style, and the content-independent syntactic structure can help identify humor and had good explanatory power. Therefore, they proposed to use syntactic structure features to enhance humor recognition ability. Compared with the baseline driven by humor theory, their method had achieved a significant improvement.

And subtask 1b and 2 are regression problems. We need to predict the humor of a sentence, and because the implicit meaning of the sentence may be offensive for someone, we also need to detect the degree of attack on each sentence. Traditionally, text regression is solved using linear models. Bitvai and Cohn (2013) proposed a method based on a deep convolutional neural network (CNN). Yang et al. (2015) recommended using copula: a powerful statistical framework. Their model clearly outperformed a strong linear and nonlinear discrimination baseline. Subramanian et al. (2018) used CNN regression with auxiliary ordinal regression objective to predict the popularity of petitions in their work. A regression task is actually a special form of the classification task. The final output is a value rather than the probability of a specific category. Therefore, the BERT model can achieve good results.

### 3 Materials and Methods

#### 3.1 Preprocessing

The given data (Meaney et al., 2021) contains the tasks required by each subtask, but some corresponding data are missing. For example, if a sentence is judged as not humorous in 1a, there will be no data in the column (the fourth and fifth column) corresponding to subtask 1b and 1c. To facilitate the experiment, I added 0 to all missing values.

#### 3.2 Data set

Given a sentence, for 1a, the system must assign the label to 1 if it is recognized as *is\_humor*, otherwise, assign it to 0. And if there is a *humor\_controversy* in 1c, the corresponding label is 1. For this task, the available sentences including 6948 training sentences, 1052 development sentences, and 1000 testing sentences. The label distribution in the training set is almost balanced for 1c, but for 1a, label 1 accounts for only 38.1% of the total after assigning all missing values to 0. The number of sentences for each label is listed in Table 2.

task	label 0	label 1
subtask 1a	2652	4296
subtask 1c	2149	2147

Table 2: The distribution of training set

I divide all the data of subtask 1b and 2 into 5 intervals (take 1 as the step size) and count the total of each interval. It can be seen from Figure 1 that most of the data of *humor\_rating* are between 1 and 2 (1361 sentences), and there is no data between 4 and 5. The label *offense\_rating* scores of 0 accounted for the majority (2913 data in total).

#### 3.3 Classification

Text classification is the most basic and very necessary task in natural language processing (NLP). Two of this task belongs to classification problems. In subtask 1a, I combine ALBERT with BiGRU-Attention. In subtask 1c, I combined RoBERTa with BiLSTM+BiGRU.

Figure 1: The data distribution of subtask 1b and 2

### 3.3.1 ALBERT + BiGRU-Attention

The ALBERT model is an improvement based on the BERT model. The ALBERT model<sup>2</sup> has designed parameter reduction by changing the result of the original embedding parameter  $P$  (the product of the vocabulary size  $V$  and the hidden layer size  $H$ ).

$$V * H = P \rightarrow V * E + E * H = P \quad (1)$$

Where  $E$  represents the size of the low-dimensional embedding space. In ALBERT,  $H \gg E$ . The self-supervised loss is used to focus on the internal coherence in the construction of sentences<sup>3</sup>.

The BiGRU-Attention model<sup>4</sup> is divided into three parts: text vector input layer, hidden layer, and output layer. Among them, the hidden layer consists of three layers: the BiGRU layer, the attention layer, and the Dense layer (fully connected layer). The output of the ALBERT model will be used as the input. After receiving the input, the BiGRU neural network layer will extract features of the deep-level information of the text firstly. Secondly, it uses the attention layer to assign corresponding weights to the deep-level information of the extracted text. Finally, the text feature information with different weights is put into the softmax function layer for classification.

In order to improve the classification ability of the model, I combined ALBERT and BiGRU-Attention. The model diagram is shown in Figure 2.

<sup>2</sup><https://huggingface.co/albert-base-v2>

<sup>3</sup><https://zhuanlan.zhihu.com/p/162275803>

<sup>4</sup>[https://blog.csdn.net/qq\\_40900196/article/details/88998290](https://blog.csdn.net/qq_40900196/article/details/88998290)

### 3.3.2 RoBERTa + BiLSTM + BiGRU

RoBERTa<sup>5</sup> mainly made several adjustments based on BERT: 1) Longer training time, larger batch size, more training data; 2) Removed next predict loss; 3) Longer training sequence; 4) Dynamic adjustment Masking mechanism.

Using the BiLSTM model can better capture the two-way semantic dependence. Because LSTM can learn what information to remember and what information to forget during the training process. BiGRU is a unidirectional, opposite direction, and outputs a neural network model composed of GRUs determined by the states of these two GRUs. At each moment, the input will provide two GRUs in opposite directions at the same time, and the output will be jointly determined by the two unidirectional GRUs.

In order to improve the ability of the model, I combined RoBERTa and BiLSTM+BiGRU. The model diagram is shown in Figure 3.

### 3.4 Regression

What regression predictive modeling needs to accomplish is to approximate a mapping function from an input variable to a continuous output variable. Both regression subtasks use the BERT model.

The BERT model implements three embedding layers: position embedding, word embedding, and segment embedding. BERT uses two training strategies: the masked language model and the next sentence prediction. The language model trained in this way usually has a deeper sense of language context and can be further applied to process various NLP tasks( classification et.), with an additional output layer(Fan et al., 2019).

### 3.5 Evaluation

The main metric for the classification tasks will be f1-measure(wei et al., 2020).

$$precision = \frac{true\ positive}{true\ positive + false\ positive} \quad (2)$$

$$recall = \frac{true\ positive}{true\ positive + false\ negative} \quad (3)$$

$$F1 = \frac{2 * precision * recall}{precision + recall} \quad (4)$$

<sup>5</sup><https://huggingface.co/roberta-base>

Figure 2: ALBERT+BiGRU-Attention for task 1a, where the  $E[CLS]$  and  $E[SEP]$  are added at the beginning and end of each instance respectively

Figure 3: The model for task 1c

Model	step	batch size	lr	epoch
BERT	500	32	2e-5	2
ALBERT	2500	32	2e-5	10
RoBERTa	5000	16	2e-5	10

Table 3: The parameters, where the  $lr$  stands for *learningrate*

The metric for the regression tasks will be the root mean squared error (RMSE). Below  $x$  and  $y$  are  $D$  dimensional vectors, and  $x_i$  represents the value of  $x$  in the  $i$ th dimension.

$$RMSE = \sqrt{\sum_{i=1}^D (x_i - y_i)^2} \quad (5)$$

## 4 Results

In this task, I used ALBERT, RoBERTa, and BERT models for the training task. For these models, the main hyperparameters I want to pay attention to are the training step size, batch size learning rate, and epoch. The parameters of my model are shown in Table 3.

### 4.1 Classification results

For task 1c, several sets of comparative experiments were carried out. The comparison results are listed in Table 4, and the cross-validation results are 0.92, 0.94, 0.94, 0.93, and 0.67 respectively.

All results are the results of the evaluation set. The output of the classification result is shown in Table 5. We can see that the number of label 1 is close to twice the number of label 0.

Task 1a scores 0.9190 but 1c scores 0.5561. From the distribution of their data, this may be because the data of task 1c is not balanced. Moreover, because task 1c has a dependency on task 1a, only filling in missing values with 0 may affect the judgment of the system.

Model	F1-Score
RoBERTa	0.80
RoBERTa+BiGRU	0.86
RoBERTa+BiGRU+BiLSTM	0.88

Table 4: The comparative results of task 1c, and the model is the *base* version.

task	label 0	label 1
subtask 1a	386	614
subtask 1c	331	669

Table 5: The result distribution of task 1b and 2

### 4.2 Regression results

The output of the regression result is shown in Figure 4. In subtask 1b, all predicted values are between 0 and 3. Most of the values are in the range

of 2 to 3 (412 sentences). In subtask 2, all predicted values are also between 0 and 3 (442 sentences score 0). Comparing with the data distribution in the training set, we find that the distribution of the predicted value is consistent with the distribution of the training data.

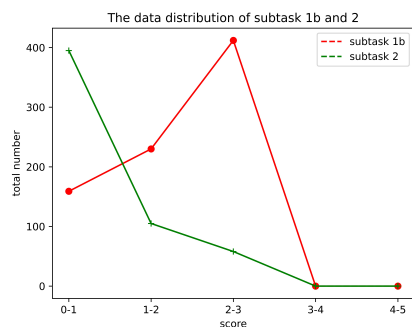

Figure 4: The predicting result of *humor\_rating*

## 5 Conclusion and Future Work

In this work, I present my result on HaHackathon: Detecting and Rating Humor and Offense which includes four subtasks. For tasks 1a and 1c, I use the BiGRU-Attention based on the ALBERT model to complete subtask 1a, and 1c is completed by RoBERTa combine with BiLSTM+BiGRU and this model works well. I also summarized the possible reasons for the low score in task 1c.

From a theoretical and computational point of view, it is difficult to establish a mechanism for computers to understand humor like humans. The reason is as follows. 1) The definition of humor is loose. It is almost impossible to identify humor by establishing rules. 2) Humor is related to context and background. Humor expects to break the common sense of readers in a specific situation. In the future, we should design features that are interpretable, calculable, and easy to implement that conform to humor theory.

## Abstract

This paper describes the approach that was developed for SemEval 2021 Task 7 Hackathon: Incorporating Demographic Factors into Shared Humor Tasks (Meaney et al., 2021) by the DUTH Team. We used and compared a variety of preprocessing techniques, vectorization methods, and numerous conventional machine learning algorithms, in order to construct classification and regression models for the given tasks. We used majority voting to combine the models' outputs with small Neural Networks (NN) for classification tasks and their mean for regression for improving our system's performance. While these methods proved weaker than modern, deep learning models, they are still relevant in research tasks because of their low requirements on computational power and faster training.

## 1 Introduction

The underpinnings of humor have proven far more vexing than those of other emotional experiences. It is a highly subjective topic that various scholars have attempted to construct theories for understanding its fundamental elements in the studies of philosophy, linguistics, psychology and sociology. Some theories, e.g. the *Benign Violation Theory* (Warren and McGraw, 2015), suggest that humor can be described as linguistic violations that still make grammatical sense. The aforementioned theory supports that for a joke to be classified as humorous, it needs to avoid being too harmless or too offensive.

There are numerous studies in humor sentiment analysis in the last decade. In microblogging, Reyes et al. (2012) considered extracting linguistic devices from tweets to be used as features for classifying these tweets as humorous or ironic, while Raz (2012) approached the classification of humorous tweets as a multi-class problem of 11 types of

humor, in his attempts to better attribute the real sentiment of a tweet. Recent attempts on humor detection on SemEval's 2020 Task 7 indicate that transformer models like BERT (Mahurkar and Patil, 2020) far outperform traditional machine learning algorithms (S et al., 2020).

This paper describes our submissions to SemEval 2021 task 7 and is structured as follows. Section 2 describes the tasks, training data, and evaluation measures. Section 3 describes key methods and algorithms used. Section 4 describes our proposed system while Section 5 analyzes our results. Finally, we draw our conclusions in Section 6, where we also propose directions for future work.

## 2 Background

In this section we describe each subtask's objective, the given data, and evaluation measures.

### 2.1 Subtasks

The main objectives of SemEval 2021 Task 7 were split into 4 subtasks. Subtask 1a required us to classify short texts as humorous or not, while Subtasks 1b and 1c required us to rate the text's humor and further classify it as controversial or not respectively. Finally, in Subtask 2, we had to rate how offensive each text was—humorous or not. All texts were in English.

### 2.2 Dataset

The organizers released the full training data in three parts: trial, development, and evaluation. Our final training dataset consisted of 9,000 different texts annotated with labels regarding each subtask in csv file format, while our test set consisted of 1,000 texts. Statistics for the training dataset are presented in Table 1 and Figure 1.

	Is humorous?	Is controversial?
Yes	5,564	2,773
No	3,436	2,791

Table 1: Humor and controversiality labels in the training set

### 2.3 Evaluation Measures

For the classification Subtasks 1a and 1c, we use the  $F_1$  measure. For the regression Subtasks 1b and 2, we use the root mean squared error (RMSE).

## 3 Experimental Setup

In this section we describe the preprocessing and vectorization methods as well as the machine learning algorithms used.

### 3.1 Preprocessing

Text preprocessing is the backbone of every text classification task. We applied the following techniques:

1. Tokenizing and Lowercasing words: We lower-cased the words in the texts and split them into tokens.
2. Stemming or Lemmatisation: Reducing noise from texts while (generally) improving system performance.
3. Removing Stopwords: Stopwords do not add much meaning to a sentence, so removing them helps in reducing the number of features and improving results.
4. Tagging words with capital letters: Tagging each word containing a capital letter that is not the first word in a sentence. Applied (when used) prior to word lowercasing.
5. Replacing Emojis: Very few emojis were found in texts, so we replaced them with their corresponding sentiment.
6. Replacing Contractions: We replace contractions into their full forms using a dictionary.
7. Removing integers: Numbers have no emotional value, so we remove them.
8. Part-of-Speech (POS) tagging: We used POS tagging of words for preprocessing the texts, following two different approaches.

Figure 1: Humor and Offense Rating density plot

- (a) Appending POS tags in words: Aims to incorporate part-of-speech information in our features.
- (b) Removing words based on their POS tag: Aims to remove words with low sentimental value from the data by targeting specific tags.

9. Numeric Feature Extraction: We extracted counts of characters, words, exclamation points, and numbers, as well as the numbers of declarative, interrogative, and imperative/exclamative sentences in a text. Finally, we extracted the counts of verbs, nouns, and adjectives, for each text.

The performance comparison of each preprocessing method is shown in Section 5. Stemming, lemmatisation, POS tagging, and most of numeric feature extractions were achieved by using tools from the well established NLTK (Elhadad, 2010), while we were guided by the survey of Ravi and Ravi (2015) of the most commonly used techniques in text preprocessing for sentiment analysis and by our previous works (Effrosynidis et al., 2017; Symeonidis et al., 2018) on this subject.

### 3.2 Machine Learning

The training of our classification and regression models aimed to improve the evaluation measure used for the corresponding task. Many probabilistic, linear and tree-based algorithms were used, as well as small neural network architectures.

The algorithms/Neural Networks (NN) that performed the best were used in our systems and are listed below:

- Linear Models: Linear SVM, Bayesian Ridge Regression and LASSO
- Non-Linear Models: Naive Bayes, Light GBM (Ke et al., 2017) and XGBoost (Chen and Guestrin, 2016)

- NN Models: Dense and Long Short-Term Memory Networks (using the Keras API<sup>1</sup>)

Linear SVM models were excluded from our final systems mainly due to our better tuning of the LGBM and XGB models during the last phase.

### 3.3 Vectorization and Embedding

We used the following scikit-learn toolkit’s vectorizers to extract features from the preprocessed data using word unigrams or bigrams:

- Tf-idf Vectorizer: translates the word counts matrix to a matrix of tf-idf features.
- Delta tf-idf Vectorizer: proposed by [Martineau and Finin \(2009\)](#), it creates tf-idf features similarly to tf-idf vectorizer but applies a weighting scheme reflecting the difference of tf-idf value of each word between the texts of two classes. We used the subtask’s 1a labels for weighting tf-idf values in every subtask.

In order to create features for the LSTM models, we translate the words of each text into word vectors. This translation is achieved through the use of a well-known, pre-trained model: GloVe ([Pennington et al., 2014](#)).

## 4 System Overview

In this section we describe the proposed system for each subtask.

### 4.1 Proposed System

We trained each model with all possible combinations of preprocessing and vectorization. During the development phase, we evaluated these models using 10-fold cross validation on the training data. These evaluations guided us through hyperparameter tuning and model selection.

During the evaluation phase, we combined the outputs of these models in order to produce our system’s predictions (Figure 2). The system’s performance was evaluated using the test data from the development phase. That data was also used as validation data for training and tuning the dense and LSTM networks.

Model selection for our final systems was a repetitive but simple process. We selected the best performing model per algorithm and vectorization method, some weaker models whose outputs had

<sup>1</sup><https://github.com/fchollet/keras>

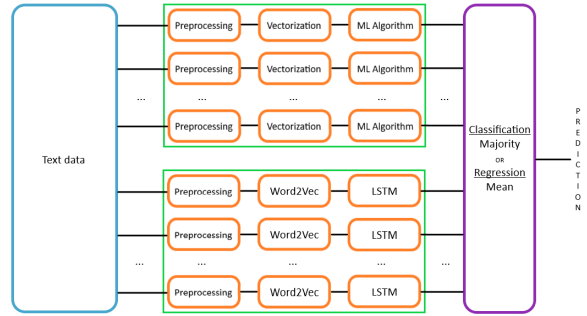

Figure 2: System Architecture

lower correlation than the outputs of the best performing models and all the NN models that we had trained. We then combined ([Symeonidis et al., 2017](#)) all selected model outputs in all possible combinations consisting of at least 3 models and picked the best performing one as our final system for task prediction.

This process was repeated for each subtask. After finding the combination that produced the best results for the development’s phase test data, we re-trained the system’s models by appending that test data on the training data.

#### 4.1.1 Subtask 1a: Humour Classification

In Subtask 1a, each text needs to be classified as humorous or not. Table 2 showcases the various preprocessing methods, vectorization tools and ML algorithms that comprised our final system. Since the number of models is even, majority voting favors the ‘non-humorous’ label in case of a tie, i.e. the less represented tag in the dataset.

Preprocessing	Vectorizer	ML
1,2,5,8a and 9	Delta tf-idf unigrams	Shallow NN
1,2 and 9	Tf-idf unigrams	LGBM
1,2,8a and 9	Delta tf-idf bigrams	Naive Bayes
1,2,6,7,8a and 9	Delta tf-idf bigrams	Naive Bayes
1,7 and 9	Tf-idf bigrams	XGB
1	Word2vec embeddings	LSTM

Table 2: Subtask 1a system composition

#### 4.1.2 Subtask 1b: Humor Rating

In Subtask 1b, each humorous text needs to be rated in a range of 0–5 on how much humorous it is. For this subtask, the best combination found amounted to 13 models. Thus, we will not include a table for this task. All proposed preprocessing techniques were used but 3 and 8b as well as every vectorizer. Interestingly, NN models were ruled out in this

subtask since a LGBM, XGB and Bayesian Ridge combination produced the best outcome.

### 4.1.3 Subtask 1c: Controversial Humor Classification

In Subtask 1c, each humorous text has to be classified as controversial or not. This is the only task that a single model outperformed any combination of models we tried to assemble. A preprocess of extracting numeric features (9), appending POS tags (8a), lowercasing and tokenization (1), a delta tf-idf vectorizer extracting bigrams and an LGBM model outperformed every other combination.

### 4.1.4 Subtask 2: Offense Rating

Finally, in Subtask 2 each text is rated in the range of 0–5 on how offensive it is. The final system is the average of the 7 individual models described in Table 3.

Preprocessing	Vectorizer	ML
1,2 and 9	delta tf-idf unigrams	XGB
1,2,3 and 9	tf-idf biwords	XGB
1	word2vec embeddings	LSTM
1 and 2	word2vec embeddings	LSTM
1 and 3	word2vec embeddings	LSTM
1 and 5	word2vec embeddings	LSTM
1 and 7	word2vec embeddings	LSTM

Table 3: Subask 2 system composition

## 5 Results

Each preprocessing method had an impact on model performance, as it is shown in Table 4 for each task.

The results for each task/subtask are shown in Table 5. We present the scores of our best performing single models and combination of models respectively on the development test set as well as our submissions for the evaluation test data.

We can detect a pattern in the difference between the winning team’s submissions and our submissions, and between the performance of our NN and non-NN models. It would be an indication—for Subtask 1a—that our conventional machine learning models, while achieving a respectable performance, cannot handle some outliers. This can be also observed through the results of Subtask 2, where outliers have a greater impact on the RMSE metric. Our false negative results on humor are mostly ironic, reference-based jokes or highly controversial ones, and our false positive

Preprocessing	Subtask 1a	Subtask 1b	Subtask 1c	Subtask 2
None	0.8325	0.5501	0.6299	0.8431
Stemming	<b>0.8372</b>	<b>0.5500</b>	0.6266	0.8560
Lemmatization	<b>0.8361</b>	0.5535	0.6130	0.8504
Stopwords	0.8206	<b>0.5465</b>	<b>0.6379</b>	0.8623
Capital Tagging	0.8284	<b>0.5550</b>	0.6099	0.8790
Emoji Replace	<b>0.8332</b>	0.5501	0.6299	0.8492
Contraction Replace	<b>0.8345</b>	<b>0.5471</b>	0.6253	0.8587
Integers Remove	<b>0.8357</b>	0.5567	0.6176	0.8664
POS Tag Append	<b>0.8331</b>	<b>0.5459</b>	<b>0.6455</b>	0.8620
POS Tag Filter	0.8170	0.5558	0.6214	1.0022
Feature Creation	<b>0.8457</b>	<b>0.5473</b>	0.5298	0.8653

Table 4:  $F_1$  or RMSE of best performing model per preprocessing method. ‘None’ stands for plain tokenization and lowercasing. Scores in **bold** are better than ‘None’.

results are mostly conversational writing texts like microblogging posts. The basic LSTM models we created were able to slightly close the gap with the superior, transformer models but there is still plenty of headroom for improvement.

On the other hand, our systems on Subtasks 1b and 1c were much closer to their superior models. While Subtask’s 1b results could be attributed to a large extend on the distribution of humor ratings, Subtask 1c seems to be a much harder task regardless the approach. With an average accuracy of 0.5 across all submissions, humor controversiality seems to puzzle even the most complex models; anyway, humor controversiality is much more subjective than humor itself.

Nevertheless, a great advantage of conventional machine learning is training speed and hardware requirements. State-of-the-art boosting models like the ones we used (LightGBM and XGB) can be accelerated through the use of GPUs while our small NNs can be trained in a couple of minutes. Training/tuning deep learning models, on the other hand, requires expensive hardware and can be very time-consuming.

## 6 Conclusions

In this report, we presented our approach on humorous and offensive text classification and rating based on the combination of outputs from different preprocessing techniques, vectorization methods and machine learning algorithms. Our proposed systems were outperformed by other teams in the main tasks, while our conventional machine learning models were mostly inferior to our neural networks. Our future work will focus on expanding our preprocessing methods, introducing further ensemble methods and stacking, as well as

	Development Test			Evaluation Test		
	Best Single non-NN Model	Best Single NN Model	Best System	Best Submission	Our Position	Winning Submission
Subtask 1a	0.8706 ( $F_1$ )	0.8952 ( $F_1$ )	0.9136 ( $F_1$ )	0.8942 ( $F_1$ )	52 out of 58	0.9820 ( $F_1$ )
Subtask 1b	0.5411 (RMSE)	0.5492 (RMSE)	0.5411 (RMSE)	0.5507 (RMSE)	12 out of 50	0.4959 (RMSE)
Subtask 1c	0.6455 ( $F_1$ )	0.6491 ( $F_1$ )	0.6636 ( $F_1$ )	0.5990 ( $F_1$ )	12 out of 36	0.6302 ( $F_1$ )
Subtask 2	0.8313 (RMSE)	0.7552 (RMSE)	0.7368 (RMSE)	0.5819 (RMSE)	40 out of 48	0.4120 (RMSE)

# DeepBlueAI at SemEval-2021 Task 7: Detecting and Rating Humor and Offense with Stacking Diverse Language Model-Based Methods

Bingyan Song Chunguang Pan Shengguang Wang Zhipeng Luo  
DeepBlue Technology (Shanghai) Co., Ltd  
{songby, panchg, wangshg, luozp}@deepblueai.com

## Abstract

This paper describes the winning system for SemEval-2021 Task 7: Detecting and Rating Humor and Offense. Our strategy is stacking diverse pre-trained language models (PLMs) such as RoBERTa and ALBERT. We first perform fine-tuning on these two PLMs with various hyperparameters and different training strategies. Then a valid stacking mechanism is applied on top of the fine-tuned PLMs to get the final prediction. Experimental results on the dataset released by the organizer of the task show the validity of our method and we win first place and third place for subtask 2 and 1a.

## 1 Introduction

Humor and offense detection continue to be challenging AI problems since humor and offense involve in-depth world-knowledge, common sense, and the ability to perceive relationships across entities and objects at various levels of understanding (Hossain et al., 2019). The recognition of humor and offense in the text has been receiving much attention (Zampieri et al., 2019; Hossain et al., 2020). Accordingly, SemEval-2021 Task 7, **Detecting and Rating Humor and Offense**, which aims to automatically recognize humor in English jokes was held (Meaney et al., 2021).

In this paper, we introduce our system for accomplishing the above task by leveraging pre-trained models (PLMs). There are two main steps for our system, i) fine-tuning two kinds of PLMs, including ALBERT (Lan et al., 2019) and RoBERTa (Liu et al., 2019) with various hyperparameters and training strategies, achieving diverse models; ii) applying a validity stacking mechanism on top of these PLMs to do the final predictions.

Our experimental results show that merging PLMs with different training strategies together can achieve great improvement which verifies the effectiveness of increasing model diversity. As a

result, our system achieves the F1-score of 96.76% in subtask 1a and the RMSE of 41.2% in subtask 2, which ranks third and first among all the participated teams respectively.

## 2 Background

### 2.1 Task Definition

The “Detecting and Rating Humor and Offense” task, shared by SemEval-2021, consists of two subtasks. Subtask 1 includes three parts, a) A binary task to predict if the text would be considered humorous; b) A regression task to predict how humorous a text is if it is classed as humorous; c) A binary task to predict if the humor rating would be considered controversial when the text is classed as humorous. Subtask 2 aims to predict how offensive a text would be with values between 0 and 5. This score can be calculated regardless of whether the text is classed as humorous or not. In this paper, we mainly focus on subtask 1a and subtask 2.

Figure 2: The overall architecture for detecting and rating humor and offense.

## 2.2 Dataset

Humor and Offense appreciation is a highly subjective phenomenon, with age, gender, race, and socioeconomic status are known to have an impact on the perception of a joke. The labels and ratings of the English dataset in this task are collected from a balanced set of age groups from 18-70 and are various in genders, political stances, and income levels. The dataset has a total of 10,000 samples, which are divided into training set, validation set, and test set according to 8:1:1. Table 1 shows the number and percentage of humor samples in the three datasets and we can find that their distributions are very similar with nearly 60% are humor ones. Figure 1 demonstrates the distribution of offense ratings in three datasets. Samples with offense ratings between (0,1) are the most and the three datasets have the same distribution of offense ratings as well.

## 3 System Overview

### 3.1 PLMs-based Method

**Architecture** In our method, we have the same architecture for dealing with subtask 1a and subtask 2. As shown in Figure 2, we utilize several pre-trained language models (e.g., RoBERTa) as the encoder and segment different texts with special tokens [CLS] and [SEP]. After the tokenization, we can get the embedding of [CLS], which can be seen as the representation for the whole input text. We pass it through a dense layer and obtain the final prediction through the Multi-Sample Dropout (Inoue, 2019). The output of dense layer  $x$  is depicted as below,

$$x = ReLU(W_0 dropout(x_{[CLS]})) \quad (1)$$

where  $W_0 \in R^{d \times k}$  is the learning weight,  $k$  is the dimension of  $e_{[CLS]}$  and  $d$  is a hyperparameter

which we set as 256 and the dropout rate here we set as 0.2 or 0.5.

**Multi-Sample Dropout** Dropout is a simple but efficient regularization technique for achieving better generalization of deep neural networks. During training, dropout randomly discards a portion of the neurons to avoid overfitting. The original dropout creates a randomly selected subset (called a dropout sample) from the input in each training iteration while the multi-sample dropout creates multiple dropout samples. The loss is calculated for each sample, and the sample losses are averaged to obtain the final loss.

Thus, the final prediction of both subtask 1a and 2 can be computed as follows,

$$\hat{y} = \frac{1}{N} \sum_{i=1}^N Sigmoid(W_i dropout_i(x)) \quad (2)$$

where  $W_i \in R^{1 \times d}$  is the learning weights,  $N$  is the number of dropout values which we set as 5. By using this training mechanism, we can accelerate training and achieve lower error rates as well. Since the Sigmoid function used here is the logistic function which maps any real value to the range (0,1), we preprocess the rating of offense in subtask 2 from (0,5) to (0,1).

**Loss function** As mentioned above, subtask 1a is a binary task and subtask 2 is a regression task, thus we choose Binary Cross Entropy (BCE) and Mean Square Error (MSE) as the loss function respectively.

### 3.2 Training strategies

To further improve the diversity and accuracy of trained models, we incorporate three training strategies as depicted below.

**Task-Adaptive Pre-training** Task-adaptive pre-training (TAPT) is an effective method to improve model performance (Gururangan et al., 2020). The data used in general pre-training usually vary from task-specific data. Thus we do task-adaptive by pre-training the masked language model task on the given Humor and Offense dataset.

**Pseudo-Labeling** Pseudo labeling (PL) is the process of using a labeled data model to predict labels for unlabeled data. We predict the unlabeled test dataset and mix these pseudo labels with the training set together to train the new model. For

Subtask 1a		Subtask 2	
Model	F1	Model	RMSE
ALBERT <sub>BASE</sub>	0.9635	-	-
ALBERT <sub>BASE+AT</sub>	0.9662	-	-
RoBERTa <sub>LARGE</sub>	0.9685	RoBERTa <sub>LARGE</sub>	0.4846
RoBERTa <sub>LARGE+AT</sub>	0.9694	RoBERTa <sub>LARGE+AT</sub>	0.4713
RoBERTa <sub>LARGE+TAPT</sub>	0.9724	RoBERTa <sub>LARGE+TPAT</sub>	0.4621

subtask 1a, we set the threshold as 0.8 which means samples with predicted scores higher than 0.8 are treated as the humor ones.

Figure 3: The comparison of F1 scores for stacking different models in subtask 1a.

**Knowledge Distillation** Inspired by (Hinton et al., 2015), we adopt the knowledge distillation (KD) mechanism into our system. The whole procedure consists of three steps. First, we train the original big model using a hard target, which is the true label given in the dataset. Next, we use the trained model to predict the soft target, which is the probability for each sample being humorous and offense. After this, we train a small model by minimizing the loss between the scores predicted by the small model and the soft target. The loss functions are still BCE and MSE. At last, we use the small model to predict the final results.

**Adversarial Training** Adversarial training (AT) is a popular approach to increasing the robustness of neural networks and has good regularization performance (Miyato et al., 2016). By adding perturbations to the embedding layer, we can get more stable word representations and a more generalized model, which significantly improves model performance on unseen data.

### 3.3 Stacking Trained Models

Model stacking is an efficient ensemble method to improve model accuracy. The main procedure

of stacking trained models in our method including five steps. First, we use two different PLMs including RoBERTa and ALBERT. Second, we do TAPT on these PLMs to achieve new pre-trained models. Third, we perform 7-fold cross-validation on the whole training process to avoid overfitting or selection bias. Fourth, we train various models with different hyperparameters and different training strategies to improve the model diversity. Ultimately, we average all the predictions from different models to get the final prediction.

## 4 Experiments

**Evaluation Metrics** As mentioned in the official evaluation procedure of SemEval-2021 task 7, the main evaluation metrics for the binary classification tasks is f1-measure and the metric for the regression tasks is Root Mean Squared Error (RMSE).

**Parameter settings** All models are implemented based on the open-source transformers library of hugging face (Wolf et al., 2020), which provides thousands of pre-trained models that can be quickly downloaded and fine-tuned on specific tasks. To do better performance estimation, We gather the training set and validation set together as the new training set and then do 7-fold cross-validation on it. We set batch size as 16 and run 10 epochs for each fold. The learning rate is 1e-5. For RoBERTa<sub>LARGE</sub> and ALBERT<sub>BASE</sub>, the k is set as 1024 and 128 respectively.

## 5 Results

### 5.1 Ablation Studies

**PLMs with Training Strategies** For subtask 1a, we use two types of PLMs including ALBERT<sub>BASE</sub> and RoBERTa<sub>LARGE</sub>. As shown in Table 2. We set five groups of models and each group is the same models with or without adversarial training (AD).

The models of the first and second groups are the base ones and we add training strategies including task-adaptive pre-training (TAPT), knowledge distillation (KD), and pseudo-labeling (PL) to the other three groups.

The results are the average scores from models with different hyperparameters (e.g. different dropout) by doing 7-fold cross-validation on the new training dataset depicted above. Since RoBERTa<sub>LARGE</sub> performs better on this task, ALBERT is not used in subtask 2 anymore. From Table 2, we find that for both subtask 1a and subtask 2, all the training strategies can improve the performance. Besides, models with AD achieve better scores than the ones without AD. The models adding TAPT, PL and AT together are the best ones.

Figure 4: The comparison of RMSE for stacking different models in subtask 2.

**Stacking trained models** To stack the trained models, we use a simple method which averaging predictions from different models. Figure 3 and 4 show the comparison for stacking different models of subtask 1a and 2. We find that all scores of the ensemble ones are better than the best score in Table 2 which from a single model. This verifies the effectiveness of stacking different models.

However, both Figure 3 and 4 demonstrate that the best score is not to stacking models of all the groups in Table 2 but to stack part of the models. This indicates that combining the least correlated results is more efficient than combining them all.

Subtask 1a		Subtask 2	
System	F1	System	RMSE
endworld	0.9854	<b>DeepBlueAI</b>	<b>0.412</b>
stee	0.9797	m m m m	0.419
<b>DeepBlueAI</b>	<b>0.9676</b>	calamity link	0.423
baseline	0.9283	baseline	0.5770

Table 3: Leaderboard

## 5.2 Official Ranking

We submitted the scores predicted by the ensemble method introduced above. The official ranking is presented in Table 3. We rank third in subtask 1a and first in subtask 2, which verifies the validity of our system.

## 6 Conclusion

In this paper, we propose a top-performing approach for the task of Detecting and Rating Humor and Offense. We fine-tune two kinds of pre-trained language models including ALBERT and RoBERTa with different training strategies such as pseudo labeling and knowledge distillation. Then, we stack them with a simple linear regression model. Experimental results show the effectiveness of this ensemble method and we win first place and third place for subtask 2 and 1a. For future work, it would be interesting to test the performance of our best-performing system on other humor detection datasets to validate its portability and robustness.

## Abstract

Humor detection has become a topic of interest for several research teams, especially those involved in socio-psychological studies, with the aim to detect the humor and the temper of a targeted population (e.g. a community, a city, a country, the employees of a given company). Most of the existing studies have formulated the humor detection problem as a binary classification task, whereas it revolves around learning the sense of humor by evaluating its different degrees. In this paper, we propose an end-to-end deep Multi-Task Learning (MTL) model to detect and rate humor and offense. It consists of a pre-trained transformer encoder and task-specific attention layers. The model is trained using MTL uncertainty loss weighting to adaptively combine all sub-tasks objective functions. Our MTL model tackles all sub-tasks of the SemEval-2021 Task-7 in one end-to-end deep learning system and shows very promising results.

## 1 Introduction

Humor is a human trait that defines the emotional and behavioral characteristics of an individual. It refers to the quality of being amusing, comic, sarcastic, etc. Most dictionaries define humor also as a message, whose ingenuity or verbal skill, or incongruity, that has the power to make individual laughing.

Humor and offensive language detection tasks are increasingly becoming hot research topics in Natural Language Processing (NLP) (Zampieri et al., 2019; Reyes et al., 2012; Gleason et al., 2019; van den Beukel and Aroyo, 2018; Cattle and Ma, 2018; Singh et al., 2020). Existing research works have tackled humor detection as either a binary classification problem (Weller and Seppi, 2019; Annamoradnejad, 2020) or a ranking task (Potash et al., 2017; Hossain et al., 2020; Zhang

et al., 2019). Similarly, most research works on offensive language detection have proposed methods and approaches to discriminate between offensive and not-offensive texts (Zampieri et al., 2019, 2020), whereas, other research works have classified offensive content into more fine-grained levels (Wiegand et al., 2018; Kumar et al., 2018; Risch et al., 2020).

Fine-tuning pre-trained transformer-based language models on the target task data has shown state-of-the-art (SOTA) results in many NLP applications (Devlin et al., 2019; Liu et al., 2019). For instance, several research works on humor and offensive language detection have achieved SOTA performances using pre-trained transformer-based language models (Zampieri et al., 2019; Weller and Seppi, 2019; Zampieri et al., 2020).

In this paper, we describe our system submitted to the SemEval-2021 Task-7 (Sub-Tasks 1 and 2) (Meaney et al., 2021). We propose an end-to-end deep Multi-Task Learning (MTL) model based on RoBERTa Encoder (Liu et al., 2019) and task-specific attention layers. The attention mechanism is applied on top of the encoder’s contextualized word embedding to extract task-specific features. The classification and regression modules are fed with their task-specific attention output and the shared pooled output of the encoder. In order to adaptively combine all tasks’ losses, we employed the MTL uncertainty loss weighting method (Kendall et al., 2017). We also investigate the base and the large variants of BERT (Devlin et al., 2019) and RoBERTa encoders for both single-task and MTL. The obtained results show that our MTL model outperforms its single-task counterparts on both Task 1 and Task2. The best performances are obtained using RoBERTa-large encoder. Our system is ranked 18th, 9th, 7th and 20th on Sub-Tasks 1a, 1b, 1c and 2a, respectively.

The remainder of this paper is organized as fol-

lows. Section 2 describes the SemEval-2021 task-7 and the provided data. Section 3 presents our MTL system. Section 4 summarizes the obtained results. Section 5 concludes the paper.

## 2 Task description

The SemEval-2021 Task 7 consists of two main tasks: the first task seeks recognizing and rating humor while the second task aims to rate offense (Meaney et al., 2021). To this end, the organizers have provided 8000 sentences for the training, and 1000 sentences for the validation and test. All training and validation sentences are labeled for humor detection and offense rating, while only humorous sentences are labeled for humor and controversy rating. The dataset is labeled by 20 annotators. They have a balanced set of age groups from 18 to 70.

### 2.1 Task 1: Humor detection

The aim is to predict four target values for the following sub-tasks:

- Task 1a: This sub-task is a binary classification task where the aim is to classify texts as humorous or not.
- Task 1b: This sub-task consists of predicting the humor degree of a text. The degree is based on the average rating (from 0 to 5) given by the annotators.
- Task 1c: This sub-task consists of predicting whether the humor rating would be considered controversial or not: i.e. whether or not the variance between the annotators’ ratings is higher than the median rating.

### 2.2 Task 2: Offensive rating

This task has one sub-task for offense rating:

- Task 2a: This task predicts the degree of offense conveyed in a text regardless of its humor label. The offense degree varies from 0 (not offensive) to 5 (very offensive).

## 3 System description

We propose an end-to-end deep MTL model based on pre-trained transformer-based language model (Devlin et al., 2019; Liu et al., 2019) and task-specific attention layers. First, we apply the encoder to the input text in order to obtain its Contextual Word Embedding (CWE). The task-specific

attention layers are applied on the CWE. The classifier (Task 1a, Task 1c) or the regressor (Task 1b, Task 2a) is fed with the concatenation of its task-specific attention output and the encoder’s pooled output. The model is then trained to minimize the binary cross-entropy loss and the RMSE loss for the classification and regression tasks, respectively. Finally, these losses are combined using uncertainty loss weighting for MTL.

### 3.1 Transformer encoder

In order to recognize the most important patterns in an input text, we encode its using the state-of-art pre-trained transformer encoder. We compare four transformer encoders, namely BERT, BERT-Large, RoBERTa and RoBERTa-Large (Devlin et al., 2019; Liu et al., 2019).

The tokenizer of the encoder splits the input sentence into wordpeices  $[T_1, T_2, \dots, T_n]$  and encodes them using its vocabulary. The transformer encoder is fed with the encoded input and outputs the pooled embedding  $h_{pooled} \in \mathbb{R}^{1 \times d}$  (embedding of  $[CLS]$  (resp.  $< s >$ ) token of BERT (resp. roBBERTa)) and the CWE  $H = [h_1, h_2, \dots, h_n] \in \mathbb{R}^{n \times d}$  ( $d$  is the embedding dimension).

### 3.2 Task-specific attention layer

We use one task-specific attention layer for each task. Using  $H$ , the CWE of the input sentence, the attention mechanism (Bahdanau et al., 2015; Yang et al., 2016) extracts the task-specific representation  $s_*$  ( $*$  denotes the task) as follows:

$$\begin{aligned} U &= \tanh(W_a H) \\ \alpha &= \text{softmax}(U^T W_\alpha) \\ s_* &= \alpha \cdot H^T \end{aligned}$$

where  $W_a \in \mathbb{R}^{d \times 1}$  and  $W_\alpha \in \mathbb{R}^{n \times n}$  are the trainable parameters of the attention layer,  $U \in \mathbb{R}^{n \times 1}$  is the attention mechanism’s context vector, and  $\alpha \in [0, 1]^n$  weights  $h_1, h_2, \dots, h_n$  according to their contribution to the task objective.

### 3.3 Task Classification/Regression module

As the SemEval-2021 Task-7 consists of two classification tasks (1a and 1c) and two regression tasks (1b and 2), we employ two classification modules and two regression modules. Each of these task-specific module is composed of one hidden layer and one output layer, and takes as input the concatenation  $[h_{pooled}, s_*]$  of the pooled output ( $h_{pooled}$ ) and its task-specific attention output ( $s_*$ ).

### 3.4 MTL objective

Our MTL model is trained to minimize the losses of the four tasks. Specifically, it minimizes the binary cross-entropy loss and the RMSE loss for classification and regression tasks, respectively. These losses are expressed as follows:

- Binary cross-entropy loss for humor classification

$$L_1(\hat{y}, y) = - \sum_{i=1}^N \sum_{j=1}^2 y_i^j \log(\hat{y}_i^j)$$

- RMSE loss for Humor rating

$$L_2(\hat{y}, y) = \sqrt{\frac{1}{N} \sum_{i=1}^N (y_i - \hat{y}_i)^2}$$

- Binary cross-entropy loss for Controversy classification

$$L_3(\hat{y}, y) = - \sum_{i=1}^N \sum_{j=1}^2 y_i^j \log(\hat{y}_i^j)$$

- RMSE loss for offense rating

$$L_4(\hat{y}, y) = \sqrt{\frac{1}{N} \sum_{i=1}^N (y_i - \hat{y}_i)^2}$$

where  $y$  and  $\hat{y}$  are the ground-truth and the predicted values, respectively. In order to adaptively weight the losses of the four tasks, we combine them using MTL uncertainty loss weighting (Kendall et al., 2017), given by:

$$\begin{aligned} L_{total}(\hat{y}, y) &= \frac{1}{2\sigma_1^2} L_1(\hat{y}, y) + \frac{1}{2\sigma_2^2} L_2(\hat{y}, y) \\ &+ \frac{1}{2\sigma_3^2} L_3(\hat{y}, y) + \frac{1}{2\sigma_4^2} L_4(\hat{y}, y) \\ &+ \log(\sigma_1 \sigma_2 \sigma_3 \sigma_4) \end{aligned}$$

where  $\sigma_i$  ( $i = 1..4$ ) captures the amount of noise that exists in the output of each task, and used to tune the impact of each loss in MTL optimization. Finally, the MTL model is trained to minimize the overall loss  $L_{total}$  with respect to the network parameters as well as the noise parameters  $\sigma_i$ .

## 4 Results

### 4.1 Experiment Settings

We have evaluated the performance of our model and its single-task counterparts using both the *base* and the *large* models of BERT and RoBERTa:

- **BERT-base**: 12 transformer blocks,  $d = 768$ , 12 attention heads, and 110M parameters.
- **BERT-large**: 24 transformer blocks,  $d = 1024$ , 16 attention heads, and 336M parameters.
- **RoBERTa-base**: 12 transformer blocks,  $d = 768$ , 12 attention heads, and 125M parameters.
- **RoBERTa-large**: 24 transformer blocks,  $d = 1024$ , 16 attention heads, and 355M parameters.

For text preprocessing, we have implemented a simple pipeline that normalizes contractions. All evaluated models are trained using Adam optimizer (Kingma and Ba, 2014) with a learning rate of  $1 \times 10^{-5}$ . The batch size and the number of epochs are fixed to 16 and 5, respectively. We have investigated both single-task training and MTL for all tasks. It is worth mentioning that, for single-task learning, we also apply an attention layer on top of the contextualized word embedding. This has improved single-task models as well. All models are trained on the full train sets, validated on the validation set, and evaluated on the test set of each task. For evaluation purpose, we have used the shared task’s evaluation metrics, namely the **F1-score**, the **Accuracy**, and the Root Mean Squared Error **RMSE**. It is worth mentioning that models’ validation is performed using the development set, while the presented results are obtained employing the test set.

### 4.2 Experiment Results

Table 1 presents the obtained results for all tasks using single-task and MTL models. The results show that our MTL model surpasses its single-task counterparts on all tasks. The large variants of BERT and RoBERTa encoders offer better performance compared to their base variants. The best performance is obtained using our MTL model on top of RoBERTa large encoder. These results can be explained by the fact that deep encoders can capture more complex pattern from the input text.

		Task 1a		Task 1c		Task 1b	Task 2
		Accuracy	F1-score	Accuracy	F1-score	RMSE	RMSE
<b>Single-Task</b>	BERT	0.9171	0.9318	0.4216	0.6023	0.5852	0.5649
	BERT-large	0.9372	0.9425	0.4296	0.6122	0.5748	0.5571
	RoBERTa	0.9408	0.9433	0.4302	0.6035	0.5711	0.5556

	RoBERTa-large <sup>‡</sup>	<b>0.951</b>	<b>0.9606</b>	<b>0.4537</b>	<b>0.6242</b>	<b>0.5401</b>	<b>0.4696</b>

Table 1: The obtained results using our MTL model and its single-task counterparts, with different encoders. The subscript ‡ denotes our official submission to SemEval-2021 Task-7. Results are obtained employing the test set.

		Task 1a		Task 1c		Task 1b	Task 2
		Accuracy	F-score	Accuracy	F-score	RMSE	RMSE
<b>w/o task-attention</b>		0.9335	0.9472	0.4456	0.6122	0.5636	0.4891
<b>w/o uncertainty loss weighting</b>		0.9498	0.9582	0.4516	0.6198	0.5516	0.4722
<b>MTL RoBERTa-large</b>		<b>0.951</b>	<b>0.9606</b>	<b>0.4537</b>	<b>0.6242</b>	<b>0.5401</b>	<b>0.4696</b>

Table 2: Ablation study of our MTL model using MTL RoBERTa-large encoder (w/o denotes without the corresponding component). Results are obtained using the test set.

Besides, MTL leverages useful signals from the related tasks.

To investigate the effectiveness of the task-specific attention layers and the uncertainty loss weighting on the performance of our MTL model, we have performed an ablation study. Table 2 presents the results of our model without these components. The results show that both components improve the performance of our MTL model. We achieve the most performance gain by incorporating the task-specific attention layers into our model. Besides, the adaptive losses weighting component outperforms the simple combination of task losses ( $L_{total} = l_1 + l_2 + l_3 + l_4$ ).

## 5 Conclusion

In this paper, we have presented our system for humor and offense detection and rating. Our system consists of an end-to-end MTL model based on the state-of-art pre-trained transformer encoder and task-specific attention layers. The latter layers are applied on top of the contextualized word embedding to extract task-discriminative features. We have employed two classification and regression modules to tackle the four tasks. Our MTL model is trained to minimize the four tasks losses,

while weighting them adaptively using the MTL uncertainty loss weighting. We have also investigated the performance of our MTL model as well as its single-task counterparts using four pre-trained transformer-based encoders. The best performances are obtained using our MTL model while employing RoBERTa-large encoder.

In future work, we would like to improve our model, by considering the relationship between the different tasks. Besides, we want to use our model not only to detect humorous and offensive content, but also to perform other related tasks.

## Abstract

This paper introduces the system description of the hub team, which explains the related work and experimental results of our team's participation in SemEval 2021 Task 7: Ha-Hackathon: Detecting and Rating Humor and Offense. We successfully submitted the test set prediction results of the two subtasks in the task. The goal of the task is to perform humor detection, grade evaluation, and offensive evaluation on each English text data in the data set. Tasks can be divided into two types of subtasks. One is a text classification task, and the other is a text regression task. What we need to do is to use our method to detect the humor and offensive information of the sentence as accurately as possible. The methods used in the results submitted by our team are mainly composed of ALBERT, CNN, and Tf-Idf algorithms. The result evaluation indicators submitted by the classification task are F1 score and Accuracy. The result evaluation index of the regression task submission is the RMSE. The final scores of the prediction results of the two subtask test sets submitted by our team are task1a 0.921 (F1), task1a 0.9364 (Accuracy), task1b 0.6288 (RMSE), task1c 0.5333 (F1), task1c 0.0.5591 (Accuracy), and task2 0.5027 (RMSE) respectively.

## 1 Introduction and Background

Perceiving humor has always been a unique ability of human beings. So what is the use of humor? The research results of Martin and Kuiper on humor show us the influence of humor on a person's physical and mental health (Martin, 2004; Kuiper et al., 2004). In recent years, the use of automated methods to detect humorous information in text has attracted widespread attention (Barbieri and Saggion, 2014; Reyes et al., 2012).

SemEval 2021 Task 7: Ha-Hackathon: Detecting and Rating Humor and Offense's task goal is to

use automated techniques and methods to automatically detect humor and grade in the text. Besides, this task also needs to evaluate the offensive level of the text data. The task is divided into two parts, one part is the detection and evaluation related to humor. There are three subtasks in this part of the task. It involves text classification and regression. The other part is to assess the offensive level of the text data. This is a separate text regression task. The purpose is to predict how offensive the text will be to ordinary users. This task is an interesting challenge for the machine. Humor is a very subjective emotion. People with different cultural backgrounds and life experiences have different feelings about the same sentence. This task is to detect and score humor on the English data set. There are similar tasks and studies in other languages, such as humor scores on Spanish data from tweets (Castro et al., 2018; Chiruzzo et al., 2019).

In text detection and classification tasks, semi-supervised and supervised methods are widely used. Davidov et al. use a semi-supervised method to detect text from social media. The purpose is to detect whether the text data contains ironic information (Davidov et al., 2010). But these methods alone are not enough to make humor ratings on text data. We need to combine semantic information in context. The ELMo (Peters et al., 2018) method based on LSTM (Olah, 2015) overcomes the difficulty that the model cannot learn the context. In the follow-up work, an improved method of ELMo feature extractor appeared. The BERT (Devlin et al., 2018) model based on Transformer Encoder (Vaswani et al., 2017) achieved the best results in many NLP tasks.

## 2 Data and Methods

In this section, we will introduce the data we use in the task and the models and methods we use.

ID	Text	Is humor	Humor rating	Humor controversy	Offense rating
35	Learn from the scars of others	0	0	0	0.05
119	What do you call a sad terrorist? A crisis	1	2.16	1	0.85

Table 1: The training set sample data we used in the task.

Figure 1: The word cloud diagram of the training and test data provided by the task organizer team. The result shown in the figure is the data after removing the stop words.

## 2.1 Data Description

The task organizer team provides each team with training data sets, validation data sets and test data sets related to the “Detecting and Rating Humor and Offense” task (Meaney et al., 2021). We analyze the structure and characteristics of the data sets. The training data set includes ID, Text, Is Humor, Humor Rating, Humor Controversy, Offense Rating. Among them, Is Humor, Humor Rating, Humor Controversy 3 tags are the three subtasks a, b, and c of task 1. Is Humor and Humor Controversy are two binary classification labels, consisting of 0 or 1. Humor Rating is a continuous value between 0-5. Offense Rating is the label of task 2. It is a continuous value between 0-5. The sentence length in the Text is different. Compared with the training data set, the test set only contains the above ID and Text parts. During the development phase, the task organizer also provides a test set. But we did not use this test set in our system, so we do not analyze the test set. We need to use our method to predict the values of Is Humor, Humor Rating, Humor Controversy and Offense Rating labels in the test set. Table 1 shows a sample of the data we used in the task.

8000 and 1000 different sample data constitute the training set and the validation set. The numbers of labels belonging to 1 and 0 in the training set Is Humor label are 4932 and 3068, respectively.

The numbers of labels belonging to 1 and 0 in the training set Humor Controversy label are 2465 and 5535, respectively. The test set consists of 1000 different sample data. We use word cloud graphs to visualize text data. Text data in the training set and test set. The word cloud image clearly shows us the characteristics of word frequency distribution in the text data set. The figure shows the text data after the stop words are deleted. Figure 1 shows word frequency information in the training set and the test set.

## 2.2 Methods

Combined with the analysis and understanding of task description and task data set, we chose to develop an artificial neural network system based on the combination of ALBERT, Tf-Idf and CNN. We also tried to use the combination of BERT and Tf-Idf to verify its impact on the verification set. Both BERT and ALBERT (Lan et al., 2019) are pre-trained language models that are implemented based on the ideas and structure of Transformer. Compared with BERT, ALBERT not only has fewer parameters but also has the characteristics of parameter sharing between different layers. The pre-trained language model also occupies less memory space. Therefore, ALBERT is better than BERT in training effect. The CNN block we use in the system is mainly composed of two-dimensional

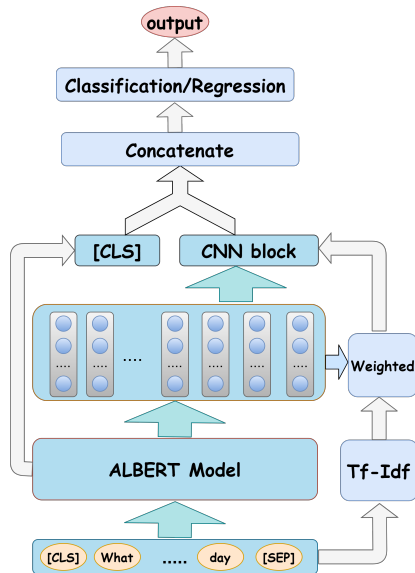

Figure 2: The model structure and data flow we used in the task.

convolution and two-dimensional maximum pooling. The convolution kernel has three (3, 4, 5) different sizes. The processed results of three convolution kernels of different sizes are connected as the output result of the CNN block.

In the system we use to predict the results of the test set. The first step is to input the preprocessed text data into the ALBERT model. At the same time, the text is processed with Tf-Idf to get Tf-Idf\_output. In the ALBERT model, we will get two output values. One is [CLS] (the shape is [batch\_size, hidden\_size]) that contains the entire sentence information. The other is the last layer output of the ALBERT model last\_layer\_output (the shape is [batch\_size, seq\_length, hidden\_size]). In the second step, we use Tf-Idf\_output to perform a weighted operation on last\_layer\_output to get weighted\_output (the shape is [batch\_size, seq\_length, hidden\_size]). In the third step, we use weighted\_output and last\_layer\_output respectively as the input of the CNN block. The two output results have the same shape as [CLS]. In the fourth step, we stitch together the results of the two CNN blocks obtained in the previous step and the results of [CLS] to obtain Concatenate\_output (the shape is [batch\_size, hidden\_size\*3]). In the fifth step, we use Concatenate\_output as the input value of the classifier for the classification or regression task to obtain the predicted output result. Figure 2 shows our model structure and data flow.

### 3 Experiment and Results

In this section, we will introduce the data preprocessing methods and experimental settings we used in the task and the final results.

#### 3.1 Data Preprocessing

Combining our understanding of tasks and data, we removed the stop words in the text data. For the stop word list, we use the stop word package provided by NLTK. Besides, to use the Tf-Idf algorithm to obtain a weighted output, and to ensure that the shape of the text code processed by the Tf-Idf algorithm is consistent with the shape of the ALBERT output, we removed the text code that exceeded the maximum sentence length. For those texts that are less than the maximum sentence length. For text encoding, we perform zero padding.

The validation set we get is unlabeled data, so the validation set we use in the training phase comes from part of the data in the training set. Randomly extract 20% from the training set as the validation set data we will use next.

#### 3.2 Experiment setting

To test the influence of different systems on the prediction results of the task data set. We design several different models and observe the result scores of different models on the validation set. We adjust the parameters as much as possible to obtain the best results for each different model, so different models use different parameter combination settings.

The difference between BERT+Tf-Idf+CNN and the system we introduced above is only to replace the ALBERT model. BERT+Tf-Idf and ALBERT+Tf-Idf directly splice the output results of BERT and ALBERT with the weighted result of Tf-Idf. The other parts are the same as we introduced in section 2.2. BERT and ALBERT directly use their [CLS] output results. The task of classification uses the BCEWithLogitsLoss loss function. The regression task uses the MSELoss loss function.

- ALBERT+Tf-Idf+CNN: The epoch, batch size, maximum sequence length, and learning rate for the model are 5, 32, 70, and  $3e-5$ , respectively.
- BERT+Tf-Idf+CNN: The epoch, batch size, maximum sequence length, and learning rate

Method	task1a	task1	task1b	task1c	task1c	task2
	F1	Acc	RMSE	F1	Acc	RMSE
ALBERT+Tf-Idf+CNN	<b>0.945</b>	0.943	<b>0.605</b>	0.522	<b>0.574</b>	<b>0.492</b>
BERT+Tf-Idf+CNN	0.930	<b>0.944</b>	0.620	<b>0.532</b>	0.561	0.502
ALBERT+Tf-Idf	0.921	0.929	0.617	0.545	0.554	0.490
BERT+Tf-Idf	0.925	0.932	0.627	0.528	0.564	0.491
ALBERT	0.915	0.927	0.634	0.532	0.544	0.510
BERT	0.917	0.923	0.625	0.542	0.551	0.497

Table 2: We use different strategies to get the scores on the validation set.

Method	task1a	task1a	task1b	task1c	task1c	task2
	F1	Acc	RMSE	F1	Acc	RMSE
Top1	0.982	0.985	0.496	0.494	0.630	0.412
Top2	0.975	0.980	0.498	0.470	0.628	0.419
Top3	0.960	0.968	0.521	0.470	0.627	0.423
Our team	0.921	0.936	0.629	0.533	0.559	0.503

Table 3: Part of the results in the leaderboard announced by the task organizer team. Among them, the results of Top1-Top3 are the combination of the scores of the top three in each subtask, not the scores of a team. The total number of participating teams in each of the four subtasks is 58, 50, 36, 48.

for the model are 4, 32, 70, and  $4e-5$ , respectively.

- ALBERT+Tf-Idf: The epoch, batch size, maximum sequence length, and learning rate for the model are 5, 32, 70, and  $3e-5$ , respectively.
- BERT+Tf-Idf: The epoch, batch size, maximum sequence length, and learning rate for the model are 4, 32, 70, and  $4e-5$ , respectively.
- ALBERT: The epoch, batch size, maximum sequence length, and learning rate for the model are 4, 32, 70, and  $3e-5$ , respectively.
- BERT: The epoch, batch size, maximum sequence length, and learning rate for the model are 4, 32, 70, and  $3e-5$ , respectively.

## 4 Results and Analysis

The evaluation indicators announced by the task organizer team in this task are divided into classification tasks and regression tasks. The classification task uses F1 scores and accuracy scores. The regression task uses root mean squared error (RMSE).

We compare the results obtained by several different methods proposed in the experimental part. The scores of different systems on the same validation set are shown in Table 2. We have the following conclusions:

- Conclusion 1: Introducing additional word frequency information as part of the input information of the model will improve the score of our validation set.
- Conclusion 2: The score difference between ALBERT and BERT on our validation set is not large. But in the same parameters and data set, the training time of ALBERT is shorter than BERT.
- Conclusion 3: Adding a CNN block improves the result score. And the result scores of the two methods based on ALBERT and BERT have their advantages.

The ranking of the test set prediction results announced by the task organizer team uses accuracy scores and RMSE scores respectively. Classification tasks are ranked according to accuracy scores. Regression tasks are ranked according to RMSE scores. We finally submitted the test set prediction result score from the ALBERT+Tf-Idf+CNN system. Because its combined result in training time and score is better than the BERT+Tf-Idf+CNN system. The prediction result scores of the test set we submitted can be seen in Table 3. The scores of our system on the test set are lower than the scores of the top three. But the results of the test set prove that our system and method are feasible.

## 5 Conclusion

In this task related to humor detection and offensive evaluation, we propose an artificial neural network system that combines a pre-trained language model with Tf-Idf and CNN. Although our system is only in the middle of the ranking, we still successfully use our system to predict humor and offensive scores. We studied the contributions of 6 different systems and found that the combination of Tf-Idf and CNN improved the prediction scores of BERT and ALBERT. At the same time, the ALBERT-based system is superior to the BERT-based system in terms of time efficiency. In future work, based on the model we use in the task, we can try to fuse other types of word embedding information, and replace the CNN block with an LSTM block or other artificial neural networks.

## Abstract

In this paper, we describe our system used for SemEval 2021 Task 7: HaHackathon: Detecting and Rating Humor and Offense. We used a simple fine-tuning approach using different Pre-trained Language Models (PLMs) to evaluate their performance for humor and offense detection. For regression tasks, we averaged the scores of different models leading to better performance than the original models. We participated in all SubTasks. Our best performing system was ranked 4 in SubTask 1-b, 8 in SubTask 1-c, 12 in SubTask 2, and performed well in SubTask 1-a. We further show comprehensive results using different pre-trained language models which will help as baselines for future work.

## 1 Introduction

Humor is an intelligent form of communication with the capability of providing amusement and provoking laughter (Chen and Soo, 2018). It helps in bridging the gap between various languages, cultures, and demographics. Humor is a very subjective phenomenon. It can have different intensities, and people may find some jokes funnier than others. In certain situations, some jokes may be offensive to a certain group of people. All these characteristics of humor pose an interesting linguistic challenge to NLP systems. SemEval 2021 Task 7: HaHackathon: Detecting and Rating Humor and Offense (Meaney et al., 2021) aims to draw attention to these challenges in humor detection. The task provides a dataset of humorous content annotated using people representing different age groups, gender, political stances, and income levels. The content of the provided dataset was in English.

Participating in all SubTasks, we propose a fine-tuning based approach on pre-trained language models. Pre-trained Language Models learn syntactic and semantic representations by training on

large amounts of unsupervised data. Recently there has been a lot of interest in PLMs. Researchers have come up with different pre-training methods using Auto Encoding(AE) and Auto-Regressive(AR) language modeling techniques. Often these pre-trained models contain millions of parameters and are computationally expensive. Fine-tuning different models may lead to different results on downstream tasks. This makes the choice of PLM an important factor. We present a comparative study of different PLM models and their performance in all SubTasks of SemEval 2021 Task 7: HaHackathon.

Our proposed fine-tuning approach for each PLM made use of a single layer of one neuron stacked on the PLM features. We performed experiments using BERT(Devlin et al., 2019), ELECTRA(Clark et al., 2020), RoBERTa(Liu et al., 2019), XLNet(Yang et al., 2019), MPNet(Song et al., 2020), and ALBERT(Lan et al., 2020). For regression tasks, we also used averaging technique, which we describe later in the paper. Our model performed well in SubTask 1-b and 1-c, achieving a rank of 4 and 8 respectively on the official leaderboard. For SubTask 2, our proposed averaging technique outperformed individual fine-tuned models by a good margin and was ranked 12. Our code is available online<sup>1</sup> for method replicability.

## 2 Background

The task of automatic humor recognition refers to deciding whether a given sentence expresses humor. The problem of humor recognition is often formulated as a binary classification problem aiming to identify if the given text is humorous. (Weller and Seppi, 2019) performed a study to identify if a joke is humorous or not using transformers

<sup>1</sup><https://github.com/04mayukh/YoungSheldon-at-SemEval-2021-Task-7-HaHackathon>

(Vaswani et al., 2017). They used the body of the joke, the punchline exclusively, and both parts together. Combining both parts lead to better performance and it was found that a punchline carries more weight than the body of a joke for humor identification. (de Oliveira and Rodrigo, 2015) experimented with SVM’s, RNN’s, and CNN’s for identifying humor in Yelp reviews using a bag of words and mean word vector representations. (Chen and Soo, 2018) used CNN-based models for identifying humor content. (Annamoradnejad, 2021) uses a neural network built on BERT embeddings learning features for sentences and whole text separately and then combining them for prediction on 200k Short Texts for Humor Detection dataset on Kaggle<sup>2</sup>. Binary classification tasks help us to separate humorous content but are unable to quantify the degree of humor. SemEval-2017 Task 6: #HashtagWars (Potash et al., 2017) aimed to study the relative humor content of funny tweets by either generating the correct pairwise comparisons of tweets (SubTask A) or finding the correct ranking of the tweets (SubTask B) based on their degree of humor content. SemEval-2020 Task 7: Assessing Humor in Edited News Headlines (Hossain et al., 2020) presented a study on editing news headlines to make them humorous. The task involved quantifying the humor of the edited headline on a scale of (0-3) as well as comparing the humor content of the original and edited headline. SemEval-2020 Task 8: Memotion Analysis- The Visuo-Lingual Metaphor! (Sharma et al., 2020) provides details on humor classification as well as predicting its semantic scale on internet memes using both images and text. OffensEval (Zampieri et al., 2020) (Zampieri et al., 2019) provides insights for identifying offensive content on social media.

Humor is an intelligent way of communication in our daily lives. It helps bridge the gap between people from various cultures, ages, gender, languages, and socioeconomic status making it a powerful tool to connect with the audience. Humor is a highly subjective phenomenon. People from different demographics may have a different perception of humor, and some may even find it offensive. This makes identifying humor a tough task. SemEval 2021 Task 7: Hahackathon: Linking humor and offense across different age groups aims to study this subjective nature of humor, which has two Sub-

<sup>2</sup><https://www.kaggle.com/moradnejad/200k-short-texts-for-humor-detection>

Tasks which we describe as:

SubTask 1: Given a labeled dataset D of texts, the task aims to learn a function that can:

- SubTask 1-a: predict if a text is humorous or not.
- SubTask 1-b: quantify humor present in a humorous text within a range of (0-5).
- SubTask 1-c: predict if the humor rating would be controversial for a humorous text, i.e., the variance of the rating between annotators is higher than the median.

SubTask 2: Given a labeled dataset D of texts, the task aims to learn a regression function that can quantify how offensive a text is for general users within a range of (0-5).

*Dataset Statistics:* Table 1 represents the dataset statistics for classification tasks. For SubTask 1-a we can see there is a slight class imbalance between humorous and non-humorous labels. We overcome the problem of class imbalance using class weights which we define as: Let  $X$  be the vector containing counts of each class  $X_i$  where  $i \in X$ . Then the weights for each class were given as:

$$weight_i = \frac{max(X)}{X_i + max(X)}$$

For SubTask 1-c the label distribution was balanced. Table 2 represents the statistics for the regression tasks. Another observation on the training set for SubTask 2 was that 3388 samples had an offensive rating of 0 and nearly 80% of samples had offense rating in the range 0-1.

### 3 System Overview

#### 3.1 Pre-trained Language Models

NLP being a diverse field contains many tasks, but most task-specific datasets contain only a few hundred or a thousand human-labeled samples. To overcome this problem, researchers have come up with a method called pre-training (Qiu et al., 2020) which involves training general-purpose language representation using enormous amounts of unannotated textual data. These language models can then be fine-tuned on various downstream tasks and have shown promising results in many natural processing tasks (Dai and Le, 2015; Peters et al., 2018; Radford and Narasimhan, 2018). Next, we briefly discuss some pre-trained language models we used for the task.

		Humorous	Non-humorous	Total
Task 1-a	Train	4932	3068	8000
	Validation	632	368	1000
	Test	615	385	1000
		Controversial	Non-controversial	Total
Task 1-c	Train	2465	2467	4932
	Validation	308	324	632
	Test	279	336	615

Table 1: Dataset statistics for classification tasks.

		Mean	Standard Deviation	Count
Task 1-b	Train	2.260	0.566	4932
	Validation	2.269	0.572	632
	Test	2.119	0.546	615
		Mean	Standard Deviation	Count
Task 2	Train	1.393	1.185	8000
	Validation	0.706	1.190	1000
	Test	0.480	0.830	1000

Table 2: Dataset statistics for regression tasks.

### 3.2 Brief overview of used Pre-trained Models

BERT: Bidirectional Encoder Representations from Transformers is a bi-directional language model that uses Transformer (Vaswani et al., 2017) architecture to learn contextual relations between different words in a text sequence (Devlin et al., 2019). It makes use of two training strategies i.e., Masked Language Modelling (MLM) and Next Sentence Prediction (NSP).

ELECTRA: It introduces a new pre-training objective called Replaced Token Detection (RTD) (Clark et al., 2020). Unlike BERT which introduces <MASK> tokens, Electra replaces certain tokens with plausible fakes. The pre-training task then requires the model to determine if the input tokens are the same or have been replaced. This binary classification task is applied to all tokens unlike the small number of masked tokens making RTD more efficient than MLM.

RoBERTa: A Robustly Optimized BERT Pre-training Approach (Liu et al., 2019) was developed by Facebook. They made use of the BERT architecture with modifications to improve the performance on downstream tasks. They made use of dynamic masking in the pre-training objective and removed

the NSP objective. They also trained the model for a longer duration with more data and a larger batch size. They outperformed BERT on several downstream tasks.

XLNet: XLNet (Yang et al., 2019) is a generalized autoregressive pre-training method that takes the best of both AR language modeling and AE modeling techniques. It proposed a permutation language modeling objective for pre-training that helps learn bidirectional contexts. It also helps overcome the pretrain-finetune (Yang et al., 2019) discrepancy present in BERT due to its autoregressive formulation.

MPNet: MPNet (Song et al., 2020) was proposed by Microsoft. It overcomes the positional discrepancy between pre-training and fine-tuning in XLNet which does not use the full position information of a sentence. It proposes a unified view of masked language modeling and permuted language modeling by rearranging and splitting the tokens into predicted and non-predicted parts. It uses MLM and PLM to model the dependency among predicted tokens and see the position information of the full sentence.

ALBERT: A Lite BERT for self-supervised learning of language representations (Lan et al., 2020) is a modification of BERT aiming to effi-

ciently allocate the model capacity to help reduce training time and reduce memory consumption. ALBERT decomposes the embedding matrix into a lower dimension which is then projected to the hidden space. This is called factorized embedding parameterization and helps in reducing the parameters. It also makes use of layer sharing across all layers which helps remove redundancy. Additionally, it uses inter-sentence coherence loss based on Sentence Order Prediction (SOP) (Lan et al., 2020).

### 3.3 Fine-tuning

We fine-tuned the pre-trained language models for each SubTask by stacking a dropout layer followed by a single neuron dense layer on top of PLM features. We used the features of [CLS] token in the case of ALBERT, BERT, XLNet, ELECTRA, and start token (<s>) features in the case of RoBERTa, and MPNet. For the classification task, sigmoid activation was used in the final layer. For the regression task, we did not use any activation. Negative values were converted to zero in regression tasks.

### 3.4 Averaging for Regression tasks

For regression tasks, we combined all fine-tuned models by averaging their predictions. For SubTask 1-b, we averaged the predictions of all models. For SubTask 2 as stated earlier, there were many zero values in the training set therefore, we averaged the predictions only when all models predicted a non-zero value. If any of the models predicted zero for a given sample, we took zero as the final prediction.

## 4 Experimental Setup

We used ekphrasis (Baziotis et al., 2017) library for pre-processing the text inputs. It normalized date, time, numbers to a standard format and also performed spelling correction. For tokenization, we used Hugging Face’s (Wolf et al., 2020) implementation of fast tokenizers for each pre-trained model. We fixed the sequence length of samples to 150 tokens. Models were developed on Keras<sup>3</sup> (Chollet et al., 2015) using the transformers<sup>4</sup> (Wolf et al., 2020) library by Hugging Face. We used Adam (Kingma and Ba, 2017) optimizer for fine-tuning. Learning rate of 1e-4 was used for ELECTRA. For other models, we experimented with 1e-5, 2e-5, and 3e-5. We used binary cross-entropy loss for classification tasks and logCosh loss for regression

<sup>3</sup><https://keras.io>

<sup>4</sup><https://huggingface.co/transformers>

Figure 1: Confusion matrix for SubTask 1-a.

tasks. Batch size of 16 was used for all models. Fine-tuning was performed on TPU’s on Google Colab. We fine-tuned for four epochs on SubTask 1 and 8 epochs on SubTask 2. F1 score and RMSE were used as an evaluation metric for classification and regression tasks. Weights with the best performance on the development set were used for making predictions on the test set.

## 5 Results and analysis

Table 3 shows the results of our proposed fine-tuning approach for different pre-trained models. Our simple averaging technique worked quite well for regression tasks. Our model was ranked 4 in SubTask 1-b and ranked 12 in SubTask 2. The averaging method proposed by us for SubTask 2 provided a significant improvement in the RMSE score against the individually pre-trained models. Upon examination of the test set, we found 40.8% of samples were given zero offense rating. Thus, our decision to predict zero if any of the model predicted zero helped in improving scores against individual models. For classification tasks, our model was ranked 8 in SubTask 1-c and performed well for SubTask 1-a.

Figure 1 and Figure 2 show plots of confusion matrices for our best performing model fine-tuned on BERT. For Subtask 1-a, our model was efficient in separating the humorous and non-humorous content as false positives are low for each class. For SubTask 1-c, our model performed well in identifying the controversial text but did not perform

Model	Precision		Recall		F1		Accuracy	
	1-a	1-c	1-a	1-c	1-a	1-c	1-a	1-c
Subtask								
BERT-base	.9254	.4630	<b>.9691</b>	<b>.9426</b>	<b>.9467</b>	<b>.6210</b>	<b>.9330</b>	.4780
ELECTRA-base	.9269	.4747	.9073	.7419	.9170	.5790	.8990	.5105
RoBERTa-base	.9518	.4708	.8991	.8960	.9247	.6172	.9100	.4959
MPNet-base	<b>.9658</b>	<b>.4879</b>	.9203	.7275	.9425	.5841	.9310	<b>.5300</b>
XLNet-base	.9489	.4812	.9365	.6881	.9427	.5663	.9300	.5219
ALBERT-large	.9632	.4666	.8943	.8530	.9274	.6032	.9140	.4910

Table 3: Test set results for SubTask 1-a and SubTask 1-c.

Figure 2: Confusion matrix for SubTask 1-c.

very well for non-controversial text. The model has a very high recall but low precision due to high false positives for the controversial class which is evident from the confusion matrix. BERT, MPNet, and XLNet performed better than other PLMs for SubTask 1-a. For SubTask 1-b individual models had a similar performance. Averaging helped in improving the performance. BERT, ELECTRA, and ALBERT had the best performance on the test set for SubTask 1-c.

## 6 Conclusion

The paper describes our system used for competing in all SubTasks of SemEval 2021 Task 7: Ha-Hackathon: Detecting and Rating Humor and Offense. We used a simple fine-tuning approach for analyzing the performance of various pre-trained language models for the task of humor detection. We performed well in all SubTasks except SubTask 1-a. A lot of research is happening around

Model	RMSE	
	Task 1-b	Task 2
SubTask		
BERT-base	.5380	.5066
ELECTRA-base	.5418	.6071
RoBERTa-base	.5428	.5046
MPNet-base	.5401	.5142
XLNet-base	.5380	.5298
ALBERT-large	.5307	.5004
PLM Average	<b>.5257</b>	<b>.4499</b>

Table 4: Test set results for SubTask 1-b and SubTask 2.

pre-trained language models with new and better models coming up. These models are large and computationally expensive. Choosing a model becomes a difficult task as they may have different results on downstream tasks. We, therefore, performed experiments with the recent state-of-the-art models and provide a comparative analysis of their performance. In the future, we would like to work on the effect of pre-training PLMs with additional task-specific data and then fine-tuning to see their performance on downstream tasks.

## Abstract

This paper describes MagicPai’s system for SemEval 2021 Task 7, HaHackathon: Detecting and Rating Humor and Offense. This task aims to detect whether the text is humorous and how humorous it is. There are four subtasks in the competition. In this paper, we mainly present our solution, a multi-task learning model based on adversarial examples, for task 1a and 1b. More specifically, we first vectorize the cleaned dataset and add the perturbation to obtain more robust embedding representations. We then correct the loss via the confidence level. Finally, we perform interactive joint learning on multiple tasks to capture the relationship between whether the text is humorous and how humorous it is. The final result shows the effectiveness of our system.

## 1 Introduction

Humor is the tendency of experiences to provoke laughter and provide amusement. Regardless of gender, age or cultural background, it is a special way of language expression to provide an active atmosphere or resolve embarrassment in life while being an important medium for maintaining mental health (Lefcourt and Martin, 1986). Recently, with the rapid development of artificial intelligence, it becomes one of the most hot research topics in natural language processing to recognize humor (Nijholt et al., 2003). The task of humor recognition consists of two subtasks: whether the text contains humorous and what level of the humor it is. Early humor recognition methods tackle this task mainly by designing heuristic humor-specific features on classification models (Khodak et al., 2018) and have proved that this automatic way can attain satisfactory performance. Nowadays, researchers try to resolve this task by statistical machine learning or deep learning technologies.

The SemEval 2021 Task 7, HaHackathon: Detecting and Rating Humor and Offense, consists of four subtasks: Subtask 1 simulates the previous humor detection task, in which all scores are averaged to provide an average classification score. Subtask 1a is a binary classification task to detect whether the text is humorous. Subtask 1b is a regression task to predict how humorous it is for ordinary users in a value range from 0 to 5. Subtask 1c is also a binary classification task to predict whether the humor grade causes controversy if the text is classified as humorous. Subtask 2 aims to predict how offensive text for an ordinary user is in an integral value range from 0 and 5.

Due to the highly subjective nature of humor detection, the data is labeled by people with different profile in gender, age group, political position, income level, social status, etc. The tasks are extremely challenging because they lack a unified standard to define humor.

To tackle the tasks, we first preprocess the text, including stemming, acronym reduction, etc. We then apply the pre-trained language model to get the representation of each subword in the text as the model input. Meanwhile, we add a perturbation to the embedding layer and design an optimization goal that maximizes the perturbation of the loss function. After that, we perform interactive multi-task learning on judging whether humor exists and predicting how humorous it is. That is, based on maximizing the likelihood estimation under the Gaussian distribution with the same variance, we construct a multi-task loss function and automatically select different loss weights in the learning to improve the accuracy of each task.

## 2 Related Work

The early stages of humor recognition are based on statistical machine learning methods. For example,

Taylor and Mazlack (2004) try to learn statistical patterns of text in N-grams and provide a heuristic focus for a location of where wordplay may or may not occur. Mihalcea and Strapparava (2005) show that automatic classification techniques can be effectively deploy to distinguish between humorous and non-humorous texts and obtain significant improvement over the Apriori algorithm, a well-known baseline. In addition, three human-centric features are designed for recognizing humor in the curated one-liner dataset. Mikolov et al. (2011) apply SVM models for humor recognition as a binary classification task and prove that the technique of metaphorical mapping can be generalized to identify other types of double entendre and other forms of humor. Kiddon and Brun (2011) present several modifications of the original recurrent neural network language model to solve the humor recognition task. Castro et al. (2016) collect a crowd-sourced corpus for humor classification from Spanish tweets and conduct extensive experiments to compare various machine learning models, such as Support Vector Machine (SVM), a Multinomial version of Naïve Bayes (MNB), Decision Trees (DT), k Nearest Neighbors (kNN), and a Gaussian version of Naïve Bayes (GNB). Yan and Pedersen (2017) observe that bigram language models performed slightly better than trigram models and there is some evidence that neural network models can outperform standard back-off N-gram models. Chen and Soo (2018) extend the techniques of automatic humor recognition to different types of humor as well as different languages in both English and Chinese and proposed a deep learning CNN architecture with high way networks that can learn to distinguish between humorous and nonhumorous texts based on a large scale of balanced positive and negative dataset.

With the rapid development of deep learning technology, various pre-training models have made great progress in the field of natural language processing (Yang and Shen, 2021; Wang et al., 2021; Yang et al., 2021). Liu et al. (2018) propose to model sentiment association between elementary discourse units and compare various CNN methods of humor recognition. Weller and Seppi (2019) employ a Transformer architecture for its advantages in learning from sentence context and demonstrate the effectiveness of this approach and show results that are comparable to human performance. Ma et al. (2020) propose a new algorithm Enhance-

ment Inference BERT (EI-BERT) that performs well in sentence classification. Fan et al. (2020) propose an internal and external attention neural network (IEANN) Attention mechanism (Fan et al., 2020; Jiao et al., 2019) has been applied and show good model performance. The existing work can be borrowed or inspired our proposal in this paper.

### 3 Overview

In the following, we present the implementation of our system for the competition.

#### 3.1 Virtual Adversarial Training Based on Loss Correction

Recently, adversarial examples (Szegedy et al., 2014) have been generated to increase the robustness of training deep learning models (Pan et al., 2019; Lei et al., 2020). This work is motivated by the significant discontinuities between the input-output mappings of deep neural networks. When an imperceptible perturbation is added to the input, it may make the original normal network misclassify the result. The characteristics of these perturbations are not random artifacts of learning generated by the network during the learning process, because the same perturbation will cause different networks trained on different data sets to produce the same classification errors. Adversarial examples are samples that significantly improve the loss of the model by adding small perturbations to the input samples.

The adversarial training (Miyato et al., 2017) is a training process that can effectively identify the original sample and the adversarial sample model. Usually, the adversarial training requires labeled samples to provide supervision loss because the perturbation is designed to increase the model loss function. Virtual adversarial training (Liu et al., 2020) extends the adversarial training to semi-supervised mode by adding regularization to the model so that the output distribution of a sample is the same as the output distribution after perturbation while attaining good performance in both supervised and unsupervised tasks. When the training sample is mixed with noise, it is easy to overfit the model and learn wrong information. Therefore, it is necessary to interfere to control the influence of noise.

Figure 1(a) illustrates the perturbation in our implementation. For a word with a sequence length of  $n$ , we let  $w_i$  denote the  $i$ -th subword, where  $i = 1, \dots, n$ . The representation of  $w_i$  is then

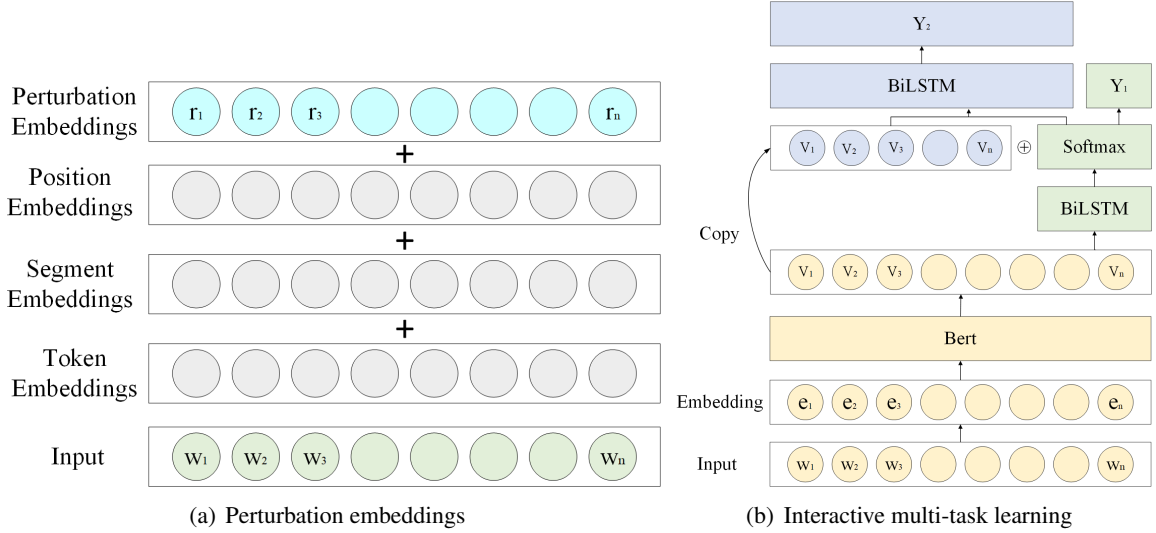

Figure 1: The main implementation of our proposed system.

computed by the sum of token embedding, segmentation embedding, position embedding, and perturbation embedding, an additional embedding. This makes it slightly different from the existing pre-trained language models, e.g., BERT.

The virtual adversarial training can be unified by the following objective:

$$\min_{\theta} \mathbb{E}_{(x,y) \sim D} [\alpha \max_{\beta} L(f(x + \beta; \theta), f(x; \theta)) + L(f(x; \theta), y)], \quad (1)$$

where  $D$  is a training dataset consisting of input-output pairs  $(x, y)$ ,  $\alpha$  is a hyperparameter to control the trade-off between the standard error and the robust error.  $\beta$  is the adversarial perturbation,  $y$  represents the true label,  $\theta$  is the model parameter,  $L$  is the loss function.  $x + \beta$  quantifies the perturbation  $\beta$  injecting into  $x$ . The goal of  $\beta$  is to maximize the difference between the two decision function values,  $f(x + \beta; \theta)$  and  $f(x; \theta)$ , i.e., to make the prediction of the existing model as incorrect as possible. To make  $\beta$  meet a certain constraint, a conventional setting is to let  $\|\beta\| \leq \epsilon$ , where  $\epsilon$  is a constant. After constructing an adversarial sample  $x + \beta$  for each sample, Eq. (1) tries to seek the model parameter  $\theta$  by minimizing the prediction loss.

Since the training samples are mixed with noise, it is easy for the model to overfit and learn wrong information (Reed et al., 2015), interference is adopted to control the influence of noise. The loss

function is defined as follows:

$$\mathcal{L} = - \sum_{i=1}^N ((1 - w_i)y_i + w_i\tilde{y}_i) \log(l_i) \quad (2)$$

where  $y_i$  is the true label,  $\tilde{y}_i$  is the predicted label, and  $l_i$  is the predicted probability distribution.  $w_i$  is a hyperparameter to control the trade-off between true label and predicted label. By minimizing the loss defined in Eq. (2), we can reduce the attention to noise points by adding the model's own predictions to the true labels and the prediction to the noise point.

### 3.2 Interactive Multi-task Training

According to the description of the first two tasks, task 1a is a binary classification task to predict if the text would be considered humorous for an average user while task 1b is a regression task to determine how humorous it is for an average user when the text is classed as humorous, where the values vary between 0 and 5. In order to capture the relationship between whether text is humorous and how humorous it is, we designed the network structure shown in Fig. 1(b). The input, as illustrated in Fig. 1(a), is the sum of the token embedding, position embedding, segment embedding, and perturbation embedding. The sum of four embeddings is sent to a pre-trained language model (PLM) to yield an input for a BiLSTM model. After that, a Softmax layer is placed to recognize whether the text is humor. Meanwhile, the output of the PLM and the output of the Softmax layer are concatenated together and sent to another BiLSTM model

to predict how humorous it is. In Fig. 1(b), the notation  $\oplus$  represents the concatenation operation. Because two tasks have different noise patterns, learning two tasks simultaneously can make features interact in the tasks. For task 1a, it is easy to learn some important features while for task 1b, it is difficult to extract them. The reason may come from the following facts: the interaction between task 1b and the features may be too complicated, or some other features may hinder the learning procedure (Xia and Ding, 2019). Hence, by deploying interactive multi-task learning, we can get a more generalized representation.

Since different loss functions have different scales, loss functions with a larger scale will significantly dominate the loss functions with a smaller scale (Liang et al., 2020; Zhang et al., 2020). Therefore, a weighted summation of the loss function is required to make balance on the loss functions. Motivating by (Kendall et al., 2017) that modeling is based on task-dependent and homoscedastic aleatoric uncertainty, i.e., for a certain sample, the model not only predicting its label but also estimating the task-dependent homoscedastic uncertainty, we present a multi-task loss function derived by maximizing the Gaussian likelihood of the same variance uncertainty. Suppose the input is  $X$ , the parameter matrix  $W$  is the model parameter for the output,  $f^W(x)$ . For the classification in task 1a, the Softmax likelihood can be defined by:

$$p(y_1|f^W(x)) = \text{Softmax}(f^W(x), \sigma_1), \quad (3)$$

where  $\sigma_1$  is the observed noise scalar for the classification model.

For the regression task in task 1b, we can define its probability as the Gaussian likelihood by:

$$p(y_2|f^W(x)) = G(f^W(x), \sigma_2), \quad (4)$$

where  $\sigma_2$  is the observed noise scalar for the regression model.

Here, to learn the models in the multi-task mode, we define the multivariate probability by

$$\begin{aligned} & p(y_1, y_2|f^W(x)) & (5) \\ & = p(y_1|f^W(x)) \cdot p(y_2|f^W(x)) \\ & = \text{Softmax}(f^W(x), \sigma_1) \cdot G(f^W(x), \sigma_2). \end{aligned}$$

Maximizing the probability defined in Eq. (5) is

equivalent to minimizing the following objective:

$$\begin{aligned} & L(W, \sigma_1, \sigma_2) & (6) \\ & = -\log p(y_1, y_2|f^W(x)) \\ & = -\log \text{Softmax}(f^W(x), \sigma_1) \cdot G(f^W(x), \sigma_2) \\ & \propto \frac{1}{\sigma_1^2} L_1(W) + \frac{1}{2\sigma_2^2} L_2(W) + \log \sigma_1 + \log \sigma_2 \end{aligned}$$

where  $L_1 = -\log \text{Softmax}(f^W(x), y_1)$  defines the cross entropy loss between the prediction and  $y_1$ .  $L_2 = \|y_2 - f^W(x)\|^2$  defines the Euclidean loss between the prediction and  $y_2$ . By minimizing the above objective, we can learn the parameters of  $W$ ,  $\sigma_1$ , and  $\sigma_2$  accordingly.

## 4 Experiments

In the following, we present the data, experimental setup and analyze the results.

### 4.1 Data and Experimental Setup

The data is collected from the official release in (Meaney et al., 2021). We preprocess the data by spelling correction, stemming, handling special symbols, and converting all letters to lowercase, etc. Finally, we obtain the data and report the statistics in Table 1.

In the experiment, we choose the large version of four popular pre-training language models, i.e.,

BERT, XLNet, RoBERTa, and ERNIE. The hyperparameters of each model are tuned based on our experience and shown in Table 2. To train a good classifier, we deliver the following procedure: 1) conducting five-fold cross-validation on the training set and obtaining 20 models; 2) applying the 20 models to get the pseudo-labels of the data in the test set and extracting the data with high confidence, i.e., the predicted label score greater than 0.95 or smaller than 0.05, as new training data; 3) the pseudo label data from the test set are mixed with the original training set to train new models. Finally, 892 pseudo label data are selected and mixed with the training set to train the final models. The regression model is jointly trained with the classification models. The models that performed well in cross-validation are selected and averaged by the weighted fusion based on the confidence.

Models	AT	LC	AT + LC
BERT	0.9459	0.9490	<b>0.9534</b>
RoBERTa	0.9480	0.9482	<b>0.9569</b>
XLNet	0.9462	<b>0.9487</b>	0.9470
ERNIE	0.9491	0.9499	<b>0.9512</b>

Table 3: The performance (accuracy) of task 1a with different training strategies.

Models	1a (Acc.)	1a (F1)	1b (RMSE)
ST	0.9569	0.9470	0.6059
MT	0.9577	0.9480	0.5823
MT+WL	<b>0.9637</b>	<b>0.9550</b>	<b>0.5701</b>

Table 4: Comparison of different strategies. ST: single task. MT: multi-task. WL: weigh loss.

## 4.2 Results

In order to prove the effectiveness of adversarial training (AT) and loss correction (LC), we verify task 1a on four pre-training models. AT denotes the models through adversarial training by adding perturbations in the embedding layer. LC denotes the strategy to make correction on the classification cross entropy to interfere with the influence of noise on the model. AT+LC means to apply both strategies in the training. Results reported in Table 4 show that by employing individual strategy, the models can attain good performance on task 1a while employing both strategies can gain better accuracy in BERT, RoBERTa, and ERNIE.

Moreover, we verify the effectiveness of the in-

teractive multi-task training strategy on RoBERTa. MT+WL denotes that the weighted hyperparameters in the loss function are adjusted based on uncertainty, determined by the learned  $\sigma_1$ 's and  $\sigma_2$ , during interactive multi-task training to scale the output the loss function of each task in a similar range. Results reported Table 4 show that the multi-task joint training mechanism can reduce the RMSE of the regression task (i.e., 1b) significantly while adjusting the loss weight can further decrease the error.

Finally, we attain the F1 score of 0.9570 and the accuracy of 0.9653 on task 1a, respectively. The RMSE on task 1b is 0.5572. The RMSE on task 2 is 0.446.

## 5 Conclusion and Future Work

This paper presents our system for SemEval-2021 task 7. Several techniques, such as interactive multi-task joint training, adversarial training, and loss correction, are applied to tackle the task. More specifically, the perturbation is first added to the input embedding layer and the predicted labels are also added with the real labels to reduce the loss of the noise point data. Next, the output of task 1a by the Softmax is concatenated with the input of the task 1b to perform joint training on both tasks. Meanwhile, the uncertainty weighting scheme on the loss allows the simple task to have a higher weight. Finally, multiple models are ensembled to yield the final prediction results. Our system attains the first place in the competition.

In the future, we can explore and verify three other effective strategies. The first strategy is the task-adaptive funetuning on the pre-trained language models. Relevant sentences can be continuously fed into the pre-trained language models to improve the model performance. The second strategy is to build a graph neural network (GNN) model to exploit all vocabulary for text classification. Because BERT is relatively limited to capture the global information from a larger language vocabulary, it is promising to facilitate the GNN, which captures the global information, with the in-depth interaction of BERT's middle layers, which embed sufficient local information. We will further investigate discourse structures (Lei et al., 2017, 2018) for humor detection. Because, both BERT and GNN models information from word relations, it is necessary to involve the study of discourse structures, which describe how two sentences are

logically connected to one another. By such novel design, we can attain better representations and improve the classification performance.

## Abstract

Detecting humor is a challenging task since words might share multiple valences and, depending on the context, the same words can be even used in offensive expressions. Neural network architectures based on Transformer obtain state-of-the-art results on several Natural Language Processing tasks, especially text classification. Adversarial learning, combined with other techniques such as multi-task learning, aids neural models learn the intrinsic properties of data. In this work, we describe our adversarial multi-task network, AML-Humor, used to detect and rate humor and offensive texts from Task 7 at SemEval-2021. Each branch from the model is focused on solving a related task, and consists of a BiLSTM layer followed by Capsule layers, on top of BERTweet used for generating contextualized embeddings. Our best model consists of an ensemble of all tested configurations, and achieves a 95.66% F1-score and 94.70% accuracy for Task 1a, while obtaining RMSE scores of 0.6200 and 0.5318 for Tasks 1b and 2, respectively.

## 1 Introduction

Sentiment analysis studies expressed opinions and feelings, affective states, and subjective information introduced while conveying ideas to others. In recent years, social media has encountered a major change in ways of interaction and in the freedom of expressing moods to others. For example, individuals frequently use emojis, or even abbreviations, to emphasize their feelings. Therefore, new machine learning systems are developed to predict sentiment valences; however, this task is not trivial, as the detection of sentiments is challenging even for humans. This is mainly generated by the diversity of contexts and differences among people, such as socio-cultural status, age, or gender. For example, certain jokes might be confusing due to

past experiences or the current mood while reading the joke. Similarly, language ambiguity can introduce difficulties in understanding the text and in altering the perceived emotions.

Moreover, individuals express a wide range of sentiments, such as happiness, humor, or anger. Words that are used to express such feelings, might share multiple valences and meanings, depending on the context. Therefore, a sequence of words that is, for example, humorous in a certain context, can be considered offensive in another situation. Such examples can rely on bad jokes regarding a person's position in society, ethnicity, or political ideology. Another characteristic that impacts a text's level of humor is how clear the idea is conveyed to the reader.

In this regard, SemEval-2021 Task 7 - HaHackathon: Detecting and Rating Humor and Offense (Meaney et al., 2021) introduced four sub-tasks: *Task 1a* (classification) includes the class of the text, which can be either humorous or not; *Task 1b* (regression) presents the level of humor as a value between 0 and 5; *Task 1c* (classification) covers the rating of the class of being controversial (i.e., some annotators considered a text to be humorous, while others considered the opposite); *Task 2* (regression) contains the level of offensiveness from the text (i.e., how offensive is the text as an aggregate score agreed by all annotators).

Each example in the dataset contains four labels, one for each task. The labels for Tasks 1b and 1c depend on whether the text contains humor or not. Task 2 is independent of Task 1 and all examples from the dataset have assigned scores corresponding to their level of offensiveness.

In this work, we introduce an adversarial multi-task learning (Liu et al., 2017) architecture to detect humor in texts, as well as other related sub-tasks. We focus on Tasks 1a, 1b, and 2, while using the data for all tasks during training. Our model con-

siders BERTweet (Nguyen et al., 2020) for contextualized embeddings, followed by Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Capsule layers (Sabour et al., 2017) as feature extractors. We observe that adversarial learning increases performance for certain choices of hyper-parameters. Moreover, training the branch for Task 1c on the data for Task 1a improves the performance for Task 1a. In addition, an ensemble method increases the overall performance on all tasks.

The paper is organized as follows. Section 2 presents related work associated with the provided tasks. Section 3 describes our method, followed by details on the experimental setups and results. Finally, Section 5 provides conclusions and future research paths.

## 2 Related Work

Several studies (Roberts et al., 2012; Marasović and Frank, 2018; Zaharia et al., 2020) address the problem of detecting sentiments from texts by using multiple related tasks to further improve the performance of the model. Adversarial multi-task learning was introduced by Liu et al. (2017) and consists of using multiple branches for each individual task (i.e., private branches), and another branch shared among all tasks (i.e., shared branch). A discriminator trained to distinguish between features from multiple tasks is used to separate shared and task-related features in the latent representation from each branch. This is the Adversarial Shared-Private Multi-Task Learning (ASP-MTL) framework that was also employed in other works such as (Marasović and Frank, 2018), where the goal was to label opinions and the associated semantics from texts. Results showed that ASP-MTL might not achieve better results when compared to classical MTL, and there are other factors that should be taken into consideration, such as dataset split and hyper-parameters.

Other works (Zhou et al., 2019; Spiliopoulou et al., 2020) used the multi-task technique alongside adversarial learning, but in other configurations than ASP-MTL. For example, Zhou et al. (2019) employed a model that has a shared feature extractor, and then it is followed by branches for each task with an attention mechanism for the first layer from each branch. By adding new branches to the model, as well as adversarial learning, the F1-score increased when compared to the baseline

model. Spiliopoulou et al. (2020) adopted domain adaptation to improve the performance of a classifier. Their idea was to add a discriminator after the feature extractor, as a separate branch, that is used to distinguish between different domains. The experiments showed that adversarial learning aided in reducing the bias found in the dataset, thus increasing the model’s capability to generalize.

There are multiple Natural Language Processing (NLP) techniques that can be effectively employed to perform text classification in general, as well as sentiment analysis as a specific task (Paraschiv and Cercel, 2019; Tanase et al., 2020b,a; Paraschiv et al., 2020). For example, neural network methods can be used to detect propaganda in articles by pre-training models on related tasks (Vlad et al., 2019) or emotions in memes using multimodal multi-task learning (Vlad et al., 2020a,b). Other methods rely on classical machine learning methods (e.g., Support Vector Machine, Naive Bayes, or Random Forest classifiers) and can be successfully used for related tasks, such as fake news detection, obtaining accuracies over 90% on specific datasets (Dumitru and Rebedea, 2019; Busioc et al., 2020).

## 3 Method

### 3.1 Corpus

The provided dataset for SemEval-2021 Task 7 (Meaney et al., 2021) consists of 10,000 texts (6,179 texts are considered to have humor, while the rest do not present humor), written in English, with different degrees of humor, and labeled by different categories of people; therefore the labeling is highly subjective. Given the texts with humor, the scores for the Task 1b follow a Gaussian distribution, with the mean of 2.24 (out of 5) and the standard deviation of 0.56. Also, approximately 46.39% of the texts for Task 1c were labeled as controversial. Furthermore, 42.46% of the texts were rated as not being offensive at all for the last task, while the 75th percentile is 1.55 (out of 5) for the offensive samples. This means that the data is biased towards not being offensive for the Task 2.

The dataset was already split into train/dev/test sets, such that 8,000 samples were used for training, 1,000 for development, and 1,000 for testing, following similar distributions. Only the entries from training and development sets were provided with annotations during the competition. The annotations for the test set were provided after the evaluation phase ended.

### 3.2 Neural Architecture

An increasing trend of applying adversarial learning alongside MTL leads to improvements in baseline models (Liu et al., 2017; Marasović and Frank, 2018; Srivastava et al., 2020). The underlying intuition for this setting is to concurrently use potential information hidden in the correlation between multiple tasks through MTL, while storing this representation in a shared-private architecture.

Inspired by the three previously mentioned works, Figure 1 shows an overview of our proposed adversarial multi-task learning architecture, namely *AMTL-Humor*. Blue denotes the shared branch among all tasks, whereas task-specific branches are in white. The discriminative part from the network is represented in green.

Figure 1: Overview of the AMTL-Humor architecture.

We employ a pre-trained Transformer-based model (Vaswani et al., 2017) for generating contextualized embeddings, namely BERTweet, which was trained on 850M tweets written in English. The input is preprocessed in the same way as the input on which the Transformer was trained on, by using the TweetTokenizer from NLTK toolkit (Bird et al., 2009). The representation of the input text given by the BERTweet is further fed into five branches. One branch is shared among all other tasks and learns information that is non-task-specific. The output of this branch is concatenated with each

private branch, which is then fed to a linear classifier responsible for outputting the final results. A discriminator classifier takes as input the outputs from all branches before the concatenation, having as goal to learn which representation is from what task. In this scenario, labels concerning the branch from which the discriminator took the values are known.

Each branch is composed of five layers, based on a Recurrent Neural Network (Cho et al., 2014) and Capsule layers (Lei et al., 2019; Srivastava et al., 2020). First, the *Bidirectional LSTM (BiLSTM)* layer acts as a feature extractor and encodes the high-level features. It is used to provide a latent representation of the input space that captures the dependencies from both left-to-right and right-to-left. Second, the *Primary Capsule* layer captures the local order of words in the latent space of the BiLSTM output. It encodes the hidden properties, such as positional information for words and the relations between words, from the latent representation into a vector. Third, the *Convolutional 1D Capsule* layer learns the child-parent relationships and predicts the parent Capsules in the next layer by using a dynamic routing algorithm (Sabour et al., 2017). Fourth, the *Dense (Fully Connected) Capsule* layer takes the output of the previous layer, flattens it into a list of Capsules, and then a Capsule is produced to encode the features and their probability by using routing-by-agreement. Fifth, the *Dense (Fully Connected)* layer is the classical Perceptron that takes as input the representation from the last Capsule layer and computes the final output for that branch (which can be for either classification or regression task).

The idea of using Capsule layers was first introduced in Computer Vision by Sabour et al. (2017) and was studied in various NLP tasks (Yang et al., 2018; Xiao et al., 2018; Wang, 2019; Lei et al., 2019; Srivastava et al., 2020; Zaharia et al., 2020). Capsule networks are based on how human vision works - i.e., Capsules create groups of neurons that are specialized in recognizing certain properties of the input (Sabour et al., 2017).

### 3.3 Optimization Problem

Binary cross-entropy loss is used for the classification problems (i.e., humor classification and humor controversy tasks), while the mean squared error loss function is used for regression tasks (i.e., tasks for predicting humor and offensive scores). Thus,

the loss associated with the tasks is computed as follows:

$$L_{tasks} = \sum_{i=1}^4 \alpha_i L_i \quad (1)$$

where  $\alpha_i$  represents the weight associated with the task  $i$  and  $L_i$  is the loss value for the task  $i$ .

A problem arises when employing standard MTL, namely, there is a high possibility that part of the shared information may arrive inside the task-related space and vice-versa. This problem can be alleviated by using adversarial learning to enforce the network to make the separation between the private and shared representations. Also, a generalization of the loss function (Liu et al., 2017) for training the Generative Adversarial Networks (Goodfellow et al., 2014) is used because we are dealing with multiple tasks, thus multiple classes for the discriminator:

$$L_{Adv} = \min_{\theta_S} \left( \lambda \max_{\theta_D} \left( \sum_{k=1}^5 \sum_{i=1}^{N_k} d_i^k \log[D(E(x^k))]) \right) \right) \quad (2)$$

In order to further ensure the separation between the shared and private branches, we add an orthogonality constraint function (Bousmalis et al., 2016) to the objective function during the training, which is defined as:

$$L_{Diff} = \sum_{k=1}^4 \left\| \left\| S^k \top H^k \right\|_F \right\|^2 \quad (3)$$

where  $S^k$  and  $H^k$  are the outputs of the from each branch, before the final classification layer, and  $\|\cdot\|_F$  is the Frobenius norm.

The total loss for the optimization problem is the sum of all three losses, parametrized by  $\lambda$  and  $\gamma$ , which control the importance for the adversarial and orthogonality losses, respectively:

$$L_{Total} = L_{Tasks} + \lambda L_{Adv} + \gamma L_{Diff} \quad (4)$$

### 3.4 Experimental Settings

#### 3.4.1 Text Preprocessing

The texts were not cleared; as such emojis were transformed into text to be further considered as tokens. The TweetTokenizer applies a normalization step to change noise constructs from the text (e.g., URLs) into special tokens. Missing values were replaced with 0 instead of NaN for Tasks 1b and 1c that depend on whether the text was considered to be humorous or not in Task 1a.

#### 3.4.2 Implementation Details

A public implementation of the Capsule layer<sup>1</sup> was converted from TensorFlow 1.x to TensorFlow 2.4; this updated version was also publicly<sup>2</sup>. Also, the gradient reversal layer (Ganin and Lempitsky, 2015) was used for implementing the adversarial learning between the discriminator and the shared branch, which negates the gradient for the adversarial loss during back-propagation.

The Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001 was considered for training the networks between 10 and 20 epochs, while the batch size was set between 8 and 16. The size of the hidden state for BiLSTMs was set to 128, with a dropout rate of 0.5, as suggested by Srivastava et al. (2014). The number of filters in the Primary Capsule layer was set to 8 and the size of the kernel was set to 3x1. Also, the number of filters in the Convolutional 1D Capsule layer was set to 4 and the size of the kernel was set to 3x1. Moreover, the output size was set to 4x1 for all used Capsules, running the routing-by-agreement algorithm for 3 iterations.

During the experiments, different AMTL-Humor configurations were considered by enabling or disabling adversarial learning, the orthogonality constraints, and different parts of the architecture. Table 1 introduces our configurations, with values lower than 0.5 for hyper-parameters  $\lambda$  and  $\gamma$ , and with conditions concerning adversarial loss being prioritized over the orthogonality loss.

#### 3.4.3 Baseline Models

Two configurations were used as baseline, namely: a) a larger network (i.e., *MTL-Large*) with 512 hidden states for LSTM cells, 16 primary Capsule filters, and 8 filters for the convolutional Capsule layer with 5x1 filters, and b) a smaller model (i.e., *MTL-Small*) with the previously introduced parameters, sharing the same configurations as the other networks we have tested that use adversarial learning. The optimization step does not involve adversarial learning, nor the orthogonality constraints.

#### 3.4.4 AMTL-Humor Variants

Different models based on the ASP-MTL architecture were tested on the provided dataset. Our base model AMTL-Humor has two variants (i.e. *AMTL-*

<sup>1</sup><https://github.com/naturomics/CapsLayer>

<sup>2</sup><https://github.com/razvanalex/CapsLayer>

Model	Adversarial Training	Orthogonality Constraints	Capsule Layers	$\lambda$	$\gamma$
MTL-Large	-	-	-	0	0
MTL-Small	-	-	-	0	0
AMTL-LSTM	✓	✓	-	0.1	0.01
AMTL-Adv	✓	-	✓	0.1	0
AMTL-Humor-1	✓	✓	✓	0.1	0.01
AMTL-Humor-2	✓	✓	✓	0.5	0.1
AMTL-T1a-Twice*	✓	✓	✓	0.05	0.01

Table 1: The settings for each configuration. The star (\*) indicates that the model uses the third branch (i.e., for Task 1c) to solve Task 1a instead. Note that two branches are used for solving Task 1a.

*Humor-1* and *AMTL-Humor-2*), as presented in Table 1. The only difference between these is the choice for the  $\lambda$  and  $\gamma$  parameters. Also, *AMTL-Adv* is a model without orthogonality constraints, whereas *AMTL-LSTM* does not contain the Capsule layers in the architecture. Throughout our experiments, we observed that the network always outputs 0 on Task 1c for all inputs; therefore, the model does not manage to learn anything. As such, the *AMTL-T1a-Twice* configuration uses the Task 1a branch twice for both the first and third branches.

### 3.4.5 Ensembles

Ensemble learning was also considered; the modal value (i.e., the most frequent class) is taken for classification tasks, while the average of scores is used for regression tasks. *Ensemble-1* combines the results obtained by *MTL-Large*, *AMTL-Humor-1*, *AMTL-T1a-Twice*, and *AMTL-Adv* respectively, while *Ensemble-2* adds to the previous list the models *MTL-Small*, *AMTL-LSTM*, and *AMTL-Humor-2*.

### 3.4.6 Evaluation Metrics

F1-score and accuracy were used to evaluate the classification tasks, whereas root mean squared error (RMSE) was used to assess performance on the regression tasks from the SemEval-2021 Task 7 competition.

## 4 Results

Table 2 presents the results obtained on both development and test sets. On the development set, we observe that increasing the values of the parameters impacts more the regression tasks (i.e., higher RMSE values). Using only adversarial learning, without orthogonality constraints seems to add a small improvement in our case. Removing the ad-

versarial learning has a very small negative impact on Task 1a, and a decrease of RMSE for the regression tasks. Removing only the Capsule layers seems to generate an improvement for this development set. The *AMTL-T1a-Twice* configuration achieves the highest F1-score due to the symmetry of our architecture. The increase in performance is notable, more than 2% when compared to *AMTL-Humor-1*.

We observe that our baseline models achieve on the test set similar scores for Task 1a, whereas differences exist for the other two tasks, with no clear better configuration. The larger network tends to learn better on Task 1b, whereas RMSE is worse on Task 2 when compared to *MTL-Small*. All models that use our adversarial multi-task framework show a small improvement over the baselines on Task 2; nevertheless, almost all models perform worse on Task 1b, especially our system (i.e., *AMTL-Humor-1*) that registers the highest RMSE scores. All adversarial models achieve or the Task 1a similar results, or even better when compared to the baseline models, and this was our main focus during the training.

The *AMTL-T1a-Twice* model manages to obtain the highest F1-score on one of the two branches for Task 1a. However, accuracy and F1 scores were low when making predictions for Task 1.c (46.34% and 61.18%, respectively). These low performance values may be indicative of bias in the dataset towards either 0 or missing values for this task.

Ensemble models complement the inner configurations and provide more stable predictions. *Ensemble-1* was the model submitted during the competition for evaluation. The differences between our *Ensemble-1* configuration and the best models reported for each task were the following:

Model	Development Set				Test Set			
	Task 1a		Task 1b	Task 2	Task 1a		Task 1b	Task 2
	F1 (%)	Acc. (%)	RMSE	RMSE	F1 (%)	Acc. (%)	RMSE	RMSE
MTL-Large*	94.80	<b>93.40</b>	0.6434	0.7390	95.05	93.90	0.6359	0.5891
MTL-Small	93.08	90.90	0.6747	0.6649	95.07	93.80	0.6699	0.5796
AMTL-LSTM	94.12	92.50	0.6939	0.6738	95.39	94.30	0.6569	0.5552
AMTL-Adv*	93.52	92.10	0.6979	0.7053	93.61	92.40	0.6882	0.5631
AMTL-Humor-1*	93.27	91.40	0.7294	0.7294	94.93	93.80	0.7116	0.5616
AMTL-Humor-2	93.75	92.10	0.7426	0.6759	95.32	94.30	0.7151	0.5680
AMTL-T1a-Twice	<b>95.88</b>	92.09	0.6977	0.6881	<b>96.29</b>	92.85	0.6774	0.5772
Ensemble-1*	94.05	92.50	<b>0.6361</b>	0.6656	95.66	94.70	0.6200	0.5318
Ensemble-2	94.54	93.10	0.6383	<b>0.6497</b>	95.82	<b>94.90</b>	<b>0.6164</b>	<b>0.5270</b>

Table 2: The results obtained on both development set (left) and test set (right). The best scores are marked in bold. The star (\*) indicates the models we used for the submissions during the evaluation phase.

2.88% less F1-score and 3.5% less accuracy for Task 1a, 0.124 higher RMSE for Task 1b, and 0.119 higher RMSE for Task 2. During the post-evaluation phase, we assessed the Ensemble-2 configuration that performs better than Ensemble-1 on all tasks by a small margin (i.e., less than 1%).

#### 4.1 Visualizations

t-SNE visualizations (Van der Maaten and Hinton, 2008) were considered to better grasp the adequacy of our model. t-SNE is an algorithm used to visualize high-dimensional data into a two-dimensional representation by minimizing the Kullback-Leibler divergence between the joint probability distributions for both lower-dimensional and higher-dimensional data from the input. Since the output from BERTweet has 59,904 dimensions (i.e., 78 tokens in a sequence, each having 768 features given by the hidden units), we first reduced the representation to 100 dimension by applying a Principal Component Analysis (Jolliffe and Cadima, 2016). This way, t-SNE runs faster, without losing too much information when considering the principal components.

The results using the Ensemble-2 configuration are shown in Figure 2 for Tasks 1a, 1b, and 2. Each point represents the embedding of the input sample, while the colors represent the classes or the values for each sample. Based on the ground-truth visualizations (left side), we can observe that the points are not linearly separable. Our best configuration was capable to learn the inner representation of the input data. For the offensive rating task, the examples with higher scores are in the middle of the manifold. We can also observe for the offensive

rating task that the majority of classes are biased towards lower rather than higher values.

## 5 Conclusions and Future Work

In this work, we present AMTL-Humor, an adversarial multi-task learning method to deal with the problem of detecting and rating humor and offense for SemEval-2021 Task 7. More specifically, our model is inspired by the ASP-MTL framework and considers BiLSTM and Capsule layers as feature extractors on top of the BERT layer that provides contextualized embeddings.

Two ensemble models were created using variations of our AMTL-Humor architecture. These configurations were trained either on different settings (such as adversarial learning) or by modifying the structure of the branches. We observed that adversarial learning might perform better than other architectures with similar structures, while considering specific configurations and tasks. Another improvement was observed when the model was trained on two tasks using the same branch, namely the AMTL-T1a-Twice model. This approach of duplicating branches may be used in other context as it adds redundancy to the network and supports generalization. Finally, the best results were obtained by using an ensemble over all trained models.

In the future, we aim to study how performance can be improved, especially on Task 1c, by adapting the hierarchical multi-task learning technique (Søgaard and Goldberg, 2016) to the AMTL-Humor architecture.

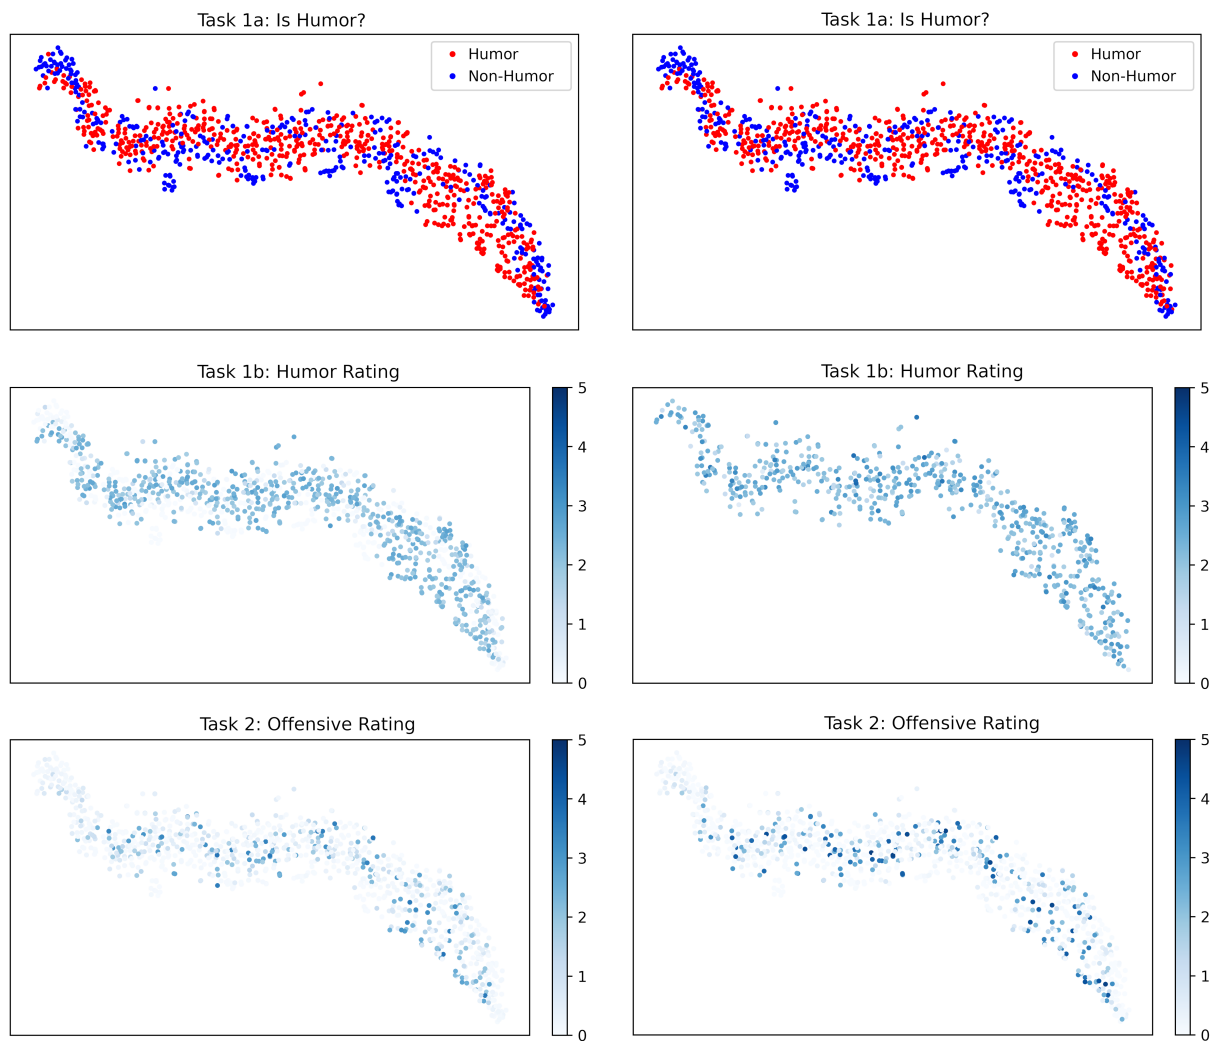

Figure 2: t-SNE projection for the development set data on the output of the BERTweet layer. On left are the plots for predicted outputs, whereas on right are the corresponding plots for ground-truth. Best viewed in color.

## Abstract

This paper describes the system submitted to SemEval-2021 Task-7 for all four subtasks. Two subtasks focus on detecting humor and offense from the text (binary classification). On the other hand, the other two subtasks predict humor and offense ratings of the text (linear regression). In this paper, we present two different types of fine-tuning methods by using *linear layers* and *bi-LSTM* layers on top of the pre-trained BERT model. Results show that our system is able to outperform baseline models by a significant margin. We report F1 scores of 0.90 for the first subtask and 0.53 for the third subtask, while we report an RMSE of 0.57 and 0.58 for the second and fourth subtasks, respectively.

## 1 Introduction

Automatic humor and offense detection have considerable importance in the modern age, especially in chatbots and virtual assistants (Augello et al., 2008). Detection of humor and offense in the text is a highly subjective phenomenon that varies with age, gender, race, socio-economic status, etc. Therefore, it is one of the most challenging research fields in Natural Language Processing (Taylor, 2009).

Task-7 of SemEval 2021 (Meaney et al., 2021) is concerned with humor detection (binary classification) primarily. The first subtask is to check if a text is humorous, another subtask follows up: how humorous is the text (rated from 0-5). We also have to predict whether the text is generally offensive (binary classification task). The last subtask predicts how generally offensive a text is (rated from 0-5), regardless of whether it is classed as humorous or offensive overall. The dataset consists entirely of English texts.

The traditional methods deployed earlier for humor detection include Support Vector Machine

(SVM) with RBF kernel, Random Forest Classifier, and SGD with Logical Classifier, all of which provide modest results (de Oliveira and Rodrigo, 2015). Recently more state-of-the-art transformers have provided better results (Weller and Seppi, 2019). The system presented in this paper is fine-tuning one of the best and most popular state-of-the-art models, Bidirectional Encoder Representations from Transformers (BERT). We have used pre-trained BERT embeddings to represent the words and used the features of the last layer of the 12-layers BERT Model to *detect* and *rate* both *humor* and *offense*. BERT can model complex interactions between different levels of hierarchical information (Tenney et al., 2019). This task is perhaps the first task that focuses on the humor and offense ratings and combines humor and offense detection.

Our model obtained an F1 score of 0.92 and 0.56 for the first and the third subtasks, respectively, on the test data. We obtained an RMSE of 0.57 and 0.58 for the second and fourth subtasks, respectively, on the test data.

The rest of the paper is organized as follows. Section 2 discusses the related work. Section 3 describes the dataset for the task. Section 4 provides the experimental setup and evaluation metric. Section 5 presents the systems implemented to address the task. Section 6 shows the results and Section 7 concludes the paper.

## 2 Related Work

We found the following works very relevant for the task to be addressed, *i.e.*, humor and offense detection.

**Lexical Syntactic Feature (LSF):** This architecture (Chen et al., 2012) was used to detect offensive language in social media. It bridges the gap between message-level and user-level offensive language detection. In particular, this paper

incorporates a user’s writing style, structure, and specific cyberbullying content as features to predict the user’s potentiality to send out offensive content.

**Netflix-style collaborative filtering:** This method (Gultchin et al., 2019) identifies a mean humor direction, analyses sense-of-humor word embeddings to predict individual differences in word humor. It proposes Netflix-style collaborative filtering to predict humor ratings.

**BERT-base and BERT-large:** BERT models have been used previously for automatic humor detection and scoring (Mao and Liu, 2019). The pre-trained model is fine-tuned on the available data, producing appreciable results.

Our system lies in close proximity to the last work. We have fine-tuned a pre-trained BERT model as well. The difference lies in the fine-tuning process. Different approaches have been used to building the neural network, varying from linear layer approach to bi-LSTM approach, for both the classification and regression tasks.

### 3 Dataset

The dataset used in this paper is obtained from Task 7 of SemEval 2021. In this task, the organizers collected labels and ratings from a balanced set of age groups from 18 to 70. The annotators also represented a variety of genders, political stances, and income levels. The training set consists of 8000 texts, and the development and test datasets consist of 1000 texts each. The variation of the number of texts vs. word length of texts is shown in Figure 1.

Figure 1: The distribution of lengths of the texts from the training set.

Each text is represented by a unique ID, and each subtask has a separate column for each text. The annotators were asked:

1. Is the intention of this text to be humorous?
2. (If it is intended to be humorous according to the rater) How humorous do you find it? (1-5)

The annotators could also give a rating of 0 to the second question if they do not get it due to the text’s structure or content. The label of the first task is *is\_humor* and is based on the majority class given by 20 annotators. In case of a tie, the humor label was selected. The humor rating is based on the annotators’ average rating, under the label *humor\_rating*.

Table 1 gives an insight into the distribution of *is\_humor* label. The distribution of *humor\_rating* is shown in Figure 2.

<i>is_humor</i>	No. of texts
0	4932
1	3068

Table 1: The distribution of texts considered either humorous (1) or not (0).

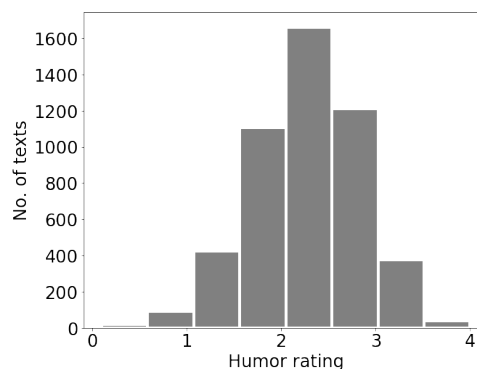

Figure 2: The distribution of *humor\_rating* of the texts from the training set.

The annotators were further asked:

3. Is this text generally offensive? (0 or 1)
4. (If the rater considers the text to be generally offensive) How generally offensive is the text? (1-5)

By generally offensive, the organizers mean that the text targets a person or group for merely belonging to a specific group and ask users if they think that a significant number of people would find this offensive. If the variance of a text was higher than the median variance of all texts, the humor of the text was labeled as controversial under the label *humor\_controversy*. It is a binary classification task.

In the last question, we consider the ratings 1-5 and also consider a no rating to be 0. This score (average of all the ratings) was calculated regardless of whether the text is classed as humorous or offensive overall, under the label *offense\_rating*.

Table 2 gives an insight into the distribution of *humor\_controversy* label. The distribution of *offense\_rating* is shown in Figure 3.

<i>humor_controversy</i>	No. of texts
0	2467
1	2465

Table 2: The distribution of texts considered either offensive (1) or not (0).

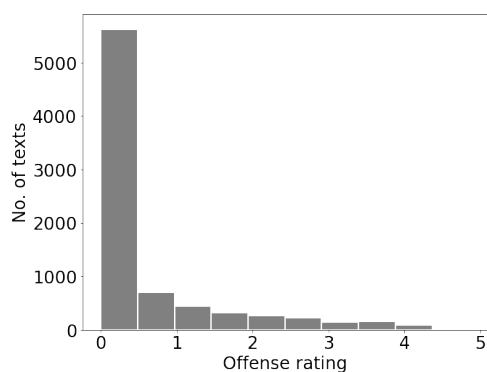

Figure 3: The distribution of *offense\_rating* of the texts from the training set.

## 4 Experimental Setup and Evaluation Metric

**Preprocessing:** A data pipeline preprocesses the raw data to remove irrelevant features. The stop-words and emojis (if any) are removed from the data, and the output of the pipeline is lower-case stemmed word sequences. The stop-words are selected from the NLTK stop-words list (Sarica and Luo, 2020).

**Max Sequence Length:** From Figure 1, we observe that there is no sequence having a length greater than 70 words. So, we restrict our *max\_seq\_length* parameter of the BERT Tokenizer to 70. We pad the sentences to the maximum sequence length.

**Adam Optimizer:** For optimizing the model, we use Adam Optimizer. Adam combines the best properties of the AdaGrad and RMSProp algorithms to provide an optimization algorithm that can handle sparse gradients on noisy problems and

works well on deep neural networks (Zhang, 2018). For subtasks-1 and 3, we used a learning rate of  $2e-5$ , and for subtasks-2 and 4, a learning rate of  $1e-5$  was used.

**Experimental Tools:** We used Google Colab to run the experiments, which provided us GPU to run our model. The external libraries used are publicly available Transformers (version 3.0.0) from the PyTorch HuggingFace API<sup>1</sup> and Python-based Scikit-learn package.

**Evaluation Metric** The metric for the classification tasks (subtask 1 and 3) is F1 score.

$$F_1 = \frac{2 \cdot Precision \cdot Recall}{Precision + Recall} \quad (1)$$

For the regression tasks (subtask 2 and 4), the metric is Root Mean Square Error (RMSE).

$$RMSE = \sqrt{\sum_{i=1}^N \frac{(Predicted_i - Actual_i)^2}{N}} \quad (2)$$

## 5 System

The task organizers suggested the following baseline models:

1. Classification task: For the classification tasks, the baseline strategy is a Naive Bayes model with bag of words features.
2. Regression task: The baseline strategy proposed for the regressions tasks is the Support Vector Regression (SVR) model.

BERT has proven promising for many NLP tasks (Devlin et al., 2019). Our system implements fine-tuning strategies on pre-trained BERT architecture. It is a bidirectional transformer pre-trained using a combination of masked language modeling objective and next sentence prediction on a large corpus comprising the Toronto Book Corpus and Wikipedia.

### 5.1 BERT base model

We have experimented with the BERT-base model from PyTorch HuggingFace API. It is the bare BERT Model (BertModel) transformer outputting raw hidden-states without any specific head on top. The 768 hidden features are extracted from the last layer of the 12-layered BertModel.

<sup>1</sup><https://huggingface.co/>.

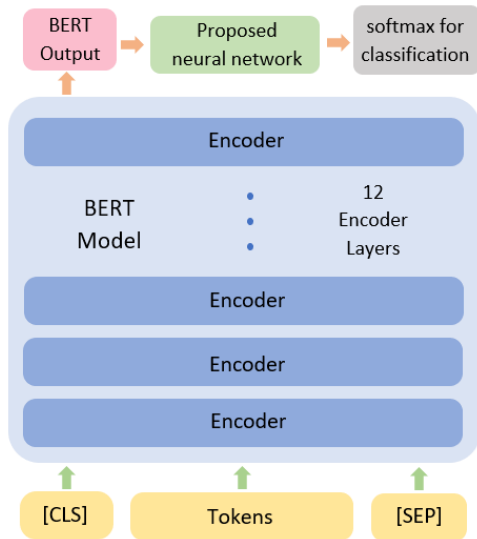

Figure 4: The proposed model architecture for the classification subtasks

### 5.1.1 Classification Tasks

We have experimented with two independent approaches.

- **Linear approach:** After experimenting with single and double layers, we decided to use three linear layers on top of the features, as it produced better results. The layers are of the dimensions  $768 \times 512$ ,  $512 \times 256$ , and  $256 \times 2$  respectively. Rectified linear unit (ReLU) is used as the nonlinear activation function at the first two layers' output, followed by a dropout regularization of 0.1.
- **Bi-LSTM approach:** We use one bi-LSTM (Bi-directional long short term memory) layer of 512 dimensions at first instead of the initial linear layer. We keep the rest of the architecture the same (including the activation and regularization), altering the dimensions as required.

The output layer is a softmax layer for the classification job (for both approaches). The reason behind experimenting with the Bi-LSTM model is that it fully considers the context information and can better obtain the text representation of the comments (Xu et al., 2019).

In the BERT training process, the model receives pairs of sentences as input in a specific format. A [CLS] token is inserted at the beginning of the first sentence and a [SEP] token is inserted at the end of each sentence, with the words in the middle being converted to tokens, as shown in Figure 4.

### 5.1.2 Regression Tasks

Three neural network architectures have been tried on top of the BERT features enumerated below for the regression tasks.

- **3 linear layers:** The same linear layer architecture used for the classification tasks is implemented here; only the dimensions of the last layer are altered appropriately. 3 linear layers of dimensions  $768 \times 512$ ,  $512 \times 256$ , and  $256 \times 1$  respectively are used. ReLU is applied as the activation function at the output of the first two layers, followed by a dropout regularization of 0.1. The loss function used for this regression task is the mean squared error (MSE) loss function.
- **One linear layer:** Only one linear layer is used in this approach of the dimension  $768 \times 1$ . MSE loss function is used for the cross-entropy loss.
- **Bi-LSTM layers:** One bi-LSTM layer of 512 dimensions is applied on top of the extracted features from BertModel. On top of that, a linear layer is used to predict the ratings. The same loss function as used in the first two approaches is applied here.

## 6 Results and Analysis

For each subtask, we trained our data on the entire training set of 8000 texts. We used the development set of 1000 texts as cross-validation data. The results tabulated in this section are reported on the gold test set of 1000 texts.

Each proposed model for all the subtasks was run for 10 epochs with a batch size of 32. Hyper-parameters are discussed in Section 5.

Method	Accuracy	F1 score
Linear approach	0.9030	0.9233
bi-LSTM approach	0.8970	0.9177
Naive Bayes	0.8570	0.8840

Table 3: Accuracy and F1 score for the models trained on the humor classification task

The results of the considered BertModel and baseline methods for the *is\_humor* subtask-1 are summarized in Table 3 in terms of the F1 score and accuracy. Table 4 shows the results of the *humor\_controversy* subtask-3. We observe that the linear approach works better than the bi-LSTM

Method	Accuracy	F1 score
Linear approach	0.5301	0.5628
bi-LSTM approach	0.5203	0.5455
Naive Bayes	0.4374	0.4624

Table 4: Accuracy and F1 score for the models trained on the humor controversy task

approach in both cases. On the other hand, both the proposed models perform better than the baseline model (Naive Bayes with bag of words features).

Method	RMSE
3 linear layers approach	0.5741
Single linear layer approach	0.5847
Bi-LSTM layer approach	0.5694
SVR	0.8609

Table 5: RMSE for the models trained on the humor rating task

Method	RMSE
3 linear layers approach	0.5936
Single linear layer approach	0.6082
Bi-LSTM layer approach	0.5800
SVR	0.6415

Table 6: RMSE for the models trained on the offense rating task

Tables 5 and 6 represent the results of all the three approaches along with the given baseline (SVR) for the regression subtasks in terms of RMSE. Results show that the 3-layered method works better than the single-layer method. We observe that among all three methods, the bi-LSTM approach works the best for both the subtasks. Our proposed methods have significantly lower RMSEs than the baseline SVR model.

In the humor detection subtask, we ranked 48th with the leaders achieving an F1 score of 0.98. We achieved a rank of 23 in the humor rating subtask, leaders getting an RMSE of 0.49. In the humor controversy subtask, the leaders got an F1 score of 0.63, giving us a rank of 15. In the last subtask of offense rating, we achieved a rank of 38, with the leaders getting an RMSE of 0.41.

The section where our model struggles the most is detecting underlying sarcasm in sentences, especially where the context is explored for the first time. For example, in the text: “I asked my

North Korean friend how it was there... he said he couldn’t complain.”, our model classifies the text as not humorous however in the gold set the text has been classified as humorous. This is one of several examples where our classifier mislabeled the text. The same problem exists with other sub-tasks too.

## 7 Conclusion

In this paper, we describe a system developed to address the SemEval Task-7. The task has four subtasks, *viz.*, detecting humor, detecting offense, predicting humor rating, and predicting offense rating. Our system is able to perform all four subtasks with varying levels of performance for each task. Our system deploys linear layers and bi-LSTM layers independently to process the features produced by the BERT model. Results show that our system using BERT with Linear layers outperforms the baseline model by a significant margin for the first and the third subtasks. On the other hand, the bi-LSTM layers-based system gives the best performance for the other two fine-grained rating prediction tasks.

## Abstract

Although humorous language can bring joy to people, it is also easy to cause offense. Therefore, in order to effectively identify whether a sentence is humorous or offensive, the system needs to obtain abundant semantic information. This article introduces the submission of subtask 1 and subtask 2 that we participate in SemEval-2021 Task 7: HaHackathon: Detecting and Rating Humor and Offense, we use a model based on ALBERT that uses ALBERT as the module for extracting text features. We modify the upper layer structure by adding specific networks to better summarize the semantic information. Finally, our system achieves an F-Score of 0.9348 in subtask 1a, RMSE of 0.7214 in subtask 1b, F-Score of 0.4603 in subtask 1c, and RMSE of 0.5204 in subtask 2.

## 1 Introduction

A sense of humor is a positive psychological quality that can make people feel better about themselves, relieve stress, and gain a sense of connection with others. Humor can help bring about happiness experiences and optimism. Humor, by its nature, stirs up emotions. The speaker presents the audience with an unexpected conflict. The audience feels nervous and anticipatory, and at the same time feels pleased and released. Humor is also a highly subjective phenomenon, with age, gender, and socioeconomic status is known to influence the perception of jokes. That's why some things make people laugh and others don't. When the brain lacks the cognitive resources to accurately understand the context in which a joke takes place, it generalizes it into an everyday behavior, and the benign offense becomes hostile aggression. Like most metaphorical languages, humor emphasizes multiple word meanings, cultural knowledge, and pragmatic capabilities, making it a challenging task to detect humor and offense in a sentence.

SemEval-2021 Shared Task 7: HaHackathon: Detecting and Rating Humor and Offense (Meaney et al., 2021) shared task has two subtasks. Subtask 1 emulates previous humor detection tasks in which all ratings were averaged to provide mean classification and rating scores. Subtask 1a: predict if the text would be considered humorous (for an average user). This is a binary task. Subtask 1b: if the text is classed as humorous, predict how humorous it is (for an average user). The values vary between 0 and 5. Subtask 1c: if the text is classed as humorous, predict if the humor rating would be considered controversial, i.e. the variance of the rating between annotators is higher than the median. This is a binary task. Subtask 2 aims to predict how offensive a text would be (for an average user) with values between 0 and 5. This score was calculated regardless of whether the text is classed as humorous or offensive overall.

In this paper, we use ALBERT: A Lite BERT for self-supervised Learning of Language (Lan et al., 2019) as the module for extracting sentence semantic information. The features extracted by ALBERT are then further processed through a specific structure. Besides, for subtasks 1a and 1c, since it is a binary classification problem, we use k-fold stratified sampling to reinforce the training process. The rest of the paper is organized as follows. Part 2 gives a brief introduction to the relevant work. Part 3 describes the dataset and our approach. Part 4 describes the hyperparameters of the study method used and our results. Finally, the fifth part summarizes our work.

## 2 Related Work

Computational research in the field of humor detection has been going on for some time, and the diversity of tasks allows for different analyses according to the type and expression of humor. In

previous shared tasks, T3 team (Vanroy et al., 2020) used the pre-trained language model Roberta in the SemEval-2020 shared task7 on Assessing the Fun-  
 niness of Edited News Headlines (Hossain et al., 2020) to learn the latent features in news headlines and predict how funny each headline is. UniTue-  
 bingenCL team (Ammer and Grüner, 2020) used a Ridge Regression model using Elmo and Glove embeddings as well as Truncated Singular Value  
 Decomposition at SemEval-2020 Task 7: Humor  
 Detection in News Headlines. Humor and emotions  
 such as offense and hatred are not only different but  
 also related to one another. It is often challenging  
 to classify them accurately. Badlani et al. (2019)  
 proposed a composite two-step model. In the first  
 step, features related to irony, humor, hate speech,  
 and emotion are extracted, and in the second step,  
 these features are combined to classify emotions.  
 This multi-step method is better than a single step.  
 Models that predict sentiment have better empirical  
 performance in sentiment classification.

Sentiment analysis of humor data requires a  
 deep semantic understanding of the text, and sig-  
 nals of nuances in the language may enhance or  
 completely change the sentiment of the sentence.  
 Morales and Zhai (2017) proposed a generative lan-  
 guage model based on incongruity theory to model  
 humorous text, using background text sources, such  
 as Wikipedia entry descriptions, and being able to  
 construct multiple features to identify humorous  
 comments. Besides, Deep Learning (DL) (Good-  
 fellow et al., 2016) methods of multi-layer Neural  
 Networks (NN) (Mikolov et al., 2011) stacked was  
 also a common method. Ortega-Bueno et al. (2018)  
 used a recurrent neural network(RNN) (Mikolov  
 et al., 2010) that combines language features and  
 attention-based to classify Spanish tweets as hu-  
 morous or not and predict how funny they are. The  
 attention (Vaswani et al., 2017) layer helps calcu-  
 late the contribution of each term to the target hu-  
 mor category. In recent years, various pre-training  
 models based on Transformer have shown outstand-  
 ing performance, and some researchers have also  
 applied them in the field of humor detection. Weller  
 and Seppi (2019) used a Transformer framework  
 to evaluate whether a joke was humorous, and per-  
 formed well on the short joke and pun datasets.

Figure 1: K-fold stratified sampling to the training set

### 3 Methodology and Data

#### 3.1 Data description

The organizer of Semeval-2021 Shared Task 7 provided a complete training data set for our system, including 8000 pieces of data for the training set, 1000 for the validation set, and 1000 for the test set. Each piece of data has four tags.

In our experiment, for subtasks 1a and 1c, we use a Stratified-K-fold technique to randomly segment all combined training datasets. As shown in Figure 1, we use the Stratified-K-fold cross-validation instead of the ordinary K-fold cross-validation. Stratified-K-fold can ensure that the proportion of each class in the generated training set and validation set is consistent with the original training set, thus avoiding the generated data distribution disorder. In this experiment, we set the value of K as 5.

#### 3.2 Description of the system

Our model is one based on ALBERT, which is shown in Figure 2. BERT (Devlin et al., 2018) has good performance, but too many parameters and long training time are also its disadvantages. ALBERT is designed by Google mainly to solve the problem of BERT, which is a simplified model based on BERT. ALBERT solves these problems by using two parameter reduction techniques, one of them is cross-layer parameter sharing, in order to avoid quantity increases along with the network depth; factorized embedding parameterization is another approach, by putting a big word embedded matrix is decomposed into two small matrix makes the relationship between the size of the hidden layer and dictionary apart, thus, when the size of the hidden layer is increased, the parameter size of

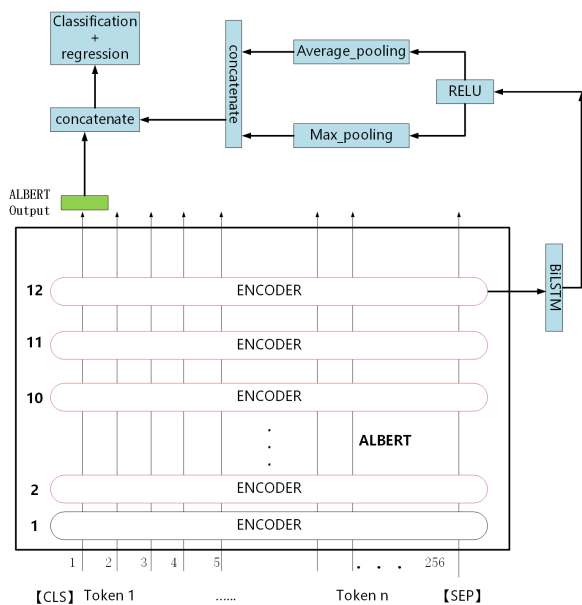

Figure 2: Schematic overview of the architecture of our model

the vocabulary embedding will not be significantly increased.

We input the preprocessed text into the model through the input layer, and then carry out vector representation. Position vector representation, text vector representation, and word vector representation make up the vector representation. Then the ALBERT model takes the sum of the input embedding, position encoding, and token type embedding as input, which is further processed by the Transformer Encoder module. After that, we input the output of the last ALBERT hidden layers into BiLSTM. Then, through the Relu function, the vector is nonlinearly mapped to the lower dimension. After average pooling and maximum pooling are achieved to obtain the feature vector, we concatenate the average pooling and maximum pooling output. Finally, the feature vector will concatenate with the original output of ALBERT, the classification or regression task is then performed.

## 4 Experiment and results

### 4.1 Experiment setting

In this experiment, `albert_base_v2` is used. After adding a new module based on ALBERT, the whole model is fine-tuned. The main hyper-parameters we adjust are the maximum sequence length, the learning rate, the gradient accumulation steps, and batch size. As is shown in Table 1.

<b>maximum sequence length</b>	<b>learning rate</b>
128	2e-5
<b>gradient accumulation</b>	<b>steps batch size</b>
4	4

Table 1: Details of the hyper-parameters.

<b>Team Name: ZYJ</b>	
<b>Task 1a Humor Detection</b>

0.4603	33
<b>Task 2 Average Offensiveness Score</b>	
RMSE	Rank
0.5204	31

Table 2: The results of our methods.

## 4.2 Results

According to the leaderboard provided by the organizer, our team's F-score is 0.9348, ranking 41st place in subtask 1a Humor Detection. RMSE is 0.7214, ranking 43rd place in subtask 1b Average Humor Score. F-Score is 0.4603, ranking 33rd place in subtask 1c Humor Controversy. RMSE is 0.5204, ranking 31st place in subtask 2 Average Offensiveness Score. As shown in Table 2.

## 5 Conclusion

In this task, we detect and rate humor and offense using a deep-learning-based model. In the construction of the model, we use ALBERT as a module of the model and add a custom network structure to further process the extracted feature vector. As for the classification task, we perform Stratified-K-Fold cross-validation based on the model and get the optimal value through the voting mechanism. Although our system has fewer parameters and is easier to train, the performance needs to be improved. In future work, we will further optimize the system structure, so that the model can obtain rich semantic information characteristics.

## Abstract

Humor detection is an interesting but difficult task in NLP. Humor might not be obvious in text because it may be embedded into context, hide behind the literal meaning of the phrase and require prior knowledge to understand. We explored different shallow and deep methods to create a humour detection classifier for task 7-1a. Models like Logistic Regression, LSTM, MLP, CNN were used, and pre-trained models like DistilBERT were introduced to generate accurate vector representation for textual data. We focused on applying a multi-scale strategy on modelling, and compared different models. Our best model is the DistilBERT+MultiScale CNN which used different sizes of CNN kernel to get multiple scales of features. This method achieved 93.7% F1-score and 92.1% accuracy on the test set.

## 1 Introduction

Humor detection is an interesting but difficult task in Natural language processing (NLP) and requires various techniques to understand the meaning of a sentence and identify humor. For example, humour by sarcasm can mean that a piece of text can have two very different meanings and the NLP algorithm needs to be able to understand which meaning is intended.

The aim of task 7-1a of SemEval 2021 (Meaney et al., 2021) was to address the challenge of classifying humour in text. Provided for this task was a dataset constructed of short phrases in English along with a label classifying whether or not each phrase is intended to be humorous. The labels have been obtained by surveying a group of people that represent a variety of genders, political stances and income levels. The given dataset includes training set with 8000 labeled sentences, a development set of 1000 sentences and a test set of 1000 sentences.

The dataset was made up of English phrases that were labeled by their intent to be humorous. This means the label annotators were not saying whether or not they found the text funny but whether the writer of the text intended it to be funny. The texts were predominantly one sentence long with a small proportion being two or three sentences. Each phrase was labeled for humour intent and, if humour was intended, then a rating was given for how funny it is. Also of the texts intended to be humorous, a label was given for whether it is offensive, and if so, how offensive it is.

The texts covered a range of types of jokes such as puns, sarcasm, dark jokes and “Dad” jokes. One example is “I never finish anything. I have a black belt in partial arts.” which contains a pun and is labeled as humorous.

Our best approach is DistilBERT+MultiScale CNN. It introduced a pre-trained DistilBERT model to extract textual features, and created a multi-scale CNN model for humour classification. First, the DistilBERT tokenizer generated a word token vector and an attention mask vector for each sentence. Then, we fed these vectors into a pre-trained DistilBERT model to get hidden features. After that, five CNN layers with different kernel sizes were used to get features of different scales. Each feature vector was subsequently concatenated together. Finally, the fused features were fed into dense layers in order to classify text into humorous or not humorous classes. It achieved 93.66% of F1 score and 92.10% of accuracy in using test set.

## 2 Related Work

We used four shallow models as a benchmark for our main approach. The first method was K-nearest neighbors (KNN) (Fix, 1951) in which an unlabeled query point is given the label of the majority of the K neighboring points. The second method

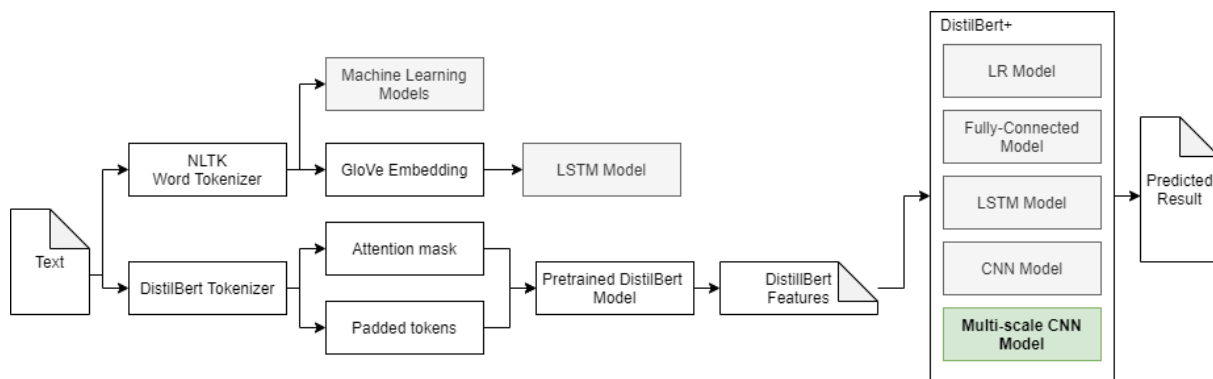

Figure 1: Pipeline of our experimental process

is Naive Bayes (Sammut C., 2011a) which utilizes Bayes rule together with a strong assumption that the attributes are conditionally independent. The third is a random forest (Sammut C., 2011b) which is an ensemble of decision trees trained on a bootstrap sample from the original dataset. The fourth method is the support vector machine (SVM) (Burges, 1998) which transforms the input data to a higher dimensional space and seeks to define a hyper-plane separating the classes. We also implemented voting to combine these methods where the prediction of the voting is simply the majority label predicted by the shallow models.

We also tried deep models. Long short-term memory (LSTM) is a very effective Recurrent neural networks for processing sequence data, which considers long and short term memory over time (Hochreiter and Schmidhuber, 1997). Convolutional Neural Network (CNN) uses a convolution kernel to extract hidden features from input, which is widely used in the field of computer vision (Le-Cun et al., 2010). 1-dimension CNN layer can fit with sequence data, so it can be used to extract textual features.

Transfer learning methods are widely used in the field of NLP. Pre-trained word embeddings are usually trained on unlabelled dataset and maps each word token into a fixed vector representing the meaning of the word in a hidden space. For example, Global Vectors for Word Representation (GloVe) is trained on a 6 billion word corpus using an unsupervised learning method in order to find word co-occurrence (Pennington et al., 2014).

Unlike conventional embeddings, contextualized embeddings dynamically map a word token into vectors based on the context using a pre-trained encoder. By extracting the features and adapting new data to the model, we can implement general down-

stream tasks based on the pre-trained model. BERT uses a deep Transformer as its encoder, and trains on language modelling tasks and next sentence prediction, which is often used in NLP with excellent performance (Tenney et al., 2019). DistilBERT uses knowledge distillation method to compress the model, which retains 97% of the performance of original BERT but is 60% faster (Sanh et al., 2020).

### 3 System Overview

In our BERT-based models, we used DistilBERT which is a light version of BERT to extract textual features. The BERT model is a transformer-based model, which is pretrained on vast amounts of textual data in language modelling tasks (Sanh et al., 2020). Therefore, the weights in the BERT model, which contains semantic information, can be used as contextualized embedding for general purposes. It can better represent textual data than a random tokenizer. Due to hardware limits, we only used the DistilBERT uncased base model in our system. It retains 97% performance of the original BERT but is 60% faster (Sanh et al., 2020). For comparison, we also used GloVe pretrained embedding to represent text and created a 2-layer LSTM model as our baseline. Shallow machine learning models were also explored for comparison. Figure 1 shows the pipeline of our experimental process.

Regarding feature extraction, we first used the DistilBERT tokenizer to vectorize the textual data then padded them into the same size. An attention mask was built to use binary vectors to differentiate padded zeros and word tokens. The vectors and mask were fed into the BERT model, and we stored the output of the last layer as the representation of text. Because the task was a text classification problem, we only used the “[CLS]” value in the text

representation for Logistic Regression (LR) and LSTM model, which was the first vector of each row. The length of each text representation was 768. For example, the sentence "Told my mom I hit 1200 Twitter..." was firstly tokenized into vectors "[101, 2409, 2026, 3566, 1045, 2718, 14840, 10474...]", and the [CLS] vector of DistilBERT output of this sentence was "[6.7492e-02, -1.6599e-01, 1.0417e-01, ...]", which had length of 768. For the Fully Connected (FC) model and all CNN models, we used the full output of the DistilBERT model as features, which were in shape of 136 x 768.

After extracting the features, we applied different models to predict the humor class. First, we implemented the LR model with default parameters. The package scikit-learn was used to build and train linear shallow models, such as LR, KNN, naive Bayes, random forest, and SVM. And then, we created a LSTM model. It consisted of two 32-node LSTM layers and a 32-node fully-connected layer. Also, we built a fully connected network, which had a 128-node dense layer and 64-node dense layer. In addition, we tried a CNN model which contained 2 64-node CNN-1D layer and a 128-node dense layer. For each network, we took the extracted features as input, and used a 1-node dense layer with sigmoid activation to collect output. In addition, dropout layers were used in each model to handle over-fitting problems.

For comparison, we also implemented a GloVe based LSTM. NLTK module was used to tokenize sentences and remove stop words and special characters. GloVe (Pennington et al., 2014) is pre-trained word vectors representation, which was used as the initial weights of the embedding layer. The GloVe+LSTM model used 50-dim embedding which connected to two 32-node LSTM layers. The output of LSTM was flattened and then fed into 16-node fully connected layer. And a 1-node dense layer with sigmoid activation was used to output probability of humorous class. It used the same model compiling parameters as the DistilBERT-based models.

Moreover, previous research proved that multiple scale of CNN layers can capture hidden features in different granularity, which improves performance (Cui et al., 2016; Yuan et al., 2018). Therefore, we build two multi-scale CNN models. The first model is DistilBERT+MultiScale CNN, Figure 2 shows its structure. It used five 64-node CNN-1D layers with different kernel size of [1, 2, 3, 4, 5].

These 5 layers could extract hidden information from the features in various granularity. Each CNN layer was then connected to a GlobalMaxPool1D layer to get a down-sampled representation in the shape of (batch size, 64). Also, dropout layers were applied on each output, and the 5 outputs were concatenated to a single vector in the shape of (batch size, 320). Subsequently, the combined vector was fed into a 512-node fully-connected layer. Rectify Linear Unit (ReLU) activation functions were applied to all CNN and fully-connected layers. Finally, a 1-node fully-connected layer with sigmoid activation function was added at the end of the network to collect the output value. We used 0.5 as a threshold to categorise the probability value into 0 (not humorous) and 1 (humorous) categories. In addition, we used "rmsprop" optimizer and binary cross entropy loss for stochastic gradient descent optimization.

In addition, we tried other multi-scale strategies, inspired by the deep multi-scale fusion hashing model (Nie et al., 2021). To differentiate two multi-scale models, we called this one MultiPool CNN. It used 5 different kernel size of MaxPooling layers to scale input features into different resolution. For each Maxpooling layer we set strides to 1 and used "valid" padding methods, and it connected to a 64-node CNN-1D layer with a kernel size of 1 and ReLu activation. Therefore, 5 CNN layers can extract features from different resolution of input. Similar to the multi-scale CNN, each output subsequently connected to a GlobalMaxPool1D layer and dropout layer. Finally, 5 different outputs were concatenated together and fed into a 512-node fully-connected layer. The output layer and compiling method are the same as the multi-scale CNN model.

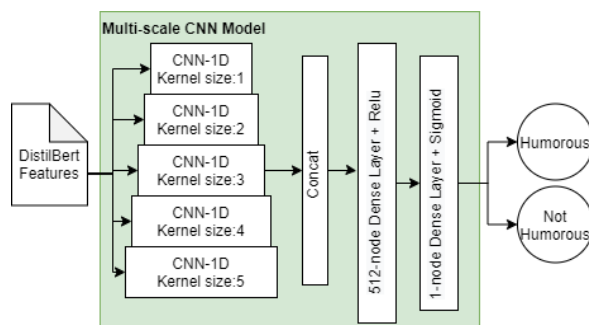

Figure 2: Structure of DistilBERT+Multi-Scale CNN

Model	F1@Dev	Accuracy@Dev	F1@Test	Accuracy@Test

Table 1: Evaluation results of various implemented models on the dev set and test set (the gold data)

## 4 Experimental setup

We implemented our experiments on the university’s virtual machine, which has a python environment with a shared 16 GB Tesla v100 GPU. Tensorflow 2.0 and Keras were used to build neural networks. Python “transformers” module was used to import the DistilBERT model. “Pandas” and “Numpy” modules were utilised to manipulate data, and we used “scikit-learn” to import basic machine learning models and evaluation metrics.

Moreover, we used the training set to train our models and took 20% split of training set as validation set to tune hyper-parameter in development stage. The dev set was used to assess performance of models in evaluation stage, and we applied our models on test set in order to submit results. In data preprocessing, we load the data into a pandas data frame, and tried to remove all the tags and special characters in the text. After that, we used the DistilBERT tokenizer to vectorise and encode the text into the format that the DistilBERT model required. In all the models, we set 1 and 2 as random seeds for Numpy and TensorFlow respectively. Also, we used early stopping strategy when training models. All DistilBERT based neural network models were stopped at 23 epochs. Also, the batch size was set to 64.

Regarding evaluation, we evaluated our model on dev set and test set (gold data). F1 score and accuracy were used to evaluate performance. The accuracy score shows the ratio of correct prediction. Since the F1 score considers both precision and recall, which would be more informative metric, we selected our model based on the F1 score.

## 5 Results

We found that the features extracted by DistilBERT boosts the model performance significantly and it is difficult to generate a good results without using a pre-trained embedding or model. Due to hardware limits, we only tried the light version of BERT, and only implemented shallow layer models. Our official submission used DistilBERT+FC model, which achieved 92.41% F1-score and ranked 47th in task 7-1a. We modified our model in post-evaluation stage, and our best model is DistilBERT+Multi-scale CNN, which had 93.66% of F1 score and 92.10% of accuracy in using test set. The given official baseline is 85.7% of F1 score and 88.4% of accuracy. All of our DistilBERT based models and one GloVe embedding based model had better performance than the baseline. Detailed evaluation scores on dev set and test set were included in Table 1.

In comparison, the SVM model achieved an F1-score of 85.04% and an accuracy 81.70% on the test set, which is our best shallow model. However, all of these model generated scores lower than the given baseline.

Also, our GloVe-based LSTM model achieved 88.5% F1-score, and DistilBERT-based LSTM achieved 89.6%. It makes sense that transformer-based pretrained representation is better than traditional pretrained embedding. Due to efficiency considerations, we only used 32 nodes in the LSTM layer. So, these two models have poorer performance than other models using more nodes. Even the DistilBERT+LR model has higher F1 score (90.4%) and accuracy (88.0%). Surprisingly, a

	Not Humorous	Humorous
Not Humorous	337	48
Humorous	31	584

Table 2: Confusion matrix of DistilBERT+MultiScale CNN’s result

simple 2-layer fully connected network achieved 92.5% F1 on test set. But in the dev set, DistilBERT+CNN outperformed the DistilBERT+FC model. The CNN model had more stable performance, which achieved 90.7% F1 in both dev and test set. Because we used the same epochs for all models, CNN may converge better than the fully-connected model. The multi-scale strategy further improved the performance of the CNN model, which is our best model.

However, our best model still made mistakes on predicting humorous classes of a few sentences. An error analysis is helpful to understand the wrong predictions. In the prediction results of the DistilBERT+MultiScale CNN model, 79 out of 1000 sentences are incorrectly predicted. The Table 2 is a confusion matrix of the result. It shows that 48 predictions were false positive, which assigned a Not-Humorous sentence into the Humorous class. For example, ”I think in order to have a great business you have to like the product you’re selling more than the money you get.”, this sentence is misclassified as humorous. Also, 31 sentences are false negatives. Those sentences are labeled as humorous but ignored by our model. For example, ”If alcohol influences short-term memory, what does alcohol do?”, and ”And then there’s my dad...????”. Those sentences hide the humor within the context, which is hard for a model to detect. Some of sentences are also difficult for us to understand why they are humorous. Since the humor labels were created based on subjective judgement, even human beings would have diverse opinions and understanding.

## 6 Conclusions

To conclude, we explored various methods to build humour detection classifiers for task 7-1a. Models like Logistic Regression, LSTM, FC, CNN were used, and pre-trained models like DistilBERT were introduced to generate an accurate vector representation for textual data. Our best model is the DistilBERT+MultiScale CNN, which achieved 93.7% F1-score and 92.1% accuracy on the test set. We

focused on applying multi-scale strategy on modelling, and compared different models. And our results shows that CNN are more suitable for this task than LSTM FC and other shallow models. Also, we found that pre-trained embeddings, weights or representations are crucial for our model performance. We only explored multi-scale from the wide dimension, this strategy can also be used in deep dimension. In the future, a deeper network with more nodes can be explored and the full version of BERT model can be exploited.

## Abstract

This paper describes the system used for detecting humor in text. The system developed by the team TECHSSN uses binary classification techniques to classify the text. The data undergoes preprocessing and is given to ColBERT (Contextualized Late Interaction over BERT), a modification of Bidirectional Encoder Representations from Transformers (BERT). The model is re-trained and the weights are learned for the dataset. This system was developed for the task 7 of the competition, SemEval 2021.

## 1 Introduction

Natural language processing faces the challenges working with humor as it is a highly subjective phenomena and the age, gender and socio-economic status are known to have an impact on the perception of the joke. It usually involves multiple word senses and cultural knowledge to appreciate humor to its best. Now a days chatbots and virtual assistants require automated humor detection systems for a better interaction with the user by understanding what a human-like approach to humor is. It is crucial to understand the real motive of the user and provide appropriate answer to have a better experience of the user with the virtual assistants (Chen and Soo, 2018). Based on the general linguistic structure of humor, we propose an approach for detecting humor in short texts using ColBERT in this paper.

We have developed a system in the name of TechSSN for previous SemEval tasks (Sivanaiah et al., 2020; Logesh et al., 2019) for offensive language detection using various machine learning and deep learning networks. In SemEval 2021, we participated in subtask-1a and

1c of humor and offensiveness detection in task 7- HaHackathon (Meaney et al., 2021).

## 2 Related Work

Continuous research is going on in this field of humor detection and the systems are getting better every year. De Oliveira and Rodrigo (2015) developed a model for humor detection in Yelp reviews and used convolutional networks with a maximum of 81.57% accuracy.

The system developed by Ortega-Bueno et al. (2018) used UO\_UPV, a Attention-based Long Short-Term Memory Network. The model consists of a Bidirectional LSTM neural network with an attention mechanism that allows to estimate the importance of each word and then, this context vector is used with another LSTM model to estimate whether the tweet is humorous or not. The F1 score for this system is approximately 0.78 with accuracy, 0.84.

Mao and Liu (2019) developed a system with BERT, a multi-layer bidirectional transformer encoder which can help to learn deep bidirectional representations, and the pretrained model is fine-tuned on training data. Their best F1 Score on the test set is 0.784.

Risch et al. (2020) explained the need and various methods used for offensive language detection. BERT model is used with transfer learning for the offensiveness detection by (Liu et al., 2019) with F1 score as 0.8286 and accuracy as 0.8628.

## 3 Methodology

ColBERT base model is chosen for humor text classification which has 8 layers with the last layer's activation function as the sigmoid func-

tion, as it is performing binary classification. The remaining layers have ReLU activation function.

### 3.1 Model Architecture

This classification model uses a separate line of hidden layers especially designed to extract features from each sentence. The used model is a neural network that includes two parallel lines of hidden layers: One to view text as a whole and another to view each sentence separately. Figure 1 displays the architecture of the proposed method.

First, to assess each sentence separately and extract numerical features, the sentences are separated and are tokenized individually. To prepare these textual parts as proper numerical inputs for the neural network, they are encoded using BERT sentence embedding (Devlin et al., 2018). This step is performed individually on each sentence and also on the whole text (shown in Figure 1). As we get the BERT sentence embedding for each sentence, they are fed into the parallel hidden layers of the neural network to extract mid-level features for each sentence (could be related to context, type of sentence, etc). The vector size obtained from this layer for each sentence is 20.

While the main idea is to detect relationships between sentences (especially with punchline), it is also essential to find out the word-level connections in the whole text (such as synonyms and antonyms). Identifying this relation will have meaningful impacts in determining congruity of the text. Similar to the previous step, we feed BERT sentence embedding for the whole text into hidden layers of the neural network. The vector size is 60. Finally, there are three sequential layers in the neural network model. These final layers combine the output of all previous lines of hidden layers in order to return the final output. These final layers are used to determine the congruity of sentences and detect the transformation of reader’s viewpoint after reading the punchline.

Figure 1: Model Architecture

### 3.2 Dataset Collection

For building the model we have used the training dataset provided by the organizers of the Hahackathon - (Meaney et al., 2021). This dataset has 8000 instances of which 4932 belong to humor class and 3068 belong to non-humor class. Out of the 4932 humor instances, 2465 are controversial and 2467 are not controversial. Each instance in the dataset has four features: `is_humor`, `humor_rating`, `humor_controversy` and `offense_rating`. We have trained our model for the classification features only; `is_humor` and `humor_controversy`. Both features have binary values.

### 3.3 Data Preprocessing and Tokenization

For data preprocessing the function `convert_to_transformer_inputs` is used to convert the tokenized input into ids, masks and segments for the transformer. The tokenization of the dataframe columns is done by the function

*compute\_input\_arrays*. BERT Tokenizer pre-trained on the ‘BERT-base-uncased’ model is used for tokenization. The maximum sequence length for reading the data is set as 200 that will be used as the input to BERT.

### 3.4 Model Creation

For the model we have used BERT-base. We use a function *create\_model* that has the architecture which is used to fine tune BERT to our chosen dataset, and we compute the competition metric for the validation set with the help of the function spearman rank correlation coefficient.

### 3.5 Training, Cross Validation and Testing

The model is trained with cross validation for 3 epochs with a learning rate of  $3e-5$  and the size of each batch is 6. As we have performed binary classification for the humor detection task, we have set the loss function as a simple binary crossentropy.

## 4 Results and Discussion

The test dataset given by SemEval organisers (gold-test-27446.csv) was tested on different models and the F1 score for all these models are discussed in the following sections.

### 4.1 ColBERT

We have used Contextualized Late Interaction over BERT (ColBERT) (Khattab and Zaharia, 2020). ColBERT differs by providing a late interaction architecture that independently encodes the query and the document using BERT. It then uses a powerful interaction step that analyze their similarity in a fine grained mode. Eventhough the interaction learning is delayed it also maintains this fine-granular interaction in a better manner. ColBERT can leverage the expressiveness of deep language models and simultaneously gaining the ability to pre-compute document representations in an of-line structure. This will speed up query processing since the representations are learnt in offline. Beyond reducing the cost of re-ranking the documents retrieved by a traditional model,

ColBERT’s pruning-friendly interaction mechanism enables leveraging vector-similarity indexes for end-to-end retrieval directly from a large document collection.

### 4.2 Decision Tree

Decision tree (DT) is a popular supervised technique used for classification problems. It identifies the relation between the features and form the set of rules that can be used to classify the given data into any one of the class labels. The method uses the train dataset to generate branch-like segments that construct an inverted tree with a root node, internal nodes, and leaf nodes.

### 4.3 SVM

Support Vector Machine (SVM) is a supervised machine learning technique used for both classification or regression problems. It uses the concepts of separating the classes using maximal margin hyperplane. We fed pre-processed data into Support Vector Classifier (SVC) with Gaussian Radial Basis (RBF) kernel for training and testing.

Table 1 shows the F1 score and accuracy for the best, baseline and our approach.

No.	System	F1	Accuracy
1	Best Approach	0.982	0.9854
2	Baseline	0.857	0.848
3	Our Approach	0.884	0.9081

Table 1: Official results of the humor detection task

Figure 2 shows the F1 score and the accuracy for the various models we tested for humor detection. ColBERT model provides better accuracy when compared to decision tree and support vector machine models.

No.	Model	F1	Accuracy
1	ColBERT	0.884	0.9081
2	SVM	0.747	0.617
3	Decision Tree	0.736	0.62

Table 2: Results for various models used for humor detection

The humor testset contains 1000 instances of which 615 are humorous and 385 are not. The confusion matrix for ColBERT model is given in Table 3.

		Actual	
		Humor	Not
Predicted	Humor	553	30
	Not	62	355
	Total	615	385

Table 3: Confusion matrix of ColBERT for humor detection

There are 279 offensive texts and 336 non offensive texts in 615 humor instances. Table 4 shows the results for ColBERT and SVM model used for humor controversy or offensiveness detection.

No.	Model	F1	Accuracy
1	ColBERT	0.53	0.56
2	SVM	0.487	0.530

Table 4: Results for various models used for humor controversy detection

## 5 Conclusion

There is a lot of demand for automatic humor detecting systems in the market as it can be used in chatbots and AI assistants to achieve human-like experience while talking to a machine. SemEval-2021 task 7 involves a subtask-1a as identifying humor in text. A modification of the BERT called ColBERT is used to classify such text sentences into humorous or not. ColBERT is a 8-layer model with 110M parameters outperforms the machine learning models we tested with a large margin, showing the importance of utilizing linguistic structure. The preprocessing techniques can be enhanced to get better accuracy.

## Abstract

This paper describes our submission to the SemEval’21: Task 7- HaHackathon: Detecting and Rating Humor and Offense. In this challenge, we explore intermediate finetuning, backtranslation augmentation, multitask learning, and ensembling of different language models. Curiously, intermediate finetuning and backtranslation do not improve performance, while multitask learning and ensembling do improve performance. We explore why intermediate finetuning and backtranslation do not provide the same benefit as on other natural language processing tasks and offer insight into the errors that our model makes. Our best performing system ranks 7th on Task 1b with an RMSE of 0.5339.

## 1 Introduction

With the advancement in deep learning methods, NLP tasks like sentiment analysis and opinion mining have achieved high accuracy, however detection of some salient forms of figurative language such as humor remain difficult tasks.

Being able to infer humor and offense with a high accuracy can help improve and lead to better performance on downstream applications, such as content moderation, sentiment analysis, etc. This would be useful for various downstream applications, such as understanding tweets, reviews and feedback. However, humor detection is not trivial.

What makes identifying humor hard? Humor can consist of styles ranging from sarcastic to slapstick comedy, and it factors in both individual preferences and underlying cultures. Context, sounds, and vision or any combination of these can be key in building to a punchline (Cai, 2019). Humor appreciation is also highly subjective, as age, gender, and socio-economic status often impact the perception of a joke. Meaney (2020) identify 3 ways that classification of humor is difficult:

- (1) Humor can differ between cultures,
- (2) Humor can also differ within cultures, and
- (3) Humor differs within the same person.

Our contributions are as follows: (1) we explore whether intermediate finetuning on other humor and offense datasets is helpful for this task, (2) we seek to identify if backtranslation augmentation is useful for humor detection, (3) we show that multitask learning is helpful when classifying and scoring both humor and offense, and (4) we find that ensembling different language models leads to improved results on some tasks. The code for our experiments is available at our Github repository<sup>1</sup>.

## 2 Related Work

The challenge of humor detection has gained traction since 2017. Meaney (2020), explains in their proposal that prior work has explored humor detection as an objective task, averaging all annotations for a joke, to produce a single classification or rating. This treats humor as an objective concept, which is not the case. This motivated their challenge for SemEval’21 (Meaney et al., 2021) to explore these dimensions of humor and offense. We discuss some of the previous efforts to explore humor and offensiveness in the following paragraphs.

Badlani et al. (2019) explains how text in reviews is quite complex as they can be sarcastic, humorous, or hateful. An ordinary sentiment analysis would fail to perform well in such cases. They first extract features pertaining to sarcasm, humor, hate speech, and sentiment, and then use these features to inform sentiment classification. Their work is quite sensitive to catching negative sentiment, however, it does not do as well when sentiment changes halfway through the text. It also does not address the subjectivity of humor.

<sup>1</sup><https://github.com/bzylich/humor-by-demographic>

ColBERT (Annamoradnejad, 2020) is among the first to use BERT (Devlin et al., 2018) for humor detection, reaching 98% classification accuracy and outperforming variants using recurrent neural networks and convolutional neural networks. Mao and Liu (2019) is another work that uses BERT to classify if a tweet is a joke or not and predict how humorous the tweet is. The work of Weller and Seppi (2019) explores extending humor detection capability by trying to assess whether or not a joke is humorous. They use transformers to identify humorous jokes based on ratings from Reddit pages, reaching human-level performance.

Earlier work, like (Donahue et al., 2017), use recurrent deep learning methods with dense embeddings to predict humorous tweets. In order to factor both meaning and sound in their analysis, they use GloVe embeddings combined with a novel phonetic representation as input to an LSTM.

Hossain et al. (2020) hosted the SemEval’20 event for humor detection in news headlines. The event challenged participants to classify whether an original headline or an altered headline is funnier and rate the funniness of the edited headline on a 0-3 humor scale. The winning teams (Morishita et al., 2020) combined the predictions of several models using sentence pair regression and ensembled the pre-trained language models BERT, GPT-2, (Radford et al., 2019) RoBERTa, (Liu et al., 2019), XLNet (Yang et al., 2019), Transformer-XL, and XLM (Dai et al., 2019) to form the final prediction.

Similar to humor detection, there has been some work to explore offense in text. SemEval ’19 had a task (Zampieri et al., 2019), aimed at identifying and categorizing offensive language in social media. The top performing teams used ensembles of random forest, linear models, recurrent networks, and pretrained transformer language models.

Our work is motivated by the SemEval challenges which encourage interesting techniques to handle multiple word senses, cultural knowledge, and pragmatic competence. Through this challenge, we try to detect humor and explore the subjectivity of humor appreciation with a controversy score to examine the variance in humor ratings for each different text.

## 3 Dataset

### 3.1 Data

We use three types of datasets in this work: the HaHackathon competition dataset (Meaney et al.,

2021), datasets for offensive text detection, and datasets for humor detection. We describe each of these in the following subsections.

#### 3.1.1 HaHackathon Competition Dataset

The training dataset consists of 8000 texts (Meaney et al., 2021) and four subtasks: humor classification, humor rating, humor controversy, and offense rating. For our initial experiments we created a randomized 90-10 train-development split of 7200 training examples and 800 sentences for model development. In addition, the competition has its own development dataset of 1000 texts. The labels for this dataset were released during the final stage of the evaluation. The gold-standard test dataset (Meaney et al., 2021) is the one we use for our system results.

#### 3.1.2 Humor Datasets

For the humor component of the competition, we use two datasets for intermediate finetuning: 200k Short Texts for Humor Detection (Annamoradnejad, 2020) and a self-compiled dataset of jokes and other texts scraped from Reddit.

The 200k Short Texts for Humor Detection dataset consists of 200,000 short text snippets, each labeled as either humorous or not humorous, with an even split between the two classes. The non-humorous texts are news headlines from the Huffington Post while the humorous texts were taken from Reddit communities such as /r/jokes and /r/cleanjokes.

The other dataset was one which we compiled ourselves, consisting of 200,000 snippets of text scraped from various reddit communities. This was primarily to address shortcomings we noticed in the 200k Short Texts dataset; namely the limited range of lengths for jokes and the singular source for the negative examples. For the positive examples of humor, we scraped the /r/jokes subreddit. For negative examples, we scraped subreddits such as /r/reddit.com and /r/worldnews, which offer more variability in the types of non-humorous texts than just news headlines from one news website.

#### 3.1.3 Offense Datasets

The Offensive Language Identification Dataset (OLID) (Zampieri et al., 2019) is one dataset for identifying offensive language in texts, specifically tweets. It contains 14,200 tweets as well as binary annotations indicating whether or not they are offensive.

Another similar dataset is the Hate Speech and Offensive Language dataset (Davidson et al., 2017). This dataset consists of 26,953 tweets as well as labels corresponding to how many crowdflower users labeled them as hateful and/or offensive.

Together, we experiment with intermediate finetuning on both of these datasets in the hope that it would provide some benefit for offensive language detection in task 2.

## 4 System Overview

As a starting point, we use the HuggingFace Transformers library<sup>2</sup>, along with their large collection of pretrained language models. From there, we finetune these transformers on the competition training dataset during development and the combined training and development datasets for the final evaluation phase.

Building on this basic paradigm, we experiment in four different ways with the goal of improving model performance: (1) using various datasets for intermediate finetuning, (2) using backtranslation to expand the competition datasets, (3) training multitask models to predict all labels simultaneously, and (4) ensembling predictions using different pretrained language models as starting points.

### 4.1 Intermediate Finetuning

We tried using intermediate finetuning on larger datasets for humor detection and offensive language detection in the hope that these larger datasets would provide a better starting point for training on the competition data, which is relatively small at just 8000 texts.

We perform intermediate finetuning in the same manner as the previously described basic transfer learning setup, and then we perform an additional transfer from the intermediate task to the competition task. For intermediate tasks we try using the two offensive language identification datasets previously mentioned, and for humor we tried using the 200k humor dataset and the Reddit dataset we collected.

We also try using ColBERT (Annamoradnejad, 2020), a pretrained BERT model that has been finetuned for humor prediction, as a starting point for intermediate finetuning and as a pretrained language model for the standard transfer approach.

<sup>2</sup><https://huggingface.co/transformers>

### 4.2 Backtranslation Augmentation

As another method of expanding the training dataset and introducing variation, we use backtranslation to create paraphrases of the texts in the dataset. These paraphrases are generated by first translating the text into a different language using the Google Translate python library<sup>3</sup>, and then translating the text back into the original language, usually with some small variations in the wording or sentence structure. This augmentation is useful in other tasks, but it was not clear whether the backtranslation would preserve humor, as some humor is generated based on the specific words or sounds used (e.g. puns).

### 4.3 Multitask Models

Initially, we train one model for each task or subtask. We also try training one model to learn to predict the labels associated with all four tasks or subtasks at the same time. To accomplish this, we attach four different heads on top of the final transformer outputs. Each prediction head consists of two fully-connected feed-forward layers matching the dimensionality of the transformer layers used by the pretrained language model, and an output layer that produces a single regression score or binary probabilities depending on the task.

### 4.4 Ensembling Model Predictions

We did most of our development with DistilBERT (unless otherwise specified) because it is relatively fast to train and run, allowing us to iterate more rapidly. We hypothesized that different pretrained language models would have different strengths and weaknesses when finetuned due to the different pretraining data used and the different model architectures. By ensembling (+Ens) many language models together, we might then counterbalance the weaknesses of individual models to improve overall performance.

Ultimately, we experimented with 6 model variants: “distilbert-base-uncased”, “distilroberta-base”, “bert-base-uncased”, “roberta-base”, “bert-large-uncased-whole-word-masking”, and “roberta-large” pretrained language models from the HuggingFace Transformers library. To get the predictions for each model, we average together the predictions from 5 different random restarts to mitigate the effect of variance induced by the random initialization. To ensemble the different models

<sup>3</sup><https://pypi.org/project/googletrans/>

together, we simply averaged the predictions from each model together to form the final predictions, taking the argmax of the averaged probabilities for classification tasks.

For a slightly more advanced ensembling method, for each task we select the models to average together by trying all possible combinations and selecting the combination that leads to the best performance on the development dataset (+Ens-Best). Then, we use the same model combinations to generate predictions to submit to the competition leaderboard.

## 4.5 Experimental Setup

To facilitate transfer learning on top of the original language model, we add two linear layers for each task on top of the CLS token of the transformer. The first linear layer has the same dimension as the language model. After the first linear layer, we use ReLU activation, and the second layer produces the prediction (classification or regression depending on the task). For training each model we use the same hyperparameters: a batch size of 10, a learning rate of  $5e-5$ , 3 epochs, 500 warmup steps, and a weight decay of  $0.01^4$ . During intermediate finetuning, we transfer all weights from each prior finetuning step and all weights remain trainable at each step.

## 4.6 Results

We find that intermediate finetuning on other datasets for humor and offense identification do not improve performance. Similarly, using ColBERT as a starting point does not outperform other pretrained language models. This may be due to differences in how these datasets were sourced, and more analysis is provided in section 5. We also find that backtranslation augmentation is not helpful for humor detection, likely because it does not always preserve humor. While not beneficial, it is noteworthy as it is not clear whether prior work has explored backtranslation for expanding humor datasets, and this work suggests that backtranslation should not be used in contexts such as humor which are highly dependent on the specific words and sounds in a text.

Here, we show an example where backtranslation does not preserve humor since the word *imaginary* is a key part of the joke and it is substituted during the translation process:

<sup>4</sup><https://github.com/bzylich/humor-by-demographic>

- Original: My girlfriend is like the square root of -100. She's a 10 but she's imaginary.
- Backtranslation: My girlfriend is like the square root of -100. She is 10 but she is fantastic.

While many translations do not preserve humor, some translations do successfully preserve humor while introducing some word variation into the text:

- Original: My father doesn't trust anyone. In fact he has a saying... But he won't tell me.
- Backtranslation: My dad doesn't trust anyone he has a saying ... but he doesn't tell me.

Next, multitask learning improves performance over training models for each task individually, especially for some tasks such as humor rating prediction and humor controversy prediction. Finally, ensembling different pretrained language models together leads to an increase in performance, suggesting that these models complement each other by mitigating other models' weaknesses. Table 1 shows which submissions perform best on each individual task.

## 5 Error analysis

One of the possible sources of confusion and bias in our model seemed to be centered around atypical punctuation such as question marks and exclamation marks. For example, when a question mark was placed in the middle of a sentence, the model often erroneously labels it humorous regardless of the actual content. When manually reviewing the data, we found that the vast majority of texts that contain a mid-text question mark are humorous due to their setup and punchline structure. Without balancing with negative examples with similar structures, the model can become reliant on punctuation structure rather than the actual relationship between the words.

Another driver of error seems to be the actual source of the competition dataset. Through further analysis, we found that the vast majority of the negative examples seemed to be sourced from tweets. This can be seen in the length distribution of the dataset; there is a sharp cutoff around 140 characters, which used to be the maximum length for a tweet. However none of the other datasets we found or compiled ourselves (for Humor tasks)

Approach	Humor F1 / Acc	Humor RMSE	Controversy F1 / Acc	Offense RMSE
RoBERTa-Large Multitask	<b>0.9510 / 0.9604</b>	<b>0.5339</b>	0.5220 / <b>0.4842</b>	0.4564
Multitask +Ens=6LM	0.9460 / 0.9565	0.5457	<b>0.5528</b> / 0.4841	0.4606
Multitask +Ens-Best=6LM	<b>0.9510 / 0.9604</b>	0.5411	0.5415 / 0.4659	<b>0.4530</b>

Table 1: Competition Results

contained information from Twitter specifically, almost all relied heavily on news headlines instead. When pulling individual examples, we found that tweets tended to use more colloquial language, with a greater variety of punctuation, vocabulary, and capitalization when compared to news headlines.

One final potential driver of error were song lyrics and quotes. There were a proportionally large number of movie, song, and TV show quotes used in the dataset, by a rough estimate based on sampling, approximately 5% of the example fell in one of those categories. Our model was often able to differentiate between these quotes, though it was not something that was found in our own custom datasets.

After performing this deep dive analysis on our results, and seeing the various areas of where our model got confused, we believe that the primary reason our models did worse with the inclusion of extra datasets was due to the source of our data. The wider range of punctuation, capitalization, and vocabulary expressed in twitter posts was not well captured by utilizing news headlines as a negative source, and thus likely allow our model to use syntax and punctuation structure as a substitute for the actual substance of the text.

## 6 Conclusion

In this competition, we explored the use of intermediate finetuning, backtranslation augmentation, multitask learning, and ensembling of different pretrained models. Unlike in many natural language processing tasks, intermediate finetuning on other related datasets provided no benefit in this task, perhaps because prior datasets used non-humorous texts that were much easier to identify. Next, although backtranslation augmentation did not improve performance, this is still a noteworthy result because it indicates that humor is likely not preserved through paraphrasing. Finally, multitask learning across humor and offense detection, as well as ensembling of different pretrained language models improved overall performance.

# DuluthNLP at SemEval-2021 Task 7: Fine-Tuning RoBERTa Model for Humor Detection and Offense Rating

Samuel Akrah

Department of Computer Science  
University of Minnesota Duluth  
Duluth, MN 55812 USA  
akrah001@d.umn.edu

## Abstract

This paper presents the DuluthNLP submission to Task 7 of the SemEval 2021 competition on Detecting and Rating Humor and Offense. In it, we explain the approach used to train the model together with the process of fine-tuning our model in getting the results. We focus on humor detection, rating, and offense rating, representing three out of the four subtasks that were provided. We show that optimizing hyper-parameters for learning rate, batch size and number of epochs can increase the accuracy and F1 score for humor detection.

## 1 Introduction

Humor detection poses a challenge to humans, not least because of the mix of irony, sarcasm, and puns which underlie humor. To understand the funniness of humor requires a certain grasp of context, culture and, for some, even country.

If rating the funniness of humor is any challenge, ranking its offensiveness is even more so, especially when doing so requires an appreciation of the sensibilities of the humor target – whether race, religion, and/or gender – and, in most cases, context.

It is little wonder humor detection has been central to NLP tasks in the past few years. The last few SemEvals have featured tasks focused exclusively on either detecting the funniness of humor (Hossain et al., 2020; Van Hee et al., 2018; Potash et al., 2017) or detecting offense (Zampieri et al., 2019). What SemEval-2021 task 7 seeks to do is combine the detection of both humor and offense for a given corpus.

Our approach uses pretrained RoBERTa model (Liu et al., 2019b) trained on a RoBERTa classifier implemented by HuggingFace (Wolf et al., 2019). The intuition here is that RoBERTa model achieves state of the art performance for tasks requiring contextual information. Our goal is to measure the

effect of varying three hyperparameters – batch size, learning rate, epoch size - whilst maintaining default values for others. Our results show that varying the three hyperparameters can increase performance for humor detection, humor ranking, and offense rating. The codebase for our participation of this SemEval Task is available on github <sup>1</sup>

## 2 Related Work

Earlier works on humor detection and rating showed modest gains. With the advent of attention mechanism (Vaswani et al., 2017), though, and the transformer model a few years later (Dai et al., 2019), not only has interest in the NLP community on humor detection has soared, but performance on humor and offense detection has increased (Weller and Seppi, 2019).

This has been particularly so in the last few years, where humor detection and offense rating have been featured in some of SemEval tasks. SemEval-2019 Task 6 on offense rating (Zampieri et al., 2019) attracted 800 participants and 115 submissions, the interest prompting a second SemEval-2020 Task 12 the following year (Zampieri et al., 2020). Around the same period, humor rating have attracted similar interest (Hossain et al., 2020) in SemEval Tasks. To the best of our knowledge, however, SemEval-2021 Task 7 (Meaney et al., 2021) is the first to measure humor and offense for a given task.

Most of the winning teams (Morishita et al., 2020; Rozental and Biton, 2019; Wiedemann et al., 2020), for both humor and offense rating alike, implemented BERT and its variants, including Albert and RoBERTa, in their model, an approach that tended to yield the best results. And more often than not, the teams exploit ensembles of BERT,

<sup>1</sup><https://github.com/akrahdan/SemEval2021>

GPT-2, RoBERTa and their variants (Morishita et al., 2020), whilst others stick to a single pre-trained model.

Our approach in this task is to use RoBERTa model, an approach that will fine-tune a select number of hyperparameters and to measure the model performance for every change of hyperparameter set.

### 3 System overview

In this section, we review our system’s adoption of the pretrained RoBERTa model (Liu et al., 2019a) for SemEval tasks. We also describe the Bayesian hyperparameter optimization technique, which we used in our hyperparameter sweeps for selecting optimal values for learning rate, batch size, and epoch cycles.

#### 3.1 Model description

Our system’s adoption of RoBERTa model is based on its ability to achieve state-of-the-art performance for most NLP tasks with minimal effort, including, in our case, humor detection. The RoBERTa model, itself a re-implementation of BERT (Devlin et al., 2019), is first pre-trained on unlabeled text corpus and subsequently fine-tuned on downstream tasks with labeled data.

The RoBERTa model is a significant improvement over the BERT model, and it differs from BERT for its usage of dynamic masking for training, Next Sentence Prediction (NSP), and a larger mini-batch size (which, it has been observed, correlates with performance (Liu et al., 2019a)).

Again, the RoBERTa model outperforms BERT for its size and diversity of data used in pretraining, with its 160GB of training data drawn from multiple sources compared to BERT’s 16GB of training data.

Our system implements the RoBERTa model with a classification layer on top using HuggingFace transformer model<sup>2</sup>.

We adopt Bayesian optimization to automate the selection of optimal hyperparameter values for the training and evaluation of the three Subtasks. Details of the Bayesian optimization method are found in Appendix A

#### 3.2 Sweeps

We use Bayesian optimization to run hyperparameter sweeps for our model, but not before manually

<sup>2</sup><https://huggingface.co/transformers/>

selecting a sensible list of hyperparameter values in fine-tuning the RoBERTa model (Liu et al., 2019a) on the SemEval tasks, including a learning rate of 0.000025, a batch size of 4, all for 16 epochs. The initial weights are based on standards followed by BERT and RoBERTa (Devlin et al., 2019; Liu et al., 2019a). The remaining parameters are based on open source implementation by HuggingFace<sup>3</sup> (Wolf et al., 2020).

Whilst the initial approach of selecting sensible defaults for hyperparameters achieved state of the art results, the random, manual process was painful, the results sometimes unpredictable. Applying Bayesian optimization, however, in running a sweep over a range of hyperparameter values helped in the selection of hyperparameters, including epoch size, batch size, and learning rates, across the 24 layers of RoBERTa<sub>LARGE</sub> model. Our system’s implementation of the Bayesian Optimization is based on the open source wandb client by Weights & Biases<sup>4</sup> (Biewald, 2020)

### 4 Experimental Setup

In this section, we present the experimental setup for the our model and hyperparameter sweeps for the SemEval tasks.

#### 4.1 Implementation

For all experiments for the RoBERTa model (using RoBERTa<sub>BASE</sub> and RoBERTa<sub>LARGE</sub> variants), we use the PyTorch<sup>5</sup> implementation of it in the HuggingFace transformer open source library<sup>6</sup> (Wolf et al., 2020) together with the simpletransformer<sup>7</sup> (Rajapakse, 2019) wrapper library. We maintain the default weights and hyperparameters whilst only changing the learning rate, batch size and finetuning for different values of epochs. All experiments were run on V100 GPUs with 16GB memory.

#### 4.2 Data Processing

The training and evaluation data, as shown in Table 1 is based on the training, development and test data supplied for the SemEval-2021 Task 7 (Meaney et al., 2021). Train data for each Subtask is the same but the the number of annotations are

<sup>3</sup><https://github.com/huggingface/transformers>

<sup>4</sup><https://github.com/wandb/client>

<sup>5</sup><https://pytorch.org>

<sup>6</sup><https://github.com/huggingface/transformers>

<sup>7</sup><https://simpletransformers.ai>

Task	Type	Metric	Train
<b>Task 1a</b>	Classification	F1-Score	8000
<b>Task 1b</b>	Regression	RMSE	4932
<b>Task 2a</b>	Regression	RMSE	8000

Table 1: A Summary of Subtasks and dataset. Both development and test set have the same have sizes of 1000.

different, with 8000 annotations for Subtask 1a and 2a; and 4932 annotations for Subtask 1b. Data splits between training and evaluation is 80% and 20%.

The annotators for the dataset for the tasks were a diverse group of individuals from differing age group (18-70), genders, political views and income levels – their backgrounds reflecting their perceptions of jokes or humor. For each text in the dataset, annotators were asked to rank as either humorous or not, and to rate the humor level on a scale of 1 to 5.

The subjectivity level of each text is also captured as a controversy score. Each text is labeled as controversial if the variance of its humor rating is greater than the median variance of all texts. Otherwise, it is labeled as not controversial.

As a way of combining humor and offense detection in the same task, a first in SemEval tasks, annotators were asked to classify humor as either offensive or not, and, if offensive, to rate the offensiveness on a scale of 1 to 5. Non-offensive humor received a zero rating.

Overall, the SemEval task divides into four subtasks. Task 1a, a binary task, predicts if a given text should be considered humorous. The second Task 1b, a regression task, assigns a rating between 1 to 5 to text considered humours, and 0 otherwise. The third Task 1c, itself a binary task, gives a controversy score to a text. The fourth task predicts the general offensiveness of a text on a scale of 0 to 5. Our system’s implementation only experiments with three of the Subtasks, including Task 1a, Task 1b, and Task 2a.

### 4.3 Hyperparameter tuning

Our approach to hyperparameter tuning involves two steps – one manual (implemented during the evaluation phase) , the other using Bayesian optimization (implemented during post-evaluation). In the first step, though, we experiment with a range of hyperparameter values on Task 1a, and the results applied to train our model on the various subtasks.

But during the second step, implemented during the post-evaluation phase, we implement hyperparameter sweeps on each task.

In the first step, we manually select from a range of tunable hyperparameters, with batch sizes  $\in \{4, 16\}$ , learning rates  $\in \{2e - 5, 4e - 5, 1e - 4\}$  and we fine-tune for epochs in  $\in \{6, 9, 12, 16\}$  . The remaining hyperparameters, including dropout rates, and the parameter weights, are based on the default values for RoBERTa model implementation in the HuggingFace transformer library.

Using the results of the first step as our initial defaults for batch size and learning rate, we consider a fine-grained hyperparameter sweep using the Bayesian optimization across the 24 pretrained layers of the RoBERTa<sub>LARGE</sub> model. We select a range of learning rates between 0 &  $1e - 3$  for the pretrained layers. We fine-tune for a range of 6 to 40 epochs, applying early stopping and using accuracy as the evaluation metric on the valuation set for Task 1a, and RMSE as the evaluation metric for Task 1b and Task 2a.

Runs on hyperparameter sweeps are taken on all the three Subtasks - Task 1a, 1b, and 2a. We then use the results of learning rates across the pretrained layers, together with the batch size to train our model for the selected number of epochs on each Subtask. Table 5 shows the results of each hyperparameter sweep.

## 5 Results

In this section we present the results of our SemEval tasks and our analysis for each step. We present, in the first step, our baseline method and results. We then follow up with the results obtained evaluation phase; here, we analyse the impact of the manual sweep and finetuning on the pretrained RoBERTa model on the subtasks. In the last step, and using the results of the codalab scores, we analyse the impact of hyperparameter sweeps on the scores during the post-evaluation phase.

Tasks	Metric	Scores evaluation
<b>Task 1a</b>	F1-Score	0.939
	Accuracy	0.926
<b>Task 1b</b>	RMSE	0.646
<b>Task 2a</b>	RMSE	0.506

Table 2: Official evaluation scores for each task.

Tasks	Metric	Scores
		post-evaluation
<b>Task 1a</b>	F1-Score	0.957
	Accuracy	0.947
<b>Task 1b</b>	RMSE	0.5802
<b>Task 2a</b>	RMSE	0.469

Table 3: Post-evaluation scores. These were scores generated during the post-evaluation stage after multiple hyperparameter sweeps.

## 5.1 Baseline

For our baseline method for the regression tasks, we use a very simple linear regression class by scikit-learn. For the classification task, though, we use logistic regression, also by scikit-learn, but with binarized ngram counts, a method proposed by Wang and Manning (2012). The baseline result for the classification task is 89%. RMSE baseline results for the regression tasks, for both Task 1b and 2a, are 0.54 and 0.74 respectively.

## 5.2 Official Evaluation

As the evaluation results in Table 2 shows, the F1-Score of 0.939 for **Task 1a** is very high, and that is even for manual values of learning rate, epoch and and batch size. What this shows is that using the recommended learning rate and batch size to fine-tune pretrained RoBERTa model on humor classification tasks can achieve very high results. On the the hands, the same hyperparameter values achieved average RMSE metric score for **Task 1b** and average F1 score for **Task 2a**, which suggest that our approach of using the same hyperparameter values for all subtasks is not working.

## 5.3 Post Evaluation

During the post-evaluation phase the team carried out an extensive hyperparameter finetuning with the bayesian optimization. Table 3 also shows substantial gain in the F1-score, 0.95, for **Task 1a**, RMSE scores (0.5802 and 0.469) for **Task 1b** and **Task 2a** respectively, after applying the results of the Bayes-optimized hyperparameter sweep in Figure 5 during the second step in the post-evaluation stage.

## 6 Error Analysis

In an attempt to measure our model’s predictions against the annotations by humans, we calculate the confusion matrix, comparing the predicted re-

Figure 1: Confusion matrix for Subtask 1a during evaluation phase

sults with the values in the gold test for Subtask 1a. Figure 1, the confusion matrix during the evaluation phase, shows comparable results for false positives and false negatives. In Figure 2, however, the number of false positives (34) are almost twice the number of false negatives, which is so because the train set has more label 1 data (4932) than label 0 data (3068), a slight difference that can lead to the false positives. Again, the total number of true positives (596), almost twice the number of true negatives (351), shows the model is biased towards positive labels, which will make it difficult to generalize.

Moreover, as shown in Table 4, about half of the number of the false positive predictions are also offensive, in part because most of the labeled texts in the train set that are labeled as humorous are also labeled as offensive.

The higher number of accurate predictions for both the evaluation phase(926) and post-evaluation phase(947) shows our model is efficient in detecting humor.

However, the RMSE scores for humor rating – that is Task 1b, including even the improved RMSE score of 0.58 during the post evaluation phase – still lags behind the RMSE results for Task 2a , the offense-rating subtask. And what this suggest is that our model performs better with offense rating than with humor rating. And that might suggest that the higher scores associated with Task 1a are based on the model’s ability to detect offense, which explains why most of the false positive texts also contain offensive content.

ID	text	is humor	offense
9200	Black trans-masculine barbers in NY where ya at? We tryna sumn.	0	0.55
9307	What 's a Black Competitive Swim Skills Clinic? ' feeling motivated	0	1.55
9756	Being told that because I'm a Reform Jew that I'm not actually a Jew and that my smicha as a reform rabbi isn't recognized is a pretty shitty thing to hear from someone.	0	1

Table 4: Examples of gold test results wrongly labeled by our model

Figure 2: Confusion matrix for Subtask 1a during post-evaluation phase

## 7 Discussions and Future Works

One major limitation of our approach was that the hyperparameter runs, during the evaluation phase, were experimented only on Task 1a, a binary classification task, and the results applied on the two regression tasks to train our model, which may explain the subpar results for the Task 1b and Task 2a. However, the steps taken during the post-evaluation phase, by independently running the sweeps on each Subtask, showed substantial increase in performance.

In addition, the RoBERTa model, as implemented by HuggingFace, is used as is, without any modification to either the classification layer on top of the RoBERTa model or any of the pretrained layers. In the future, it will be worth pursuing how modifying either of the layers will impact on humor and offense detection.

Overall, however, our system shows that getting optimal values for learning rate, batch and epoch size can yield higher performance for humor detection.

## 8 Ethical Considerations

The training of RoBERTa, along with other language models such as BERT and its variants, has been shown to be costly, both for its effect on the environment and finance (Strubell et al., 2019). Again, the embeddings used for these language models tend to amplify racial, sexist, and homophobic biases. Mindful of these tendencies, our model experiments included steps to minimize bias and reduce energy cost.

What SemEval-2021 Task 7 (Meaney et al., 2021) intends to achieve is not only to rank humor but also to rate humor offensiveness, the first of any SemEval task. To achieve this, the dataset contains as much as humor as hate, which covers racial slurs, gender bias, trans/homophobic comments, etc. Knowledge of what ranks as offensive in humorous text can help our system moderate humorous content.

To ensure that dataset used for training and development do not over-represent hegemonic viewpoints, Meaney et al. (2021), organizers for the SemEval-2021 Task 7, employed annotators from disparate backgrounds, in age, gender, political views, to ensure that humor ratings and rankings, a subjective process, reflected the varied viewpoints.

Annotators were limited to English speakers, however, which implies that the system's ability to detect and identify humor is largely reflect views inherent in the English language.

Training and testing were carried out on 1 V100 GPUs with less than 16GB of memory, a step taken to ensure minimal, if any, impact on the environment.

The model, however, is prone to classifying offensive content as humorous, which may suggest that applications based on our model will be more likely to rate as humorous any content that might be deemed offensive.

## A Appendix

The Bayesian optimization is used in hyperparameter optimization techniques for getting a combination of hyperparameters that returns the best performance as measured by a validation set. More formally, for an expensive function  $f : \mathcal{X} \rightarrow \mathbb{R}$ , hyperparameter optimization can be represented below:

$$\mathbf{x}_{opt} = \underset{\mathbf{x} \in \mathcal{X}}{\operatorname{arg\,max}} f(\mathbf{x})$$

The objective function,  $f(x)$ , represents the score to maximize – in our case, say, the accuracy score – over the validation set;  $\mathbf{x}_{opt}$  is the set of hyperparameters that will yield the highest value of the score – or, in the the case of error rate or RMSE, the lowest value.

The Bayes optimization (or search) is one of the standard algorithms for hyperparameter sweeps; the others are grid and random search (Bergstra and Bengio, 2012). Grid search creates a grid of hyper-parameters and runs through all the range of hyperparameter values. Whilst the grid search is

better than manual selection, it is computationally expensive; it is also inefficient because the choice of the next hyper-parameter values in a cycle run is not informed by previous values.

The Bayes search, on the other hand, keeps record of previous results, and uses the results to build a probabilistic model for mapping hyperparameter values to a probability of score on the objective function (Dewancker et al., 2016).

Our system implements the Sequential Model-Based Optimization (SMBO) method, which is a succinct formalization of Bayesian Optimization (Hutter et al., 2011, 2013). Sequential Model-Based Optimization technique iterates between fitting a model and then using that model to determine the next location to evaluate. The pseudocode in Algorithm 1, adopted from SigOpt<sup>8</sup> (Dewancker et al., 2016), encapsulates the technique.

---

### Algorithm 1 Sequential Model-Based Optimization

---

```

Input:  $f, \mathcal{S}, \mathcal{X}, \mathcal{M}$ 
 $\mathcal{D} \leftarrow \text{INITSAMPLES}(f, \mathcal{X})$ 
for  $i \leftarrow \mathcal{D}$  to  $T$  do
   $p(y | \mathbf{x}, \mathcal{D}) \leftarrow \text{FITMODEL}(\mathcal{M}, \mathcal{D})$ 
   $\mathbf{x}_i \leftarrow \underset{\mathbf{x} \in \mathcal{X}}{\operatorname{arg\,max}} \mathcal{S}(\mathbf{x}, p(y | \mathbf{x}, \mathcal{D}))$ 
   $\mathbf{y}_i \leftarrow f(\mathbf{x}_i)$ 
   $\mathcal{D} \leftarrow \mathcal{D} \cup (\mathbf{x}_i, \mathbf{y}_i)$ 
end for

```

---

From a domain  $\mathcal{X}$  of tunable hyperparameters, the system would select a small set to initialize a probabilistic regression model  $\mathcal{M}$ . Afterwards, subsequent locations are selected sequentially from the domain by optimizing the acquisition function  $\mathcal{S}$ , which uses the current model – the Gaussian process, in our implementation – as a surrogate of the objective function  $f$ . Each suggested result is then used to produce the real result  $\mathbf{y}_i = f(\mathbf{x}_i)$ , the values of which are appended to  $\mathcal{D} = \{(\mathbf{x}_1, \mathbf{y}_1), \dots, (\mathbf{x}_i, \mathbf{y}_i)\}$ ; the updated values are then used by the regression during the next iteration.

## Abstract

With the emerging trends of using online platforms, peoples are increasingly interested in express their opinion through humorous texts. Identifying and rating humorous texts poses unique challenges to NLP due to subjective phenomena i.e. humor may vary to gender, profession, age, and classes of people. Besides, words with multiple senses, cultural domain, and pragmatic competence also need to be considered. A humorous text may be offensive to others. To address these challenges SemEval-2021 introduced a HaHackathon task focusing on detecting and rating humorous and offensive texts. This paper describes our participation in this task. We employed a stacked embedding and fine-tuned transformer models based classification and regression approach from the features from GPT-2 medium, BERT, and RoBERTa transformer models. Besides, we utilized the fine-tuned BERT and RoBERTa models to examine the performances. Our method achieved competitive performances in this task.

*Keywords:* humor and offense rating, transformers, BERT, RoBERTa, stacked embedding.

## 1 Introduction

The exponential evolution of technologies and social platforms increases the growth of user-generated content. Therefore, detecting specific information from a pile of web data is ubiquitous. Humor, like most figurative language, poses interesting linguistic challenges to NLP, due to its emphasis on multiple word senses, cultural knowledge, and pragmatic competence. The automated humor detection and rating is one of the challenging and promising tasks for their significance in the field of opinion mining, sentiment analysis, and emotion intelligence domain.

Numerous works have been done on humorous text identification task. (Weller and Seppi, 2019) proposed pre-trained BERT architecture to identify humorous jokes from Reddit dataset, puns, and short jokes dataset. (Khatri and Pranav, 2020) used BERT and GloVe embeddings with linear support vector classifier (SVC), naive Bayes, and random forest for predicting the final label to detect sarcasm in tweets. (Badlani et al., 2019) extracted features pertaining to sarcasm, humor, hate speech, as well as sentiment and ensemble them for sentiment classification. In (Liang et al., 2020), the pre-trained BERT is adapted to the distantly supervised NER (named entity recognition) task with early stopping. Some evaluation campaigns related to automatic humor detection also has been performed. (Swamy et al., 2020) includes a logistic regression baseline, a BiLSTM + attention-based learner, and a transfer learning approach with BERT to tackle the Internet humor at SemEval-2020 Task 8.

However, most of the existing work addressed the humorous text identification problem as a binary classification task. But the humorous rating of a text can be varied at different scales based on its contents. Moreover, a humorous text may portray offensive context to other users due to a variety of users' perceptions. To bridge this gap (Meaney et al., 2021) introduced a shared task at SemEval-2021 focusing on detecting and rating humorous and offensive texts. The task comprises of four subtasks: Task 1a is to predict whether a text is humorous or not, task 1b is to rate a humorous text with a score between 0 and 5, task 1c represents the subjectivity of humor appreciation by foretelling a humorous text is controversial or not, and task 2 intend to rate a text with a value between 0 and 5 based on its offensiveness.

To tackle the challenges of this task, we employed a stacked embedding of various transformer models including GPT-2 medium, BERT, and

---

The first two authors have equal contributions.

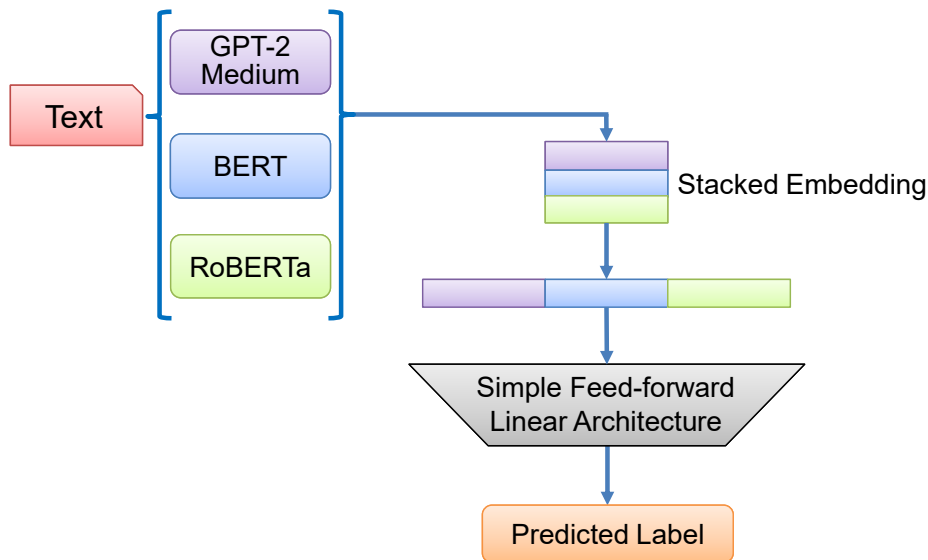

Figure 1: Proposed framework.

RoBERTa with a simple linear architecture. Besides, we conduct experiments and examine the individual performance of these three models. We used transformer-based models as they can learn the context of the sentence effectively and pushed the state-of-the-art for a wide range of downstream NLP tasks.

The rest of the paper is structured as follows: Section 2 describes our proposed framework. Section 3 illustrates our experiment and evaluation. Finally, we come to end with some conclusion and future research directions in Section 4.

## 2 Proposed Framework

In this section, we present the details of our proposed approach for humorous and offensive text identification and rating. The overview of our proposed framework is depicted in Figure 1.

Given a text, we have extracted embedding features from three state-of-the-art transformer-based models including GPT-2 medium, BERT, and RoBERTa. The extracted embeddings are then unified through the stacked embedding scheme and the unified feature vector is then passed to the simple feed-forward linear architecture to obtain the prediction score.

### 2.1 Text Encoding

**GPT-2:** GPT-2 (Radford et al., 2019) stands for generative pretrained transformer 2, which is trained on eight million text documents scraped from the web. It has an outstanding ability to gener-

ate coherent text from minimal prompts. We utilize GPT-2 medium version to get a 1024 dimensional feature vector from each text for sub-task 1a.

**BERT:** BERT (Devlin et al., 2019) stands for bidirectional encoder representations from transformers, which is a new method of pre-training sentence representations. It is trained on a large corpus of unlabelled text which includes the entire Wikipedia (that’s about 2500 million words) and a book corpus (800 million words). We deploy BERT-base uncased version with fine-tuning to get a 768-dimensional feature vector for a given text. We also conduct experiments with the fine-tuned BERT-large uncased architecture to encode each text into a 1024-dimensional feature vector.

**RoBERTa:** RoBERTa (Liu et al., 2019) stands for robustly optimized BERT pre-training approach. An improvement on BERT which introduced as a robustly optimized method for pre-training NLP systems. BERT’s language masking strategy is used in RoBERTa, wherein the system learns to predict intentionally hidden sections of text within otherwise unannotated language examples. RoBERTa modifies key hyperparameters in BERT including removal of BERT’s next-sentence pre-training objective, training with much larger mini-batches, and learning rates. This allows RoBERTa to improve on the masked language modeling objective compared with BERT and leads to better performance on downstream tasks. We use the RoBERTa base model with fine-tuning to get a 768-dimensional feature vector.

## 2.2 Stacked Embeddings

Stacked embeddings are one of the most important concepts that combine different embeddings to capture the benefits of different embedding models. Stacked embeddings concatenate embedding vectors generated from various models to form the final word vectors. The representation of stacked embedding-based framework is depicted in Figure 1. We combine GPT-2 medium, BERT-base, and RoBERTa-base embeddings using Flair’s (Akbiik et al., 2018) stacked embeddings approach. For each text, we extract a 1024-dimensional transfer learning feature vector from the GPT-2 medium, a 768-dimensional feature vector from the BERT-base uncased, a 768-dimensional feature vector from the RoBERTa-base model. We combine these embeddings and get a 2560-dimensional feature vector for each text.

## 2.3 Classification Module

The transfer learning feature vector obtained from the stacked embedding approach goes through a simple feed-forward linear architecture which applies a linear transformation to the incoming feature vectors and classifies each text either as humorous or non-humorous. Besides, we employ the fine-tuned BERT and RoBERTa based classifiers.

For the regression tasks, fine-tuned BERT and RoBERTa based regression models are utilized. We implement these models from the Huggingface transformers library (Wolf et al., 2020).

# 3 Experiments and Evaluations

## 3.1 Dataset Description

SemEval-2021 task 7 organizers (Meaney et al., 2021) provided a benchmark dataset to evaluate the performance of the participant’s proposed systems. The given training set consists of 8000 texts whereas the development set contains 1000 texts and the test set contains 1000 texts. The data set contains one row for each text. Each row has a unique identifier, the text, and the values for `is_humor`, `humor_rating`, `humor_controversy`, and `offense_rating`. If the sentence is humorous the value of `is_humor` is 1 otherwise 0. The value of `humor_rating` and `offense_rating` defines the level of humor or offensiveness in the contents. The value of `humor_controversy` determines whether the humorous text is controversial or not. The value of `humor_rating` and `humor_controversy` is subject to

Parameters List	Sub-task 1a	Other sub-tasks
Epochs	4	20
Batch size	16	16
Learning rate	3e-5	2e-6
Maximum length	default	160
Patience	3	5
Optimizer	Adam	AdamW
Anneal factor	0.5	–

Table 1: Optimal value of parameters used in this work.

the value of `is_humor`. If a given text is not humorous, `humor_rating` and `humor_controversy` contain no value for that particular text. Therefore, we converted all empty cells of `humor_rating` and `humor_controversy` to label 0. We used the train data set to train our model. The development data was used for hyperparameter tuning. Finally, we used the given test dataset to evaluate our models.

## 3.2 Evaluation Measures

The organizers employed different strategies to evaluate the performance of participants’ systems. Standard evaluation measures including F1-score and accuracy were applied to estimate the performance for sub-tasks 1a and 1c. The regression subtasks i.e. 1b and 2a were evaluated by the metric root mean squared error (RMSE).

## 3.3 Experimental and Parameter Settings

We used Google Colab’s GPU for training and parameter tuning of our system. We evaluated our system’s performances through Codalab platform.

Now, we describe the value of optimal parameters that we’ve used to design our model. While evaluating for the sub-tasks, we fine-tuned our systems based on the number of epochs, batch size, learning rate, anneal factor, patience, and optimizer to obtain the improved performances. We utilize the early-stopping method to overcome the system’s overfitting on the training dataset. We interchange epochs in range [4,8,15,20] with different value of patience, batch size in range [8,16,32], learning rate in range [2e-5, 3e-5, 4e-5, 2e-6, 3e-6, 4e-6] with optimum `max_length`. While evaluating sub-task 1a, we use Flair’s (Akbiik et al., 2018) framework and for other sub-tasks, we utilize transformers from HuggingFace transformers library (Wolf et al., 2020). We note that compared to BERT, RoBERTa has slightly different hyper-

parameters. In particular, RoBERTa uses weight decay with  $\lambda = 0.1$  and no gradient clipping (Mosbach et al., 2020). Table 1 describes the summarized parameters settings used in this work. The default settings are used for the rest of the parameters. In this paper, we reported the results based on these settings. However, if the prediction for the rating sub-tasks is less than 0.35, the value is converted into 0.0 according to our result analysis on the development set.

### 3.4 Results and Analysis

We used the full training dataset for training our proposed model and the validation set for hyperparameter tuning. The comparative performance of our method based on test data against the top-ranked participants’ systems in individual sub-task are presented in Table 2 and 3, respectively.

Team (Rank)	Accuracy	F1-Score
Comparative Performance on Subtask-1a		
PALI (1st)	0.9820	0.9854
stce (2nd)	0.9750	0.9797
<b>CSECU-DSG (34th)</b>	<b>0.9380</b>	<b>0.9496</b>
mayukh (35th)	0.9330	0.9468
Avilshmam (56th)	0.816	0.8489
Comparative Performance on Subtask-1c		
PALI (1st)	0.4943	0.6302
reynier (10th)	0.4732	0.6197
<b>CSECU-DSG (34th)</b>	<b>0.5366</b>	<b>0.4423</b>
GuanZhengyi (35th)	0.5593	0.4271

Table 2: Comparative results with other participants’ systems in binary classification tasks.

We now report the best performing model for each sub-task. Stacked embeddings based method used for sub-task 1a and BERT’s large model is used for sub-task 1c. However, for the regression subtasks 1b and 2a, BERT’s large and RoBERTa’s base models are employed, respectively.

Results showed that our proposed system obtained competitive results in sub-task 1a and 1c whereas in the other sub-tasks our system lags behind. Ensembling transformer’s embedding achieved good performance for binary classification. In our system, we have tuned a few hyperparameters and used features from all intermedi-

Team (Rank)	RMSE Score ↓

Table 3: Comparative results with other participants’ systems in regression tasks.

ate layers of transformers. We didn’t apply any approach to find out effective intermediate layers combination to obtain the best performance from transformers. Though the training set contains 8000 sentences, only 4932 sentences are humorous. That’s why we get only 4932 perfect humor-rated sentences to train the system which is scanty. All these requirements limit our system performance for regression tasks 1b and 2a.

## 4 Conclusion and Future Plan

In this paper, we have tackled the problem of identifying and grading humorous texts as defined in SemEval-2021 task 7. Achieving high performance in humor and offensive text identification or ranking is hard due to its diverse contextual form. We have presented transformer-based language models including GPT-2 medium, BERT, and RoBERTa in a unified architecture using a stacked embedding scheme. Experimental results demonstrated its effectiveness for the classification tasks. However, we have seen that finetuned transformer models performed better in the regression task.

In the future, we have a plan to focus on direct inducing topic information into the transformer-based models. We also intend to explore how to tune the parameters for regression tasks in more efficient ways, which could yield better performances.

## Abstract

An understanding of humor is an essential component of human-facing NLP systems. In this paper, we investigate several methods for detecting humor in short statements as part of Semeval-2021 Shared Task 7. For Task 1a, we apply an ensemble of fine-tuned pre-trained language models; for Tasks 1b, 1c, and 2a, we investigate various tree-based and linear machine learning models. Our final system achieves an F1-score of 0.9571 (ranked 24 / 58) on Task 1a, an RMSE of 0.5580 (ranked 18 / 50) on Task 1b, an F1-score of 0.5024 (ranked 26 / 36) on Task 1c, and an RMSE of 0.7229 (ranked 45 / 48) on Task 2a.

## 1 Introduction

Humor detection is the process of identifying sequences of text that are amusing—an important task, as such sequences are present in most channels of communication. Although humor detection comes naturally to humans, it is difficult for artificial systems to do the same. Part of the challenge is that it is debatable what constitutes humor; what one reader finds funny may be found utterly prosaic by the next. The problem is only complicated when demographic factors come into play; now, the element of offense is also a factor.

SemEval-2021 Shared Task 7 attempts to address some of these open problems (Meaney et al., 2021). Rather than definitively labeling text as humorous or not, Task 1a aims to determine whether the author intended for the sentence to be humorous, Task 1b predicts its humor rating by the average user (its first moment), and Task 1c attends to whether the variance of its humor ratings (its second moment) exceeds the median. Task 2a, meanwhile, considers the text’s average offensiveness score, a metric that often correlates with whether the author meant the text to be humorous and—perhaps equally importantly—affects whether the joke would be consid-

ered acceptable. Overall, training models to perform well on these tasks is of central importance to developing systems that are responsive to a wide range of input, whether in complete jest or meant to be taken at face value.

## 2 Dataset

We train and validate our models on the SemEval-2021 Task 7 training set (Table 6). Each English sentence is annotated for the following four labels, with continuous annotations labeled using a Likert scale from 1 to 5.

#	Description	Label
1a	Is the intention of this text to be humorous?	Binary
1b	How generally humorous is the text for the average user?	Continuous
1c	If the sentence is humorous, is the the humor controversial? <sup>1</sup>	Binary
2a	How generally offensive is the text?	Continuous

Table 1: Annotations/subtasks with their descriptions. We submit separate models for each of these tasks.

### 2.1 Train-test split

The dataset has a total of 10000 examples, split 8000–1000–1000 between train, validation, and test sets. However, the official development set lacked labels until the last phase of the competition, so we created our own held-out validation set for our experiments. Consequently, our train set has 6,400 examples, and our validation set has 1,600 examples. In our paper, all “validation set” performance is reported on this internal held-out set.

<sup>1</sup>In gold standard labels, an example is deemed controversial if its variance exceeded the median variance of all examples.

### 3 Methods

#### 3.1 Task 1a: Humor Prediction

The goal of this task is to model whether a given text is intended to be humorous. Hypothesizing that pretrained language models could effectively model the presence of humor in statements, we investigate the following models:

- **BERT** (Devlin et al., 2019) is a pretrained masked language model. We use BERT-Large in our experiments (335M parameters).
- **RoBERTa** (Liu et al., 2019) is a robustly optimized BERT pre-training approach that utilizes changes including a larger pre-training dataset and a dynamic masking pattern strategy. We use RoBERTa-Large (335 parameters).
- **ELECTRA** (Clark et al., 2020) is a pretrained model that uses a discriminative replaced-token identification loss rather than a demasking objective, resulting in greater data efficiency. We use ELECTRA-Large (336M parameters).

**Ensemble** We also investigate an ensemble which incorporates one BERT-large, one RoBERTa-large, and nine ELECTRA-large models. Our models were averaged with equal weights. Each ELECTRA model was trained with a different random seed from 100 to 900; in the row corresponding to the ELECTRA model’s performance, we have only included the result from the best seed (200).

**Pretraining details** We trained with binary cross-entropy loss for 3 epochs, using a learning rate of  $1 \times 10^{-5}$  and batch sizes of 16 (ELECTRA) and 8 (BERT, RoBERTa).

##### 3.1.1 Results

We find that all models achieve high F1 and accuracy, with ELECTRA performing the best of any individual model. However, we achieve the highest performance using our ELECTRA + BERT + RoBERTa ensemble. Notably, the ensemble achieves a slightly superior performance to each of its individual component models. Overall, we are ranked 24th out of 58 on this task, achieving an F1-score of 0.9571.

Model	# params	F1	Accuracy
BERT	335M	0.941	0.928
RoBERTa	355M	0.952	0.940
ELECTRA	336M	0.956	0.944
<i>Ensemble</i>	—	<b>0.957</b>	<b>0.946</b>

Table 2: Performance of our candidate models on the official evaluation set for Task 1a (humor prediction). Out of the individual models, ELECTRA achieves the strongest results, and ensembling the predictions of multiple pretrained models slightly helps both F1 and accuracy.

#### 3.2 Tasks 1b, 1c, and 2a: General Humor, Controversy, and Offensiveness

##### 3.2.1 Models

Despite their success on Task 1a, we were unable to achieve strong results with pretrained language models on the other tasks. Consequently, we experimented with several other machine learning methods, using lightweight features as inputs. We examine a number of different supervised learning algorithms, implemented using the **Scikit-learn** (Pedregosa et al., 2011) framework:

- **Support Vector Machine** is a lightweight classification algorithm that employs a hyperplane that divides a dataset into two subsets.
- **Random Forest** is a supervised learning technique that utilizes independently trained decision trees that sample from a random selection of data.
- **Gradient Boosting** is a technique that ensembles a number of weak learners (typically decision trees) and optimizes based on a differentiable loss function.
- **LightGBM** (Ke et al., 2017) is a highly efficient gradient boosting decision tree that takes advantage of GOSS (gradient-based one side sampling) and EFB (exclusive feature bundling).
- **AdaBoost** (Schapire, 1999) (**Adaptive Boosting**) is an instance of gradient boosting that optimizes by re-weighting weak learners based on high-weight data points (rather than using a differentiable loss function).
- **Multilayer Perceptron** is a feed-forward deep neural network.

Model	Features	F1 (1c)	Accuracy (1c)	RMSE (1b)	RMSE (2)
AdaBoost	GloVe	0.48	0.48	0.564	1.355
CatBoost	GloVe	0.51	0.51	0.563	0.877
GradientBoosting	GloVe	0.52	0.52	0.572	0.848
<b>LGBM</b>	<b>GloVe</b>	0.50	0.50	0.552	<b>0.808</b>
Logistic Regression	GloVe	0.52	0.52	—	—
Logistic Regression	Manual	0.50	0.53	—	—
MLP	GloVe	0.49	0.49	0.562	0.798
<b>RandomForest</b>	<b>GloVe</b>	0.52	0.53	<b>0.548</b>	0.928
<b>SVM</b>	<b>GloVe</b>	<b>0.55</b>	<b>0.55</b>	0.551	0.874
XGBoost	GloVe	0.52	0.52	0.556	0.858

Table 3: Validation set performance of candidate models on Task 1b, 1c, and 2a (controversy classification). For tasks 1b (humor rating), 1c (humor controversy), and 2a (offense rating), the highest-performing models are the random forest model with  $n_{trees} = 1000$ , the support vector machine, and the LGBM, respectively. We did not run experiments for entries marked —.

- **CatBoost** (Dorogush et al., 2018) is a variant of gradient boosting that prioritizes low latency via symmetric trees.
- **XGBoost** (eXtreme Gradient Boosting) (Chen and Guestrin, 2016) is an implementation of gradient boosting that efficiently makes use of parallel computation.

### 3.2.2 Features

Given that the subjectivity of humor is often correlated with the subject matter of the joke, we also examine its impact on humor controversy in an alternative approach to Task 1c. Often, a joke regarding a sensitive topic may be comical to one reviewer but downright unamusing to a second, whose sense of humor is entirely disparate from the first’s.

In this approach, we use a suite of engineered one-hot features with logistic regression (Table 4). Our manual features consist of groups that are typically stereotyped: more specifically, each manual feature consists of a set of tokens, and its value is the number of times a token from its set appears in the input.

In an effort to interpret the significance of these features, we calculate logistic regression (LR) coefficients with respect to the controversy label. The results show that several features were unrelated or inversely correlated to humor controversy (most notably the “Black” feature); they also indicate that a few were strongly positively correlated (such as the “White” feature).

For our final models, we use 300-dimensional GloVe word vectors (Pennington et al., 2014) mean-pooled over each sentence.

### 3.2.3 Results

The official evaluation set performances for our Transformer-based models in Task 1a are listed in Table 2, while the unofficial validation set performances for our regressors and classifiers are listed in Table 3.

For Task 1b (humor rating), we achieve the highest performance using our Random Forest model. Overall, we are ranked 18th out of 50 on this task, achieving an RMSE of 0.5580.

For Task 1c (humor controversy), we achieve the highest performance using our SVM model. Overall, we are ranked 26th of 36 on this task, achieving an F1-score of 0.5024.

For Task 2a (offense rating), we achieve the highest performance using our LGBM model. Overall, we are ranked 45th out of 48 on this task, achieving an RMSE of 0.7229.

## 4 Conclusion

We have presented models trained to predict various aspects of humor in text: the level of intended humor, the level of humor for average users, and the level of controversy and offense of a given humorous statement.

We find that large pretrained models such as ELECTRA, RoBERTa, and BERT are effective at predicting the level of intended humor. Furthermore, we note that ensembling these models slightly improves performance. However, our ex-

Feature	Description	LR Coefficient
BLACK	Words referring to those of African descent.	-0.508
AMERICAN	The word “American.”	-0.493
GENDER	Words associated with women.	-0.234
INTELLIGENCE	Words associated with stupidity.	-0.169
ISLAM	Words referring to the religion or associated institutions.	-0.102
RELIGION	All major religions not including Islam.	-0.096
RACIAL	Words referring to those of Asian, Latin American, and African descent.	-0.062
SEXUALITY	Words relating to sexuality.	-0.051
HOUSING	The word “homeless.”	-0.008
BRUTALITY	Words heavily connoting violence.	0.064
COUNTRIES	Words relating to nationalities not included in “Racial” or “American” features.	0.077
BLONDE	The word “blonde.”	0.112
PARTNER	Significant others or family members; controversial jokes often include words regarding female partners.	0.164
SEXUAL	Words relating to sexual activity.	0.171
VULGAR	Profanity.	0.242
WHITE	Words referring to those of Caucasian descent.	0.547

Table 4: Manual features for Task 1c (controversy classification)

periments highlight that pretrained models yield weaker results when faced with regression tasks, as well as when faced with the goal of trying to predict whether a given statement’s humor rating has high controversy. This may be due to difficulty in predicting inter-rater disagreement (i.e. if the humor metric’s variance exceeds the median variance).

Next, we note also that our engineered one-hot feature approach toward humor subjectivity does not perform significantly better than the baseline models. While our results do reveal a positive correlation between certain manual features and humor controversy—illustrating that humor subjectivity is to some degree affected by subject matter—our results suggest that on the whole, the effects of this relationship are limited.

Overall, our results suggest that reasonably lightweight models can achieve strong results in modelling humor in human language.

## Acknowledgments

The authors would like to thank Ethan A. Chi for his support and guidance throughout this project. We would also like to acknowledge Google Colab- oratory for their free compute services.

## Abstract

This paper describes Humor-BERT, a set of BERT (Devlin et al., 2019) Large based models that we used to solve the SemEval-2021 Task 7: Detecting and Rating Humor and Offense (Meaney et al., 2021). It presents pre and post processing techniques, variable threshold learning, meta learning and Ensemble approach to solve various sub-tasks that were part of the challenge. We also present a comparative analysis of various models we tried. Our method was ranked 4<sup>th</sup> in Humor Controversy Detection, 8<sup>th</sup> in Humor Detection, 19<sup>th</sup> in Average Offense Score prediction and 40<sup>th</sup> in Average Humor Score prediction globally. F1 score obtained for Humor classification was 0.9655 and for Controversy detection it was 0.6261. Our user name on the leader board is ThisIsTheEnd and team name is EndTimes.

## 1 Introduction

The purpose of this paper is to present different approaches that we tried towards various sub-tasks in SemEval-2021 Task 7 Detecting and Rating Humor and Offense task (Meaney et al., 2021). It consists of following sub-tasks:

- Task 1a: Classifying text based on whether they are humorous or not.
- Task 1b: Predicting Humor rating score
- Task 1c: If the text is classed as humorous, predict if the humor rating would be considered controversial, i.e. the variance of the rating between annotators is higher than the median
- Task 2a: predict how generally offensive a text is for users. This score was calculated regardless of whether the text is classed as humorous or offensive overall.

We participated in all of the above sub-tasks. Task 1a and Task 1c are classification problems with F1 score as metric whereas, Task 1b and Task 2a are regression problems with RMS error values as scoring criteria. All the above tasks shared the same training, development and test set (Meaney et al., 2021). Training set consisted of 8000 text sentences, containing labels for all the subtasks. Size of development and test set was 1000 text sentences each.

Humor, is an interesting linguistic challenge. It's an abstract concept and depends a lot on audience and their interpretation of the jargon used to generate humor. Notion of humor changes from culture to culture, age group, gender and social status of target audience. It is a subjective and personal phenomenon. What's humorous to one person could be non humorous or even offensive to the other. In this task, labels and ratings were collected from a balanced set of age groups from 18-70 and variety of genders, political stances and social status (Meaney et al., 2021). Humor detection and rating tasks have been the defined before but the task of detecting Controversy (Meaney et al., 2021) is new and interesting. It captures the variance in humor rating due to variance in age, gender and other demographic features of the user.

This task is also unique in the way that it combines humor and offense rating tasks for the same dataset. What is humorous to one user could be offensive to other depending on their demographic characteristics.

## 2 Related Works

Humor and offense related tasks have been pursued before as well. Various NLP techniques from classical N-gram techniques (Taylor and Mazlack, 2004) to transfer learning over pre-trained language models like BERT (Devlin et al., 2019) have been tried

for humor related tasks. (Yang et al., 2015) extract humor anchors and use a k-NN based classifier to detect humor. (Chen and Soo, 2018) used CNN and highway network whereas, (Weller and Seppi, 2019) used BERT fine tuning to classify humor in text. Apart from text, multimodal data for humor was curated by (Hasan et al., 2019). In other works on multimodal data (Yang et al., 2019) tag video comments data automatically and use audio data alone to predict humor. They used Random Forest and CNN over MFCC features. (Chen and Lee, 2017) take transcripts from TED talk and detect audience laughter using CNN.

### 3 System overview

In development phase, we split the data as training:validation :: 7200:800, but for evaluation phase we take entire 8000 texts for training and 1000 size development set. Later on, we also tried bagging, which will be described later.

#### 3.1 Models

Humor is an abstract linguistic concept, hence a model which can understand the nuances of language should be great for detecting and rating humor, offense and controversy in text. Naturally we tried one of the best language model, BERT and modified it according to the task at hand. We describe below models for each sub tasks separately.

##### 3.1.1 Task 1a: Humor Detection

Various models that we tried for this sub-task are following:

1. BERT-Large fine tune [BERT-L]
2. Fully connected layer over BERT-Large [BERT-FFN]
3. BERT-Large textual entailment [BERT-ENT]
4. CNN over BERT embedding [BERT-CNN]
5. BERT-Large based Ensemble [BERT-ENS]

For BERT-Large fine tune model(BERT-L), we used uncased BERT Large model and fine tuned over train set. We selected the best performing model over development data. For this we selected COLA as task type as it is GLUE task which models standard binary classification. It simply uses softmax classifier over CLS token from last layer of BERT Large model.

In the second approach (i.e. for BERT-FFN), we

tried a 128 size fully connected layer over CLS token from last layer and then two class softmax classifier to get humor probability scores. We also used dropout after CLS and fully connected layer. We also tried textual entailment kind of classification model over BERT Large (BERT-ENT), for this task. Each of the text data is modified to indicate whether humor is implied from any given text. For example training example:

*I'm the Michael Jordan of lazy sports analogies.# 1*  
 becomes  
*I'm the Michael Jordan of lazy sports analogies.### It is humorous. # 1*

Where label 1 represents the presence of humor in original sentence whereas, in case of textual entailment instance it represents whether "It is humorous" is implied by the text sentence. # is just a separator for illustration here. We also used entailment model to augment the dataset by adding various paraphrases of the sentence "It is humorous". For example, the original text above can be augmented in the following way:

*I'm the Michael Jordan of lazy sports analogies.### It is humorous. # 1*  
*I'm the Michael Jordan of lazy sports analogies.### It is funny. # 1*  
*I'm the Michael Jordan of lazy sports analogies.### It is not humorous. # 0*

In another approach (i.e. BERT-CNN), we tried freezing the BERT parameters and used it only to get the sentence embedding from the last layer. We took word embeddings for each word in the sentence from the last layer of BERT and then applied a one layer 1-D CNN over those embeddings, then a fully connected layer and softmax layer to detect humor.

BERT-Large based Ensemble model (i.e. BERT-ENS), is our best model which gave F-1 score of 0.9655. First thing we tried is Bagging of BERT-large models. The base model used in bagging was the model from approach 2. We split the train data in 10 random datasets (i.e. bags) of size 7200(train) and 800(validation). Train 10 base models over each of those datasets and select the best performing model on validation set of size 800. Now com-

bine these 10 models using soft/hard voting ensembling approach. We predict the labels using best models from each of the bag and then take a majority vote among the 10 selected models. We tried variants of this approach where each of the 10 models had different hyper-parameter values, for example different values of dropout and maximum sentence length varies between 64 to 128. In another approach, we sum the softmax score of each epoch of all the 10 bags and then use argmax to predict the labels for each bag. After that, we take a majority vote among 10 such models created (This was our best performing model). The development data of size 1000 was used for hyper-parameter tuning and selection of the final ensemble model. We used **Binary cross entropy** as loss function.

### 3.1.2 Task 1b: Humor Rating

Taking hint from Task 1a, we tried fewer models that we felt would perform better for this sub-task. Following models were tried

1. Fully connected layer over BERT-Large [**BERT-FFN**]
2. BERT-Large based Ensemble [**BERT-ENS**]

The architecture of models 1 is same as the corresponding models in Task 1a (3.1.1), except for the last layer and loss function. Here instead of two class softmax layer we used a linear regression layer to predict the humor rating and used **Mean squared Error** and **Root Mean squared Error** as metric to be minimized. For model in approach 3, we use the same setting as described in Task 1a (3.1.1), except that instead of voting method we used averaging of humor rating predicted by all the base 10 models. As in Task 1a, models from each bag are selected based on which model has least RMS error i.e. the best model among all epochs. In other approach, We took the average of rating predictions from all the epochs that were trained for 10 bags (This was our best model). We also tried bagging models with different hyper-parameter values as in Task 1a. The best hyper-parameter values are described in 4.3.

### 3.1.3 Task 1c: Humor Controversy

We tried models similar to the Task 1a (3.1.1) as described below.

1. BERT-Large fine tune [**BERT-L**]
2. Fully connected layer over BERT-Large [**BERT-FFN**]

### 3. BERT-Large based Ensemble [**BERT-ENS**]

The architecture of models 1 and 2 are same as the corresponding models in Task 1a (3.1.1), except for additional meta learning of softmax thresholds to predict whether the humor is controversial or not. There is class imbalance here and so models were less confident in detecting controversy in humor. Also, it's a challenging task, in the sense that detecting controversy is not so obvious. In order to balance the odds we tried various softmax score threshold values to predict controversy. Instead of taking argmax we tried different values of softmax probability score for Controversy class. For, standard binary classification a threshold of 0.5 is used to predict a particular class. We tried different lower values of threshold in favour of Controversy class, since model were not very confident in detecting it. Threshold value 0.1 worked best for approach 1 and 2.

In 3<sup>rd</sup> approach we use bagging ensemble setting similar to Task 1a (3.1.1) with the difference that we used softmax score averaging of models rather than a voting, and thereafter we used threshold tuning. Threshold value 0.15 worked best for our method. All the threshold values were obtained by fine tuning over development dataset of size 1000.

### 3.1.4 Task 2a: Average Offensiveness Score

This is a regression task, hence we tried models similar to that of Task 1b (3.1.2).

1. Fully connected layer over BERT-Large [**BERT-FFN**]
2. BERT-Large based Ensemble [**BERT-ENS**]

The architecture, loss function and all other settings are same as that of corresponding models in Task 1b (3.1.2).

## 4 Experiments

In this section, we describe the dataset and various experiments performed. For classification tasks we used **Binary Cross-Entropy** loss, whereas for regression tasks we used **Mean Squared Error** as metric to be minimized.

### 4.1 Dataset

We used the dataset provided by the SemEval-2021 Task 7 organizers (Meaney et al., 2021). Dataset consisted of 8000 English text sentences for training and 1000 text sentences for development and

evaluation each. We trained our model on the training dataset only, no external dataset other than that was used. Dataset split for each model has already been described in section 3.

## 4.2 Pre-processing

We removed various special characters which do not contain any useful information. We also expanded emoji symbols to their meaningful definition using existing preprocessing package spaCy since they are really important for tasks such as humor detection and humor rating prediction. Afterwards, texts were lower cased and tokenized using Sentencepiece (Kudo and Richardson, 2018) tokenizer.

## 4.3 Hyperparameters

We tried various values for the hyper-parameters. The one that worked best for us is described in table 1.

Hyper-parameter	Value
Batch Size	32
Learning rate	2e-5
Maximum Sentence length	64, 128
CLS layer Dropout	0.3
FFN layer Dropout	0.5
Number of Bags	10
Number of Epochs	25
FFN Activation	<i>tanh</i>
FFN hidden size	128

Table 1: Hyper-parameter values

Changing Maximum sentence length didn't make much difference in results. Activation function *tanh* worked better than *relu* and *gelu*. CLS layer dropout is dropout after last layer of BERT. FFN layer dropout is applied after Feed forward network layer of hidden size 128. Dropout was required because the model was too complex for 8000 size dataset. No of Bags is the no of bags/no of base models we trained during Bagging ensemble approach. All the models were developed using Tensorflow (Abadi et al., 2015) library. Training was done on NVIDIA Tesla P-40 GPUs.

## 5 Results and Analysis

We describe the results for each of the sub-tasks and analyse the results. Baseline for classification

task was Naive Bayes model with bag of words features, and for the regression task, it was Support Vector Regression.

Model	F1 Score
Baseline	0.884
BERT-L	0.926
BERT-FFN	0.935
BERT-ENT	0.912
BERT-CNN	0.937
<b>BERT-ENS</b>	<b>0.966</b>

Table 2: Humor Detection Results

Model	RMS Error
Baseline	0.861
BERT-FFN	0.667
<b>BERT-ENS</b>	<b>0.654</b>

Table 3: Average Humor Score Results

Model	F1 Score
Baseline	0.462
BERT-L	0.567
BERT-FFN	0.586
<b>BERT-ENS</b>	<b>0.626</b>

Table 4: Humor Controversy Results

Model	RMS Error
Baseline	0.642
BERT-FFN	0.522
<b>BERT-ENS</b>	<b>0.469</b>

Table 5: Average Offensiveness Score Results

We see in table 2 that applying a Feed Forward network with dropout layer improves the result. This is expected since a FFN layer after BERT results in non-linear combination of BERT features. Dropout is required because model is more complex now. BERT-CNN also performs reasonably well because of efficacy of CNN in learning and combining  $N - Gram$  features. Not to mention, here we have frozen the BERT layer so no of parameters is less. Relatively poor performance of BERT-ENT can be attributed to the fact that this task is not suitable for Textual Entailment

classification. **BERT-ENS** outperforms other models by huge margin. Here we see the effect of bagging as a way to reduce error due to variance. Different base models learn different features and peculiarities. BERT-Large is a complex and strong classifier, so understandably, it has high variance. Combining multiple BERT-Large models using voting mechanism provided quite a significant jump in F1 score.

For Average Humor score results in table 3 we again see that a single BERT model with FFN does perform well but bagging reduces the error caused by high variance. We see same pattern for Average Offensiveness score. In fact the effect of bagging is even more prominent there.

Meta-learning in form of variable softmax threshold worked really great for Humor Controversy detection. Humor Controversy is even more abstract than Humor and hence difficult to detect. There is class imbalance as well, since, very few examples are actually Controversial. So, we had to lower the softmax probability threshold values for Humor Controversy class. Individual BERT model is a weak learner in this case that's why combining them results in a huge jump in F1 score. On comparing our results with the baseline models we see that even a single BERT-Large model outperforms the baseline by large margin. This solidifies our notion that a great language model like BERT will always be a top performer in NLP tasks. And, combining the BERT with ensemble methods has potential to outperform other competing models.

## 6 Conclusion and Future Work

Humor is a abstract linguistic construct. That is why a strong language model like BERT-Large performs really well on these tasks. Our models were ranked under 10 in 2 tasks and under 20 in 1 task, this shows that BERT based models outperform other models. Especially, if many BERTs are combined using a good ensemble technique. For future work ensemble methods like stacking and blending could be tried. Also, different models with different hyper parameter values could be combined in a more effective way to get better results.

# IITH at SemEval-2021 Task 7: Leveraging transformer-based humorous and offensive text detection architectures using lexical and hurtlex features and task adaptive pretraining

Tathagata Raha, Ishan Sanjeev Upadhyay, Radhika Mamidi, Vasudeva Varma

IIT Hyderabad, India,

{tathagata.raha, ishan.sanjeev}@research.iiit.ac.in

{radhika.mamidi, vv}@iiit.ac.in

## Abstract

This paper describes our approach (IITH) for SemEval-2021 Task 5: HaHackathon: Detecting and Rating Humor and Offense. Our results focus on two major objectives: (i) Effect of task adaptive pretraining on the performance of transformer based models (ii) How does lexical and hurtlex features help in quantifying humour and offense. In this paper, we provide a detailed description of our approach along with comparisons mentioned above.

## 1 Introduction

Humour is an important part of human conversation. It has a social function as well and can play an important role in group cohesiveness(Ziv, 2010). Hence humorous content is also found on various social media websites. While there has always been a fine line between funny and offensive humour, the anonymity, distance and isolation provided by being online can increase instances of offensive or controversial humour being posted online. (Weitz, 2017)

In this task, we have presented a transformer based approach combined with lexical and hurtlex feature sets to quantify humour and offense of a piece of text.

We achieved an F1 score of 0.959 in the humor classification task and 0.592 in the humor controversy task. For the regression tasks, we achieved a RMSE score of 0.541 and 0.488 in the humor regression and offense regression task respectively.

## 2 Related work

There have been many attempts made at computational humour detection. In this section, we briefly describe other work in this area. In this approach(Blinov et al., 2019), the authors have used universal language model fine-tuning method

for humour recognition. Convolutional neural networks (CNN) have also been used for this task by (Chen and Soo, 2018) whereas (Weller and Seppi, 2019) used transformers to classify humour.

There has also been a lot of shared tasks and workshops related to computational humour. One of them is SemEval-2020 Task 7: Assessing Humor in Edited News Headlines(Hossain et al., 2020) where Zhang(Zhang et al., 2020) used bidirectional neural networks with an attention mechanism and incorporated lexical features to assess humour in edited news headlines.

There has been a lot of work done on hate speech and offensive speech detection as well. CNN's and gated recurrent units (GRU) have been used for this task (Zhang and Luo, 2018). Recurrent neural networks combined with user-related information have also been used for hate speech detection in Twitter Data (Pitsilis et al., 2018) whereas multilingual transformer architectures were leveraged by (Ghosh Roy et al., 2021) to detect hostile content in English, Hindi and German.

## 3 Task and dataset overview

The task(Meaney et al., 2021) is divided into 4 sub-tasks.

1. **Humour detection:** This is a binary classification task where the model needs to predict if the text is humorous or not where the values are either 0 and 1.
2. **Humour Rating:** This is a regression task where the model needs to rate how humorous the text is where the value can vary between 0 to 5.
3. **Controversy detection:** This is a binary classification task where the model needs to classify text as controversial or not if it has been classified as humorous. It can be either 0 or 1.

4. **Offense Rating:** This is a regression task where the model needs to rate how offensive the text is. It can vary between 0 to 5.

The dataset for the tasks was provided by The workshop organizers. It consisted of 10,000 sentences. 8,000 sentences were provided for training and 1,000 for validation. The remaining 1,000 were used for testing. Each row consisted of a unique identifier, the text and the label values of "is\_humor", "humor\_rating", "humor\_controversy" and "offense\_rating".

## 4 Methodology

### 4.1 Hurltlex features

HurtLex (Bassignana et al., 2018) is a lexicon of offensive, aggressive, and hateful words in over 50 languages which is further categorized into 17 categories. Identifying these kinds of words can potentially help in offensive content detection. Also, in some cases, a humorous piece of text might contain such a word to denote humour. We have also experimented with this feature for humour classification and regression task.

### 4.2 Lexical features

The structure of humorous and offensive texts can be a bit different from normal texts. We have leveraged a lexical feature set that would help us capture that information and distinguish humorous and offensive texts. The set of lexical features are:

- Counting the total number of letters, punctuation, upper case letters and numbers within the text.
- Identifying the presence of any named entity. For detecting named entities, we have used the AllenNLP named entity recogniser<sup>1</sup> which uses pretrained GloVe vectors for token embeddings and a GRU encoder. (Peters et al., 2017)
- Detecting the presence of interrogation by identifying "??" symbol or any WH-word
- Detecting the number of personal pronouns and what kind of personal pronouns they are: first-person, second-person or third-person.

<sup>1</sup><https://demo.allennlp.org/named-entity-recognition/named-entity-recognition>

For detecting the personal pronouns, we have used a pre-defined list of personal pronouns.

### 4.3 Sentence embeddings

For generating the sentence embeddings, we have experimented with 4 different pre-trained transformer models: bert-base-uncased (Devlin et al., 2018), roberta-base (Liu et al., 2019), google/electra-base-discriminator (Clark et al., 2020) and xlnet-base-cased (Yang et al., 2019). Initially, we finetuned each of the pre-trained models for each task and made predictions on the validation set. On the basis of the performance, we have selected one pre-trained model to proceed to our final setup 4.5. For the binary humour classification, humour regression and offensive regression task, we have selected roberta-base. On the other hand, google/electra-base-discriminator gave the best performance for humour controversy task.

### 4.4 Task adaptive pretraining

In the paper (Gururangan et al., 2020), we can see the benefits of continued pretraining of pre-trained transformer models on unlabelled task-specific data or Task Adaptive Pretraining (TAPT) before finetuning them on a downstream task like text classification. This paper (Raha et al., 2021) showcases the gains attributed to further pre-training of the IndicBERT (Kakwani et al., 2020) model for hostility detection in Hindi. We have experimented with the same approach for all our downstream tasks where a pretrained transformer model (roberta-base for humor classification, regression and offensive regression) is further pretrained on training data with the masked language modelling (MLM) objective. In our results 5, we have shown the benefits gained from task adaptive pretraining for each task. Note that task adaptive pretraining was not done on google/electra-base-discriminator for the humour controversy classification.

### 4.5 Final setup

In this subsection, we outline our final architecture from the set of input features to the final label generation for each task.

At first, we have generated the set of lexical features and the hurltlex features on both training, validation and testing data. For generating the hurltlex features, we have used the featurizer in hurltlex

Setting	Task 1a (F1-Score)	Task 1b (RMSE)	Task 1c (F1-Score)	Task 2 (RMSE)
TRANS	0.944	0.572	<b>0.592</b>	0.522
TRANS + LEX	0.956	0.547	0.521	0.524
TRANS + HURT	0.949	0.570	0.347	<b>0.488</b>
TRANS + LEX + HURT	<b>0.959</b>	<b>0.541</b>	0.375	0.505

Table 1: Results on the Validation split for each task with and without hurtlex and lexical features. TRANS refer to transformer embeddings, LEX refer to lexical features and HURT refers to hurtlex features. Task 1a refers to humour classification, Task 1b refers to humour regression, Task 1c refers to humour controversy and Task 2 refers to the offensive regression task. For Task 1a, 1b and 2 we have used the TAPT roberta-base and for task 1c we have used pre-trained google/electra-base

Github repository <sup>2</sup>. We have used Pytorch(Paszke et al., 2019) <sup>3</sup> and Pytorch Lightning as our primary deep-learning framework <sup>4</sup>. For our pre-trained transformer models, we chose the roberta-base <sup>5</sup> and google/electra-base-discriminator<sup>6</sup> as a part of HuggingFace’s Transformers library. For performing the task adaptive pretraining(TAPT) on downstream tasks, we have used AllenAI’s implementation of Task Adaptive Pretraining<sup>7</sup>. The roberta-base model was further pretrained on MLM objective for 100 epochs with the other hyperparameters being set to their default values. For all the transformer architectures, we have set the maximum sequence length to 128. As this is a classification task, we have used the embeddings of [CLS] as the transformer representation of the whole sentence.

Finally, the embeddings generated from the transformer models are concatenated with hurtlex features and lexical features to form the final vector representation for a particular text. For optimization, we have used the Adam (Kingma and Ba, 2017) optimizer where the learning rate was set to 1e-5 and a dropout (Srivastava et al., 2014) with the probability of 0.1. We updated weights based on cross-entropy loss values for the classification tasks and Mean Squared Error for the regression tasks. A dense multi-layer perceptron serves as the final binary classifier head or regression head. The model weights were saved and evaluated on the development set at the end of every epoch and the finetuning continued for 10 epochs. We have

Task	Without TAPT	With TAPT	Gains
Task 1a (F1-Score)	0.933	0.944	0.011
Task 1b (RMSE)	0.616	0.572	0.044
Task 2 (RMSE)	0.579	0.522	0.057

Table 2: Results on the Validation split for each task with and without Task Adaptive Pretraining(without considering the lexical and hurtlex features). Task 1a refers to humour classification. Task 1b refers to humour regression and Task 2 refers to the offensive regression task.

reported the scores of the models that yielded the best F1 score on the development set and used them to further predict on the test set. We have also experimented with or without considering the hurtlex and lexical features to showcase the gains or losses attributed to them.

## 5 Results

The gains attributed to task adaptive pretraining of roberta-base on the humour classification is shown in table 2. We can see that continued pretraining of roberta-base has improved the model performances significantly.

In table 1, we can see the results of inclusion and exclusion of the lexical and hurtlex features for each task. We notice that lexical and hurtlex features do contribute to the performance of humour classification. Combining hurtlex features and lexical features with transformer embeddings have improved the results of both humour classification and humour regression task. For offensive regression, the hurtlex features played an important role while lexical features degraded the performance. This is probably because the lexical features were curated for the identification of humour. For the

Task	Score	Rank
Task 1a (F1-Score)	0.9616	14
Task 1b (RMSE)	0.5263	5
Task 1c (F1-Score)	0.6242	6
Task 2 (RMSE)	0.4772	23

Table 3: Results on the test split for each task and their respective ranks on the leaderboard during the evaluation phase. Task 1a refers to humour classification, Task 1b refers to humour regression, task 1c refers to humor controversy and Task 2 refers to the offensive regression task.

humour controversy, excluding lexical and hurtlex features gave the best results. This might be because textual features played much more important role than lexical and hurtlex features.

In table 3, we report the results obtained on the test set during the evaluation phase and the rank of our models on the official leaderboard<sup>8</sup>. We used the best performing models on the validation set to achieve those results.

Overall, this work shows how task adaptive pre-training can improve model performance for downstream tasks and the role of hurtlex and lexical features for humor and offensive detection.

## 6 Conclusion

All the experiments performed above were done with default hyperparameters (unless explicitly mentioned) due to resource constraints. The model performances could have improved if we could search for optimal hyperparameters using cross validation. Furthermore, the regression tasks could improve if we could use an ensemble of the best performing models for our final predictions.

## Abstract

The “HaHackathon: Detecting and Rating Humor and Offense” task at the SemEval 2021 competition focuses on detecting and rating the humor level in sentences, as well as the level of offensiveness contained in these texts with humoristic tones. In this paper we present an approach based on recent Deep Learning techniques by both trying to train the models based on the dataset solely and by trying to fine tune pretrained models on gigantic corpus.

## 1 Introduction

The figurative language of Social Media is one of the most challenging topics facing natural language processing (NLP). In this study, we refer at humor that requires a multidisciplinary approach for its detection (Dan Alexandru and Daniela Gifu, 2020). Imagine, a viral topic on social media as elections (Gifu, 2010) or a political crisis (Delmonte, Rodolfo and Tripodi, Rocco and Gifu, Daniela, 2013). Social media users themselves introduce a specific language based on common practices (e.g., humor, irony), making their message analysis very challenging (Reyes, Antonio and Rosso, Paolo and Buscaldi, Davide, 2012). The legitimate research questions of this paper intend to answer: Is humor an insurmountable barrier for Artificial Intelligence (AI)? We propose an approach based on recent DL techniques for sentiment analysis (SA). Furthermore, we experimented with multiple types of DL architectures ranging from Convolutional Neural Networks (CNN) to Recurrent Neural Networks (RNN) which we tried to train using only the dataset provided by the SemEval-2021 Task 7 competition, but we also used pretrained Transformer architectures which we fine-tuned using the available data. The rest of the paper is organized as follows: section 2 describes the literature related to sentiment analysis and humor detection, section

3 presents the dataset and method of this study, section 4 summarizes the results of the conducted experiments, with discussions after experiments, followed by section 5 with the conclusions.

## 2 Related Work

This topic has attracted significant attention in recent years, evidenced by increasing number of workshops of the same competition (e.g., SemEval-2017 Task 6: HashtagWars: Learning a Sense of Humor or SemEval-2020 Task 7: Assessing Humor in Edited News Headlines). Such a competition is attractive, especially since the problem of labeled data is somewhat solved, considering the fact that the automatic humor recognition depends on these. For the binary task, as in this case, there are many computational models to solve it or to detect the humor intensity or humor dimension (Yang, Diyi and Lavie, Alon and Dyer, Chris and Hovy, Edward, 2015) (Chen, Peng-Yu and Soo, Von-Wun, 2018). Thus, work on this topic was never followed by high results, as this problem is still almost subjective and text classification even for humans is very controversial and biased. Never the less, the task can be approached like any SA task for which most of the authors used LSTMs (Murthy, Dr and Allu, Shanmukha and Andhavarapu, Bhargavi and Bagadi, Mounika, 2020) or CNNs (Ouyang, Xi and Zhou, Pan and Li, Cheng Hua and Liu, Lijun, 2015). New approaches concentrate on using attention based methods (Vaswani, Ashish and Shazeer, Noam and Parmar, Niki and Uszkoreit, Jakob and Jones, Llion and Gomez, Aidan N and Kaiser, Lukasz and Polosukhin, Illia, 2017), in particular transformer architectures such as BERT (Devlin, Jacob and Chang, Ming-Wei and Lee, Kenton and Toutanova, Kristina, 2018), RoBERTa (Liu, Yinhan and Ott, Myle and Goyal, Naman and Du, Jingfei and Joshi, Mandar and Chen, Danqi and

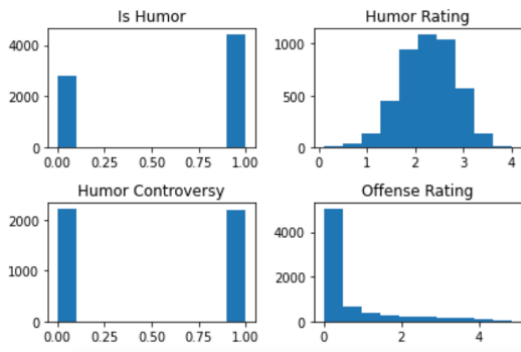

Figure 1: Data distributions by subtasks.

Levy, Omer and Lewis, Mike and Zettlemoyer, Luke and Stoyanov, Veselin, 2019), ALBERT (Lan, Zhenzhong and Chen, Mingda and Goodman, Sebastian and Gimpel, Kevin and Sharma, Piyush and Soricut, Radu, 2019), and VideoBERT (Sun, Chen and Myers, Austin and Vondrick, Carl and Murphy, Kevin and Schmid, Cordelia, 2019). These transformers are pre-trained on unlabeled data to be later fine-tuned for a variety of tasks. For this task we used the BERT architecture.

### 3 Dataset and Methods

This section contains details about the dataset built as part of SemEval-2021 Task 7 HaHackathon: Detecting and Rating Humor and Offense, which was the basis for solving the subtasks of this competition.

#### 3.1 Dataset

The dataset (Meaney, J.A., and Wilson, Steven R. and Chiruzzo, Luis and Lopez, Adam and Magdy, Walid, 2021) consists of 8000 short texts that have four labels corresponding to the four subtasks of the competition. The first label is binary and determines if the text is humorous. If this label is 1, then it has associated two additional labels: one for the second task which is a number from 0 to 5 representing the average humorous score of the annotators and another denoting if the kind of humor is controversy, again a binary classification. Regardless of the previous 3 scores, the fourth is score from 0 to 5 denoting if the text is offensive. Because of these conditions we used the entire dataset only for the first and the fourth tasks, and for the second and third we only used the texts which were labeled to be humorous. Table 1 shows some examples from the dataset of SemEval-2021 Task 7.

Note that for the third task, the labels seemed to be randomly assigned, neither of our methods succeeding in obtaining a better performance than one we would obtain by flipping a coin. Because of this situation we will only present the results for the remaining three subtasks.

#### 3.2 Method

In order to apply DL-based modeling techniques, we first need to embed the words in a vector form that the neural networks can work with. In order to achieve this, we used two methods depending on the architecture trained. For the models that we trained from scratch we used a tokenizer implemented in the Keras library <sup>1</sup> (TextVectorization) which performs the following steps exemplified on the sentence: “The quick brown fox jumps over the lazy dog.”

1. lowercasing and punctuation stripping; “the quick brown fox jumps over the lazy dog”
2. splitting the text into words; [“the”, “quick”, “brown”, “fox”, “jumps”, “over”, “the”, “lazy”, “dog”]
3. assembling tokens, assessing each token an index; “the”:1, “quick”:2, “brown”:3, “fox”:4, “jumps”:5, “over”:6, “lazy”:7, “dog”:8
4. transforming the text into a sequence of integers. [1, 2, 3, 4, 5, 6, 1, 7, 8]

After the tokenization, we mapped these indexes to the words from the GloVe embeddings which contains a vocabulary size of 400k words, more than enough for our task. We chose the predefined embedding size of 100 and standardized the texts to a length of 70. Figure 2 shows a histogram of the number of words after splitting the texts by space.

We also fine-tuned a pretrained BERT model which uses its own set of embeddings. In this case the huggingface <sup>2</sup> library which also provides the pretrained model offers the tools to embed the words into the necessary vectors specific to the selected model. After having the embeddings for either set of methods, we further describe the architectures used. We trained the following models from scratch:

<sup>1</sup><https://keras.io/>

<sup>2</sup><https://huggingface.co/transformers/>

id	text	is humor	humor rating	controversy	offense rating
35	Learn from the scars of others	0			0.05
119	What do you call a sad terrorist? A crisis	1	2.16	1	0.85
81	January is the Monday of months	1	2.43	0	0.00

Table 1: Examples of texts and their humor labels.

Figure 2: Histogram for the number of words in texts.

1. Convolutional Neural Networks (CNN). We created simple sequential models with 1D convolutions and max pooling layers followed by global average pooling and a few fully-connected layers. We haven't experimented with more advanced architectures like ResNet (Kaiming He and Xiangyu Zhang and Shaoqing Ren and Jian Sun, 2015) and Inception (Christian Szegedy and Wei Liu and Yangqing Jia and Pierre Sermanet and Scott E. Reed and Dragomir Anguelov and Dumitru Erhan and Vincent Vanhoucke and Andrew Rabinovich, 2014) because we found that even the simplest model drastically overfits the data.
2. Bidirectional LSTM and GRU cells. In order to take advantage of the natural structure of sentences we used the two most popular recurrent cells and we also wrapped them into a Bidirectional wrapper. Each cell was used in a separate architecture and we didn't stack more than one cell because we again found that it tends to overfit.
3. Transformer blocks. In order to take advantage of the recent developments in the NLP tasks, we created the encoder part of the original Attention is all you need paper. We used six encoding blocks followed by a global average pooling layer and a few fully-connected layers.

We employed a pretrained transformer model (BERT) from the huggingface library which was trained on cased datasets. We used the base model which has around 100 million parameters and used our dataset to only fine tune this model. Because only the first and fourth tasks used the entire dataset, we applied all these methods only on the first task, the classification between humorous and non-humorous. As it can be observed from Figure 1 the dataset is imbalanced, therefore we applied class-weight on the 0 class such that the loss from the two classes among the entire dataset will be equal. After experimenting with the hyperparameters (mainly with the dropout rate which finally we chose it to be 0.2) on this single task, the best configuration was used on the other three tasks, changing only the activation function for the regression tasks from Sigmoid to Rectified Linear Units (ReLU). For the classification tasks, the threshold for the prediction was 0.5 and for the regression ones the predictions from the neural networks were sealed to 5 in order to correspond to the competition's requirements. A diagram summarizing the system architecture can be seen in Figure 3.

The first step is to split randomly the available dataset into a training set and a validation set. We kept 10% of data for the validation set. Then, the next step is to preprocess the data. In order to have a good representation of the metrics on the validation set, we only computed the necessary tools for preprocessing on the training set and then applied these tools to the validation step. Most importantly, the vocabulary used in the models was selected based on the training set solely. For the pretrained BERT model, the tokenizer already contains a large vocabulary meant to cover most of the common words. After preprocessing the dataset, we moved forward to train the models with the corresponding embeddings. As mentioned, we did all the experiments on the first task and we experimented with the hyperparameters on this set. We did not employ a test set due to the small size of the dataset. Finally, we adapted the classification model trained

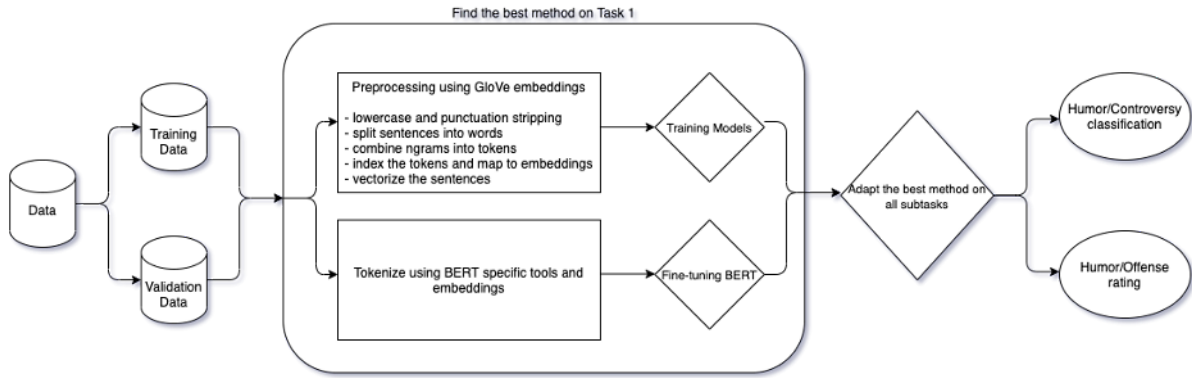

Figure 3: System Architecture.

Task Name	RMSE	Position
Average Humor	0.5598	19 of 50
Average Offensiveness	0.4788	24 of 48

Table 2: Official scores for the regression tasks.

previously to the regression tasks and trained a separate model for each task using only the samples that had the corresponding labels. After all the four models have been trained, we made predictions on the evaluation set using the tokenizer for BERT and the corresponding model.

#### 4 Results and Discussion

Below are presented the official results for all subtasks. For the classification tasks we also report the results in the post-evaluation phase and the ranking as of March 2021. In the official competition we accidentally performed a mistake for the Humor Detection task and reverted the labels that we submitted. That is why we obtained such a poor performance and this is the reason we also report these results as it better reflect the actual performance. We report Accuracy (Acc), F1-score (F1), and Root Mean Square Error (RMSE). The official results are summarized in Tables 2 and 3 and the results in the post-evaluation phase are presented in Table 4.

The results on our validation set for all the techniques are summarized in the graphics depicting the evolution of the metrics over the epochs (Figure 4). The test label refers to our validation set and not the official test set from the competition.

We can easily see that all the methods overfitted the training set. Techniques such as dropout and regularization have been applied, but we observed that they only delayed the moment when overfitting

occurred and did not increase the performance on the validation set. The best accuracy on the validation set of the techniques used on the first task is presented in Table 5.

As it can be observed from the table, the best method turned out to be to fine tune a pretrained BERT model, therefore we used this technique on the rest of the tasks. Despite of its success we can still observe that the accuracy on the validation set (95.4%) differs from the one we obtained in the competition (92.2%). For approaches to SA on a small dataset, the best way is to fine tune pretrained models, rather than trying to train a model from scratch with the available data. The humor detection task turned out to be a very challenging one, fact that can be best expressed by the results on the second classification task where we assume that the very diverse interpretations of the annotators on what constitutes a controversy humor made the task impossible to solve with any DL model. But for more approachable tasks like the first classification task or the regression tasks, probably the more consensus among annotators made the task more tractable to an artificial intelligence model.

#### 5 Conclusion

According with the legitimate question, we still consider that detecting someone’s sense of humor is a difficult problem and identifying the level of offensiveness and irony is an even harder one. In this case, a figurative content could be consider irony, satire, joke, and sarcasm. As with humor, all these figures of speech depends on the listener or reader to be in on this context. This paper presents a system participating at SemEval 2021 Task 7 and tried to adapt existing Deep Learning techniques to the problem of humor detection. This approach indi-

Task Name	Acc	F-Score	Position
Humor Detection	7.8%	0.063	58 of 58
Humor Controversy	50.08%	0.4752	29 of 36

Table 3: Official scores for the classification tasks.

Task Name	Acc	F-Score	Position
Humor Detection	92.2%	0.9374	27 of 39
Humor Controversy	50.08%	0.4752	24 of 41

Table 4: Scores in the post-evaluation phase for the classification tasks as of March 2021.

Figure 4: Evolution of accuracy .

Model	CNN	GRU	LSTM	Transformer	BERT
Validation Acc	84.9%	90.1%	90.1%	88.6%	95.4%

Table 5: The accuracy on the validation set for the 5 techniques on the Humor detection task.

cates promising results since they offer compelling results regarding the accuracy. We also found that we can get the best performance by adapting pre-trained models on other, bigger, datasets, indicating that the internal representation of language of the model acquired in other contexts can be extremely helpful in trying to identify the humor of a sentence. For further research ideas, we consider trying to use data augmentation techniques such as replacing words with synonyms, as well as using similar datasets in order to increase the dataset and the performance of the discussed methods.

ashutoshm@cse.iitk.ac.in

## Abstract

This paper presents the system for SemEval 2021 Task 8 (MeasEval). MeasEval is a novel span extraction, classification, and relation extraction task focused on finding quantities, attributes of these quantities, and additional information, including the related measured entities, properties, and measurement contexts. Our submitted system, which placed fifth (team rank) on the leaderboard, consisted of SciBERT with [CLS] token embedding and CRF layer on top. We were also placed first in Quantity (tied) and Unit subtasks, second in MeasuredEntity, Modifier and Qualifies subtasks, and third in Qualifier subtask.

## 1 Introduction

SemEval 2021 Task 8 (Harper et al. 2021) is a task for extracting entities and semantic relations between them from a corpus of scientific articles coming from different domains. Instead of just identifying quantities, the task gives more weightage to parsing and extracting important semantic relations among the extracted entities. This is challenging because texts are ambiguous, and inconsistent, and extraction relies heavily on implicit knowledge. The results of this task can also be used for extractive scientific data summarization.

Given a scientific text, the task is to identify the span of quantities, units, and other attributes of those quantities and related measured entities, properties, and qualifiers, if any. The organizers have divided the task into five subtasks and submissions will be evaluated against all five sub-tasks<sup>1</sup>.

1. **Quantity Extraction:** For each paragraph of text, identify all Quantity spans.

\* Authors equally contributed to this work.

<sup>1</sup><https://competitions.codalab.org/competitions/25770>

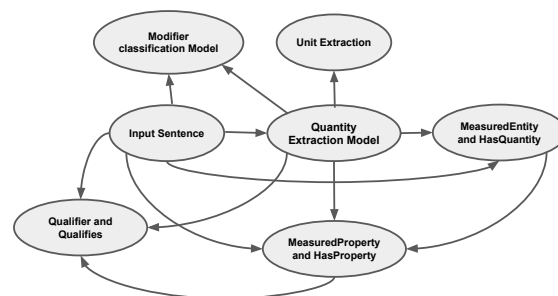

Figure 1: Overview of our proposed approach

2. **Unit Detection and Modifier Classification:** For each identified Quantity, identify the Unit of measurement and classify additional value Modifiers (count, range, approximate, mean, etc.) that apply to the Quantity.
3. **MeasuredEntity and MeasuredProperty Extraction:** For each identified Quantity, identify the MeasuredEntity and MeasuredProperty associated with it.
4. **Qualifier Extraction:** Identify and mark the span of any Qualifier that is needed to record additional related context.
5. **HasQuantity, HasProperty and Qualifies Extraction:** Identify relationships between Quantity, MeasureEntity, MeasuredProperty, and Qualifier.

We consider subtask 1 as an entity extraction task, and subtask 3, 4, and 5 are viewed as relation extraction tasks. After extracting the quantities, other attributes (MeasuredEntity, Property, and Qualifier) related to those quantities need to be predicted. The directed graph in Figure 1 gives an overview of our proposed approach. The set of incoming edges to each node represents the input to the trained model (represented by node), and the label at each node represents the prediction made by the model. The task data is extracted from CC-BY ScienceDirect Articles and made available by

the Elsevier Labs via the OA-STM-Corpus<sup>2</sup>. This motivated the use of SciBERT (Beltagy et al. 2019) model for various subtasks. “SciBERT leverages unsupervised pretraining on a large multi-domain corpus of scientific publications to improve performance on downstream scientific NLP tasks”.

Our final submitted system consisted of SciBERT with [CLS] token embedding and CRF layer on top, and it achieved an overall F1-overlap score of 0.432. We were ranked fifth on the global leaderboard. The top performance on the leaderboard achieved an overall F1-overlap of 0.519. The implementation of our system is made available via Github<sup>3</sup>.

The rest of this paper is arranged as follows. Section 2 introduces the previous work in this field and describes the organizers’ dataset. Section 3 explains our overall approach. Section 4 contains the experimental setup for training the model. We conclude with the analysis of our model performance in section 5 and concluding remarks in section 6.

## 2 Background

### 2.1 Related work

Magge et al. 2018 attempted to recognize the Clinical Entities using a LSTM CRF based architecture. The authors used the word and character level embedding obtained from word2vec (Mikolov et al. 2013). For relation extraction between these entities, authors build a binary classifier using random forest classifier. This approach has higher time complexity as it checks for all possible relationships that could exist and classifies them. The more recent work in entity extraction is by Lee et al. 2019, where they fine-tuned the BERT model using the Bio-Medical data, and have shown SOTA performance. Some other works in entity extraction includes Taher et al. 2020, where they fine-tuned BERT followed by a fully connected layer and a CRF layer.

The work by Wu and He 2019 on Relation Extraction uses BERT to identify the different types of relations between pair of entities in the given text. The system does not automatically recognize the entities between which relation exists, rather entities of interest need to be manually specified.

<sup>2</sup><https://github.com/elsevierlabs/OA-STM-Corpus>

<sup>3</sup><https://github.com/akashgnr31/Counts-And-Measurement>

### 2.2 Task setup

The scientific articles in the training and test corpus are from the following sub-domains: Astronomy, Engineering, Medicine, Materials Science, Biology, Chemistry, Agriculture, Earth Science, and Computer Science. These articles were manually annotated. The inter-annotator agreements was calculated using Krippendorff’s Alpha IAA score (Table 1).

Class	IAA Score
Quantity	0.943
MeasuredEntity	0.640
MeasuredProperty	0.545
Qualifier	0.333
Units	0.866

Table 1: IAA scores of various classes

The training dataset comprised of 298 paragraphs containing 1164 quantities, 1148 measured entities, 742 measured properties, and 309 qualifiers. The evaluation set included 135 paragraphs.

## 3 System overview

### 3.1 Pre Processing

Since we are using the SciBERT model, a maximum of 512 tokens can be passed as input to the model. Therefore, we used SciSpaCy (Neumann et al. 2019) to split the paragraph into sentences, and these sentences were passed as input to the SciBERT model.

### 3.2 Subtask 1 (Quantity Extraction)

Input sentences were tokenized using a SciBERT tokenizer from HuggingFace (Wolf et al. 2020) implementation. The Quantity span were transformed into BIO / IOB format (Ramshaw and Marcus 1995) and used as the true-labels for training the model.

The tokenized sentence is passed through SciBERT. Tanh activation function is applied over the final hidden state of SciBERT i.e.

$$H'_i = W_1[\tanh(H_i)] + b_1 \quad i = 0, 1, \dots, len$$

Here  $H_i$  is the hidden units corresponding to token  $i$  and  $len$  is the maximum length of the tokenized sentence. Similarly, [CLS] token is processed.

$$H'_{cls} = W_0[\tanh(H_0)] + b_0$$

Finally, we get the final representation for the sentence by concatenating  $H'_{cls}$  and  $H'_i$  and this is used for prediction via the softmax.

$$H''_i = W_2[\text{concat}(H'_i, H'_{cls})] + b_2 \quad i = 0, 1, \dots, len$$

$$H'' = [H''_0, H''_1, \dots, H''_{len}]^T$$

$$p = \text{softmax}(H'', \text{dim} = -1)$$

Matrices  $W_0$  and  $W_1$  have same dimension, i.e.,  $W_0 \in R^{d \times d}$ ,  $W_1 \in R^{d \times d}$ ,  $W_2 \in R^{t \times 2d}$ , where  $d$  is the hidden state size from BERT and  $t$  represent the number of tags, i.e.,  $t = 3$  in our case as we are using BIO encoding.

CRF (Conditional Random Field) (Lafferty et al. 2001) is a probabilistic model that makes it possible to extract structural dependencies among the BIO tags. The tag probability vector for all the tokens, i.e.,  $p$ , is passed through the CRF layer to generate the most probable output sequence.

We trained the model using CRF loss and Adam optimizer. The overall architecture of the model is shown in Figure 2. The tuned hyper-parameters are reported in appendix A.1.

### 3.3 Subtask 2 (Unit Detection)

The Quantity phrases are tokenized using Spacy (Honnibal et al. 2020) character-based tokenizer. The true-label for training is formatted as a binary vector marking one at the indices for characters in the unit’s span in the Quantity phrases.

We trained a Character-based Bi-LSTM (Hochreiter and Schmidhuber 1997) model with trainable word embeddings using BCE (Binary Cross Entropy) loss and Adam optimizer. The model architecture and tuned hyper-parameters are reported in appendix A.2

### 3.4 Subtask 2 (Modifier Classification)

We formulated this subtask as a multi-label classification problem with 12 labels (HasTolerance, IsApproximate, IsCount, IsList, IsMean, IsMeanHasSD, IsMeanHasTolerance, IsMeanIsRange, IsMedian, IsRange, IsRangeHasTolerance, None). To enable the BERT module to capture the location of a quantity, we insert the special symbol “\$” at the beginning and end of the Quantity span. If there are multiple Quantities in a sentence, multiple copies of the same sentence are generated with “\$” at different positions. Suppose  $H_i$  to  $H_j$  are the final hidden state vector for the Quantity span. Then, the average operation is applied to get the vector

representation of the Quantity. The averaged output is passed through a fully connected layer followed by softmax activation.

$$H'_q = W \left[ \tanh \left( \frac{1}{j-i+1} \sum_{k=i}^j H_k \right) \right] + b$$

$$p_q = \text{sigmoid}(H'_q)$$

Matrix  $W$  has dimension  $R^{l \times d}$ , where  $l$  represents the number of classification label, i.e.,  $l = 12$  in our case and  $d$  is the hidden state size from BERT.

The above model was trained using BCE (Binary Cross Entropy) and Adam optimizer. The threshold value for prediction was determined using cross-validation. The model architecture and tuned hyper-parameters are reported in appendix A.3.

### 3.5 Subtask 3 and 5 (MeasuredEntity and HasQuantity Extraction)

As done in the previous subtask to capture the location, we insert the special symbol “\$” at the beginning and end of the quantity span. The modified sentences are tokenized using a SciBERT tokenizer. The span of the MeasuredEntity related to Quantity enclosed in the “\$” symbol is transformed into BIO / IOB format and used as the true-label for training the model.

The formatted data is used to train a model similar to the Quantity Extraction (SciBERT + CRF Model). The above model extracts the MeasuredEntity associated with the Quantity enclosed in “\$”. Thus, it predicts the MeasuredEntity as well as the HasQuantity relationship of the predicted MeasuredEntity.

### 3.6 Subtask 3 and 5 (MeasuredProperty and HasProperty Extraction)

To extract MeasuredProperty and HasProperty relationship, we used a similar approach as used for MeasuredEntity and HasQuantity. We enclosed the Quantity span in “\$” symbol and the MeasuredEntity span in “#” symbol. The modified sentences are passed through the SciBERT tokenizer. The span of MeasuredProperty related to MeasuredEntity, Quantity pair is transformed into BIO / IOB format and used as the true-label for training the model.

The formatted data is used to train a model similar to the Quantity Extraction (SciBERT + CRF Model). The model trained is used to extract MeasuredProperty linked with the MeasuredEntity, Quantity pair. If the above model predicts

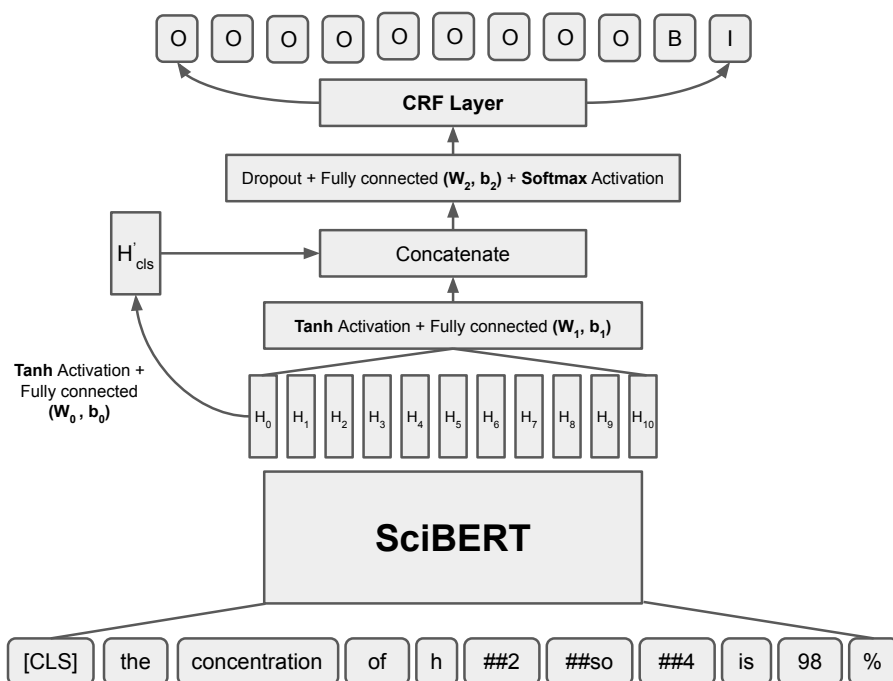

Figure 2: SciBERT with [CLS] token embedding and CRF layer on top (SciBERT + CRF Model)

Measured-Property’s span, then the HasQuantity relation is updated to MeasuredProperty, and the HasProperty relation is added to MeasuredEntity.

### 3.7 Subtask 4 and 5 (Qualifier and Qualifies Extraction)

To extract Qualifier and Qualifies’s span, two separate models similar to Quantity Extraction (SciBERT + CRF Model) were trained. While training the first model, we insert “\$” at the beginning and end of the Quantity span because we assumed that Qualifier Qualifies Quantity. During the second model training, we enclosed the MeasuredProperty span in “\$” because of the assumption that Qualifier Qualifies MeasuredProperty.

### 3.8 Post Processing

Once the predictions from all the models are available, we need to transform the predicted BIO/ IOB format into entity span format. We initially map each token’s span in the tokenized sentence and use it to determine the predicted entity’s span. While finding the span of the MeasuredEntity, MeasuredProperty, or Qualifier, if our model predicts multiple entities, then we predict the one which is closest to the Quantity span. After that, we convert the sentence span of each entity extracted to the paragraph span.

## 4 Experimental Setup

The dataset is split into two parts - train set and dev set in a ratio of 90:10. The models were trained on the train set and were validated on the dev set. The environment and packages used for training and pre-processing are listed in appendix B.

### 4.1 Evaluation Metrics

The official metrics used by the SemEval organizer are F1-measure, F1-overlap, and Exact Match. Exact Match is a binary value of 0 or 1, while F1-measure is a token level overlap ratio of submission to true spans, where tokenization is done using simple white space delimiters. F1-overlap is a SQuAD (Rajpurkar et al., 2016) style Overlap score based on F1-measure, which penalizes the negative submissions more strictly. The final evaluation is based on a global F1-overlap score averaged across all subtasks.

## 5 Results

### 5.1 Model Variants Used

We tried various models like BERT-Base, BERT-Medium (Devlin et al., 2018), SciBERT, and BioBERT (Lee et al. 2019). We could not try BERT-Large due to computational limitations. The results for the top two models are shown in Table 2.

We also experimented with Bi-LSTM layers on top of BERT, but the model was overfitting due

Model	Data Set	Quantity	Unit	Modifier	MeasuredEntity	MeasuredProperty
SciBERT	eval	0.861	0.804	0.614	0.406	0.245
SciBERT	dev	0.887	0.744	0.696	0.322	0.216
BERT-Med.	eval	0.791	0.675	0.379	0.302	0.163

Table 2.A

Model	Data Set	Qualifier	HasQuantity	HasProperty	Qualifies	Overall F1 overlap
SciBERT	eval	0.077	0.311	0.183	0.064	<b>0.432</b>
SciBERT	dev	0.083	0.270	0.137	0.083	0.410
BERT-Med.	eval	0.0	0.193	0.114	0.0	0.330

Table 2.B

Table 2: Table 2.A represents the F1-overlap score for subtask 1, 2, 3, and Table 2.B represents the F1-overlap score for subtask 4, 5 and overall F1-overlap

Metric	SciBERT + CRF	Base line
Precision	0.703	-
Recall	0.560	-
F-Measure	0.623	-
F1-overlap	0.432	0.239
Exact Match	0.371	0.211

Table 3: Overall Results on evaluation set

to its high complexity. Consequently, it was not included in the final model.

## 5.2 Results on evaluation set

The results achieved on the evaluation set for each subtask are shown in Table 2, and the overall results are shown in Table 3. Figure 3 represents the results achieved in the various subdomains.

Figure 3: F1-Overlap scores of various sub-domains

The difference between the Exact Match score and F1-overlap score shows that the spans predicted by our model were precisely the same as gold data whenever they matched.

We achieved an overall fifth rank (among 19 participating teams) in the competition. We were also placed first in Quantity (tied) and Unit subtasks,

second in MeasuredEntity, Modifier and Qualifies subtasks, and third in Qualifier subtask.

## 5.3 Error Analysis

The relation extraction subtask was challenging because associating entities with the quantities they are related to is context-dependent and based on one's understanding. This is also evident from the IAA scores reported for the train data that even humans can achieve deficient performance.

Some of the aspects where our model did not work well are:

1. Our model looks for relations only within a sentence, which may cause problems when a relation exists outside the same sentence.
2. There is loss in reconstructing the TSV files from entities because the neighboring data may/maynot be part of the same entity group
3. Our model didn't work well on MeasuredProperty and Qualifiers as it did on other subtasks, which is evident as we achieved only 0.53 and 0.35 F1-overlap on training data for these two subtasks.

## 6 Conclusion

This paper proposed SciBERT + CRF Model (SciBERT with [CLS] token embedding and CRF layer on top) for span extraction, classification, and semantic relation extraction. Our model shows significant improvement in performance over the baseline model and works equally well across all the scientific sub-domains. In the future, we plan to explore various other pre-trained contextual models for our approach.

## Abstract

This paper presents our contribution to *SemEval 2021 Task 8: MeasEval*. The purpose of this task is identifying the counts and measurements from clinical scientific discourse, including quantities, entities, properties, qualifiers, units, modifiers, and their mutual relations. This task can be induced to a joint entity and relation extraction problem. Accordingly, we propose CONNER, a cascade **count and measurement** extraction tool that can identify entities and the corresponding relations in a two-step pipeline model. We provide a detailed description of the proposed model hereinafter. Furthermore, the impact of the essential modules and our in-process technical schemes are also investigated. Our code is released and available at <https://github.com/yuejiaxiang/CONNER>.

## 1 Introduction

Clinicians are currently coping with a massive amount of information, both from raw experimental data and scientific publications recording their results. However, the ever-expanding information sources have exceeded the ability of clinicians to digest and utilize them properly (Botsis et al., 2011; Cao et al., 2018; Zhou et al., 2010). Clinical information extraction tools (Zhang et al., 2020; De Bruijn et al., 2011; Li and Huang, 2016; Yehia et al., 2019; Mulyar and McInnes, 2020) in the text-mining field make an effort to alleviate the clinician’s burden according to exploit how to better utilize the knowledge contained in scientific discourse, accessible in the form of natural human language. Automating the process of understanding the relevant parts of the scientific literature allows for effective searching, and enabling inference of new information and hypothesis generation for clinical research.

\* Corresponding author

Counts and measurements are an important part of information source from the scientific discourse (Harper et al., 2021). However, extracting these count and measurement entities and their interactions is challenging, since the way scientists write them can be ambiguous and inconsistent, and the location of this information relative to the measurement can vary greatly.

In this paper, we focus on the SemEval 2021 MeasEval task which is composed of five sub-tasks that cover span extraction, classification, and relation extraction. As shown in Figure 1 it firstly demands to identify all the quantity spans given a paragraph from a scientific text. For each identified quantity, we need to extract the measured entity, measured property and qualifier which are corresponded to identified quantity. Besides, the relationships between quantity, measured entity, measured property and qualifier are also required to be identified. Lastly, the unit and type of the quantity is also needed to be recognized if they exist.

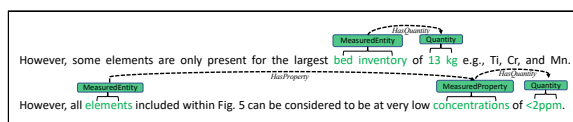

Figure 1: A sample of annotated snippet of dataset.

To tackle this challenging task aforementioned, we propose CONNER, a **cascade count and measurement** extraction tool, of which it primarily contains four components: (1) Model encoder gains the representation of both scientific paragraph text and the entities. (2) Quantity tagger extracts all the potential quantity entities within the paragraph. (3) Relation-specific object tagger recognizes the possible measured entities, measured properties and qualifiers, as well as their mutual relations. (4) Unit and modifier extractor identifies units and modifier by both rule-based approach and a simple classifier.

The rest of the paper is organized as follows. In Section 2, we elaborate on the whole workflow of CONNER and a detailed analysis of our experiments and results in Section 3. The paper is summarised and concluded in Section 4.

## 2 Model Description

### 2.1 Overview

The goal of CONNER is designed to identify all possible aspects of quantity items, including `Quantity`, `MeasuredEntity`, `MeasuredProperty`, `Qualifier`, `Unit` and `Modifier`, as well as their relations.

Inspired by (Wei et al., 2019), we assign a cascade framework that models relations as functions that map quantity to other objects in a sentence, which is contrary to the conventional prospective of relational triple extraction task (Gupta et al., 2016; Adel and Schütze, 2017; Zeng et al., 2018; Zheng et al., 2017) that firstly identity all the possible entities, then predict their relations. Based on our observation, there are roughly 90% entities overlapped in our tasks, which can be tackled smoothly by a cascade framework. Besides, our proposed method can just generate a limited amount of negative samples since there are only three types of relations in our tasks, which further prevent from the long-tail problem (Zhang et al., 2019; Li et al., 2020).

The basic idea of CONNER is a two-step pipeline model as shown in Figure 2. We firstly deploy a quantity tagger to identity all the possible `Quantity` from input paragraph in Section 2.2, for each predicted `Quantity`, we check all the potential relations to see if a relation can associate `MeasuredEntity`, `MeasuredProperty` and `Qualifier` with the `Quantity` in Section 2.4. In contrast of utilizing the proposed cascade framework, we adopt a rule-based method and a simple classifier in terms of extraction of unit and modifier in Section 2.5. We describe the detailed workflow below.

### 2.2 Model Encoder

The model encoder aims at gaining the semantic representations  $H$  of input paragraph text  $X$ , which will be further used in the following tagging module. In terms of the input paragraph that exceeds our pre-defined maximum length, we split them into pieces via full stop and encoder them separately. We experiment both ROBERTA (Liu

et al., 2019) and BERT model (Devlin et al., 2018) to encode the context information. We adopt  $H = \text{Encoder}(X)$  for brevity, and  $L$  denotes the length of the input paragraph.

### 2.3 Quantity Tagger

The lower level tagging model shown in Figure 2 is designed to predict the entire potential quantities in the input paragraph, which is an ensemble model incorporating a CRF layer and a PointerNet Layer. We illustrate the whole workflow as follows.

**PointerNet layer.** Driving from the PointerNetwork (Vinyals et al., 2015), two identical binary classifiers are adopted to detect the start and end position of quantities respectively. Each token is fed into the binary classifiers to predict whether the current token is aligned to a start or end position of a quantity span. Formally, given a contextual representation  $h_i \in H$ , we have:

$$p_i^{start} = \sigma(\mathbf{W}_{start}h_i + \mathbf{b}_{start}) \quad (1)$$

$$p_i^{end} = \sigma(\mathbf{W}_{end}h_i + \mathbf{b}_{end}) \quad (2)$$

where  $\mathbf{b}$  is the bias matrix and  $\sigma$  is the sigmoid activation function.  $p_i^{start}$  and  $p_i^{end}$  denotes the probability of identifying the  $i$ -th token in the input paragraph as the start or end position of a quantity, respectively. We set up a threshold score as 0.7, of which the current token will be assigned to 1 if its probability surpasses the threshold score, otherwise assigned to 0. The loss function of the quantity tagger is the following:

$$\mathcal{L}_{qt} = \frac{1}{L^2} \sum_{i=1}^L y_i^{start,end} \log P_i^{start,end} \quad (3)$$

where  $L$  denotes the length of the input paragraph,  $y_i^{start,end}$  is the ground truth label. In terms of multiple quantities appeared in the same paragraph, We adopt the same strategy as (Wei et al., 2019) that we adopt the nearest start-end pair match principle to decide the span of any quantity based on the results.

**CRF layer.** In this layer, we consider quantity recognition as a sequence-labeling problem. We select BIOS(Beginning, Inside, Outside, Single) as our label schema. Accordingly, given the representation sequence  $H = (h_1, h_2, \dots, h_L)$  we adapt a probability-based sequence detection conditional random field (CRF) model (Zheng et al., 2015),

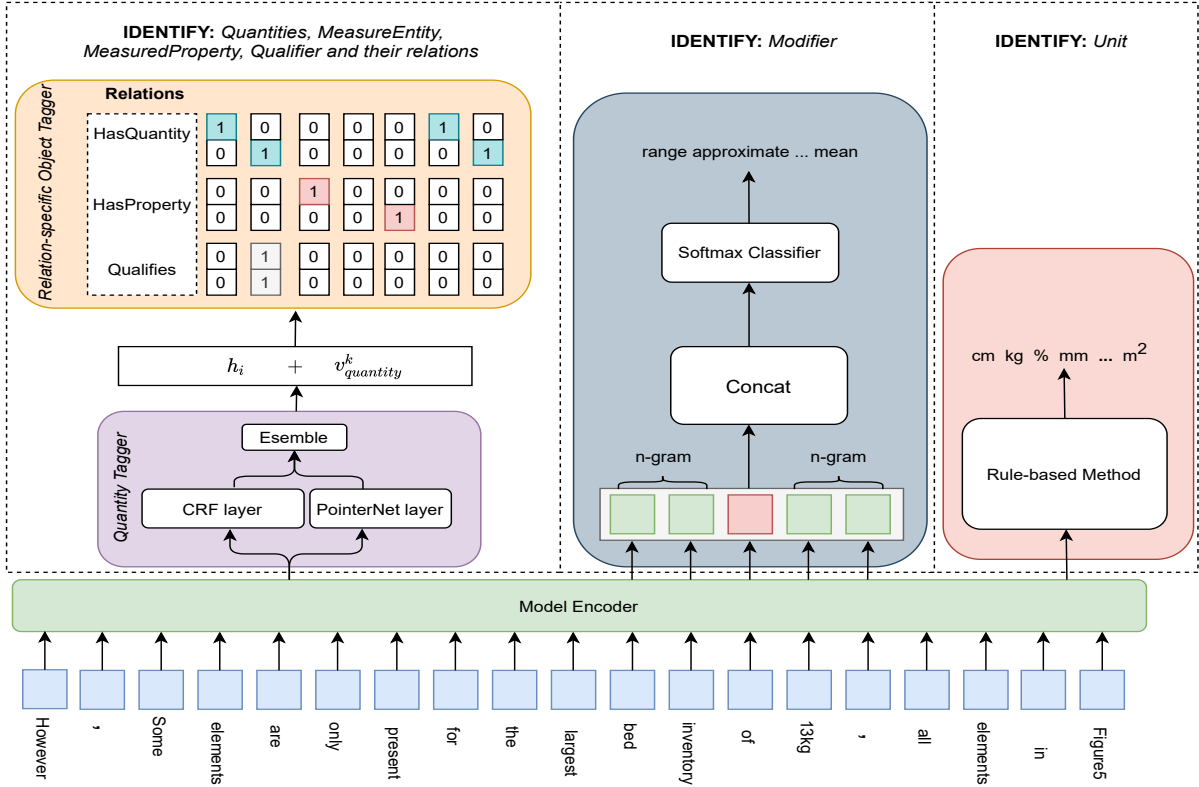

Figure 2: Overall model structure: the left dashed box corresponds to the Subsection 2.3 and 2.4, the right and middle ones correspond to Subsection 2.5.

which defines the conditional probability distribution  $P(Y|H)$  of label sequence  $Y$  given contextual word representation  $H$  aforementioned. We maximize the log-probability during training. In decoding, we set transition costs as infinite if it is invalid. The expected label sequence  $Y = (y_1, y_2, \dots, y_L)$  is predicted based on maximum scores in the decoding.

**Ensemble.** The experimental results are relatively comparable in terms of CRF layer and pointerNet layer (See Table 2.3). However, an empirical observation on the predicted results suggest that CRF layer tends to extract shorter spans, while PointerNet layer does the opposite. Presumably, the ensemble model can gain better results since the distribution of entities in the dataset exists both long and short spans.

We deploy our model ensemble considering the predicted quantities that are partly overlapped. To be more specific, we firstly obtain the predicted quantities from PointerNet as our final result, besides, if a predicted quantity from CRF layer strictly does not exist in the PointerNet result, i.e., there is no overlap between the two quantities, we add it to our final result as well.

## 2.4 Relation-specific Object Tagger

The upper level tagging module identifies the `MeasuredEntity`, `MeasuredProperty` and `Qualifier` as well as the involved relations with respect to the quantities obtained in the previous section. It consists of a set of relationship-specific taggers with the same structure as the quantity tagger in the lower-level for all possible relations. All object taggers identify the corresponding object for each detected quantity simultaneously.

Distinguish from the quantity tagger using representation vector  $h_i$  as input, the relation-specific object tagger also takes the quantity semantic features into account. Given each contextual representation of the current token  $h_i$ . The detailed tagging operations are as follows:

$$\tilde{p}_i^{start} = \sigma(\mathbf{W}_{start}^r(h_i + \mathbf{v}_{quantity}^k) + \mathbf{b}_{start}^r) \quad (4)$$

$$\tilde{p}_i^{end} = \sigma(\mathbf{W}_{end}^r(h_i + \mathbf{v}_{quantity}^k) + \mathbf{b}_{end}^r) \quad (5)$$

where  $\tilde{p}_i^{start}$  and  $\tilde{p}_i^{end}$  denotes the probability of predicting the start and end position of current token.  $\mathbf{v}_{quantity}^k$  represents the representation of  $k$ -th identified quantity via model encoder in Section 2.3.

We iterate all the possible relations across the given quantities. Accordingly, given the token representation  $h_i$  and quantity  $k$ , the loss function of relation-specific object tagger is as follows:

$$\mathcal{L}_{rot} = \frac{1}{L^2 \cdot R} \sum_{r=1}^R \sum_{i=1}^L y_{i,r}^{start,end} \log P_{i,r}^{start,end} \quad (6)$$

where  $r \in R$  denotes the  $r$ -th relation. The rest of symbol keeps the same as Equation 3. Note that tags  $y_i^{start,end} = 0$  if the objects are empty.

## 2.5 Unit and modifier extractor

**Unit extraction.** We design a set of rules to identify the units which are corresponding to each predicted quantity. The detailed description of schema is presented in Algorithm 1.

---

### Algorithm 1 Unit Method

---

**Require:** Quantity  $Q$ , which is a string of  $n$  characters.

- 1: The collection of all units that have appeared in train & trial:  $V$
  - 2:  $p = n$
  - 3: **for**  $i = 1$  to  $n$  **do**
  - 4:   **if**  $Q[i : n] \in V$  **then**
  - 5:     **return**  $Q[0 : i]$
  - 6:   **end if**
  - 7:   **if**  $Q[i]$  is a space **then**
  - 8:      $p = i + 1$
  - 9:   **end if**
  - 10: **end for**
  - 11:  $s = p$
  - 12: **while**  $s > 0$  and  $Q[s - 1]$  is a character **do**
  - 13:    $s = s - 1$
  - 14: **end while**
  - 15: **if**  $s > 0$  **then**
  - 16:    $p = s$
  - 17: **end if**
  - 18: **return**  $Q[p : n]$
- 

**Modifier Classification.** As none of the relations attached to the modifier in the input paragraph, we can not apply the relation-specific object tagger in terms of modifier extraction. Given a candidate quantity token  $x_i$ , we select its n-gram contextual tokens  $\{x_{i-n}, x_{i-n+1}, \dots, x_i, x_{i+1}, x_{i+n}\}$  and concatenate them as model input and then simply introduce a plain classifier to predict its labels:

$$c_i = \text{BERT}([x_{i-n}; \dots; x_i; \dots; x_{i+n}]) \quad (7)$$

$$y_i = \arg \max_{\theta} (\text{softmax}(c_i)) \quad (8)$$

where  $c_i$  denotes the representation of quantity and contextual tokens after BERT encoder and  $y_i$  is the predicted label of modifier in terms of current

token  $x_i$ . The training loss is the conventional cross entropy loss, we will not elaborate on it due to the space limit.

## 3 Experimental Results

### 3.1 Dataset

This SemEval evaluation has released the dataset online<sup>1</sup>, which includes a text file for each paragraph of scientific text along with annotations. As shown in Table 1, the overlapping entities are 9.3%, 0% and 90.7% in total of NEO, EPO and SEP in terms of train/dev/test set, respectively, which indicates the merit of applying CONNER to our tasks since it can naturally handle the overlapping entities.

	Train+Trial	Test
Sentence number	647	593
Avg. Sentence length	45	39
Max. Sentence length	200	304
Triples	2199	-
Cross Sentence Triples	65	-
NEO	203	-
EPO	0	-
SEO	1996	-

Table 1: Statistics of dataset, NEO represents none entity overlap, EPO represents entity pair overlap, SEP represents single entity overlap.

### 3.2 Experimental Settings

We adopt mini-batch mechanism to train our model with batch size as 8; the pretrained language model finetuning learning rate is set to  $2e-5$ , crf decoder learning rate is set to  $5e-3$ ; the hyper-parameters are determined on the validation set. We also complete words with wrong boundaries by design rules, e.g., "emain mostly neutral" in the raw text is corrected to "remain mostly neutral". The maximum length of sentence is set as 350. The number of n-gram is 0. We adopt Adam (Kingma and Ba, 2014) for optimization.

### 3.3 Main Experiments

The experimental results are conducted in test set, of which each entity category and relations are listed in Table 2. The result of extracting quantity outperforms the rest of entity categories by a large margin regarding named entity recognition. While the HasQuantity naturally achieves the best result in relation extraction task.

### 3.4 Auxiliary Experiments

During the process of building our proposed system, we tested different schemes for each module of the our model and did relative experiments to compare their experiment results, the scheme with best performance is selected as our final modules consisting of CONNER. We present the in-depth analysis and experimental results listed below.

**Model encoder.** In Subsection 2.2, we separately adopt BERT-based and ROBERTA-based our model encoder. To examine the performance regarding different model encoder, we conduct experiments in the quantity identification stage for both identification of entities and relations. As we can notice in Table 3, ROBERTA-base all outperforms BERT-base so that it is selected as our final model encoder.

	Prec.(%)	Rec.(%)	F1(%)
<b>Entities</b>			
BERT-large	58.85	56.02	57.40
ROBERTA-large	60.37	57.68	58.99
<b>Relations</b>			
BERT-large	49.52	45.67	47.39
ROBERTA-large	49.52	52.94	51.17

Table 3: Experimental results of different model encoders

**Settings of ensemble scheme.** We tested the result of utilizing CRF layer and PointerNet layer independently, it shows comparable results as listed in Table 4. As we mentioned in in Subsection 2.3, combining the results of CRF and PointerNet can make the best use of both models, and results verified our assumption that ensemble models all outperform the singular models.

we also carried out two different ensemble approach for quantity tagger. The first one is as il-

lustrate in Subsection 2.3. The second approach is simpler: we take the union of the predicted quantities of CRF layer and PointerNet layer, and remove duplicate as our final prediction result. The experimental results in Table 4 suggested the first ensemble model achieve the best result, so that it is selected as our final ensemble scheme.

	Prec.(%)	Rec.(%)	F1(%)
CRF layer	60.37	57.68	58.99
PointerNet layer	59.67	56.53	58.06
Union ensemble	58.54	59.78	59.15
ensemble in Section 2.3	60.47	59.02	59.73

Table 4: Experimental results of different model encoders

**Settings of  $n$ -gram.** Different number of  $n$ -gram can affect the model performance to some extent, we thus tested introducing different length of context regarding extraction of the modifier. As shown in Table 5, the model achieves best performance with 45.13% F1 score when  $n$  is 0, meanwhile, we speculate the underlying reason is that model is not capable of capturing valid semantics from contextual tokens due to the limited amount of the modifiers in the whole dataset.

$n$ -gram	F1(%)
none context	<b>45.13</b>
window_char_5	42.22
window_char_10	41.84
window_word_1	44.63
window_word_3	44.08

Table 5: Experimental results of different model encoders

## 4 Conclusion

We proposed CONNER, a cascade count and measurement extraction tool to jointly identify the quantities and their attached items, as well as the corresponding relations for SemEval 2021 Task 8: Measurement. Our model extracts these entities and relations in a two-step pipeline method. We also exploited various of technical schemes during the competition and select the one that gains the best performance in the experiments, which help us win second-place in the final ranking.

## Abstract

This paper presents our system for the Quantity span identification, Unit of measurement identification and Value modifier classification subtasks of the MeasEval 2021 task. The purpose of the Quantity span identification task was to locate spans of text that contain a count or measurement, consisting of a value, usually followed by a unit and occasionally additional modifiers. The goal of the modifier classification task was to determine whether an associated text fragment served to indicate range, tolerance, mean value, etc. of a quantity. The developed systems used pre-trained BERT models which were fine-tuned for the task at hand. We present our system, investigate how architectural decisions affected model predictions, and conduct an error analysis. Overall, our system placed 12 / 19 in the shared task and in the 2nd place for the Unit subcategory.

## 1 Introduction

The growing ease of access to large bodies of scientific information and research has not been accompanied by an improvement in ease of analysis or understanding of scientific text. While the performance of natural language processing tasks such as part-of-speech (POS) tagging and dependency parsing have seen improvements, analyzing counts and measurements in scientific texts has remained a largely unaddressed problem, though some work has been done by (Berrahou et al., 2013).

Measurements involve quantification (in units such as litres or kilograms), entities and the measured properties (e.g. growth rate of a fungus) and value modifiers (e.g. mean, range, tolerance). Extracting semantic relations between quantities, entities, value modifiers, and units of measurement and deriving meaning from those components is challenging because scientific communication can be ambiguous or inconsistent. In addition, the loca-

tion of this information relative to the measurement tends to vary.

The precise extraction and contextualization of measurements could enable accurate summarization of large bodies of scientific literature. Additionally, this could allow for unordered measurement and numeric data from scientific texts to be transformed into standardized ordered data for easier analysis.

In this paper, we describe a rapidly implemented, lightweight model that extracts measurement context in natural language. Our pipeline was implemented in approximately 48 hours by the first three authors, who had minimal formal neural NLP experience. Despite this, we were able to achieve strong results in the two categories (*Quantity* and *Unit*) that we entered, achieving second place in the *Unit* category and 12 / 19 overall.

## 2 Background

### 2.1 MeasEval Task Setup

Data for this task is made available through the MeasEval repository (Harper et al., 2021). Input data are formatted as a paragraph of scientific text in English from which measurements would be extracted. Text annotations are provided in the BRAT Annotation format (Stenetorp et al., 2012) and evaluated in a tab separated value format.

These annotations are provided in four types of spans. A **Quantity** contains a measurement of an entity, such as *300 ml* or *10%*. **Quantities** are associated with their respective *Unit*, such as *ml* or *%* respectively. Each **Quantity** can also contain additional **Modifiers** which will be outlined later. A **MeasuredEntity** contains the entity the **Quantity** is referring to, such as *a flask* or other object. Subtasks 3-5 also include identifying **MeasuredEntities**, **MeasuredProperties** and **Qualifiers**, though due to time constraints, this paper mainly focuses

on identifying **Quantities** and **Units** (subtasks 1 and 2).

For example, given the sentence “*However, some elements are only present for the largest bed inventory of 13 kg e.g., Ti, Cr, and Mn.*”, an identifiable **Quantity** is *13 kg*, with the **Unit** being *kg*. Each paragraph can have multiple quantities, modifiers and units associated with them.

## 2.2 Prior Work

The system this paper outlines is based on the BERT architecture (Devlin et al., 2019). BERT, which stands for Bidirectional Encoder Representations from Transformers, employs the self-attention based Transformer mechanism described in (Vaswani et al., 2017). BERT allows for pre-trained bidirectional representations to be used for each word token, which can then be applied to a wide variety of tasks. As such, only a limited amount of fine-tuning is required to model NLP tasks including sentence classification and sequence tagging.

One NLP task that is especially relevant for the Unit of Measurement identification task is sequence tagging and Named Entity Recognition (NER). This task involves identifying a span of text (such as a person or location) from a given body of text. There has been significant research in the past dedicated towards NER (Li et al., 2018). (Devlin et al., 2019) also addresses sequence tagging directly in their original paper describing BERT. Therefore, we found that applying BERT towards the shared task would prove transferable and effective.

## 3 System Overview

### 3.1 Quantity Identification

Since subtask 1, quantity span identification, involves the classification of individual phrases, we fine-tuned a pre-trained BERT-Large model (Devlin et al., 2019) to perform token-level classification on an IO labeling strategy based on the IOB labeling scheme (Ramshaw and Marcus, 1995). Each token in the training and trial sets is labeled as “I” if it is inside a labeled quantity, and “O” if it is outside the labeled quantity. Since consecutive entities are very rare, we do not use the “B” label. Such an encoding scheme is common for named-entity recognition. Tokenization is implemented using BertTokenizerFast from the Hugging Face

Transformers library.<sup>1</sup>

As with the tokenizer, we used Hugging Face library for a pre-trained BERT model. Instead of using the base BERT hidden layers (BERTModel) and manually building a few fine-tuning layers for classification, we decided to use BERT’s built-in BERTForTokenClassification class, which adds a single linear layer for classification on top of the hidden layers. This choice was made in the interest of saving programming time; we did not believe that adding multiple fine-tuning layers would cause a significant increase in accuracy to justify the time that would be spent. The model outputs labels for each of the tokens, labeling them with the aforementioned IO labeling scheme. Sequences of consecutive “I” labels are then recombined into segments of text, which we use as our predicted quantities.

We trained this model on a cross entropy loss metric, with loss on “I” labels upweighted by a factor of K to account for the low relative number of quantity tokens versus non-quantity tokens. We optimized on minibatches using the Adam optimizer (Kingma and Ba, 2015), and applied a cosine-annealing scheduler (Loshchilov and Hutter, 2016) to scale the down learning rate. Both of these have been shown to be effective in fine-tuning pretrained Transformer language models.

### 3.2 Unit Identification

Once a quantity had been identified, the next step involved identifying the respective unit for each quantity. For consistency, we once again used a BERT tokenizer to achieve this task. Intrinsically, unit identification is considered a NER task; therefore, by using Hugging Face Transformers and the BERTForTokenClassification class, we implemented a quick, yet robust method for identifying units.

The Unit Identification approach is essentially the same as the quantity identification approach: the model labels tokens as either “I” or “O” based on whether each token is considered to be inside or outside a quantity. This approach proved to be ubiquitous and simple to implement. We identified that tokens for units were consecutive, so this model was tasked with searching for a specific word or words that could be identified as units. For example, given the Quantity *20%*, the *%* token would

<sup>1</sup>[https://huggingface.co/transformers/model\\_doc/bert.html](https://huggingface.co/transformers/model_doc/bert.html)

be labeled as an “I” while all other tokens would be labeled as “O”. By implementing a consistent approach, we tested the capabilities of pretrained robust models such as BERT, which proves to be useful for creating robust models with low computational resources.

### 3.3 Modifier Multilabel Classification

In the final part of subtask 2, we were tasked to classify Quantity spans by “Modifiers.” Unlike the previous two parts of the pipeline, we approached this task as a multilabel classification task. Each quantity could be associated with multiple labels, such as *IsRange* and *IsApproximate*, or no labels at all. This model mapped out each label as an individual class, such that there were 10 total classes.

To predict the likelihood that a Quantity span is associated with a class, we first tokenized each quantity using BERT. These tokens were then passed into a simple one layer dropout and linear model which output 10 features. From here, each feature was considered as an independent binary classification problem in order to predict multiple classes. For simplicity, any logit greater than 0.5 was predicted as a “true” value. Binary Cross Entropy loss was used as the criterion for training.

This is a simple, yet effective approach. As this approach uses the same BERT models as the first two sections, with the key difference being the classification problem itself, we demonstrate the versatility of BERT for these tasks. Once again, we used the Hugging Face Transformers library for a pre-trained BERT model, which allowed for quick deployment. The results obtained in later sections highlight how quick and inexpensive models can still obtain acceptable results.

## 4 Experimental Setup

For all of the subtasks, we used the provided training split of 2531 annotations across 249 texts versus 832 annotations across 66 texts.

Besides tokenizing the text and applying IO labels (see section 3.1) to get the data into a format fit for the BERT token classifier, we did not preprocess the data significantly. We tested filtering unrecognizable and irrelevant characters using regex but found no meaningful improvement in performance. We thus decided to omit preprocessing to keep with the simplistic theme of this paper.

During the hyperparameter tuning phase, we compared models based on token-level F1 score,

implemented using the classification report from the metrics module of PyTorch, yielding results consistent with the provided testing script, which evaluated on the F1 overlap score. Due to the limit on the total number of iterations we could go through due to the deadline, we tuned hyperparameters by hand. We found that out of the hyperparameters we tuned, the scheduler hyperparameters were irrelevant because the scheduler was rarely used at all. The number of training epochs likewise did not come into play so long as we let the training continue until trial loss stopped decreasing; around 15 epochs was almost always enough. The only hyperparameters that seemed to significantly impact training results were the learning rate and the weight difference between quantity and non-quantity labels. After some manual tuning, we found that a learning rate of around  $10^{-5}$  and no weight-difference adjustment performed best on the trial set for this task, resulting in our final token-level quantity identification F1 score of 0.85 on the trial set.

For the quantity identification subtask, several post-processing steps were implemented to correct simple errors in our model’s predictions, based on common errors detected via manual error analysis in the model’s predictions. First, commas and spaces were removed from the ends of the predicted quantities to correct for potential small character offsets on the edges of predictions, from either model error or the tokenization-detokenization process. Furthermore, all quantities that did not contain either numeric characters or strings that commonly occur in numbers (such as *two* or *-teen*) were discarded from the prediction pool. Additionally, all prepositions from a hand-picked set like *beyond* and *at* were cut from the front of each input string in order to better isolate numeric quantities from relational terms. The trial set results with and without post-processing are shown in Table 1. All the post-processing steps reduce the amount and length of predicted quantity spans. Therefore, the significantly higher precision score after post-processing indicates that the base model tends to overpredict identified quantities.

## 5 Results

Our model’s overall precision, recall, and F1 score on overlap on the trial set are as shown in Table 1. The model’s performance on evaluation metrics across the subtasks are shown in Table 2.

Metric	With	Without
Precision	0.8153	0.564
Recall	0.2912	0.301
F1 (overlap) score	0.2615	0.211

Table 1: Trial set results with and without post-processing

Category	F1 score	Ranking
Overall	0.272	12
Quantity	0.818	10
Unit	0.76	2
Modifier	0.408	8

Table 2: Evaluation set results and ranking (out of 19)

These results are promising given the speed of implementation of our system. Across all 5 sub-tasks, our final F1 score was 0.272. Overall, the model ranked 12th out of 19 teams in the evaluation phase of MeasEval: Counts and Measurements.

## 6 Conclusion

We propose a BERT-based model for information extraction of measurements and their contextual qualifiers from text. As scientific texts become increasingly open for public consumption, we hope that such systems will help present findings to broader audiences in an accessible manner. Going forward, possible areas of exploration include replacing BERT with more powerful models and augmenting training data that the model frequently makes erroneous predictions on.

## Acknowledgments

This research effort would not have been possible without the support of Stanford ACM Lab. The authors thank Corey Harper, Jessica Cox, Ron Daniel, Paul Groth, Curt Kohler and Antony Scerri for organising SemEval 2021 Task 8: MeasEval - Counts and Measurements. We also thank Jillian Tang for helpful discussions.

## Abstract

This work describes our approach for subtasks of SemEval-2021 Task 8: MeasEval: Counts and Measurements which took the official first place in the competition. To solve all subtasks we use multi-task learning in a question-answering-like manner. We also use learnable scalar weights to weight subtasks' contribution to the final loss in multi-task training. We fine-tune LUKE to extract quantity spans and we fine-tune RoBERTa to extract everything related to found quantities, including quantities themselves.

## 1 Introduction

SemEval-2021 Task 8 consisted of five subtasks that covered span extraction, classification, and relation extraction tasks. This paper presents solutions to all five of them which showed the best results in the competition<sup>1</sup>.

In the subtask 1(A) participants were asked to retrieve *Quantity* (**Q**) spans from texts. For example, in the following text **"The soda can's volume was 355 ml."**, the system should retrieve **"355 ml"** as **Q** span. The rest of the subtasks were to extract information related to retrieved *Quantities* (**Qs**) from subtask A.

The subtask 2(B) was to extract the *Unit of measurement* (**UoM**) of the extracted **Q** and also to classify it into 10 classes: *HasTolerance*, *IsApproximate*, *IsCount*, *IsList*, *IsMean*, *IsMeanHasTolerance*, *IsMeanIsRange*, *IsMedian*, *IsRange*, *IsRangeHasTolerance*. It should be noted that some

<sup>1</sup><https://github.com/davletov-aa/meas-eval>

**Qs** could be related to more than one type and there were ones which didn't belong to any type. The subtask 3(C) was to extract *Measured Entity* (**ME**) and *Measured Property* (**MP**) spans. In the subtask 4(D) additional *Qualifier* (**Qlfr**) spans, which helped to validate or understand the extracted **Q**, were asked to be extracted. And finally, subtask 5(E) was to extract relations between **Qs**, **MEs**, **MPs** and **Qlfrs**.

More detailed information about the competition could be found in the Harper et al. (2021)'s shared task description paper.

## 2 Related Work

Span extraction and classification problems have a long history of studies and are often studied as a part of Named Entity Recognition (NER). For example, the NER dataset Ontonotes v5 (Weischedel et al., 2013) contains such entities as "Quantity", which also includes measurements, and "Money". However, the general NER approach used in Ontonotes or ConLL 2003 (Sang and De Meulder, 2003) datasets is not so fine-grained as the one that is used in the task under study.

Most state-of-the-art models for named entity recognition and relation extraction are based on Transformer architecture by Vaswani et al. (2017). For example, the top three best models for Ontonotes v5 according to paperswithcode.com use BERT<sup>2</sup>. BERT is a large pre-trained language model based on Attention (Devlin et al., 2019).

<sup>2</sup><https://paperswithcode.com/task/named-entity-recognition-ner>

Figure 1: Data example. It shows that one named entity may have several incoming and outgoing relations.

BERT has a unique training procedure where the model is trained using Masked language objective, where some tokens are replaced with a special '[MASK]' token and the model should predict the original token. BERT also had an additional training objective - the model had to predict whether a sentence was random or it followed the first sentence. However, some papers have investigated that BERT is undertrained and that training BERT on more data and for a longer time might increase model performance. RoBERTa was one of the first and more influential papers of such kind (Liu et al., 2019). RoBERTa modifies BERT’s pretraining procedure. The RoBERTa model is trained longer, with bigger batches over more data and on longer sequences. RoBERTa’s authors have also found that removing the next sentence prediction objective from BERT matches or slightly improves BERT performance. Researchers have also suggested ways of leveraging the nature of the task and adding some problem bias to named entity recognition. Among such works, which is currently the best performing for Ontonotes v5 and CoNLL 2003 according to paperswithcode.com, is LUKE (Yamada et al., 2020). The authors of LUKE have added a new language modeling task that consists of predicting randomly masked words and entities in an entity-annotated corpus retrieved from Wikipedia. The authors have also expanded the self-attention mechanism to entity types and consider entity types when computing attention scores. The proposed approach allowed the authors to achieve state-of-the-art results not only for named entity recognition but for a bunch of other unrelated tasks such as SQuAD1.1 question answering.

For relation extraction, Transformer-based models also outperform other approaches. A promising approach is treating relation extraction as a question answering problem. Among works implementing this approach, we can mention (Cohen et al., 2020) where the authors restructured relation classification as a Question answering (QA) like span

prediction problem. It allowed them to get state-of-the-art results for TACRED and SemEval 2010 task 8 datasets.

### 3 System Description

#### 3.1 Data

The data provided by the organizers contained plain text files and their annotations in tsv format. There were in total 248 training texts, 65 trial ones, and 135 for the evaluation phase. There were 2764, 897, and 1620 annotated entities respectively. The files have been approximately equally distributed among several domains: Agriculture, Astronomy, Biology, Chemistry, Computer Science, Earth Science, Engineering, Materials Science, Mathematics, Medicine. Entities could have been labeled into 5 classes: **Q**, **ME**, **MP**, **UoM** or **Qlfr**.

As input data in the competition was in the form of plain text extracts, we first split them into sentences using PunktSentenceTokenizer and PunktTrainer from NLTK library (Bird et al., 2009). We trained PunktTrainer on texts from the training set. We did data augmentation by including text extracts consisting of two sentences following each other for each text document. So if we had original sentences  $[s_1, s_2, s_3, s_4]$  we get an augmented set of texts  $[s_1, s_2, s_3, s_4, s_1s_2, s_2s_3, s_3s_4]$ . Then we split each example into tokens using RegexpTokenizer from the NLTK library with the following  $\backslash w+ | \backslash ( | \backslash ) | \backslash [ | \backslash ] | [- | . | , | ] | \backslash S+$  regular expression. We used the train set for training and the trial set for development.

Also, we relabeled *Qualifier* to *QuantityQualifier* (**QQ**), *MeasuredEntityQualifier* (**MEQ**), and *MeasuredPropertyQualifier* (**MPQ**). By this little trick we solved the problem with examples having multiple **Qlfrs** corresponding to either **Q**, **ME**, or **MP**.

Figure 2: Architecture of the QuAnt system. It takes tokenized text with marked *MeasuredEntity* as input and predicts all needed spans and the class of the *Quantity*.

Table 1: Training hyperparameters of **QuAnt** system, submitted to competition

### 3.2 QuAnt System

The architecture of the QuAnt<sup>3</sup> is shown in Figure 2. As could be seen, our model uses the RoBERTa model to extract features for each example. It solves all subtasks of the competition in a multi-task question answering way. We ask our model to predict all BPE subword-level start and end positions of spans (answers) related to **Q** (question). We ask the model by inserting special tokens “•” and “/” around **Q**. Also, the model makes multi-class multi-label predictions regarding the *type of the Quantity* (QT).

It takes text extracts containing some **Qs** and positions of the **Q** regarding which it should make predictions.

For example, for the input text “**The soda can’s**

<sup>3</sup>QuAnt - the system deals with quantities in a question-answering-like manner

volume was 355 ml.” and for subword-level positions (6, 7) of the **Q** “355 ml”, the model should predict the following start and end positions: (6, 7) for **Q** (A), (7, 7) for **UoM** (B), (3, 3) for **ME** (C), (4, 4) for **MP** (C), (2, 2) for **MEQ** (D). Also, the model shouldn’t predict any label for **QT** (B).

#### 3.2.1 Extract Quantities

So, our approach needs quantity span information as input. And to get that information we went with fine-tuning the LUKE model (Yamada et al., 2020) on the NER task to predict **Q** spans. We used the code provided by the authors of the model. We trained it on the augmented dataset in BIO format with the following hyperparameters: maximum-entity-length, maximum-sequence-length, learning rate, and batch size were set to 64, 256, 1e-5, and 4 respectively. We trained two models with the weight\_decay hyperparameter equal to 0.1 and 0.01 for 10 epochs. We were validating our models four times per epoch on the development set and saving the top 3 best checkpoints during training, resulting in a total of 6 models.

So after two training runs, we got 6 trained models. Using the development set we chose the best combination of them for a simple word-level voting ensemble.

#### 3.2.2 Extract Everything

During training and validation, we use **Q** spans from the annotated set. During test prediction, we use spans predicted by the ensemble of quantity extractors from the previous section. Because of our test time augmentation process, we had been able to get up to three entries per each **Q**: for the sentence containing it and for it with either its left

or right context sentences.

We split tokenized examples into byte-pair-encoding (BPE) subwords with RoBERTaTokenizer which resulted in the following RoBERTa inputs marked by symbols "•" and "/" "Qs":

[CLS] {Optional question prefix [EOS]}  $s_1 \dots \cdot w / \dots s_n$  [EOS].

To vectorize **QT**, we use the output from the last layer corresponding to [CLS] token. And to predict start and end probabilities for each subword of each span type we use outputs from the last layer. We feed them to linear layers to predict **QTs** and span starts and span ends.

During training we optimize the following weighted loss:

$$L_{total} = -\frac{w_{QT}}{bs} \sum_{i=1}^{bs} QT_k^i * \log(\hat{QT}_k^i) - \sum_{ST \in ST_s} \left( -\frac{w_{ST}}{2bs} \left( \sum_{i=1}^{bs} ST_{start}^i * \log(\hat{ST}_{start}^i) + \sum_{i=1}^{bs} ST_{end}^i * \log(\hat{ST}_{end}^i) \right) \right)$$

, where  $bs$  – batch size,  $[w_{QT}; w_{ST} | ST \in ST_s] = softmax([w_{qt}; w_{st} | st \in ST_s])$  – learnable weights vector initialized with ones,  $QT^i$  – one-hot encoded **QT** of  $i$ -th example (which could be zero vector in some cases and will not contribute during training),  $\hat{QT}^i$  – predicted **QT** probability distribution,  $ST_s$  – set of following span types: [**Q**, **ME**, **MP**, **Qlfr**, **UoM**, **QQ**, **MEQ**, **MPQ**],  $ST_{start}^i$  – one-hot encoded start position of the corresponding span.  $\hat{ST}_{start}^i$  – predicted start positions probability distribution. The same goes for  $ST_{end}^i$ .

We trained our model without adding an optional question prefix to RoBERTa inputs. We used hyperparameters from Table 1.

As our test predictions include duplicated predictions for the same **Q** due to the test time augmentation, we remove identical predictions. Worth noting, that there still might be duplicates left in the case of different extracted values for the same **Quantity**. Because of this, our submitted results are higher than the results without test time data augmentation.

So, our model takes **Q** with its context as input and predicts its type and extracts various spans. For all of the subtasks except the subtask E we treated extracted answers as is. For the subtask E we used

the following rules to extract relations between **Q**, **MP**, **ME** and **Qlfr** (**QQ**, **MEQ**, **MPQ**):

- (**MP**, *HasQuantity*, **Q**);
- if there is **MP** then (**ME**, *HasProperty*, **MP**), otherwise (**ME**, *HasQuantity*, **Q**);
- (**QQ**, *Qualifies*, **Q**), (**MEQ**, *Qualifies*, **ME**), (**MPQ**, *Qualifies*, **MP**);

## 4 Experiments and Results

In this section, we report the results of our post-evaluation experiments.

First, we experimented with base models. We tried different subtask weighting strategies. As we solve the task in a multi-task way, we need to aggregate the losses of each subtask to optimize the final loss. And here, we tried to just average them (**equal**) or take the weighted sum using learnable weights (**softmax**, **rsqr+log**) vector **W** with the length equal to the number of training subtasks. In the case of **softmax** weighting strategy we just use softmax over the vector **W**. In the case of **rsqr+log**, we divide each subtask’s loss to its squared learnable weight and sum with the logarithm of it. This approach of weighting subtasks in multi-task learning was introduced by Kendall et al. (2018).

We also experimented with data augmentation. But unlike experiments we did in the evaluation period, here we didn’t do test time data augmentation.

Also, we tried to concatenate the question prefix to an input example. We experimented with prefix *Find measured entities and properties of marked quantity*. We hoped it could give extra information to the model regarding the nature of the answer.

Table 2 shows the best results for the development dataset and Table 3 shows corresponding results for the test dataset. Also, there are our official submission results.

Table 2 shows that training time data augmentation improves the overall score. Also, we could see that including prefix question did not improve the overall scores of the models which use data augmentation. Yet we see the opposite picture for the test set in Table 3. It can also be seen that RoBERTa-large not necessarily outperforms RoBERTa base.

We see that using just the average sum of subtask’s losses demonstrates the best results.

We also tried to fine-tune the large version of XLM-R with the best hyperparameters from base

models. In the case of large models, again, **equal** weighting scheme demonstrated the best result.

In all our post-evaluation experiments we used the same settings as in Table 1. We tried learning rates from  $[5e - 5, 1e - 4, 2e - 4]$  and batch sizes from  $[32, 64, 128]$ .

## 5 Conclusion

In this paper, we introduced our solution to SemEval-2021 Task 8: MeasEval: Counts and Measurements. Our approach was based on RoBERTa and LUKE models. We show that extracting mea-

surements from a text can be treated as a question-answering task. In this work, we tried a set of different models, hyperparameters, and weighting schemes and present their effect on the final result.

## Abstract

Question answering from semi-structured tables can be seen as a semantic parsing task and is significant and practical for pushing the boundary of natural language understanding. Existing research mainly focuses on understanding contents from unstructured evidence, e.g., news, natural language sentences, and documents. The task of verification from structured evidence, such as tables, charts, and databases, is still less explored. This paper describes sattiy team’s system in SemEval-2021 task 9: Statement Verification and Evidence Finding with Tables (SEM-TAB-FACT). This competition aims to verify statements and to find evidence from tables for scientific articles and to promote the proper interpretation of the surrounding article. In this paper, we exploited ensemble models of pre-trained language models over tables, TaPas and TaBERT, for Task A and adjust the result based on some rules extracted for Task B. Finally, in the leaderboard, we attain the F1 scores of 0.8496 and 0.7732 in Task A for the 2-way and 3-way evaluation, respectively, and the F1 score of 0.4856 in Task B.

## 1 Introduction

Semantic parsing is one of the most important tasks in natural language processing. It not only needs to understand the meaning of natural language statements, but also needs to map them to meaningful executable queries, such as logical forms, SQL queries, and Python code (Pan et al., 2019; Lei et al., 2020; Zhu et al., 2021). Question answering from semi-structured tables is usually seen as a semantic parsing task (Pasupat and Liang, 2015), where questions are translated into logical forms that can be executed against the table to retrieve the correct denotation (Zhong et al., 2017).

Practically, it is significant in natural language understanding to verify whether a textual hypoth-

esis is entailed or refuted by evidence (Bentham, 2008; D. et al., 1978). The verification problem has been extensively studied in different natural language tasks, such as natural language inference (NLI) (Bowman et al., 2015), claim verification (Hanselowski et al., 2018), recognizing of textual entailment (RTE) (Dagan et al., 2005), and multi-model language reasoning (NLVR/NLVR2) (Suhr et al., 2018). However, existing research mainly focuses on verifying hypothesis from unstructured evidence, e.g., news, natural language sentences and documents. Research of verification under structured evidence, such as tables, charts, and databases, is still in the exploratory stage.

This year, SemEval-2021 Task 9: Statement Verification and Evidence Finding with Tables (SEM-TAB-FACT), aims to verify statements and find evidence from tables in scientific articles (Wang et al., 2021a). It is an important task targeting at promoting proper interpretation of the surrounding article.

The competition tries to explore table understanding from two tasks:

- Task A - Table Statement Support: The task aims to determine whether a statement is fully supported, refuted, or unknown to a given table.
- Task B - Relevant Cell Selection: given a statement and a table, the task is to determine which cells in the table provide evidence for supporting or refuting the statement.

The competition contains the following challenges:

- In task A, there is no training data for the “Unknown” category and the number of tables is small in the training set.
- The lexical expression of the table may be different from that in the statement.
- The table structure is complex and diverse. A table may contain missing values while the supporting evidence may be resided in cells across

several rows or columns.

- It is difficult to understand the statements. For example, some statements express totally different semantics meaning with only one different word. This difficulty makes it even harder to find the evidence cells from tables.

To overcome these challenges, we incorporate several key technologies in our implementation:

- developing a systematic way to generate data from the “Unknown” category;
- including additional data corpus to enrich the training data;
- exploiting existing state-of-the-art pre-trained language models over tables, TaBERT (Yin et al., 2020) and TaPas (Yin et al., 2020), and ensembling them into a powerful one;
- aligning contents in tables and statements while constructing manual rules for tackling Task B.

The test shows that our implementation can increase the performance according and finally, in the leadboard, we attain the F1 scores of 0.8496 and 0.7732 in Task A for the 2-way and 3-way evaluation, respectively, and the F1 score of 0.4856 in Task B.

The rest of this paper is organized as follows: In Sec. 2, we briefly depict related work to our implementation. In Sec. 3, we detail our proposed system. In Sec. 4, we present the experimental setup and analyze the results. Finally, we conclude our work in Sec. 5.

## 2 Related Work

Recently, pre-trained language models (PLMs), e.g., BERT (Devlin et al., 2019), XLNET (Yang et al., 2019), and RoBERTa (Liu et al., 2019), have witnessed the burgeoning of promoting various downstream NLP tasks, such as reading comprehension, named entity recognition and text classification (Li et al., 2020; Lei et al., 2021). However, the current pretrained language models are basically trained on the general text. They are not fit for some tasks, e.g., Text-to-SQL, Table-to-Text, which need to encode the structured data, because the data in the structured table also needs to be encoded at the same time. Directly applying the existing PLMs may face the problem of inconsistency between the encoded text from the table and the pretrained text.

TaBERT (Yin et al., 2020) is a newly proposed pretrained model built on top of BERT and jointly learns contextual representations for utterances and

the structured schema of database (DB) tables. This model views the verification task completely as an NLI problem by linearizing a table as a premise sentence and applies PLMs to encode both the table and statements into distributed representation for classification. This model excels at linguistic reasoning like paraphrasing and inference but lacks symbolic reasoning skills. Intuitively, encoding more table contents, e.g., type information and content snapshots, relevant to the input utterance could potentially help answer questions that involve reasoning over information across multiple rows in the table because they can provide more hints about the meaning of a column. TaPas (Herzig et al., 2020) is another newly proposed pretrained question answering model over tables implemented on BERT to avoid generating the logical forms. The model can fine-tune on semantic parsing datasets, only using weak supervision, with an end-to-end differentiable recipe.

Another stream of work on evidence finding with table is the rule-based approaches. Most evidence cells can be extracted by rules. For example, if a row head or column head appears in the statement, we infer this row or col support this statement. Although rule-based approaches suffer from the low recall issue, they exhibit high precision and can be applied to adjust the result for ensemble.

## 3 System Overview

We elaborate the task and present our system in the following.

### 3.1 Data Description and Tasks

In Task A, the original dataset is a set of XML files, where each XML file represents a table and contains multiple sections:

- *document* section represents the whole document;
- *table* section determines the unique ID of the document;
- *caption* section is a brief description of the table;
- *legend* section is a detailed description of the table;
- *multiple row* sections describe the contents of each row of the table; and
- *statements* section provides several factual statements.

This task aims to determine if a statement is entailed or refuted by the given table, or whether, as is in some cases, this cannot be determined from

		Tables	Label Distribution	Tokens in Statements	Tokens in Tables
			Entailed/Refuted/Unknown	Max./Min./Avg.	Max./Min./Avg.
Train	Task 9	981	2,818/1,688/0	88/3/11	302/1/10

Table 1: Data statistics.

the table. The competition also provides two kinds of evaluations for the task:

- 3-way F1 score evaluation: a standard precision/recall evaluation (3-way) is computed to evaluate whether each table is correctly classified into one of the three types in {Entailed, Refuted, Unknown}. It is to test whether the classification algorithm understands cases where there is insufficient information to make a determination.
- 2-way F1 score evaluation: the F1 score is computed to evaluate the performance when the statements with the “unknown” ground truth label are removed. The metric will also penalize misclassifying Refuted/Entailed statement as unknown.

In the evaluation, the score for all statements in each table is first averaged and then averaged across all tables to get the final F1 score.

In Task B, the raw dataset is a subset of task A, where unknown statements are excluded. The goal is to determine for each cell and each statement, if the *cell is within the minimum set of cells* needed to provide evidence for the statement “relevant” or “irrelevant”. For some statements, there may be multiple minimal sets of cells that can be used to determine statement entailment or refusal. In such cases, the ground truth will contain all of the versions. The evaluation will calculate the recall and precision for each cell, with “relevant” cells as the positive category. The evaluation is conducted similarly as that in Task A.

### 3.2 Data Augmentation

There are mainly two critical issues in Task A. First, the number of the tables is small. We then include more external data, the TabFact dataset (Chen et al., 2020) to improve the generalization of our proposed system. Second and more critically, “unknown” statements do not exist in the training set but may appear in the test set. To allow our sys-

tem to output the “unknown” category, we construct additional “unknown” statements to enrich the training set. More specifically, we randomly select some statements from other tables and assign them to the “unknown” category for the current table. In order to keep balance on the labels, the number of selected statements from other tables is set to half of the statements in the current table. Details about the data statistics can be referred to Table 1.

### 3.3 Model Ensemble for Task A

Figure 1 outlines the overall structure of our system, which is an ensemble of two main pretrained models on table-based data, TaBERT and TaPas, or two variants of TaBERT and four variants of TaPas. It is worth noting that the input of all models are the same. That is, given a statement and a table, the input is started with the sentence token, [CLS], followed by the sequence of the tokens in the statement, the segmentation token ([SEP]), and the sequence of the tokens in the flattened table. All the tokens in the statement and the table are extracted by wordpiece as in BERT and related NLP tasks (Devlin et al., 2019; Yang, 2019; Yang et al., 2021; Yang and Shen, 2021; Wang et al., 2021b). The flattened table means that we borrow the implementation in TaBERT by only extracting the most likely content snapshot as detailed in Sec. 3.4. The obtained tokens’ embeddings are then fed into six strong baselines, i.e., two variants of TaBERT and four variants of TaPas, to attain the classification scores for the corresponding labels. The classification scores are then concatenated and fed into a vote layer, i.e., a fully-connected network, to yield the final prediction.

### 3.4 Content Snapshot

In order to pin point the important rows and avoid excessively encode input from the table, we borrow the idea of content snapshot in TaBERT (Yin et al.,

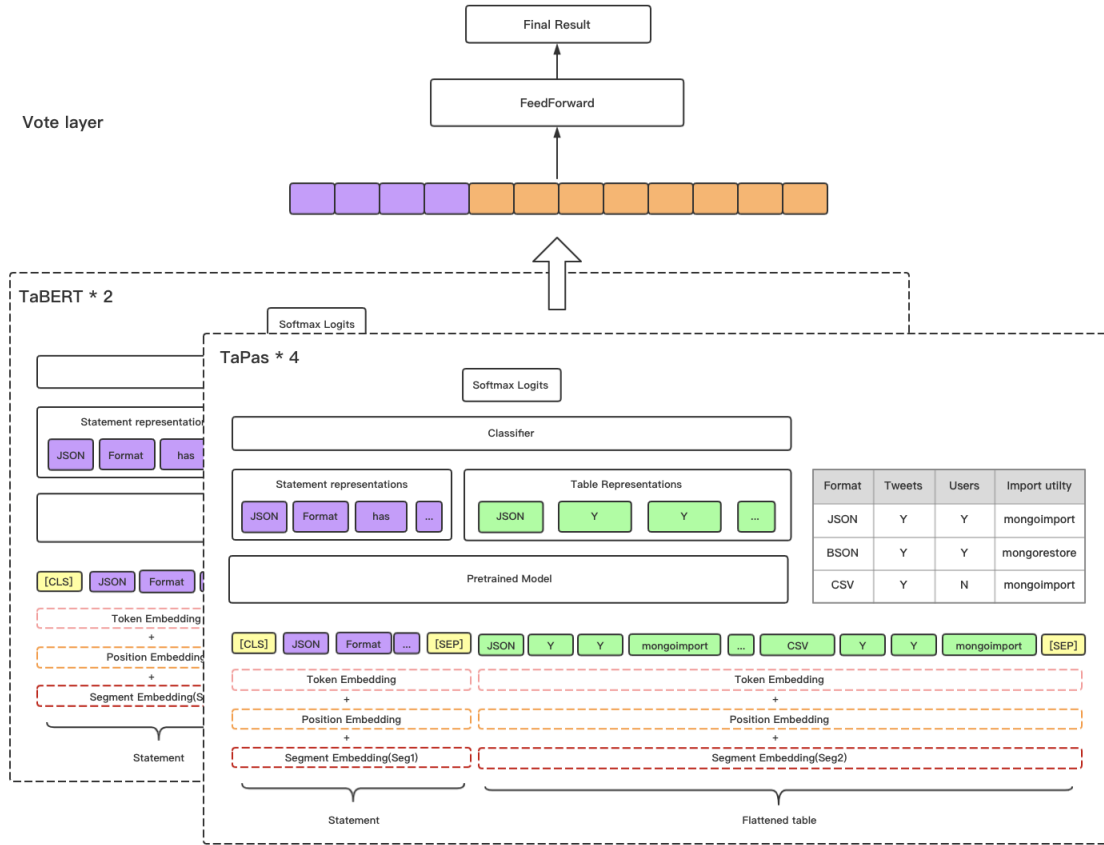

Figure 1: Ensemble architecture

snapshot of  $K$  rows based on the following simple strategy. First, we count the number of rows of each table and find their median, say  $R$ . If the number of rows in the current table is less than or equal to  $R$ , then  $K$  is set to the total number of rows in the current table and the content snapshot is the entire content of the current table. If the number of rows in the current table is greater than  $R$ , we set  $K = R$  and select the top- $K$  row with the highest overlap rate between the statement and each row of  $n$ -grams as the candidate rows.

2020) to encode only a few rows that are most relevant to the statement. We create the content

### 3.5 Rule Construction for Task B

For Task B, we apply the same model trained in Task A to find whether the current table supports the statement. If yes, we label all cells as entailed. Otherwise, we first align the word expression in tables and statements while building the corresponding rules to adjust the model prediction. That is, we change uppercase to lowercase and transform all abbreviations into the full name in statements, cells, col heads and row heads. We also conduct stemming on all words. For example, “definition” and “defined” is transformed to “define”. After that, we collect all words in a statement into a word bag and determine the supporting relation based on the following rules: 1) If a word in the word bag appears in a row head, we then infer that cells in the whole column supports the statement; 2) If a word appears in the first column of the table, we then infer that cells in the whole row supports the statement; 3) If a word appears in both a row head and a cell in the first column of a table, we then infer that the cell corresponding to the row and column supports the statement; 4) If a word appears in a cell, we then infer that this cell supports the statement.

## 4 Experiments

In the following, we present the strong baselines and the results with analysis.

We have tried different combinations of TaBERT and TaPas pre-trained models and choose the following 6 best baselines: 1) TaBERT\_1: the pre-trained TaBERT with  $K = 1$ ; 2) TaBERT\_3: the pre-trained TaBERT with  $K = 3$ ; 3) TaPas\_TFIMLR: the pre-trained large TaPas downloaded from `tapas_tabfact_inter_masklm_large_reset.zip`; 4) TaPas\_WSIMLR: the pre-trained large TaPas downloaded from `tapas_wikisql_sqa_inter_masklm_large_reset.zip`; 5) TaPas\_IMLR: the pre-trained large TaPas downloaded from `tapas_inter_masklm_large_reset.zip`; 6) TaPas\_WSMLR: the pre-trained large TaPas downloaded from `tapas_wikisql_sqa_masklm_large_reset.zip`. Our proposed system is funetuned on the above models for the original training data, the original data with the TabFact data, and the augmentation data. We also tune the hyper parameters to fit a better result in the local test dataset.

Table 2 reports the evaluation results of Task

A on the development set when funetuning the above six strong baselines on different training data. The results show that the TaPas\_WSMLR attains the best performance on the original data. The best performance is further improved from 0.7695 to 0.7952 for 2-way evaluation and from 0.6875 to 0.7058 for 3-way evaluation, respectively, by including the TabFact data. The performance is further improved to 0.8241 for 2-way evaluation and 0.7653 for 3-way evaluation, respectively, by adding the augmentation data. Finally, we apply the voting mechanism to ensemble the results and achieve the F1 scores of 0.8496 and 0.7732 on the test set, respectively.

Table 3 reports the results of Task B on the development set when funetuning the above six strong baselines on different training data. The results show that the TaPas\_WSMLR attains the best performance among all six strong baselines and the perform increases from 0.4258 after adding the TabFact data, to 0.4386 after adding the augmentation data, and to 0.4708, additional 7.3% improvement after adding the manual rules. We conjecture that TaPas\_WSMLR can provide more complementary information for solving the task. Finally, we ensemble the results by the voting mechanism and achieve the F1 score of 0.4856 on the test set.

In sum, results in Table 2 and Table 3 confirm the effectiveness of our proposed system by including more training data and the manual rules.

## 5 Conclusion

In this paper, we present the implementation of our ensemble system to solve the problem of SemEval 2021 Task 9. To include more training data and resolve the issue of lacking data from the “Unknown” category in the training set, we include external corpus, the TabFact dataset, and specially construct the augmented data for the “Unknown” category. Content snapshot is also applied to reduce the encoding effort. Six pre-trained language models over tables are funetuned on the TabFact dataset and the augmented data with content snapshot tables to evaluate the corresponding performance. An ensemble mechanism is applied to get the final result. Moreover, data alignment and manual rule determination are applied to solve Task B. Finally, our system attains the F1 score of 0.8496 and 0.7732 in Task A for 2-way and 3-way evaluation, respectively, while getting the F1 score of 0.4856 in Task B.

## Abstract

Tables are widely used in various kinds of documents to present information concisely. Understanding tables is a challenging problem that requires an understanding of language and table structure, along with numerical and logical reasoning. In this paper, we present our systems to solve Task 9 of SemEval-2021: *Statement Verification and Evidence Finding with Tables* (SEM-TAB-FACTS). The task consists of two subtasks: (A) Given a table and a statement, predicting whether the table supports the statement and (B) Predicting which cells in the table provide evidence for/against the statement. We fine-tune TAPAS (a model which extends BERT’s architecture to capture tabular structure) for both the subtasks as it has shown state-of-the-art performance in various table understanding tasks. In subtask A, we evaluate how transfer learning and standardizing tables to have a single header row improves TAPAS’ performance. In subtask B, we evaluate how different fine-tuning strategies can improve TAPAS’ performance. Our systems achieve an F1 score of 67.34 in subtask A three-way classification, 72.89 in subtask A two-way classification, and 62.95 in subtask B.

## 1 Introduction

There has been extensive work on verifying if a given textual context supports a given statement. Even though tables are also widely used to convey information, especially in scientific texts, there has been comparatively less work on verifying if a given table supports a statement. To this end, SemEval 2021 Task 9 (Wang et al., 2021) focuses on statement verification and evidence finding for tables from scientific articles in the English language. The task is divided into two subtasks - A and B. The aim of subtask A is to classify whether a given

statement is entailed or refuted according to the given table and associated table metadata (such as captions and legends) or whether the statement’s truth is unknown as it cannot be determined from the table. The aim of subtask B is to classify each cell in the table as relevant or irrelevant in determining whether the statement is entailed or refuted from the tabular evidence (the truth value of the statement is also provided).

Our systems use TAPAS (Herzig et al., 2020) trained with intermediate pre-training (Eisenschlos et al., 2020) for both the subtasks. For subtask A, we fine-tune TAPAS after adding a three-way classification head on top for classifying the statement as entailed/refuted/unknown. We also evaluate how transfer learning and standardizing tables to have a single header row can improve TAPAS’ performance. Due to the similarity between subtask B and table question-answering (which involves cell selection or cell selection followed by aggregation), we use the TAPAS architecture previously used for table question-answering and fine-tune it to select the relevant cells. We also evaluate how different fine-tuning strategies can improve TAPAS’ performance on evidence finding.

Our systems achieve an F1-micro score of 67.34 in subtask A and 72.89 in subtask A if the unknown statements are not considered while calculating the metrics (however, classifying entailed/refuted statements as unknown is still penalized). Our submitted system achieves an F1 score of 62.95 in subtask B. During the post-evaluation phase, we modified our system and achieved an F1-score of 65.48 in subtask B.

The code for our systems is available at <https://github.com/devanshg27/sem-tab-fact>.

## 2 Background

Verifying if the given textual evidence supports a given statement is a fundamental natural language processing problem. It has been extensively studied under different tasks such as RTE (Recognizing Textual Entailment) (Dagan et al., 2006), NLI (Natural Language Inference) (Bowman et al., 2015), FEVER (Fact Extraction and VERification) (Thorne et al., 2018). In recent years, large-scale pre-trained models (Devlin et al., 2019; Peters et al., 2018; Yang et al., 2019; Liu et al., 2019) have dominated these tasks and have achieved close-to-human performance. NLVR (Suhr et al., 2017) and NLVR2 (Suhr et al., 2019) focus on verifying a statement given an image as evidence. TABFACT (Chen et al., 2020) focuses on verifying a statement given a table from Wikipedia<sup>1</sup> as evidence.

Along with releasing TABFACT, Chen et al. (2020) also discuss two promising approaches for tabular fact verification, Latent Program Algorithm(LPA) and Table-BERT. LPA is a semantic parsing approach that parses statements into programs (logical forms) and executes the programs against the table to predict the entailment decision. Most of the current models (Zhong et al., 2020; Shi et al., 2020; Yang et al., 2020) for TABFACT are semantic parsing approaches similar to LPA. Table-BERT encodes the linearized tables and statements using BERT-based models and directly pre-

dicts the entailment decision. Zhang et al. (2020) inject table structural information into the mask of the self-attention layer of BERT-based models, which helps the model learn better table representations. TAPAS (Herzig et al., 2020) extends BERT’s architecture to capture the tabular structure, and it showed competitive performance on various table question answering datasets: SQA (Iyyer et al., 2017), WTQ (Pasupat and Liang, 2015) and WikiSQL (Zhong et al., 2017). Eisenschlos et al. (2020) add an intermediate pre-training step before the fine-tuning step to TAPAS and show that it achieves state-of-the-art results on TABFACT and SQA (Iyyer et al., 2017). Their model is still 8 points behind human performance on TABFACT since tabular fact verification involves table understanding and complex reasoning.

While TABFACT also focuses on fact verification using tables as evidence, it focuses on tables from Wikipedia, whereas SemEval-2021 Task 9 (SEM-TAB-FACTS) instead focuses on tables from scientific articles and has a subtask related to evidence finding. Also, TABFACT did not have a neutral/unknown class, which they left out because of low inter-worker agreement due to confusion with refuted class. Figure 1 shows an example of a table from the SEM-TAB-FACTS dataset and the labels for the two subtasks.

(b) Standardizing the header rows of the table with single cells

Figure 2: Pre-processing and header standardization applied to the table shown in Figure 1.

### 3 System Overview

In this section, we provide a general overview of our systems for the two subtasks. We use TAPAS for both subtasks.

#### 3.1 Subtask A: Statement Verification

**Pre-processing** Since TAPAS only works on tables with single cells (cells which do not span multiple columns/rows) only, we first convert the tables with multi-row/multi-column cells to tables with only single cells by duplicating the value of the cell in every single cell the multi-row/multi-column cell spans. An example of the pre-processing is shown in Figure 2a.

**Header Standardization** We experiment with standardizing the pre-processed tables with multi-row headers to tables with a single header row since TAPAS was pre-trained on single header tables and TABFACT (which we want to use for transfer learning) also contains single header tables. We first predict the number of header rows using the following rules:

1. In many pre-processed tables, we found that the left-most column contained row names,

and either (a) all the header cells in the left-most column were empty, or (b) the cell value at the top-left corner was repeated in all the header cells below it, or (c) the cell at the top-left corner was not empty, but the header cells below it were empty. Based on these cases, we initially estimate the number of header rows as the number of rows at the top, such that all cells in the left-most column in those rows are either empty or have the same value as the cell at the top-left corner.

2. We also found that in many cases, there were multi-column cells in the header, which had more specific sub-headers in the rows below. To handle these cases, we increment the estimate of header rows until no two adjacent columns have the same header cell values.

We merge the predicted header rows into a single row by joining each column’s header cell values into a single cell with a newline as a separator. An example of header standardization is shown in Figure 2b. We were provided with HTML versions of the tables in the training and development set. We compare our predictions against the `<thead>` tags in the HTML tables to analyze our header prediction system’s performance. The results are shown in Table 1. We also find that in almost all of the cases, the predictions are either correct or have an error of  $\pm 1$ .

To study the effect of header standardization, we will train all our systems with and without header standardization.

**Model** Our model takes the following input: `[CLS] <statement> [SEP] <flattened table>`, which is tokenized using the standard BERT tokenizer. We compute the class probabilities using a linear layer with a softmax activation function on top of the output of the `[CLS]` token, as shown in Figure 3a. We use the weighted cross-entropy loss, which helps in handling imbalance in the class sizes:

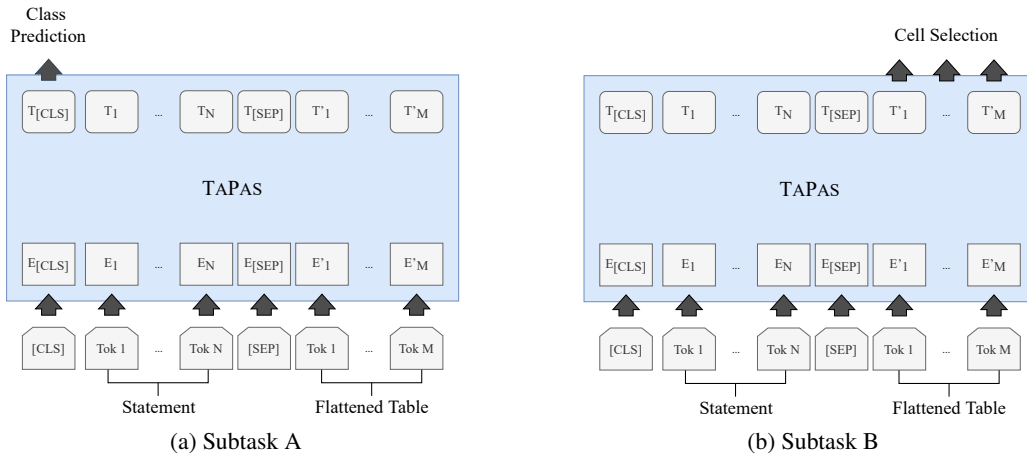

Figure 3: The architecture of our models

$$H_y(y') = - \sum_i \sum_{k=1}^K w_k y_{ik} \cdot \log(y'_{ik})$$

Where  $y_{ik}$  denotes the ground truth label, it is 1 if  $k$  is the true class label of the  $i^{th}$  token, and 0 otherwise,  $y'_{ik}$  is the corresponding model probability prediction and  $w_k$  is the weight for class  $k$ . We set  $w_k$  as the size of the biggest class divided by the size of class  $k$ .

To analyze how transfer learning can improve performance, we compare the following approaches:

- **TAPAS-stf:** We use the publicly available TAPAS checkpoint which has been pre-trained with a masked language modeling objective and fine-tune it on the SEM-TAB-FACTS dataset provided by the task organizers.
- **TAPAS-tf:** As a baseline, we directly use the publicly available TAPAS checkpoint, which had been fine-tuned on TABFACT without any further fine-tuning on SEM-TAB-FACTS. Since TABFACT has only entailed/refuted labels, this model is a binary classifier and does not predict the unknown class’s probabilities.
- **TAPAS-tf-stf:** We use the publicly available TAPAS checkpoint, which had been fine-tuned on TABFACT and further fine-tune it on the SEM-TAB-FACTS dataset released by the task organizers. This is our submitted model for subtask A.

### 3.2 Subtask B: Evidence Finding

#### Pre-processing and Header Standardization

We convert the multi-row/multi-column cells and standardize the header rows as discussed in Section 3.1. The relevant/irrelevant labels of the multi-row/multi-column cells are duplicated to all the single cells they span. We consider the relevant/irrelevant labels only for the cells of the non-header rows as TAPAS does not make predictions for header cells. Based on the performance of header standardization in subtask A (which we will discuss in Section 5), we standardize headers for all our models in this subtask.

**Model** Our model takes the following input:

[CLS] <statement> [SEP] <flattened table>, which is tokenized using the standard BERT tokenizer. We show the architecture of our model in Figure 3b. Our model computes token-level logits using a linear layer on top of each token’s last hidden state output, which are used to compute cell-level logits by averaging the logits of the tokens in each cell. The probability of selection for each cell is calculated from the cell-level logits using the sigmoid function. We use the weighted binary cross-entropy loss which helps in handling class imbalance:

$$H_y(y') = - \sum_i w_p y_i \cdot \log y'_i + (1 - y_i) \cdot \log (1 - y'_i)$$

Where  $y_i$  denotes the ground-truth label, it is 1 if the  $i^{th}$  token is part of any relevant cell, and 0 otherwise,  $y'_i$  is the corresponding model probability prediction, and  $w_p$  denotes the weight of the positive (relevant) class. We set  $w_p$  to 10.

(b) Subtask B

Table 2: Dataset Statistics for each subtask

Due to the similarity of evidence finding with table question-answering, we use the publicly available TAPAS checkpoint, which was fine-tuned in a chain on SQA, WikiSQL, and finally WTQ. We compare the following fine-tuning strategies:

- **WTQ-base:** As a baseline, we fine-tune our model directly for relevant cell selection on SEM-TAB-FACTS.
- **WTQ-statement:** We again fine-tune the model for relevant cell selection on SEM-TAB-FACTS, but we try to include the information on whether the statement was entailed/refuted by modelling the statement as ‘Which cells entail “<statement>”?’ or ‘Which cells refute “<statement>”?’ . <statement> denotes the original statement.
- **WTQ-separate:** We fine-tune two separate models, one which predicts the relevant cells for entailed statements and another one for refuted statements. This is our submitted system for subtask B.

During the post-evaluation phase, we experimented with the publicly available TAPAS checkpoint, which was fine-tuned on TABFACT. Similar to the systems described above, we compare three systems based on this checkpoint: TABFACT-base, TABFACT-statement, and TABFACT-separate.

**Post-Processing** We further apply post-processing steps to obtain the final prediction from the cell classification. To predict the header’s relevant cells, we select the header cells for any column with cells selected as a relevant cell. We label multi-row/multi-column cells as relevant if

any of the single cells they span are predicted as relevant.

## 4 Experimental Setup

### 4.1 Data Description

We used the dataset provided by the task organizers for both subtasks. We did not use the table metadata in our systems.

For subtask A, dataset statistics and the official splits are shown in Table 2a. The provided training sets do not have any statements of the unknown class. So, we used the manually annotated training set to create a training set with unknown statements. Each statement of the manually annotated training set was added as an unknown statement to a different table chosen randomly. We used this dataset for training all our models for subtask A.

For subtask B, dataset statistics and the official splits are shown in Table 2b. We use the auto-generated training set for training all our models in subtask B.

### 4.2 Implementation

For the implementation of our systems, we used the HuggingFace Transformers<sup>2</sup> library (Wolf et al., 2020) and we used the AdamW optimizer available in PyTorch<sup>3</sup> (Paszke et al., 2019) with the default parameters (learning rates are specified below). All models were fine-tuned using a single Nvidia GeForce RTX 2080 Ti GPU.

We used the base variant of TAPAS, which has a hidden dimension of 768 in all our models. All the

Table 4: Performance on subtask B: Mean and standard deviation of the metrics from 3 independent runs

TAPAS checkpoints we used had been trained with intermediate pre-training and used relative position embeddings (the position index reset when a new cell starts).

For subtask A, we first fine-tuned the classifier head with the TAPAS layers frozen for 3 epochs with a learning rate of  $1^{-5}$  and then fine-tuned the whole model for 10 epochs with a learning rate of  $1^{-6}$ . We used a batch size of 8. We saved a checkpoint every 100 steps and selected the best checkpoint based on the validation set performance.

For subtask B, we fine-tuned the whole model for 5000 steps with a learning rate of  $1^{-6}$ . We used a batch size of 8. We saved a checkpoint every 50 steps and selected the best checkpoint based on the validation set performance.

### 4.3 Evaluation Metrics

In subtask A, two evaluation metrics are used. The first evaluation metric used is the standard F1-micro score for three-way classification. The second metric again calculates the F1-micro score but does not consider statements with their ground truth label as the unknown class for evaluation; however, classifying the entailed/refuted statements as unknown is penalized.

In subtask B, the evaluation metric used is the standard F1 score with relevant cells as the positive class. If multiple minimal sets of cells can be used to determine the statement’s truth value, the dataset contains all of these versions. The score for that statement is calculated by comparing the prediction against each ground truth version and considering the highest score.

	Validation Set		Test Set	
	Length( $\leq 512$ )	Length( $> 512$ )	Length( $\leq 512$ )	Length( $> 512$ )
<i>Distribution - Number of samples</i>				
Subtask A	431(77.52%)	125(22.48%)	616(94.33%)	37(5.67%)

Table 5: Results on long sequences

## 5 Results

**Subtask A** The performance of the various systems we considered in subtask A is shown in Table 3. Header standardization improves the performance of all the systems we compared. Transfer learning from TABFACT also improves the performance of our systems. Surprisingly, TAPAS-tf without any fine-tuning on SEM-TAB-FACTS has a better two-way F1-micro score than TAPAS-stf. This shows us the potential of transfer learning from TABFACT in subtask A.

From the confusion matrix shown in Figure 4a, we observe that our model struggles with the unknown class and often misclassifies it as refuted.

**Subtask B** The performance of the various systems we considered in subtask A is shown in Table 4. Modifying the statement to include entailed/refuted class information leads to a small drop in performance for the models fine-tuned on question-answering earlier and led to a small increase in performance in models fine-tuned on TABFACT. Separate models for entailed/refuted statements perform the best among the systems we considered. It significantly improves the performance on entailed statements, with a little drop in performance on refuted statements. Surprisingly, we observe that transfer learning from TABFACT performs better than transfer learning from WTQ, even though it is a cell selection task. We believe this is because the model has to predict the cells that can be used as evidence for table entailment. The token-level embeddings of the model fine-tuned on TABFACT are better for this task than the model fine-tuned on WTQ, which is instead a question-answering dataset.

Predicted Class	R	186 75%	72 26%	21 16%
	E	50 20%	195 71%	52 40%
	U	12 5%	7 3%	58 44%
		R	E	U
		Target Class		

(a) Subtask A

Predicted Class	I	24596 92%	903 26%
	R	2128 8%	2555 74%
		I	R
		Target Class	

(b) Subtask B

Figure 4: Confusion matrices of the test set predictions by our best model for each subtask. The percentages show the ratio of the target class, which was predicted as that class.

**Long Inputs** The maximum number of tokens supported by our system is 512. In sequences longer than 512 tokens, the tables are truncated row by row to fit in 512 tokens. We compare our system’s performance on these long sequences and sequences that fit within 512 tokens. The results are shown in Table 5. We find a significant drop in performance on sequences longer than 512 tokens which had to be truncated.

## 6 Conclusion

In this paper, we presented our approach for fact verification and evidence finding for tabular data in scientific documents. We show that transfer learning from TABFACT and standardization of the tables to have a single header helps improve our system’s performance. We also show that having separate evidence finding models for entailed/refuted statements helps improve our system’s performance in the second subtask.

We also find that our model has a significant

drop in performance on large tables since they are truncated to fit in the 512 tokens, the maximum number of tokens supported by TAPAS.

In future work, we would like to experiment with table pruning methods like Heuristic entity linking (Chen et al., 2020) or Heuristic exact match (Eisenschlos et al., 2020) so that the statement and table can fit in 512 tokens. Our systems did not use the table metadata while making the predictions. In the future, we would also like to explore extending the model to encode table metadata along with the table.

## Acknowledgments

We thank the organisers of the shared task for their effort, and the anonymous reviewers for their insightful comments.

# Kaushik Acharya at SemEval-2021 Task 9: Candidate Generation for Fact Verification over Tables

Kaushik Acharya

Philips India Ltd. / Bangalore, India

acharya.kaushik@gmail.com

## Abstract

This paper describes the system submitted in the SemEval-2021 Statement Verification and Evidence Finding with Tables task. The system relies on candidate generation for logical forms on the table based on keyword matching and dependency parsing on the claim statements.

## 1 Introduction

Tables convey important information in a concise manner. This is true in many domains, scientific documents being one of them. Truth verification tasks in past (e.g. SemEval-2019 Fact Checking Task) have focused on written text without considering the tables. The current shared task (Wang et al., 2021) focuses on tables written in English language. It requires participants to develop systems to predict

- veracity of textual claims (statement verification)
- identify table cells forming relevant evidence for the claim (evidence finding)

The shared task <sup>1</sup> comprised of two sub-tasks:

1. Subtask A: **Table Statement Support**
2. Subtask B: **Relevant Cell Selection**

*Subtask A* is a classification problem in which the system needs to assign one of the following labels for the claim statement:

- *Entailed*: Table supports the statement.
- *Refuted*: Statement is contradicted by the table.
- *Unknown*: Not enough information available in the table to assess statement’s veracity.

Country	N	Board network			Family network			State network			Political network

Figure 1: Example table showing Networks across East Asia.

id	Claim statement
1	The n value is same for Hong Kong and Malaysia.
2	There are 9 different types country in the given table.

Table 1: Statement claims of table in Figure 1

*Subtask B* requires finding evidence (table cells) which are minimally required to either support or refute the claim statement. This is not applicable for the statements whose veracity is unknown.

These tables were sourced from scientific articles belonging to journals published by Elsevier and available on ScienceDirect. For details related to web scraping of the articles, selection criteria for choosing the tables, creating statement claims and assigning table cell evidence for the claim, please refer to the task description paper (Wang et al., 2021). An example table is shown in Fig. 1 with corresponding claims mentioned in Table 1.

System described in this paper generates logical form candidates on the table data frame based on the claim statement. It executes the most probable candidate and verifies the output to check whether it matches with the one mentioned in the statement. Averaged F1 score over the tables are shown in

<sup>1</sup><https://competitions.codalab.org/competitions/27748>

Table 4. Source code has been released on github <sup>2</sup>.

## 2 Related Work

Thorne et al. (2018) had conducted Fact Extraction and VERification (**FEVER**) Shared Task<sup>3</sup> to build systems to verify claims based on evidence from Wikipedia. Similar to the current shared task, systems had to label claim as **Supported**, **Refuted** or **NotEnoughInfo** (if there isn't sufficient evidence to either support or refute it). Along with that, system must extract textual evidence (sets of sentences) that support or refute the claim.

Pasupat and Liang (2015) had created question answering dataset (WikiTableQuestions) <sup>4</sup> from Wikipedia tables. Using question-answer pairs as supervision, they developed a logical-form driven parsing algorithm.

Herzig et al. (2020) build a question answering model over tables without generating logical forms by extending BERT's architecture (Devlin et al., 2019) with additional positional embeddings to encode tabular structure.

## 3 Model Description

### 3.1 XML Data

Input xml documents were parsed using the *ElementTree XML API* <sup>5</sup>. Each document is composed of table element(s). Table element is composed of row elements and statements. The row elements describe the rows and columns of the table and contains the text of each table cell. Optionally, legend and caption texts were also provided for a portion of tables.

### 3.2 Loading table

Table element was parsed and loaded into *pandas dataframe* <sup>6</sup>. The challenging part was in identifying column labels having hierarchical indexing <sup>7</sup>. An example of hierarchical columns is shown in Fig. 1, which has four columns: Broad network,

<sup>2</sup>[https://github.com/kaushikacharya/statement\\_verification\\_evidence\\_finding](https://github.com/kaushikacharya/statement_verification_evidence_finding)

#	Candidate
1	Column superlative value
2	Column values identical or unique
3	Comparison of column values for a row or vice-versa
4	Column value range

Table 2: Partial list of Candidates

Family network and so on. All these columns have three sub-columns: mean, SD, max. A simple approach to identify whether multiple table rows represent column labels was applied: Table rows from top were considered as part of column labels until all the columns of the table are filled. In the example table, *Broad network* is mentioned in table cell col:2 and *Family network* belongs to col:5. The in-between columns (i.e. 3,4) were filled in next row. Hence the first two rows were considered as column labels.

Figure 2: Dependency tree for statement id=2 in Table 1

### 3.3 Candidate Selection

A list of candidates were defined along with pattern rules to identify them and corresponding operations to execute. For instance, for the candidate superlative(highest/lowest) of column, corresponding operation on pandas dataframe gets executed. Statements are parsed to identify the candidate and fact verification is done in the following steps:

1. Match column and row labels (if available) based on approximate keyword matching.
2. Candidate operation(s) are identified based on keyword and dependency tag matching.
3. Candidate logical form is executed.
4. Output of candidate operation is matched with the one mentioned in the statement.

Table 2 enumerates subset of candidates.

For matching columns and row labels, sliding window over the tokens of statements are matched using Jaro metric (Cohen et al., 2003). Number

of tokens in column/row label is considered as the window size. As an example, for matching the row label *Hong Kong* of Figure 1 in Table 1, sliding window of two tokens is considered. If overlapping window match the same column/row label, the one with maximum Jaro metric is chosen. A span of statement tokens is considered matched if the Jaro metric is above a threshold (value considered 0.85).

**Examples:** Statement id=1 in Table 1 matches the candidate: *comparison of two rows for a column value*. The two rows referred by *Hong Kong* and *Malaysia* are compared for the value corresponding to the column *N*. Logical form: Comparing whether the cell value for the matched column corresponding the matched rows is same/different.

Statement id=2 refers to the candidate: *unique count of the values under the column Country*. Candidate is chosen based on the keyword *different* and matching of a single column **Country**. Candidate value (that needs to be verified) is identified based on the dependency tree shown in Figure 2. The token 9 with part of speech tag *NUM* has the head token of column *country* through dependency tag *nummod*. The logical form that has been assigned for the candidate is unique count over the matched column of the *pandas dataframe*.

## 4 Experimental Setup

### 4.1 Data

The data splits used were the same as provided by the task organizers. Split statistics is shown in Table 3.

split	docs	tables	claims
train	424	981	4506
dev	21	52	556
test	36	52	653

Table 3: Data split count statistics

### 4.2 External libraries

- spaCy (version: 2.3.2) <sup>8</sup>
- word2number <sup>9</sup>

### 4.3 Evaluation Metrics

**Task A - Fact Verification** The goal of this task is to determine whether a statement can be en-

<sup>8</sup><https://github.com/explosion/spaCy>

<sup>9</sup><https://github.com/akshaynagpal/w2n>

Figure 3: Distribution of number of statements per table.

tailed/refuted by the given table, or cannot be determined from the table. The classification algorithm is evaluated using the standard F1-score. Two different evaluation results were generated:

1. Two way
2. Three way

*Two way* is an easier evaluation in which **unknown** ground truth labels were ignored. Whereas in *three way* all the three labels were considered. This tests whether the classification algorithm understands cases where there are insufficient information to make prediction.

**Task B - Evidence Finding** The goal of this task is to determine whether a table cell is needed to entail/refute the given statement. In other words, whether a statement can be entailed/refuted given only the table cells marked as *relevant*. F1 score is computed for each table with *relevant* cells as the positive class and *irrelevant* cells as the negative class.

Fig. 3 shows that unlike test data, train data has many tables with very few statements. This indicates that comparing averaged F1 score (as shown in Table 4) between train and test data is not a good indicator how well the model works on unseen test data compared to its performance on train/dev data. Instead comparing confusion matrix (as shown in Table 5 and Table 6) is a better indicator.

## 5 Results

Averaged F1 score over the tables are shown in Table 4. These are the scores at the time of writing this paper. Train data didn't had the ground truth for the relevant cell selection. Hence value is non-available for Task B on train data. Due to absence of *unknown* class in train data, 2-way and 3-way averaged F1 scores are same. Confusion matrix

is displayed in Table 5 for train data and Table 6 for test data. Predicted claim class *unknown* also contains the claim statements for which the system failed to identify candidate. Hence this class shows a high value.

split	Task A (2 way)	Task A (3 way)	Task B
train	0.3669	0.3669	NA
dev	0.3804	0.4314	0.3687
test	0.4037	0.4909	0.3849

Table 4: F1 score averaged over tables

truth	predicted		
	entailed	refuted	unknown
entailed	863	472	1483
refuted	49	861	778

Table 5: Confusion Matrix for Task A on train data. Row represents truth classes and column represents the predicted classes.

truth	predicted		
	entailed	refuted	unknown
entailed	83	39	152
refuted	8	127	113
unknown	3	15	113

Table 6: Confusion Matrix for Task A on test data. Rows and columns represents truth and predicted classes respectively.

type	# statements
Total wrongly predicted statements	2782
Neither column nor row matched	786
No column matched but row(s) matched	386

Table 7: Matching columns/rows in wrongly predicted statements in train data.

**Error Analysis:** The errors can be categorized broadly into the following categories:

1. Absence of semantic matching
2. Lack of enough candidate generation rules
3. Classifying candidate in a deterministic way

Due to keyword matching the system fails to identify the columns which are mentioned with

different words in the statement even though semantically they are same. Table 7 gives a glimpse of *probable* failures under this category.

The set of candidate generation rules needs to be extended. The current system misses out candidate generation in several statements because of the absence of these not yet defined candidates. The high number of *unknown* predictions in the confusion matrices shown in Table 5 and 6 is a proof of this issue. There’s a need for a scoring system which considers multiple probable candidates for logical forms. The current system selects a single candidate based on the one which matches first in the order listed for candidate match.

## 6 Conclusion

I have described the system used for submission to the Statement Verification and Evidence Finding with Tables task. The problem has been framed as a candidate generation for logical forms over dataframe using keyword matching and dependency parsing. Future work would include extending the defined list of candidates and usage of scoring based system to identify the most probable candidate. This improvement would take ideas from (Pasupat and Liang, 2015) for feature extraction and build a log-linear model to compute score for the candidates.

## Abstract

This paper describes our approach for Task 9 of SemEval 2021: *Statement Verification and Evidence Finding with Tables*. We participated in both subtasks, namely statement verification and evidence finding. For the subtask of statement verification, we extend the TAPAS model to adapt to the ‘unknown’ class of statements by finetuning it on an augmented version of the task data. For the subtask of evidence finding, we finetune the DistilBERT model in a Siamese setting.

## 1 Introduction

Tables provide a compact and structured way of presenting information. They are easily interpretable by humans and are widely used in scientific papers, business articles, and even in government reports. At the same time, it is easy to misinterpret tabular data and even use it maliciously to spread misinformation. Thus, systems that can verify facts from tables and locate evidence in them can go a long way in ameliorating issues related to table interpretation. Such systems can also be used for question-answering over large tables, that are difficult to analyze manually, since the task of fact verification with evidence finding is closely related to that of question answering (Jobanputra, 2019).

Table entailment refers to the task of finding whether a sentence is refuted or supported by a given table. Traditionally, it has been considered a binary classification task. However, there could be instances where the table is not capable enough to either refute or accept the given statement, meaning the statement context is “unknown” for the table. In this paper, we have presented a table entailment setup that extends to three classes: refuted, entailed,

and unknown, as a part of the Sem-Tab-Fact task (Wang et al., 2021). The task could be divided into two parts: statement verification, and evidence finding. Given a table and a statement, one has to first determine whether the table entails the statement, refutes the statement, or has insufficient information about it. This forms the subtask of *statement verification*. If the table entails or refutes the statement, one would also like to know which cells in the table provided evidence for the same. This is the subtask of *evidence finding*, that can be formulated as a binary classification problem. Each cell in the table is assigned one of the ‘relevant’ or ‘irrelevant’ labels depending on whether it provided evidence for the given statement.

Recent years have seen a rise in the use of transfer learning in language processing (Malte and Ratadiya, 2019a) owing to their superior performance. Models based on underlying concepts like attention mechanism and transformers are seeing widespread use across a range of tasks (Malte and Ratadiya, 2019b; Ratadiya and Mishra, 2019). Our findings concurred with this trend as we used similar kinds of architectures as the fundamental blocks in the systems for both the subtasks. For the subtask of *statement verification*, we modify the recently released TAPAS model (Eisenschlos et al., 2020) that is pre-trained on the TabFact dataset (Chen et al., 2020). The pre-trained model is trained on only two classes: ‘entailed’ and ‘refuted’, and is not capable of classifying the ‘unknown’ samples. The training data provided to us for our task also contains the same two labels. To adapt to the ‘unknown’ statements, we augment the given data by including random statements from other tables as unknown. We then fine-tune the TAPAS model by extending it to three classes on this augmented data.

Using this approach, we achieve a three-way F1 score of 65.59 and a two-way F1 score of 71.72 on the test data. We ranked 8<sup>th</sup> on the official leaderboard for this subtask.

For the subtask of *evidence finding*, we fine-tune the DistilBERT model (Sanh et al., 2019) in a Siamese setup (Reimers and Gurevych, 2019). The model is pre-trained on the SNLI dataset (Bowman et al., 2015), the MultiNLI dataset (Williams et al., 2018) and the STS benchmark (Cer et al., 2017). For finetuning, we use the Contrastive loss (Hadsell et al., 2006) as our loss function. For making a prediction, we calculate the cosine similarity between the embeddings computed by the model for both the statement and the cell value. If the cosine similarity value crosses a set threshold, we consider the cell to be relevant to the given statement. Using this approach, we achieve an F1-score of 43.02 on the test data and secured the 7<sup>th</sup> rank on the official leaderboard for this subtask.

The source code of our proposed approach for both the subtasks has been made public<sup>1</sup> to encourage usage and improve the reproducibility of the results.

## 2 Related Work

Recently, the TabFact dataset was released, which contained 118K human-annotated statements, related to about 16K Wikipedia tables. These statements were annotated for only two labels, ‘entailed’ and ‘refuted’, leaving out the ‘unknown’ cases. A system’s ability to distinguish ‘unknown’ statements from ‘entailed’ and ‘refuted’ is quite critical, as one may elusively create seemingly believable statements that are actually ‘unknown’.

Recently, there has been work in areas related to table fact verification, especially since the release of the TabFact dataset. Many of these approaches are graph-based in nature (Shi et al., 2020; Yang et al., 2020; Zhong et al., 2020). The current state-of-the-art on the TabFact dataset is the recently released TAPAS model, which outperforms its predecessor by approximately 6%. Unfortunately, all of these models are quite far from human-level performance, suggesting ample scope for improvement.

Little to no work has been done previously on the task of evidence finding, with the closest approaches being related to table-based question

<sup>1</sup>The code is available at <https://www.github.com/vcreatek/attestable-semeval/>

answering like WikiTableQuestions (Pasupat and Liang, 2015), WikiSQL (Zhong et al., 2018) and SQA (Iyyer et al., 2017) where getting the answer for a question can be considered analogous to getting evidence for a statement.

## 3 System Overview

### 3.1 Data and Preprocessing

The training dataset for this task contains two kinds of data:

- **Manual annotations:** These are crowd-sourced from human annotators and have been validated by a second round of validation.
- **Auto-generated annotations:** These statements are auto-generated using a random paraphraser and table understanding service (Zheng et al., 2020).

A separate development set was also provided.

#### 3.1.1 Subtask A: Statement Verification

The provided dataset for this task is in XML format. We use a custom parser to convert the data into CSV format, such that each data sample is of the form (*table, statement, label*), where the table is also a CSV, extracted from the corresponding XML file. No preprocessing is applied to the statements.

In general, the table cells can span across multiple rows and columns. To simplify things, we treat a cell spanning multiple columns/rows as multiple cells with the same value. This preserves the logical hierarchy in the table while keeping the table structure simple. See Figure 1 for an example.

Figure 1: A cell spanning three columns is considered as three separate cells with the same value

A table may also have additional metadata accompanying it, like the legend, the caption, and the footer. Our final model does not use this metadata since we observe in Section 5.1.2 that including the metadata has a small negative impact on the model performance.

After the above preprocessing, we have 179,345 autogenerated and 4506 manual data samples.

### 3.1.2 Subtask B: Evidence Finding

For this subtask, we prepare the data in the form (*cell text, statement text, label*), where the label can be ‘relevant’ or ‘irrelevant’. We do not encode the table’s structural information and focus only on the semantic similarity between the statements and the cell texts.

An important point to note here is that only a few of the cells in the table actually contribute to the evidence for each statement. The average ratio of the number of relevant samples to total samples as observed in the development set for each statement is around 0.097. This causes a substantial class imbalance since a meager 7% of the total samples are ‘relevant’. To attend this problem, we undersample the ‘irrelevant’ samples by removing some irrelevant samples for each statement from the data. We try three ratios for undersampling and compare the percentage of relevant statements after undersampling in Table 1.

$n'_i$	% r	$n_t$
$0.6n_i$	10.15	10.24
$0.5(n_r + n_i)$	11.24	9.25
$0.4n_i$	14.54	7.15

Table 1:  $n_i$  and  $n_r$  stand for the number of irrelevant and relevant samples for a statement.  $n'_i$  stands for the no. of irrelevant samples kept for each statement after the undersampling. %r stands for the percentage of relevant samples after undersampling.  $n_t$  stands for the total samples after undersampling, in millions.

In the original data, the average ratio of relevant to total samples is around 9.7%, so we would want our data to reflect a similar ratio. Therefore, we use the data undersampled using the first approach for further analysis. Hence, the total number of samples after undersampling stand at 10.24M.

### 3.2 Data Augmentation

The given data has no ‘unknown’ statements; thus, we augment the data to introduce samples of this class label. Let  $S$  denote the set of all statements in our data. Let  $S_e$  denote the set of all entailed statements in our data. Let  $S_r$  denote the set of all refuted statements in our data. Then  $S = S_e \cup S_r$ .

For a given table  $t$ , let  $S_t$  denote the set of all statements associated with that table. We first calculate  $n_e$  (the number of entailed statements for that table) and  $n_r$  (the number of refuted statements for that table). We then calculate  $n_u$  (the number of

unknown statements to add) as follows:

$$n_u = \max(\min(n_e, n_r), 1) \quad (1)$$

After this, we randomly select  $n_u$  statements from  $S \setminus S_t$ . This forms the set of ‘unknown’ statements for the table  $t$ . We do this for all tables in the data.

The above augmentation scheme ensures that the resultant augmented data has an almost equal overall distribution among the three classes. It also ensures that evenness across tables is maintained, as sufficient unknown statements (at least one) are added for each table, and not just overall. After performing the above augmentation scheme, we get 85,296 unknown statements for the autogenerated data and 1,637 unknown statements for the manual data.

### 3.3 Models

#### 3.3.1 Subtask A: The TAPAS Model

TAPAS (Herzig et al., 2020) is a recently released BERT (Devlin et al., 2019) based model that encodes the structural information via column, row and rank embeddings. Eisenschlos et al. extended TAPAS for binary entailment using the TabFact dataset. We use the base variant (12 encoder blocks) of this TAPAS model, which has been pre-trained on the TabFact dataset. We use the base variant over the large variant (24 encoder blocks) due to limitations on computation power and due to the superior performance of the base variant as shown in Section 5.1.2.

For extending the TAPAS model to support the unknown class, we replace the two-neuron linear layer in the pre-trained model by a randomly initialized linear layer consisting of three neurons as the output layer. We then finetune this modified model on the augmented data containing three classes. Figure 2 shows the overview of the modified model. It consists of an embedding layer that concatenates the positional and semantic information of a cell value, the encoder block consisting of transformer layers and subsequent layers that are required for classification output. The core layers of the modified model are in accordance with the original TAPAS model (Herzig et al., 2020; Eisenschlos et al., 2020).

#### 3.3.2 Subtask B: Siamese DistilBERT

For the evidence finding subtask, we finetune the DistilBERT model on the undersampled data. The

Figure 2: The modified TAPAS architecture. ‘Classifier’ is just a linear layer with three neurons

model was pre-trained with mean pooling on the SNLI dataset, the MultiNLI dataset, and the STS benchmark. The mean pooling is applied in a Siamese setting using the Contrastive loss as the loss function.

Let  $s$  denote a statement, let  $c$  denote the cell, let  $r$  denote the relevancy/label (this is either 0 or 1) and let  $\mathcal{M}(x)$  denote the embedding computed the model for an input  $x$ . Then, the distance  $d$  and the Contrastive loss  $\mathcal{L}(d, r)$  is defined as follows:

$$d = \text{COSINEDISTANCE}(\mathcal{M}(s), \mathcal{M}(c))$$

$$\mathcal{L}(d, r) = \frac{1}{2} \left( (1 - r)d^2 + r(\max(0, m - d))^2 \right) \quad (2)$$

Here,  $m$  denotes the ‘margin’ value, which ensures that the dissimilar pairs contribute to the loss only if their distance is within this margin. For making inferences, we first use our finetuned model to compute the sentence embeddings for the statement and the cell text and then compute the cosine similarity between the two. Hyperparameter tuning and other details about the models are discussed in Section 4.

## 4 Experimental Setup

### 4.1 Hyperparameters and Data Splits

#### 4.1.1 Subtask A

For training, we first merge the autogenerated and manual augmented data. We then perform an 80 – 20 split on this merged data to get our training and

validation sets. We then fine-tune on the training data and validate on the validation set.

The ‘TAPAS Encoder’ (Figure 2) consists of a stack of 12 encoder blocks (similar to the BERT Base). For finetuning, we freeze the entire model, except the last three encoder blocks, the ‘TAPAS Pooler’, and the final classification layer.

This leaves 22M trainable parameters and 89M frozen (i.e. untrainable) parameters.

Categorical Cross-Entropy is used as the loss function. We use a batch size of 32 and finetune for 3 epochs using the AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of  $5 \times 10^{-5}$ .

Before making the final submission, the training and development sets are merged together and the model is trained for one more epoch.

#### 4.1.2 Subtask B

We take a 500K sized randomly selected sample from the undersampled data and perform an 80 – 20 split on this to get our training and validation sets. We keep the margin  $m$  as 0.5 and finetune the entire model, with no parameters frozen, for a single epoch using a batch size of 64. For making the inferences from the cosine similarity, we use an empirically selected threshold of 0.3.

## 4.2 Libraries and Tools

Google Colab<sup>2</sup> was used to perform all the experiments. The time taken per epoch for any model did not exceed 10 hours. The GPUs automatically allotted by Colab kept varying between Tesla T4, Tesla P100-PCIE-16GB, and Tesla K80. PyTorch<sup>3</sup> is used as the central framework for both the tasks. For subtask A, Huggingface’s Transformers library<sup>4</sup> was used to load the pre-trained TAPAS model. For subtask B, we use the SentenceTransformers framework<sup>5</sup> to load the pretrained Siamese DistilBERT model.

## 5 Results

### 5.1 Subtask A

#### 5.1.1 Official Metrics

The original pre-trained TAPAS (Base) model, without any finetuning, achieves a two-way F1 score of 62.56. Our final finetuned model achieves

<sup>2</sup>Free version

<sup>3</sup>Version 1.7.0: <https://pytorch.org/docs/1.7.0/>

<sup>4</sup>Version 4.1.1: <https://huggingface.co/transformers/v4.1.1/>

<sup>5</sup>Version 0.4.1: <https://www.sbert.net/>

Figure 3: Confusion matrix for the submitted model

a two-way F1 score of 71.72 and a three-way F1 score of 65.59. Figure 3 shows the corresponding confusion matrix. We ranked 8<sup>th</sup> on the official leaderboard for subtask-A.

From the confusion matrix, we observe that the most confusing cases for our model are true ‘unknown’ statements, which get classified as ‘entailed’. On manual analysis of such statements, we observe that many of these have a considerable textual overlap with the table. This misclassification seems to be a consequence of our augmentation scheme. The statements that we add as ‘unknown’ while augmentation have almost no textual overlap with the table data since they were sourced from other tables. Although, in general, as observed in the test data, unknown statements can broadly be classified into two kinds: ‘related’ and ‘unrelated’. The former being unknown statements that are related in a semantic or a directly textual way to the table’s data, and the latter are not related to the table’s data in any way. The following example should make this clear.

Orders	Week 1	Week 2	Week 3
Order 1	Peat	Straw	Silage
Order 2	Straw	Silage	Control
Order 3	Silage	Control	Combo

Table 2: A table containing data about a few weekly orders

In Table 2, a ‘related’ unknown statement will be “A total of 10L of **silage**, **straw**, **peat** or **combo** was distributed”. The boldfaced words overlap directly with the table’s contents

While, an ‘unrelated’ unknown statement can be “Earth revolves around the Sun”. Thus, both of

these sub-classes of the ‘unknown’ class are important. Synthesizing ‘unrelated’ unknown statements is a simple task, whereas synthesizing ‘related’ statements without any additional information seems to be a fairly non-trivial task.

We also observe that wrongly classified statements are, on average, 8.8 characters longer than correctly classified statements. Figure 4 shows this histogram.

Figure 4: Histogram of lengths (in characters) of 100 randomly selected correctly classified and wrongly classified statements

## 5.1.2 Ablation Study

### Effect of Table Metadata

A table may have additional metadata like the caption, legend, and footer associated with it. For simplicity, we include it directly inside the table as rows. If the table has a caption, we add it as a single row at the top of the table. Similarly, if it has a legend, it goes as a single row below the caption, and the footer is added as a row at the end of the table. Keeping other hyperparameters the same, we get the following results:

Included Metadata	Validation Accuracy
Yes	0.92
No	0.93

Table 3: Impact of inclusion of metadata on validation accuracy

We observe that including the metadata worsens the accuracy. A possible reason could be our way of including the metadata as rows. There may be other better ways of doing this, which may further improve the accuracy.

### Effect of Model Size

We try out two variants of TAPAS: Base and Large. The Base variant has 12 encoder blocks, and the

Large variant has 24, similar to BERT Base and BERT Large. On the TabFact dataset, the Base variant is only about 0.24 points behind the Large one. The following tests are performed on the original, unaugmented data, containing two classes<sup>6</sup>. We merge the original manual and autogenerated statements into a single dataset and perform an 80 – 20 split.

Variant	Validation Accuracy
Base	0.81
Large	0.71

Table 4: Effect of finetuning a larger model

## 5.2 Subtask B

Our final model achieves an F1 score of 43.02. Figure 5 shows the corresponding confusion matrix. As evident from the confusion matrix, there is a lot of room for improvement, especially in handling the ‘relevant’ statements. We ranked 7<sup>th</sup> on the official leaderboard for subtask-B.

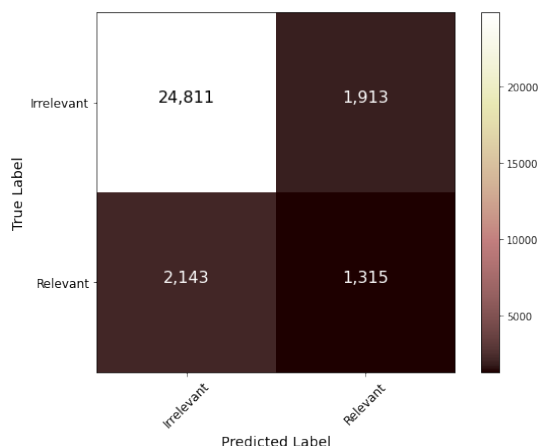

Figure 5: Confusion matrix for Subtask B

## 6 Conclusion

Thus we have presented a statement verification and evidence finding setup for tables. For subtask-A, we extended the TAPAS model to adapt to the ‘unknown’ statements. For subtask-B, we used a semantic approach for evidence finding. Our results for subtask-A show the problems encountered while generating and working with the ‘unknown’ statements. For subtask-B, our results show the effect of taking only the semantic information into

<sup>6</sup>Training the Large variant on augmented data exceeds the time limit of Google Colab (12 hours)

account. An important future prospect for subtask-A would be to find a more effective way of generating the ‘unknown’ statements. For subtask-B, utilizing the table’s available structural information to improve the results seems to be a promising prospect.

{jinquan.sjq, mickey.zq, tonggou.wangyu}@alibaba-inc.com  
lei.zhang.lz@alibaba-inc.com

## Abstract

Due to the increasing concerns for data privacy, source-free unsupervised domain adaptation attracts more and more research attention, where only a trained source model is assumed to be available, while the labeled source data remains private. To get promising adaptation results, we need to find effective ways to transfer knowledge learned in source domain and leverage useful domain specific information from target domain at the same time. This paper describes our winning contribution to SemEval 2021 Task 10: *Source-Free Domain Adaptation for Semantic Processing*. Our key idea is to leverage the model trained on source domain data to generate pseudo labels for target domain samples. Besides, we propose Negation-aware Pre-training (NAP) to incorporate negation knowledge into model. Our method wins the 1st place with F1-score of 0.822 on the official blind test set of *Negation Detection Track*.

## 1 Introduction

The *Negation Detection Track* of SemEval 2021 Task 10: *Source-Free Domain Adaptation for Semantic Processing* provides a new setting for unsupervised domain adaptation task which ask participants to conduct negation detection in target domain only with model trained on source domain (namely source model) and unlabeled target domain data. Negation detection is a span-in-context classification problem, where the model will jointly consider both the target mention to be classified and its surrounding context. For example, in sentence *Has no <e> diarrhea <e\> and no new lumps or masses*, the target span *diarrhea* is negated by its surrounding context *no*. This task is important for physicians to extract key information from clinical text. The test dataset used is based on MIMIC-III version 1.4 (Johnson et al., 2016), which is a large, freely-available english database comprising de-identified health-related data.

We approach this task as a problem of learning with pseudo labels. Our main interests include 1) negation knowledge infusion through pre-training on target domain and 2) high-quality pseudo label generation. We divide the task into two stages: Negation-aware Pre-training (NAP) stage and Pseudo label Training stage. In the NAP stage, token-level and sentence-level negation semantic are embedded into model. In the pseudo label training stage, confidence threshold search and mean self-entropy are used to select target domain samples with highly confident pseudo labels.

## 2 Related Work

Traditional negation detection method are mostly rule-based. These methods (Chapman et al., 2001; Sanchez-Graillet and Poesio, 2007; Huang and Lowe, 2007; Sohn et al., 2012) used regular expression algorithm, dependency parsing and grammatical parsing to perform negation cue detection and scope resolution. Recent years, deep learning has been applied to negation detection task. In (Qian et al., 2016), Convolutional Neural Network was used to recognize negation scope in the sentence. (Lazib et al., 2019) and (Gautam et al., 2018) leveraged recurrent neural network variants to perform negation scope resolution and achieved better performance with BiLSTM, which further indicates the potential in deep learning-based methods. Joint model to detect negation cues and targets simultaneously had been studied by Bhatia et al. (2019). More recently, popular transformer-based model (Khandelwal and Sawant, 2019) had also been used to perform negation detection.

Due to data privacy and data transmission problem, several source-free unsupervised domain adaptation methods (Liang et al., 2020; Kim et al., 2020; Yang et al., 2020) have been proposed for image classification task. These methods mostly focus

on generating high-quality pseudo labels for target domain samples before or during training phase and do not involve self-supervised pre-training.

In the natural language processing field, pre-training is popular. We train language models on huge corpora and fine-tune the pre-trained architectures (Devlin et al., 2018; Liu et al., 2019; Zhang et al., 2019; Yang et al., 2019) in downstream tasks, achieving state-of-the-art results on most NLP tasks. Prior studies (Radford et al., 2018; Chronopoulou et al., 2019; Gururangan et al., 2020; Lee et al., 2020) has further shown the potential of domain-adaptive and task-adaptive pre-training.

### 3 Method

We approach the task of source-free domain adaptation for negation detection as a problem of learning with pseudo labels. To generate high-quality pseudo labels, we use mean self-entropy as metric to search appropriate probability threshold, which is inspired by (Li et al., 2020). Besides, in order to learn more negation semantic knowledge from target domain, we propose negation-aware pre-training to incorporate negation knowledge by self-supervised training.

#### 3.1 Negation-aware Pre-training

In prior studies, negation cues are important for rule-based and machine learning-based methods. We propose Negation-Aware Pre-training NAP to embed the knowledge of negation cues into representation. As shown in Figure 1, common token masking, negation cue prediction and pseudo negation detection are included in NAP. Common token masking is conducted to capture target domain language knowledge. Negation cue prediction could help the model recognize token-level negation information based on collected negation cue lexicon. Pseudo negation detection is a sequence classification task and designed for complex sentence-level negation knowledge. It is the same as our final negation detection task, however, the target mention and corresponding label is generated by simple heuristic rules. Although these data is somewhat noisy, with the help of pseudo negation detection pre-training, more negation information could be embedded into model.

**Negation Cue Lexicon** Negation cues are key to the Negation-Aware Pre-training. Based on the lexicon created by (Weng et al., 2020), we divide negation cues into 2 categories: Pre-negation

PREN	POSN
not	unlikely
none	be ruled out
nor	be excluded
without	be resolved
deny	be absent
no evidence of	be negative

Table 1: Examples of negation cues.

(PREN), Post-negation (POSN). Pre-negation and Post-negation mean the negation cues locate before or after the target mentions respectively. Table 1 shows several examples of each type of negation cues.

**Pseudo Pre-training Data Generation** To perform pseudo negation detection task, we need a large number of labeled data. We design simple yet effective rules to generate training data. To simplify the process, we assume all clinical event mentions are single noun. For sentence *without evidence of diarrhea, vomit*, we first locate the negation cue *without*. Since *without* is a pre-negation cue, we take the 3 tokens behind it ( *evidence of diarrhea* ) as target context. In the target context, the furthest noun *diarrhea* from *without* is selected as target mention. Finally, we generate a pseudo training data: *without evidence of <e> diarrhea <e\>, vomit* with negated label. For samples with post-negation cue, the process is similar, but the target context is before the negation cue. Generally, the selected target mentions are negated by surrounding cues, but there is a special case: double negative. For instance, in sentence *The report can not rule out diarrhea*, *diarrhea* is not negated, since *rule out* is negated by *not*. We assign non-negated label for these double-negative cases. We also generate more non-negated samples by randomly select sentences including no negation cues.

**Objectives of Pre-training** As illustrated in Figure 1, there are 3 tasks included in the pre-training stage. Common token masking is inherited from RoBERTa (Liu et al., 2019). It is used to capture low level language information in test domain. Specifically, during pre-training, except for the tokens in negation cue lexicon, about 15% of input tokens are random sampled and masked. The model is trained to recover original tokens in the corrupted input sequence. We denote the objective of common token masking task as  $L_{mlm}$ . Negation cue prediction as a token classification task is import

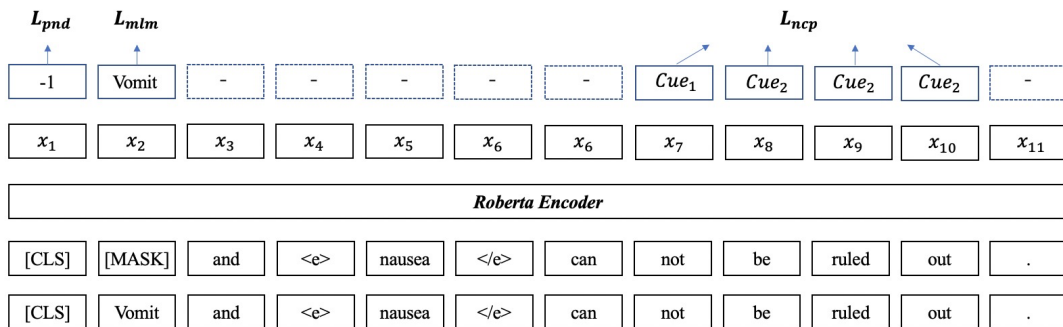

Figure 1: The framework of NAP, Negation-Aware Pre-training. The NAP includes 3 pre-training tasks: common token masking, negation cue detection and pseudo negation detection. Common token masking is inherited from prior pre-training work. Negation cue detection is a token classification task, which aims to embed negation knowledge at token level. Pseudo negation detection is similar to final negation detection task, but the training data is generated based on heuristic rule. Pseudo negation detection could help model capture the complex relation between negation cue and target mention.

for negation knowledge infusion. For each token in input sequence, the task aims to guide the model predict its negation polarity (negation or not) based on its representation  $x_i$  output by transformer encoder. Through this way, the pre-trained model could learn the negation knowledge at token level. The objective of negation cue prediction is the same as classical token classification task and is denoted as  $L_{ncp}$ . Pseudo negation detection is another crucial key to negation-aware pre-training. Compared to negation cue prediction task, this task could further help model to capture the semantic relation between negation cues and target mentions. The objective  $L_{pnd}$  for a single sample is defined as follows:

$$\hat{y} = \text{sigmoid}(Wx_1 + b)$$

$$L_{pnd} = -y \log \hat{y} - (1 - y) \log(1 - \hat{y})$$

Here  $x_1$  denotes the output vector of first token from transformer encoder. All the above 3 pre-training objectives are jointly optimized. Thus, overall pre-training objective  $L$  is:

$$L = L_{mlm} + L_{ncp} + L_{pnd}$$

### 3.2 Pseudo label Training

Although the negation knowledge is infused through pre-training tasks, the pre-trained model is still lack of the ability to understand complicated semantic information and negation relation. Since the training data and corresponding labels in pre-training stage are generated by simple heuristic rules, most training sample are easy to learn and some samples with wrong labels may harm the model. Thus, test domain samples with high-

quality labels are needed to guide the pre-trained model learn more useful information. We leverage the source model to predict the probability of each test sample to be negated or non-negated. Then inspired by *Self-entropy Descent* (SED) proposed in (Li et al., 2020), we conduct *Confidence Threshold Search* to generate high-quality test domain samples.

**Confidence Threshold Search** Self-entropy could be used as a metric to measure the prediction uncertainty (Kim et al., 2020), i.e.  $H(x) = -\sum p(x) \log(p(x))$ . The lower the self-entropy the more confident the prediction is. We set the probability threshold to be non-negated as 0.999 empirically, then search the probability to be negated from 0.985 to 0.975. The step size is set to be 0.001. The generated pseudo labels are used to fine-tune the source model and then evaluate the mean self-entropy of the dataset after training. When the mean self-entropy descends and hits the first local minimum, we take the corresponding probability as an appropriate threshold for generating labels. Samples do not reach the threshold will be excluded.

## 4 Source Model and Data

**Source Domain Data** The source domain data is from SHARP Seed dataset which consists of de-identified clinical notes from Mayo Clinic. In the SHARP data, clinical events are marked with a boolean polarity indicator, with values of either asserted or negated. There are 10259 samples provided including 902 negated instances for source model training.

**Source Model** Since the data privacy limitation, SHARP Seed dataset cannot be distributed. Thus organizers provide a "span-in-context" negation detection model trained on SHARP Seed dataset as the source model. The source model is RoBERTa-based and could achieve promising result on the SHARP Seed dataset.

**Target Domain Data** The target domain data is from MIMIC-III version 1.4 dataset (Johnson et al., 2016). MIMIC-III version 1.4 is a large, freely-available database comprising de-identified health-related data associated with over forty thousand patients who stayed in critical care units of the Beth Israel Deaconess Medical Center between 2001 and 2012. Based on rules, we extract about 50,000 pseudo samples from the file *NOTEEVENTS.csv* to perform negation-aware pre-training. The official test dataset including 9580 samples is also extracted from the file *NOTEEVENTS.csv*. To further validate the effectiveness of the proposed method, we further create a custom test dataset which includes 500 negated samples and 500 non-negated samples. In the custom test dataset, various negation cues and negation style are included.

## 5 Experiment

### 5.1 Negation-aware Pre-training Stage

We leverage the source model provided by organizers as our initial model in pre-training stage. Besides, several layers are added to perform masked language modeling and negation cue prediction. During pre-training, the learning rate is set as 0.00001, and batch size is set to be 64. We conduct pre-training in 3 epochs.

### 5.2 Pseudo Label Training Stage

We assume that a sample including no negation cue is definitely non-negated. Thus, we assign these sample without negation cues non-negated label. These samples will not be included in the training phase. Since the provided test samples are extracted directly from *NOTEEVENTS.csv* file, the format of each sample is messy, we conduct sentence split with NLTK toolkit (Loper and Bird, 2002) for each sample and only keep the sentence with target mention.

Then confidence threshold search is conducted to generate high-quality labels for the rest of test data. Finally, the confidence threshold for negated and non-negated samples are selected as 0.983 and 0.999 respectively. In other words, if a test sam-

ple assigned negated label, the probability to be negated generated by the source model should be higher than 0.983. Similarly, if a test sample assigned non-negated label, the probability to be non-negated should be higher than 0.999.

During training stage, we use the source model provided by organizers but initialize the transformer encoder with the corresponding part from pre-training model, because the transformer encoder from the pre-training model could capture various negation knowledge from input sentences. The learning rate is kept as 0.00001, and batch size is 32. The number of epoch is set to be 5. In the first 2 epoch, the parameters of *ClassificationHead* in model is frozen.

## 6 Results

The result is evaluated using the standard precision, recall and F1 scores as used in most published work. We achieve the best performance on the official blind test dataset.

### 6.1 Result on Official Test Dataset

We compare our method with two baselines, and the result is shown in Table 2. The result of source model without any domain adaptation is inferior. Masked language modeling trained on target domain data could improve the performance. However, its effect is not significant, because masked language pre-training focus more on low-level language information rather than high-level semantic knowledge about negation. With the help of NAP, the adapted model could improve the recall score with a large margin. This indicates that our negation-aware pre-training method could help embed negation knowledge into the sequence representation, and facilitate the domain adaptation from source domain to target domain.

Although the proposed adaptation method achieves superior result in the competition, there still exists a problem which harms the recall performance: the adapted model is not sensitive to long-term negation dependency. For example, in the case *He denies chest pain, dyspnea, dizziness/lightheadedness, or <e> abdominal pain <e\>*, though the mention *abdominal pain* is connected with negation cue *denies* via *or*, the model still output non-negated prediction. This phenomenon may be caused by pre-training, since in pseudo negation detection pre-training task, the training data are generated only based on simple

Methods	F1	Precision	Recall
Source	0.685	0.921	0.545
Source + MLM	0.724	0.905	0.603
Source + NAP	<b>0.822</b>	<b>0.902</b>	<b>0.756</b>

Table 2: Results of different methods on official test set. MLM, NAP denote masked language modeling (common token masking), negation-aware pre-training respectively. Our experiments are conducted on the data cleaned, so the result of source model without adaptation is better than the one organizers provide.

Methods	Precision	Recall
Source	0.761	0.502
Source + MLM	0.783	0.526
Source + NAP	0.894	0.833

Table 3: Results of different methods on customized test set.

rules: the clinical mention is a single noun and the distance between mention and negation cue is limited to no more than 3 tokens. To handle this problem, useful and effective generation method should be further explored. In addition, dependency relation between tokens may be introduced into both pre-training and training stage to solve this problem in negation detection task.

## 6.2 Result on customized Test Dataset

Negated samples in the official test dataset only include *deny*, *none*, *no*, *not* and *without*, so we also conduct experiments on the customized test data we manually created from test domain, which contains various negation cues and two negation styles (active or passive voice). As shown in Table 3, compared to the proposed method, the recall of source model and source model with MLM is much lower, because many negated samples with *never*, *resolve*, *free of*, *absent* and *exclude* can not be recognized correctly. Meanwhile, due to the lack of the ability to capture double-negative semantic, they both fail to distinguish false-positive samples from real positive ones. However, with the negation knowledge embedded through negation-aware pre-training, our method could handle both scenarios better.

## 7 Conclusion

In this paper, we model source-free domain adaptation as learning with pseudo label. We leverage mean self-entropy of dataset to search appropriate probability threshold for high-quality pseudo label generation. Besides, we propose negation-aware

pre-training to integrate different types of negation knowledge to improve the generalization of negation representation. The result shows that the additional negation-aware pre-training is helpful for negation detection task. In the future, we will work towards more robust pseudo label generation method and effective pre-training task introducing more knowledge such as part-of-speech tag and dependency relation.

## Abstract

Data sharing restrictions are common in natural language processing datasets. The aim of this study is to develop a model that is trained in a source domain to make predictions for a target domain with respect to domain data. To address this problem, the organizers provided models that fine-tuned a large number of source domain data on pre-trained models and dev data for participants. However, source domain data were not distributed. This paper describes the model provided for the name entity recognition task and ways to develop the model. Because little data are provided, pre-trained models are suitable for solving cross-domain tasks. The models fine-tuned by a large number of other domains could be effective in the new domain because the task did not change. The code of this paper is available at <https://github.com/windforfuture/SemEval-2021-Task10>.

## 1 Introduction

Data sharing constraints are common in natural language processing (NLP) datasets. For example, Twitter policies prohibit the sharing of tweet text, although tweet IDs may be shared. In clinical NLP, the situation is even more prevalent because information on patients' health must be protected. Obtaining annotations about health texts often requires the signing of complex data usage agreements. During the competition, the organizers provided models which fine-tuned on the annotated source domain data, while the source domain data could not be distributed. The organizers also provided labeled data as dev data and unlabeled target domain data as test data.

There were two sub-tasks for SemEval Task 10: 1) to classify clinical event mentions (e.g., diseases, symptoms, procedures, etc.) for whether

they are being negated by their context. This is a text-classification task (Yuan et al., 2020). 2) to find time expressions (Laparra et al., 2018) in text, this is a sequence-tagging task. SemEval Task 10 was different from traditional NLP tasks, where training and testing were in the same domain. Predictions could be out of control due to the different target domain. The domain of the dev data is related to the source and target domains, therefore the model can be developed. In SemEval Task 10, it is necessary to develop an existing model along with training the model with labeled data or unlabeled data. Furthermore, the model can be developed by fine-tuning it in different ways.

For certain reasons, only the results for the second subtask were submitted, that is, time expression recognition, which can be considered as a name entity recognition (NER) task. The participants were asked to find time expressions in the text through the task. This is a sequence-tagging task that uses fine-grained time expression annotations that are a component of SemEval 2018 Task 6 (Laparra et al., 2018). To deal with this task, deep learning models, such as long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997), bidirectional LSTM with conditional random field (BiLSTM-CRF) (Huang et al., 2015), and bidirectional encoder representation from transformers (BERT) (Dai et al., 2019) have been developed to challenge the NER task. Owing to the lack of a training set, pre-trained models (Qiu et al., 2020) were considered. The NER task can become difficult as the number of classifications increase. In this task, 33 types of entities need to be recognized, and phrases and words may be one of the types. For the base model, B-prefix and I-prefix were used to discriminate the beginning of classification and ensure the accuracy of the tokens; therefore, 65 types of entities were used in the model. In this paper, an ensemble model is proposed for time

expression recognition with a hard voting strategy. Each input sample was first tokenized using the matched model tokenizer. Base models, such as BERT (Devlin et al., 2019) and its variants, including RoBERTa (Liu et al., 2019), DistilBERT (Sanh et al., 2019) and ALBERT (Lan et al., 2019), were used to learn hidden representations for each token. Then, a fully connected dense layer with a *Softmax* function was used for classification. By using a hard voting strategy, the predictions from different base models were merged with the final result. Experimental results show that the proposed ensemble models achieve a competitive result with the official baseline model, which ranked fifth in sub-task 2.

The remainder of this paper is organized as follows. Section 2 describes the overall structure of the proposed ensemble model. The comparative experimental results and discussion are presented in Section 3. Finally, conclusions are presented in Section 4.

## 2 Ensemble Model for Source-Free Domain Adaptation

The official baseline model is a fine-tuned RoBERTa model: clulab/roberta-timex-semeval. It uses RoBERTa (Liu et al., 2019) for token classification architecture, which is pre-trained using no next-sentence prediction (NSP) and dynamic masking. The RoBERTa model achieved better performance than the BERT model because it was pre-trained by larger volume data, more steps, larger batches, and larger vocabulary than the BERT model. In addition, the provided baseline model was fine-tuned with approximately 25,000 expressions in de-identified clinical notes as well as the development dataset (Sanh et al., 2019). Four other models were also implemented using a hard voting strategy and a hard voting result for a single submission.

### 2.1 Tokenization

Transforming words to vectors is a necessary step in NLP tasks. Different word representations were used in our implementation, including word2vec (Mikolov et al., 2013; CHURCH, 2017), GloVe (Pennington et al., 2014), ELMo (Peters et al., 2018), and BERT (Devlin et al., 2019). For the RoBERTa model, we used only the matched RoBERTa tokenizer to build word vectors with a length of 514. Given a sentence  $\mathbf{x} =$

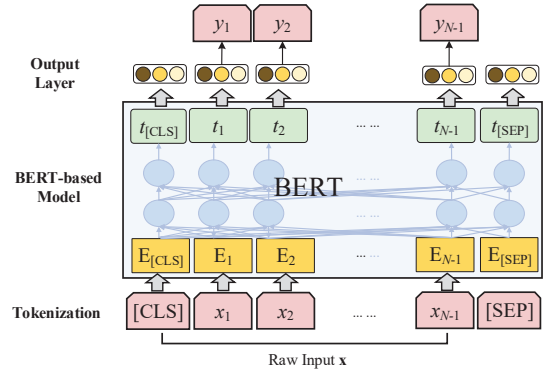

Figure 1: Overall architecture of the base model.

$[x_1, x_2, \dots, x_M]$  of length  $M$ , different lengths of the sentence will result in different lengths of the representation. Therefore, we considered the maximum sentence length as  $N - 1$ . If the length was less than  $N - 1$ , then it was padded with zero values to make it equal to  $N - 1$ . For each input, two specific tokens were added to the beginning and end of the raw input, that is,  $\langle s \rangle$  and  $\langle /s \rangle$  (or [CLS] and [SEP]). The RoBERTa tokenizer uses byte-pair encoding to obtain more relations and meanings. Then, these are converted into a sequence of subwords, which are then mapped into token, position, and segment embeddings, that is,  $[E_{[CLS]}, E_1, \dots, E_{N-1}, E_{[SEP]}]$ . In the proposed model shown in Fig.1, the raw inputs were split into one or more 514-dimensional vectors according to the number of sentences contained in the corresponding input.

### 2.2 BERT-based Model

To extract the semantic features, a pre-trained language model (Qiu et al., 2020) was used. It achieved impressive performance in various NLP tasks. It contains multiple layers of bidirectional transformer encoders (Vaswani et al., 2017) and is then pre-trained by using unsupervised learning of either the masked language model (with a masked ratio of 15%) or the NSP.

The aforementioned pre-trained language model contains 12 layers of transformers with a hidden size of 768. Then, the embeddings of both contexts are fed into a BERT model to obtain the semantic representation  $T \in \mathbb{R}^{dt}$ , denoted as

$$\begin{aligned} T^F &= [t_{[CLS]}, t_1, \dots, t_{N-1}, t_{[SEP]}] \\ &= f_{BERT}([E_{[CLS]}, E_1, \dots, \\ &\quad E_{N-1}, E_{[SEP]}]; \theta_{BERT}) \quad (1) \end{aligned}$$

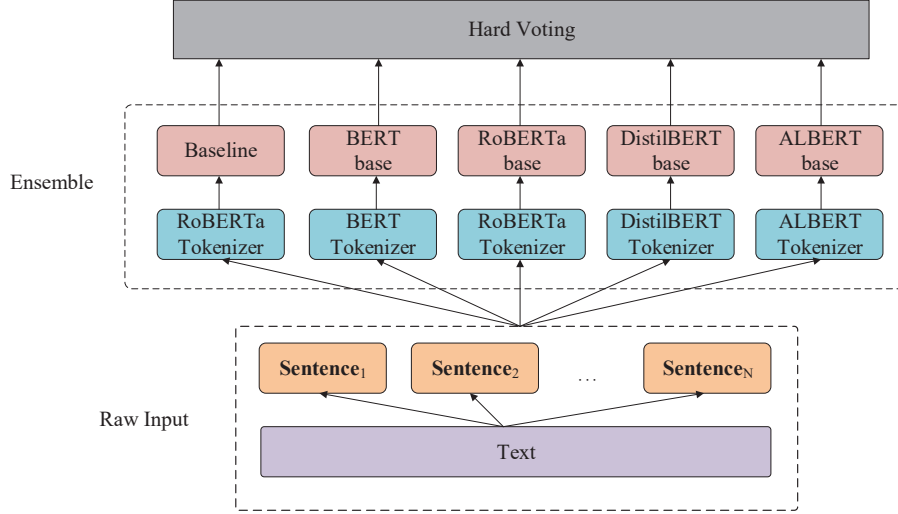

Figure 2: The ensemble of models.

where  $\theta_{BERT}$  is the trainable parameter of the BERT model, which is then fine-tuned during model training, and  $d_t = 768$  is the dimensionality of the hidden representation.

### 2.3 Output Layer

The token classification in the BERT model architecture is considered as a series of binary classifications. For each token, the classification was a one-layer MLP with a *Softmax* function. The loss function is a categorical cross-entropy, defined as:

$$\hat{y}_m^c = \text{softmax}(W_t t_m + b_t) \quad (2)$$

$$L = - \sum_{k=1}^K \sum_{c=1}^C \sum_{m=1}^M y_m \log(\hat{y}_m^c) \quad (3)$$

where  $y_m$  and  $\hat{y}_m^c$  denote the gold label and the predicted probability of samples  $k$ , respectively,  $K$  and  $C$  are the number of training samples and candidate categories, respectively;  $W_t$  and  $b_t$  are the weight and bias, respectively, which are associated with the fully connected layer. The entire network was trained by back-propagation (Rumelhart et al., 1986) while the BERT model was fine-tuned with the provided labeled data in the training phase.

### 2.4 Ensemble Learning

To output the final result, we used a hard voting strategy to integrate the results from different base models, including the official baseline, BERT, RoBERTa, DistilBERT, and ALBERT models, as shown in Fig. 2. In hard voting, every individual classifier votes for a class and the majority wins.

In statistical terms, the predicted target label of the ensemble is the mode of the distribution of the individually predicted labels.

## 3 Experimental Results

### 3.1 Datasets

The organization provided 99 news articles and matched 99 annotated data files for subtask 2. There were different types in these articles, such as ABC, APW, and CNN. The dev data provided were related to news, and the source data were related to medical data. The test data were related to the food security. The cross-domain task consisted of three domains. Each raw input was divided into sentences. The annotated data files were formed as XML files. Every XML file contained a few entities that consisted of ids, spans, and types. Span contains the start position, and the end positions and types are classified. The labels should be transformed because of the offset that were used as the input data.

### 3.2 Evaluation Metrics

Subtask 2 was evaluated using standard precision, recall, and mainly the  $F_1$ -score. The  $F_1$ -score is often used to evaluate unbalanced data, and is defined as follows:

$$F_1\text{-score} = 2 * \frac{P * R}{(P + R)} \quad (4)$$

where  $P$  and  $R$  denote the precision and recall, respectively. A higher  $F_1$ -score indicates better model prediction performance.

Model	Vocab Size	Position Embeddings	Attention Heads	Hidden Layers

Table 2: Empirical results of the ensemble model and the base models

### 3.3 Implementation Details

We fine-tuned the official baseline model (RoBERTa) and four other models: the BERT model (bert-base-uncased), RoBERTa model (roberta-base), DistilBERT model (distilbert-base-uncased), and ALBERT model (albert-base-v2). For each model, 5-fold cross-validation was performed. For each run, the datasets were split into a ratio of 8:2 for the training and dev sets.

We trained the new model by adding the same label2id and id2label JSON as the provided model to the original “config.json” We ran codes using the downloaded model and the modified “config.json.” After training, the models were used for prediction, and the results were recorded. After comparing the results, we observed that the model provided the best performance. Then, we performed hard voting that picked out one result, if three or more results of these models were the same.

To obtain additional results, we split the provided data to obtain different dev data and test data five times, and the test data were different every time. In every round, the initial models were used, and five rounds were tested. Hard voting gave the best results, followed by the provided model. Finally, we fine-tuned these initial models with the test data in the evaluation phase and chose the results of the provided model and the hard voting for submissions.

### 3.4 Fine-tuning the Parameters

To train the proposed model, the Adam optimizer applied a warmup strategy with a weight decay of 0.01 during training. The learning rates of all the base models were 5e-6. For the official baseline model, the default parameters were used in our experiments because the initial parameters usually performed well in other experiments. For other models, we fine-tuned the hyperparameters using a grid-search strategy. Once the optimal settings of the parameters were obtained, they were used for classification on the test sets. The details of the hyperparameters are summarized in Table 1.

### 3.5 Comparative Results

Table 2 shows the results of the base models on different folds, that is, R1–R5. The results showed that the hard-voting ensemble model outperformed the official baseline model with three rounds, but the average  $F_1$ -score of the ensemble model was less than the average  $F_1$ -score of the official baseline model. Considering that the evaluation data is in a new domain, we finally submitted the result of the official baseline model, which was fine-tuned by feeding numerous annotated data in the source domain and the result of the hard voting ensemble model. For the test set, the newly released official baseline model, that is, **Organizers (new)**, outperformed the previously released baseline model, that is, **Organizers (previous)**, which was only pre-trained on the source data and achieved an  $F_1$ -score of 0.794 (see Table 3). Owing to the low amount of

Team Name	$F_1$ -score

data used for fine-tuning, the performance of the proposed model is slightly lower than that of the new official baseline model. However, its performance is still competitive and finally ranked fifth on the leaderboard.

## 4 Conclusions

The SemEval-2021 Task 10 framework requests participants to develop semantic annotation systems in the face of data sharing constraints. In this study, we fine-tuned the official baseline model and then combined it with four other pre-trained models with a hard voting strategy for time expression recognition. Experimental results showed that the proposed model outperformed the previously released baseline model, achieved a competitive result with the newly released official baseline model, and finally ranked fifth on the leaderboard. Future work will attempt to improve the performance of cross-domain NER tasks.

## Abstract

This paper presents our endeavor for solving task11, NLPContributionGraph, of SemEval-2021. The purpose of the task is to extract triples from a paper in the Nature Language Processing field for constructing an Open Research Knowledge Graph. The task includes three sub-tasks: detecting the contribution sentences in papers, identifying scientific terms and predicate phrases from the contribution sentences; and inferring triples in the form of (subject, predicate, object) as statements for Knowledge Graph building. In this paper, we apply an ensemble of various fine-tuned pre-trained language models (PLM) for tasks one and two. In addition, the self-training methods are adopted for tackling the shortage of annotated data. For the third task, rather than using classic neural open information extraction (OIE) architectures, we generate potential triples via manually designed rules and develop a binary classifier to differentiate positive ones from others. The quantitative results show that we obtain the 4<sup>th</sup>, 2<sup>nd</sup>, and 2<sup>nd</sup> rank in three evaluation phases.

## 1 Introduction

The notion of Open Research Knowledge Graph (ORKG) is first proposed by (Jaradeh et al., 2019) who take steps toward a knowledge graph based infrastructure that acquires scholarly knowledge in machine actionable form. In that form, researchers can keep up with cutting edge academic achievements and eliminate cognitive overload. To accelerate the construction of ORKG, an automatic system is expected. The SemEval-21 task11 is a triple extraction task targeted at building that system. As shown in Table1, the task is divided into three sub-parts corresponding to different processing steps: Sub-task A detects contribution sen-

tences in English articles and classifies them into information units such as Approaches, Models, and Ablation – analysis; Sub-task B extracts scientific terms and relational cue phrases from contribution sentences; Sub-task C infers subject-predicate-object triples for KG building with the results of two previous sub-tasks.

For Sub-task A—contribution sentence detection—the evaluation data covers a larger sphere than the training data. Additionally, the amount of annotated samples differs among research fields. Hence, we use self-training to generate a set of silver samples for fields lacking gold data. An ensemble of fine-tuned PLM based classifiers is then deployed to categorize sentences. For sub-task B—scientific term extraction—we compared BERT based sequence labeling systems in detail and chose the best architecture. For sub-task C—triple generation—we give insight into the construction of triples and designed a rule for potential triples generation. A binary classifier is then applied to distinguish the positive triples.

Our quantitative results show data augmentation via self-training is of paramount importance for sub-task A. Although seldom is CRF used with transformer-based language models together, in the system for sub-task B, an additional CRF layer after a RoBERTa based encoder can still boost performance. In sub-task C, popular neural information extraction models are inferior to the rule based methods.

## 2 Background

### 2.1 Data description

The training process is developed on the dataset provided by the SemEval21 Task11. The training dataset involves 237 papers from 24 fields of natural language processing, organized hierarchically with contribution sentences, info units, entities, and

\*equal contribution

Objects to Identify	Examples
Sentence	We use the BERT <sub>BASE</sub> model pre-trained on English Wikipedia and BooksCorpus for 1M steps.
Information Unit	model
Scientific Term and Predicate Phrases	used, BERT <sub>BASE</sub> model, pre-trained on, English Wikipedia, BooksCorpus, for, 1M steps
Triples	(Contribution, has, ExperimentalSetup), (ExperimentalSetup, used, BERT <sub>BASE</sub> model), (BERT <sub>BASE</sub> model, pre-trained on, English Wikipedia), (BERT <sub>BASE</sub> model, pre-trained on, BooksCorpus), (BERT <sub>BASE</sub> model, for, 1M steps)

Table 1: Objects need to be identified

Figure 1: Numbers of annotated sentences in each domain

triples. Thus, for different tasks we can use disparate parts of the dataset.

Inherent challenges also come with data collection. As shown in Fig 1, first, there is a dramatic discrepancy among the number of annotated papers. The NaturalLanguageInference field received the richest resources. A total of over one hundred papers in this area are annotated. On the other hand, for the domains with poor annotation like PhraseGrounding and QueryWellformedness, only a single paper is provided. Moreover, a postdoctoral researcher with a background in natural language processing is responsible for finishing the pilot annotation task (D’Souza and Auer, 2020). Therefore, the annotated data is relatively subjective and sometimes even inconsistent. For example, some information units nested in Experiments actually also included a combination of ExperimentalSetup and Results. Alternatively, it can be combination of Tasks and their Results.

## 2.2 Related Work

A vast amount of excellent work has been done in the areas of these subtasks. Early work employing CNNs, RNNs and attention based RNN or CNN models has made great progress in sentence classification tasks. (Yang et al., 2017; Liu and Zhang, 2017). Tai et al. (2015) inspired innovation in traditional LSTM networks. The tree-LSTM structure mentioned in their paper is enhanced with dependency or constituency trees. Since Graph Neural Network (GNN) is first used for sentence classification tasks, GNN has been one of the most prevalent encoders for Natural Language Processing(NLP) tasks. Transformer based models are also popular encoders. They are so powerful that they have even been widely used in computational vision areas (Dosovitskiy et al., 2020).

The sequence labeling task is a critical component of NLP applications. There are two basic approaches. In the token level approach, a sequence of tokens is used as an input of sequence tagging models, and tags for each token can be output. Other approaches attempt to solve problem on the sentence level. Lu and Roth (2015) designed a hypergraph, which provides a resolution for the discontinuous terms.

Traditional open information extractors are based on rules and statistical approaches, like Stanford-IE(Angeli et al., 2015),OpenIE-5(Saha and Mausam, 2018) and MinIE (Gashteovski et al., 2017).These methods apply semantic parsers combined with predefined rules to extract triples. Recently, neural OpenIE methods dominate this research field. RnnOIE (Stanovsky et al., 2018) inspired by the sequence labeling systems identifies relation phrases first then combine relations with

Figure 2: An overview of the system for sentence classification

Figure 3: An overview of the system for scientific term extraction

arguments. IMOJIE (Kolluru et al., 2020) takes advantage of seq2seq architectures. It is trained on training data bootstrapped from extractions of several tradition systems such as Stanford-IE.

### 3 System Description

Systems applied for contribution sentence detection and scientific term extraction are based on the RoBERTa (Liu et al., 2019), SciBERT (Beltagy et al., 2019) and basic BERT model with task-specific modifications. For triple classification tasks, a SciBERT (Beltagy et al., 2019) based model is used for candidate triple classification. Moreover, self-training, ensemble and rule design enhanced system performance in different ways.

### 3.1 Contribution Sentence Detection

The contribution sentence detection task is handled as a sentence classification (SC) problem. Let  $U$  be the union of a predefined sentence type set and  $\epsilon$  indicate that the sentence is not a contribution sentence. According to the task description provided by D'Souza et al. (2021), one contribution sentence could belong to one of eleven categories, called info units. Hence  $U$  has twelve elements with  $\epsilon$  added. As shown in Fig2, the input data consisted of four parts: the original sentence, contextual information, a sub-title of the paragraph and the number of paragraph, with the separator token ([SEP]) in between. For contextual information, we used the adjacent sentences of the original one. We define the sub-title of a paragraph as the nearest title found previous to the begin of this paragraph. Besides, the paragraphs are numbered from zero following an increasing order. We add [CLS] token at the top of the sequence and build a classifier on top of its embedding, which is generated from BERT based model, similar to what Devlin et al. (2019) did for pre-training.

Inspired by incremental semi-supervised training (Rosenberg et al., 2005), we introduced the similar training process. Prior to that, we need to prepare the additional unlabeled data. Newest papers are downloaded according to the areas then transformed into Stanza version as the papers provided in training data. The amount of additional data for every field is about ten articles. Training process takes the following steps: first, train BERT based models that will be used in ensemble on gold

sentence	triples
We also apply 3 dense blocks based on char - ResNet which we refer to as char - DenseNet, to compare the difference between residual connection and dense connection.	(Baselines, apply, 3 dense blocks) (3 dense blocks, based on, char - ResNet) (char - ResNet, refer to as, char - DenseNet)

Table 2: A sentence and triples from it

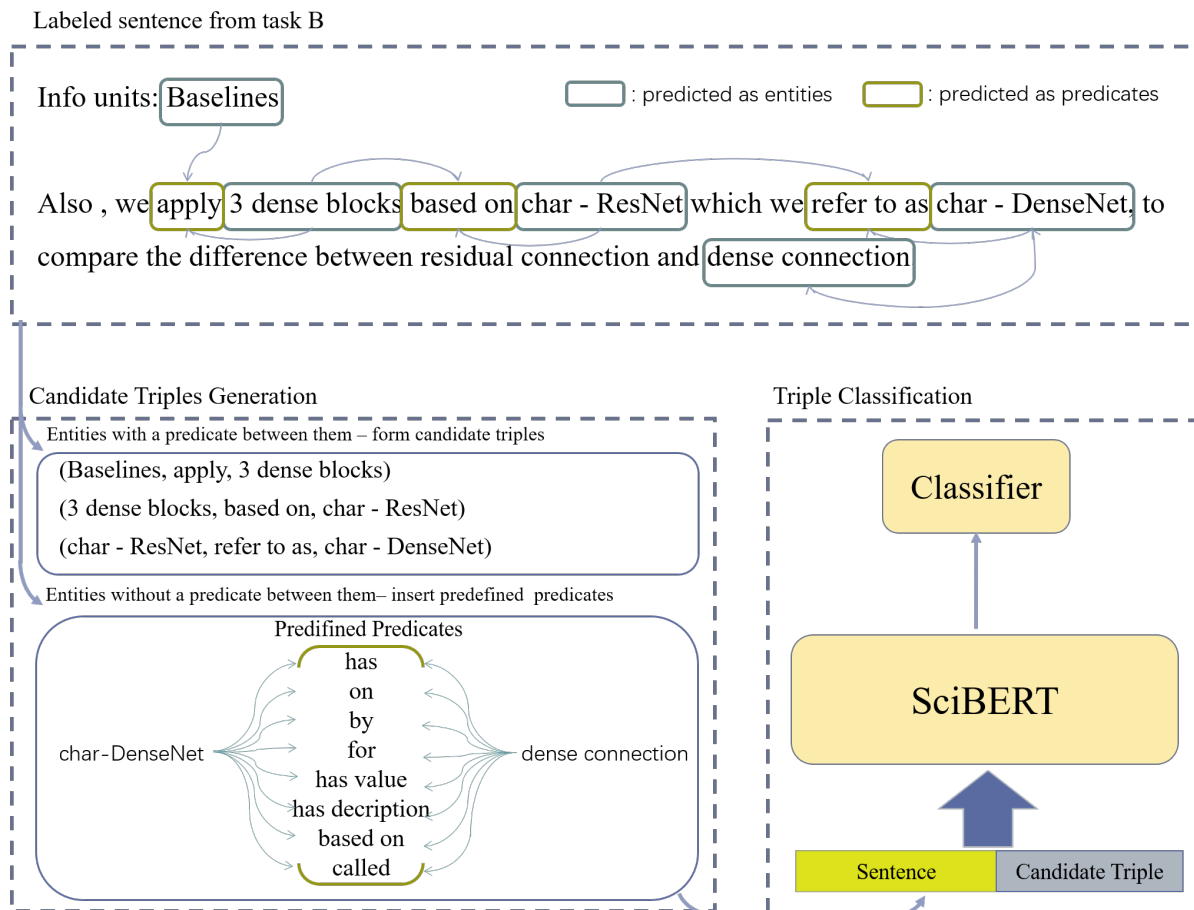

Figure 4: Model overview for triple generation

data, that is the annotated data in dataset, until parameters converged. Next, put these models in an ensemble to tag the unlabelled data for areas suffered from data insufficiency. In the rest part of this passage, we call data labeled by our models 'silver samples' or 'silver data'. Only the sentences all models in the ensemble labelled unanimously would be deemed as silver samples and used for further training. After that, a combination of gold and silver data is input for training another three models with unchanged hyperparameters. Above progress iterates until no further progress could be achieved. That means the iteration is stopped when loss becomes stable. Thus, three fine-tuned BERT based models are ready for inferring and we col-

lect them in an ensemble. When inferring, with a sentence input, each model outputs a vector  $V$ , of twelve dimensions. We calculate a weighted sum of three vectors and use the index of the max element to determine the final class of a sentence. Weights here are hyperparameters and chosen manually.

$$V = 0.25 * V_{SciBERT} + 0.2 * V_{RoBERTa} + 0.1 * V_{BERT}$$

### 3.2 Scientific Term Extraction

We consider scientific term extraction as a sequence labeling (SL) task. Specifically, as Fig 3 shows, a RoBERTa exploiting CRF layer marks every sub-word token of the input sentence with one of the label in B, I, O, where 'B' is the beginning of a term, 'I' indicates that the token is inside the term and

'O' indicates that the token stands outside of the term. In this way, one sequence of a 'B' followed by a continuing sequence of 'I' is recognized as a legal term. Input sequences are also engineered. The sub-title information is attached to the raw sentence. To facilitate triple generation, two models are trained for labeling predicate and entity individually. Discrimination of types of terms allows the system to exploit the information of a predicate more efficiently.

### 3.3 Triple Generation

Given the fact that the outcomes of supervised open information extraction architectures are not as expected, we make use of the result of term extraction. As shown in Table 2, triples from a sentence always overlap at the head and tail. Given that fact, when generating a candidate triple, a predicate acts as the anchor and its neighboring entities are seen as the subject and object, following the sentence reading order, as demonstrated in Fig4. It is rare that the subject appeared later than the object in a sentence.

At times, as task description paper (D'Souza et al., 2021) mentioned, when no suitable predicate phrases could be inferred from the sentence, one candidate from a pre-defined set of predicates could be utilized. The set including "has", "on", "by", "for", "has value", "has description", "based on", "called". We call these triples with predefined predicates "special triples". A greedy matching is introduced that each predefined predicate is inserted between every adjacent entity pair to compose a potential special triple. To illustrate, take the entity pair "char-DenseNet" and "dense connection" as an instance. In Fig4, as the result of term extraction shows that there is no phrase labelled as predicate between "char-DenseNet" and "dense connection". To form candidate triples for this entity pair, each predicate in the predefined predicate set is inserted between the entity pair. After all potential triples are generated, gather unions of each candidate triple and the sentence where the triple came from as input data. A SciBERT based binary classifier then judge if a union is rational. We refer to it as the 'candidate triple judge model' in the rest of this article.

Additionally, another rule is designed for cross-sentence triples, which takes up three percent of all triples. Such amount cannot be ignored also. We observe that when only one term can be extracted from a sentence, it is highly possible that the term

Hparam	SC	TE	TG
Number of epochs	8	20	10
Max length	200	128	256
Batch size	32	16	32
Learning rate	2e-5	1e-5	1e-5
Optimizer	AdamW		
Loss	cross entropy		

Table 3: Hyperparameters for models. SC means sentence classification, TE stands for term extraction and TG is the abbreviation of triple generation

is a composition of a cross-sentence triple. Such terms adjacent to each other are integrated into a cross-sentence triple according to the subject-predicate-object order. From example, if there are three adjacent contribution sentences that we can only extract one phrase from each, and these three phrases are predicted as entity, predicate and entity respectively. Thus we can combine them together as a cross-sentence triple. For these triples, we do not apply a further filter and add them into the final output directly.

## 4 Experimental Setup

In this section, we describe the models we used in the final submission and their parameters in detail. It should be possible to reproduce our work.

### 4.1 Models and Parameters

Before training, we divide papers into three groups: train set, dev set, and test set, with a ratio of 8:1:1. We then mix all sentences in each set together. In this way, data leakage is prevented. Otherwise, sentences in test set and train set could come from the same article. The hyperparameters for training are shown in Table3. Our implementation uses only Pytorch for the first two sub-tasks' models and AllenNLP for the last candidate triple judge model.

For Contribution Sentence Classification task, we attempt to take advantage of diverse models. An ensemble of BERT, SciBERT and RoBERTa is applied. During the training process, F1 score on dev set works as a criteria for choosing the best epoch and model weights. Additionally, because our model is consistently confused between the info units of Approach and Model, we convert sentences with the word 'approach' to the unit Approach after receiving predictions from a neural network. For Scientific Term Extraction, we used

		<b>Contribution Sentence Detection</b>	
		sentence detection	information unit classification
<b>F1 of ensemble</b>		0.3978	0.8108
<b>F1 of SciBERT</b>		0.3856	0.8049

		<b>Scientific Term Extraction</b>		<b>Triple Generation</b>	
		RoBERTa+CRF+BIO	RoBERTa+span tagging	rule based method	IMOJIE
<b>F1</b>		0.7774	0.7567	0.4473	0.1729

Table 4: F1 scores of models. For the submitted model, the F1 scores are from the leader board , for the baseline model the F1 scores are from results on dev set

RoBERTa as the encoder and elaborated more on different decoders. The basic BIO tagging model performs better than the span based one. When training the potential triple judge model, the learning rate rises first then falls following the method used by Vaswani et al. (2017)

## 4.2 Baselines

We endeavor to search for the best baselines. For sentence classification, we use single SciBERT model as our baseline, while for sequence tagging, we employ RoBERTa without CRF layer and rather using span tagging decoder as a strong baseline. In the triple generation task, we once tried to employ neural open information extraction models, so IMOJIE can be deemed as a baseline.

## 4.3 Evaluation Metric

We use F1 value as the main metric, the average F1 is arithmetic mean value of sentence F1, terms F1, info units F1, and triples F1. When computing triples F1, strict standard is employed. Only when every division of a predicted triple matched the gold answer, it can be counted as a correct inference.

$$F1 = \frac{2 * P * R}{P + R} \quad (1)$$

where  $P$  means precision of the prediction and  $R$  means recall.

$$F1_{avg} = avg(F1_{sentence}, F1_{terms}, F1_{infounits}, F1_{triples}) \quad (2)$$

## 5 Results

With the gold data of the upstream task provided, the F1 value of sentence, info units, terms, and triples are 0.3978, 0.8108, 0.7774, and 0.4473 respectively, as shown in Table4 .

The enhancement in the sentence classification is clear. As a prevalent technology, ensemble has become a necessary part of algorithm competitions.

The only restriction is that all models in ensemble should have an F1 over fifty percent. With the help of data augmentation, the info unit classification result occupied 2<sup>nd</sup> position in the final ranking.

It marvels us that the model with span based tagger performed worse than the BIO tagger. Many NER experiments shows the evidence that the span based tagging decoder outperforms the simple BIO tagger. We believe the main reason is that, when exposed to the data in this task, there is no need to discern types of entities. While the span based decoder are equipped with the ability to infer entity types, such design may be suboptimal and create additional errors.

To some extent, the improvements in the triple generation task proves that neural OIE models are inapplicable to the task on this dataset. The main cause may be the different definitions of 'predicate.' In our task, prepositions always appear in the position of predicate in triples. Likewise, the subject and object are persons or specific terms while for sentences in science papers only scientific notions can be found. Given so much elaboration in our system, terms extraction and triple generation task also achieved the second place on the leaderboard.

## 6 Conclusion

We engaged in SemEval-2021 task11 NLPContributionGraph with models integrating features suitable for disparate tasks. We took insight on the impact of different parts on the final results, fine-tuned hyperparameters, and attempted various feature engineering methods. We ranked 4<sup>th</sup>, 2<sup>nd</sup>, and 2<sup>nd</sup> in three evaluation phases and our final model demonstrated its superiority over several strong baselines.

## Acknowledgments

The task is sponsored by ICA group, East China Normal University. Besides, thanks are due to Yi-

wei Yan for her supervision as without her help it would have been impossible to finish writing so quickly.

## Abstract

Crowdsourcing has been ubiquitously used for annotating enormous collections of data. However, the major obstacles to using crowd-sourced labels are noise and errors from non-expert annotations. In this work, two approaches dealing with the noise and errors in crowd-sourced labels are proposed. The first approach uses Sharpness-Aware Minimization (SAM), an optimization technique robust to noisy labels. The other approach leverages a neural network layer called softmax-Crowdlayer specifically designed to learn from crowd-sourced annotations. According to the results, the proposed approaches can improve the performance of the Wide Residual Network model and Multi-layer Perception model applied on crowd-sourced datasets in the image processing domain. It also has similar and comparable results with the majority voting technique when applied to the sequential data domain whereby the Bidirectional Encoder Representations from Transformers (BERT) is used as the base model in both instances.

## 1 Introduction

In recent years, there has been some major advancement in the use of deep learning for solving artificial intelligence problems in different domains such as sentiment analysis, image classification, natural language inference, speech recognition object detection. They have also been used in many other numerous cases where human disagreements are encountered such as speech recognition, visual object recognition, object detection and machine translation (Rodrigues and Pereira, 2018). It is however, an essential requirement for deep learning models to utilise labelled data to undertake the representational learning of the underlying datasets. These labelled data are most at times not available and hence the need for humans to manually undertake the labelling of these data becomes a necessity.

In recent years, crowd-sourcing has been used in the annotation of large collections of data and has proven to be an efficient and cost-effective means of obtaining labeled data as compared to expert labelling (Snow et al., 2008)

It has been utilised in the generation of image annotations to train computer vision systems (Raykar et al., 2010), to provide the linguistic annotations used for Natural Language Processing (NLP) tasks (Snow et al., 2008), and has also been used to collect the relevant judgments needed to optimize search engines (Alonso, 2013).

It is a well known fact that crowd-sourced labels are known to be associated with noise and errors as a result of the annotations being provided by annotators with uneven expertise and dedication which can result in the compromise of practical applications that uses such data (Zhang et al., 2016). This paper therefore seeks to apply a novel approach to minimize and mitigate the noise and errors in crowd sourced labels. The aim is to investigate the use of a unified testing framework to learn from disagreements using crowd source labels collected from different annotators.

## 2 Related Work

Crowdsourcing has proven to be an inexpensive and efficient way to collect large labels of data and has attracted much research interest from the machine learning community to address noise and unreliabilities associated with them. The proposal for using an Expected Maximization (EM) algorithm to obtain density estimate rate of errors of patients providing conflicting responses to medical questions by Dawid and Skene (1979), is one of the key pioneer contributions to this field. This work served as the catalyst for many other approaches used for the aggregation of labels from crowd annotators with different levels of expertise, such as

the one proposed in [Whitehill et al. \(2009\)](#), which further extends Dawid and Skene’s model by also accounting for item difficulty in the context of image classification. Similarly, [Ipeirotis et al. \(2010\)](#) proposed using Dawid and Skene’s approach to extract a single quality score for each worker that low-quality workers to be pruned. The approach proposed in our paper contrast with this line of work, by allowing neural networks to be trained directly on the softmax output of the noisy labels of multiple annotators, thereby avoiding the need to resort to prior label aggregation schemes. [Smyth et al. \(1995\)](#) also collated the opinions of many experts to establish ground truth and there has been a large body of research work using EM approaches to annotate labels for datasets by many experts ([Whitehill et al., 2009](#); [Raykar and Yu, 2012](#)).

[Rodrigues et al. \(2014\)](#) also used the EM approach of labelling datasets by experts through the use of Gaussian Process classifiers. [Rodrigues and Pereira \(2018\)](#) also deployed the use of crowd layer with a CNN model to capture the biases of different annotators and correct them, our approach is the first to be built on the Wide Residual Network (WideResNet) model ([Zagoruyko and Komodakis, 2017](#)) and the Bidirectional Encoder Representations from Transformers (BERT) model ([Devlin et al., 2019](#)). Our approach differs from the method used by [Rodrigues and Pereira \(2018\)](#) because our technique initially finds the softmax of the output of the crowd responses before it is used for the modelling whereas the [Rodrigues and Pereira \(2018\)](#) approach works on the responses from the crowd directly.

### 3 Systems Description

These systems are proposed for image classification tasks and NLP tasks with sub-task-specific modifications and training schemes applied to each of the dataset.

#### 3.1 softmax-Crowdlayer

A special type of network layer known as softmax-Crowdlayer initially proposed by ([Rodrigues and Pereira, 2018](#)), was used to train a deep neural network directly from the noisy labels of multiple annotators from the crowd-sourced data. It used the output layer of a deep neural network as its input and was trained to learn from an annotator-specific mapping from the output layer to the labels of the different soft-maxed crowd annotators; and by so

doing it was able to learn the reliability and biases of each annotator in the process. As can be seen from [Figure 1](#), which is the generalised architecture encompassing either a Multi-layer Perceptron (MLP), WideResNet, or BERT as its’ base model, was used together with a softmax-Crowdlayer for the respective datasets. The output layer from the deep neural network served as a bottleneck and input for the crowd Annotators to learn from. It used a specialised cross-entropy loss known as Masked Multi Cross Entropy loss during training to handle the missing answers from Annotators. After the training of the network with the crowd layer and the specialised loss function, the crowd layer was removed to expose the Bottleneck layer which was then used to make the predictions.

The intuition behind the deployment of the crowd layer on top of the base model was that; the softmax-Crowdlayer would adjust the gradients from the labels of each annotator depending on their level of expertism and adjusts their weights and propagate the errors through the entire neural network system.

Sections [3.2](#) covers the use of WideResNet together with SAM on the CIFAR10-IC dataset whilst sections [3.3](#) and [3.4](#) covers the use of softmax-Crowdlayer for image classification whilst section [3.5](#) explores the use of BERT and softmax-Crowdlayer to cover the NLP aspect of the task which has been visualised in [figure 1](#). The motivation behind the preference of the BERT model over the baseline models was to investigate the potential of using BERT, which is a state-of-the-art model, with the softmax-Crowdlayer.

#### 3.2 WideResNet with Sharpness Aware Minimisation (SAM) For Majority Voting

The CIFAR10 dataset had a model made with WideResNet; first implemented by ([Zagoruyko and Komodakis, 2017](#)). A widening factor of 12 and convolutions of size together with 16 layers were used. A learning rate of 0.1 with weight decay of 0.001 and momentum of 0.8 was used with the SAM optimiser which had stochastic Gradient Descent (SGD) as its base optimiser. The training epochs for the dataset were scheduled in batches of 1000 for 60, 5, 10 and 20 respectively. The minimization of the commonly used loss functions such cross-entropy and the use of the custom Masked loss function designed specifically for the crowd layer on the CIFAR10-IC were not sufficient to

achieve superior results since the training loss landscapes of models used for noisy labels are complex and non-convex, with a multiplicity of local and global minima (Foret et al., 2020).

The Sharpness-Aware Minimization (SAM) Foret et al. (2020), was applied to the CIFAR dataset with the use of WideResNet model generalization which aided in the simultaneous loss in value and sharpness of the noisy labels from the crowd annotators as it has been shown to be robust to noisy labels (Foret et al., 2020). The inner working of the sharpness Aware Minimization is such that rather than using a parameter value that simply have low training loss value, a parameter value whose entire neighborhoods have uniform training loss value is the utilised.

The SAM optimiser technique was not applied to the NLP tasks because, its performance on them was not as good as that of the CIFAR-10 dataset.

### 3.3 WideResNet with softmax-Crowdlayer for CIFAR10-IC Dataset

The CIFAR10-IC data was made up of transformed Images that belonged to one of the 10 classes below: ‘plane’, ‘car’, ‘bird’, ‘cat’, ‘deer’, ‘dog’, ‘frog’, ‘horse’, ‘ship’, ‘truck’.

The WideResNet described in section 3.2 was used as the base model which had a softmax-Crowdlayer added to the output layer and through the action of back-propagation, it was able to correct the errors of the 2571 Annotators. A training epoch of 400 and batch size of 64 were used for with this approach. One hot encoding, together with a specialised function were used to generate the set of missing annotations which was then trained using the masked multi cross-entropy loss function for error corrections and predictions through the weights update.

### 3.4 MLP with softmax-Crowdlayer for LabelMe-IC Dataset

The LabelMe-IC data was made up of VGG16 encoded images that belonged to one of the 8 categories or classes below: ‘highway’, ‘inside city’, ‘tall building’, ‘street’, ‘forest’, ‘coast’, ‘mountain’ or ‘open country’

This was an image classification task that had a standard MLP architecture together with softmax-Crowdlayer applied to it. The MLP was made up of 4 hidden layers with 128 Relu Units each, an optimiser made of Adam optimizer, loss function made of categorical cross entropy and a drop out

of 0.2. A training epoch of 400 and batch size of 32 were used. The output layer had a softmax activation that outputted to the 8 distinct classes highlighted earlier. The softmax-Crowdlayer described in section 3.1 was then connected to this output layer where the Annotators errors and biases were back-propagated through a training scheme which reduced the noise in the crowd Annotators through the use of a specialised loss function to handle crowd annotations known as masked multi cross entropy loss function.

### 3.5 BERT with softmax-Crowdlayer for Gimpel-POS and PDIS Datasets

In Gimpel-POS dataset, each sample consisted of a tweeted text, a specific word/token appears in a tweeted text and a crowd label which is a list of multiple labels from different annotators. The task was to predict a part of speech (POS) of a given token. The POS labels include ‘ADJ’ (adjective), ‘ADP’ (adposition), ‘ADV’ (adverb), ‘CCONJ’ (coordinating conjunction), ‘DET’ (determiner), ‘NOUN’ (noun), ‘NUM’ (numeral), ‘PRON’ (pronoun), ‘PART’ (particle or other functional word), ‘PUNCT’ (punctuation), ‘VERB’ (verb) and ‘X’ (others). Table 1 shows an example of Gimpel-POS dataset. In this example, ‘Texas’ is a token needed to be tagged. It is at the beginning of the tweeted text shown in the first row. Considering the crowd label provided, the first and the second annotators both labeled this token as a noun, while the last annotator labeled this token as a pronoun.

Tweeted text	Texas Rangers are in the World Series! Go Rangers!
Token	Texas
Crowd label	[NOUN,NOUN,PRON]

Table 1: An example of Gimpel-POS dataset

Considering PDIS dataset, the goal was to predict whether a given noun phrase refers to new information or to old information in a document. Each sample consisted of a document (tokenised sentences), a noun phrase appear in the document, a pre-computed syntactic feature of a given noun phrase, and a crowd label. Table 2 shows an example of PDIS dataset. The document and the noun phrase are in the first and the second row of the table respectively. The noun phrase is ‘The cat’ at the beginning of the document. Syntactic feature

of this noun phrase is a feature vector shown in the third row. The fourth row shows a crowd label of the given noun phrase. The first and the second annotator labeled the noun phrase as 0 and 1 respectively 0 means that the noun phrase refers to new information and 1 means that it refers to old information.

Document	The cat ate the rat. Thereafter the dog ate the cat.
Noun phrase	The cat
Syntactic feature	[0,1,0,...,0]
Crowd label	[0,1]

Table 2: An example of PDIS dataset

In this work, we propose to fine-tune the pre-trained BERT model for both Gimpel-POS task and PDIS task based on crowd labels. To do so, the original input format of both tasks was firstly converted to the BERT conventional format. For each sample in Gimpel-POS dataset, a tweeted text and a given token were first concatenated in the following format:

[CLS] Tweeted text [SEP] Token [SEP]

where ‘[CLS]’ token is added for classification and two ‘[SEP]’ tokens are used to identify the boundary of a tweeted text and a token. Similarly, for PDIS dataset, a document is also concatenated with a noun phrase as follows:

[CLS] + Document + [SEP] + Noun phrase + [SEP]

These concatenated texts are used for fine-tuning the pre-trained BERT model.

To fine-tune the pre-trained BERT model, a dense layer was added at the end of the pre-trained BERT model. This layer took a ‘[CLS]’ token embedding from the pre-trained BERT model as an input and outputted a vector with the size equal to the number of classes in either dataset (12 for Gimpel-POS and 2 for PDIS). A softmax activation layer was added after the dense layer to compute the probabilities of each class. These additional layers can be seen as a classifier module that is added on top of the pre-trained BERT model. This is a common way to fine-tune the pre-trained BERT model for a specific task with regular labels as targets (Devlin et al., 2019).

In order to deal with crowd labels in the datasets, the softmax-Crowdlayer was added next to the classifier module. Similarly to the MLP model with

the crowd layer highlighted in 3.4, The proposed model for fine-tuning the pre-trained BERT with the softmax-Crowdlayer is illustrated in Figure 1. The Gimpel-POS example in 1 is used for demonstration in this figure. As previously mentioned, only the ‘[CLS]’ token is passed through the additional classifier module to predict primary classification output. This output is further used as an input of the softmax-Crowdlayer to predict the final output as described in the previous section. The proposed model can be instantly applied with PDIS dataset by changing the output size of the dense layer in the classifier module to 2. Due to lack of resources, the fine tuning of all the Bert model was run for 1 epoch.

## 4 Results and Discussion

The results were evaluated using two metrics known as  $F1$  score, referred to as hard evaluation and cross Entropy, referred to as soft evaluation. Models with Higher  $F1$  scores and lower cross entropy values are the desired outcomes expected from the models.

As can be seen in Table 3, The use of MLP together with the softmax-Crowdlayer on the LabelMe-IC dataset achieved the highest  $F1$  score of 0.7839, which was 0.739 greater than the majority voting model provided as the baseline model by the task organisers and also had a comparative lowest cross entropy value of 1.7693. The vast difference in the performance of the majority voting and the softmax-Crowdlayer can be attributed to the calculation of the number of missing annotations together with the ability of the softmax-Crowdlayer to learn the true labels from the crowd labels. This leads to the correction of the errors and mislabelling from inexperienced annotators through the process of back-propagation. The majority voting does not have this unique ability and therefore uses the wrong labelling without any of such adjustments.

The use of WideResNet together with SAM resulted in a superior performance with  $F1$  score of 0.7693 and cross entropy of 0.8274 as compared to the performance WideResnet with the softmax-Crowdlayer which had an  $F1$  score of 0.4427 and cross entropy of 1.9286 when applied to the CIFAR10-IC. It’s cross entropy of 1.9286 was better than the baseline majority method which was 2.8306. The PDIS data which was fine-tuned with a pre-trained BERT model plus softmax-crowdlayer

Figure 1: The proposed softmax-Crowdlayer on top of the respective Base Models

had  $F1$  score of 0.4379 and cross entropy of 0.8295. The BERT + softmax-Crowdlayer did not perform comparatively well when applied to the Gimpel-POS data since it only managed to achieve an  $F1$  score of 0.1254 and corresponding cross entropy of 2.3318. From Table 3 it can also be seen that the BERT + Majority voting had the same results as the BERT + softmax-Crowdlayer model so further investigation needs to be conducted to find out why this was so. As can be seen in Table 3, the use of the full base model provided for the PDIS and Gimpel-POS by the organisers achieved superior results and should have been used with the softmax-crowdlayer, but it could not be done because the full base model provided by the organisers was written in Pytorch framework whilst the softmax-crowdlayer was written in Keras. There should therefore have been the need to convert the full base model to Keras before using the softmax-crowdlayer and it's eventual evaluation, but as a result of the limited availability of time, it has been reserved as part of our future work to be covered in section 5

Refer to Appendix A for the analysis of the class distribution of the datasets.

## 5 Conclusion

This paper used a softmax-Crowdlayer approach combined with a deep neural network to train noisy labels from multiple crowd annotators. WideResNet together with softmax-Crowdlayer has been applied on CIFAR10-IC datasets, whilst MLP combined with softmax-Crowdlayer has been used on the LabelMe-IC data and BERT combined with

softmax-Crowdlayer has been used on Gimpel-POS and PDIS data respectively.

Future work will explore the effect of the distribution of the class annotation on the labeling accuracy and also investigate more efficient approaches of combining the BERT model with the softmax-Crowdlayer to further improve the results. It will also involve the application of the softmax-crowdlayer on the Humour dataset which was not included in this work due to time constraint posed as a result of the complicated data points of the humour dataset.

## A Class label distribution analysis

The table 4, summarises the number of Annotators, number of data points, and number classes for each data set used. The Figure 2 contains the probability density estimates of how the annotators perceived the class labels to which each respective item belonged to. Based on the simple majority voting, it can be observed from Figure 2(a) that the distribution was uniform across all classes with the labeling ; **[0:airplane, 1:automobile, 2:bird, 3:cat, 4:deer, 5:dog, 6:frog, 7:horse, 8:ship, and 9:truck ]** for the CIFAR10-IC dataset.

Figure 2(b) depicting the kernel density estimates of the LabelMe-IC data, captures the distribution of how the annotators labelled the data into their respective classes. Majority of the samples were labelled as forest with the respective encoding of the labels shown as; **[0:highway, 1:inside city, 2:tall building, 3:street, 4:forest, 5:coast, 6:mountain, 7:open country]**.

The distribution of the Gimpel-POS and PDIS datasets are represented in figures 2(c) and (d) respectively whose encoded labels have been provided earlier in section 3.5. The encoding for the Gimpel-POS class is shown as **[0:ADJ, 1:ADP, 2:ADV, 3:CCONJ, 4:DET, 5:NOUN, 6:NUM, 7:PRON, 8:PART, 9:PUNCT, 10:VERB, 11:X]**.

The labels of PDIS dataset are encoded as **[0: refer to new information, 1: refer to old information]**.

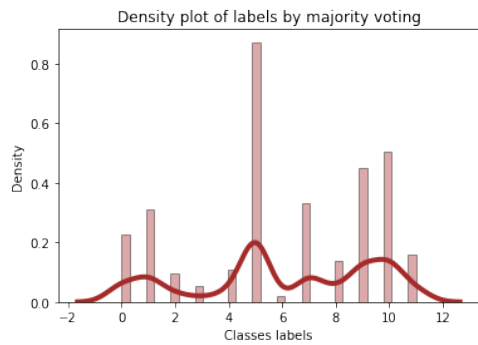

(a)

(b)

(c)

(d)

Dataset	#annotators	#classes	size
CIFAR10-IC	2571	10	7000
LabelMe-IC	59	8	5000
Gimpel-POS	177	12	8310
PDIS	1728	2	86936

Table 4: Summary statistics for each dataset used

Figure 2: The kernel density plot of the distribution of the crowd labels by Annotators for the (a) CIFAR10-IC, (b) LabelMe-IC, (c) Gimpel-POS and (d) PDIS datasets
