# Introduction

Welcome to SemEval-2021!

The Semantic Evaluation (SemEval) series of workshops focuses on the evaluation and comparison of systems that can analyze diverse semantic phenomena in text, with the aims of extending the current state of the art in semantic analysis and creating high quality annotated datasets in a range of increasingly challenging problems in natural language semantics. SemEval provides an exciting forum for researchers to propose challenging research problems in semantics and to build systems/techniques to address such research problems.

SemEval-2021 is the fifteenth workshop in the series of International Workshops on Semantic Evaluation. The first three workshops, SensEval-1 (1998), SensEval-2 (2001), and SensEval-3 (2004), focused on word sense disambiguation, each time expanding in the number of languages offered, the number of tasks, and also the number of teams participating. In 2007, the workshop was renamed to SemEval, and the subsequent SemEval workshops evolved to include semantic analysis tasks beyond word sense disambiguation. In 2012, SemEval became a yearly event. It currently takes place every year, on a two-year cycle. The tasks for SemEval-2021 were proposed in 2020, and next year's tasks have already been selected and are underway.

SemEval-2021 is co-located (virtually) with The Joint Conference of the 59th Annual Meeting of the Association for Computational Linguistics and the 11th International Joint Conference on Natural Language Processing (ACL-IJCNLP 2021) on August 5–6. This year's SemEval included the following 11 tasks:

- Lexical semantics
  - Task 1: Lexical Complexity Prediction
  - Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation
  - Task 4: Reading Comprehension of Abstract Meaning
- Social factors & opinion
  - Task 5: Toxic Spans Detection
  - Task 6: Detection of Persuasive Techniques in Texts and Images
  - Task 7: HaHackathon: Detecting and Rating Humor and Offense
- Information in scientific & clinical text
  - Task 8: MeasEval: Counts and Measurements
  - Task 9: Statement Verification and Evidence Finding with Tables
  - Task 10: Source-Free Domain Adaptation for Semantic Processing
  - Task 11: NLPContributionGraph
- Other phenomena
  - Task 12: Learning with Disagreements

This volume contains both task description papers that describe each of the above tasks and system description papers that present the systems that participated in the tasks. A total of 11 task description papers and 175 system description papers are included in this volume.

SemEval-2021 features two awards, one for organizers of a task and one for a team participating in a task. The Best Task award recognizes a task that stands out for making an important intellectual contribution to empirical computational semantics, as demonstrated by a creative, interesting, and scientifically rigorous dataset and evaluation design, and a well-written task overview paper. The Best Paper award recognizes a system description paper (written by a team participating in one of the tasks) that advances our understanding of a problem and available solutions with respect to a task. It need not be the highest-scoring system in the task, but it must have a strong analysis component in the evaluation, as well as a clear and reproducible description of the problem, algorithms, and methodology.

2021 has been another particularly challenging year across the globe. We are immensely grateful to the task organizers for their perseverance through many ups, downs, and uncertainties, as well as to the large number of participants whose enthusiastic participation has made SemEval once again a successful event! Thanks also to the task organizers who served as area chairs for their tasks, and to both task organizers and participants who reviewed paper submissions. These proceedings have greatly benefited from their detailed and thoughtful feedback. Thousands of thanks to our assistant organizers Julia R. Bonn and Abhidip Bhattacharyya for their extensive, detailed, and dedicated work on the production of these proceedings! We also thank the members of the program committee who reviewed the submitted task proposals and helped us to select this exciting set of tasks, and we thank the ACL 2021 conference organizers for their support. Finally, we most gratefully acknowledge the support of our sponsor: the ACL Special Interest Group on the Lexicon (SIGLEX).

The SemEval-2021 organizers: Guy Emerson, Aurelie Herbelot, Alexis Palmer, Natalie Schluter, Nathan Schneider, and Xiaodan Zhu

# Organizing Committee

## SemEval Organizers:

Alexis Palmer, University of Colorado Boulder  
Nathan Schneider, Georgetown University  
Natalie Schluter, IT University of Copenhagen & Google Brain  
Guy Emerson, University of Cambridge  
Xiaodan Zhu, Queen's University  
Aurelie Herbelot, University of Trento

## Assistant Organizers:

Julia R. Bonn, University of Colorado Boulder  
Abhidip Bhattacharyya, University of Colorado Boulder

## Task Selection Committee:

Eneko Agirre, Francesco Barbieri, Alberto Barrón-Cedeño, Valerio Basile, Steven Bethard, Georgeta Bordea, Davide Buscaldi, Tanmoy Chakraborty, Wanxiang Che, Colin Cherry, Keith Cortis, Giovanni Da San Martino, Amitava Das, Tobias Daudert, Franck Dernoncourt, Luis Espinosa Anke, André Freitas, Dimitris Galanis, Michael Gamon, Goran Glavaš, Ivan Habernal, Simon Hengchen, Nabil Hossain, Filip Ilievski, Els Lefever, Alessandro Lenci, Shuailong Liang, Nedim Lipka, Shervin Malmasi, Jonathan May, Tristan Miller, Ashutosh Modi, Saif Mohammad, Preslav Nakov, Roberto Navigli, Mohammad Taher Pilehvar, Manfred Pinkal, Maria Pontiki, Soujanya Poria, Marten Postma, Matthew Purver, Alan Ritter, Marko Robnik-Sikonja, Francesco Ronzano, Michael Roth, Mohammad Salameh, Juliano Efsen Sales, Dominik Schlechtweg, Fabrizio Sebastiani, Ekaterina Shutova, Vered Shwartz, Sasha Spala, Karin Verspoor, Cunxiang Wang, Xiaoyu Yang, Marcos Zampieri, Qiong Zhang, Arkaitz Zubiaga

## Task Organizers:

Task 1: Matthew Shardlow, Richard Evans, Gustavo Henrique Paetzold, Marcos Zampieri  
Task 2: Federico Martelli, Najla Kalach, Gabriele Tola, Roberto Navigli  
Task 4: Boyuan Zheng, Xiaoyu Yang, Yu-Ping Ruan, Quan Liu, Zhen-Hua Ling, Si Wei, Xiaodan Zhu  
Task 5: John Pavlopoulos, Ion Androutsopoulos, Jeffrey Sorensen, Léo Laugier  
Task 6: Giovanni Da San Martino, Hamed Firooz, Preslav Nakov, Fabrizio Silvestri  
Task 7: J. A. Meaney, Steven Wilson, Walid Magdy, Luis Chiruzzo  
Task 8: Corey Harper, Jessica Cox, Ron Daniel, Paul Groth, Curt Kohler, Antony Scerri  
Task 9: Nancy Xin Ru Wang, Sara Rosenthal, Marina Danilevsky, Diwakar Mahajan  
Task 10: Steven Bethard, Egoitz Laparra, Timothy Miller, Özlem Uzuner  
Task 11: Jennifer D'Souza, Sören Auer, Ted Pedersen  
Task 12: Alexandra Uma, Tommaso Fornaciari, Tristan Miller, Barbara Plank, Edwin Simpson, Massimo Poesio

## Invited Speakers:

Diyi Yang, Georgia Institute of Technology (shared speaker with \*SEM)  
Hannah Rohde, University of Edinburgh

## Table of Contents

<i>SemEval-2021 Task 1: Lexical Complexity Prediction</i>	
Matthew Shardlow, Richard Evans, Gustavo Henrique Paetzold and Marcos Zampieri . . . . .	1
<i>OCHADAI-KYOTO at SemEval-2021 Task 1: Enhancing Model Generalization and Robustness for Lexical Complexity Prediction</i>	
Yuki Taya, Lis Kanashiro Pereira, Fei Cheng and Ichiro Kobayashi . . . . .	17
<i>SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation (MCL-WiC)</i>	
Federico Martelli, Najla Kalach, Gabriele Tola and Roberto Navigli . . . . .	24
<i>SemEval-2021 Task 4: Reading Comprehension of Abstract Meaning</i>	
Boyuan Zheng, Xiaoyu Yang, Yu-Ping Ruan, Zhenhua Ling, Quan Liu, Si Wei and Xiaodan Zhu	37
<i>TA-MAMC at SemEval-2021 Task 4: Task-adaptive Pretraining and Multi-head Attention for Abstract Meaning Reading Comprehension</i>	
Jing Zhang, Yimeng Zhuang and Yinpei Su . . . . .	51
<i>SemEval-2021 Task 5: Toxic Spans Detection</i>	
John Pavlopoulos, Jeffrey Sorensen, Léo Laugier and Ion Androutsopoulos . . . . .	59
<i>SemEval-2021 Task 6: Detection of Persuasion Techniques in Texts and Images</i>	
Dimitar Dimitrov, Bishr Bin Ali, Shaden Shaar, Firoj Alam, Fabrizio Silvestri, Hamed Firooz, Preslav Nakov and Giovanni Da San Martino . . . . .	70
<i>Alpha at SemEval-2021 Task 6: Transformer Based Propaganda Classification</i>	
Zhida Feng, Jiji Tang, Jiaxiang Liu, Weichong Yin, Shikun Feng, Yu Sun and Li Chen . . . . .	99
<i>SemEval 2021 Task 7: HaHackathon, Detecting and Rating Humor and Offense</i>	
J. A. Meaney, Steven Wilson, Luis Chiruzzo, Adam Lopez and Walid Magdy . . . . .	105
<i>LangResearchLab NC at SemEval-2021 Task 1: Linguistic Feature Based Modelling for Lexical Complexity</i>	
Raksha Agarwal and Niladri Chatterjee . . . . .	120
<i>Complex words identification using word-level features for SemEval-2020 Task 1</i>	
Jenny A. Ortiz-Zambrano and Arturo Montejo-Ráez . . . . .	126
<i>TUDA-CCL at SemEval-2021 Task 1: Using Gradient-boosted Regression Tree Ensembles Trained on a Heterogeneous Feature Set for Predicting Lexical Complexity</i>	
Sebastian Gombert and Sabine Bartsch . . . . .	130
<i>JCT at SemEval-2021 Task 1: Context-aware Representation for Lexical Complexity Prediction</i>	
Chaya Liebeskind, Otniel Elkayam and Shmuel Liebeskind . . . . .	138
<i>IAPUCP at SemEval-2021 Task 1: Stacking Fine-Tuned Transformers is Almost All You Need for Lexical Complexity Prediction</i>	
Kervy Rivas Rojas and Fernando Alva-Manchego . . . . .	144
<i>Uppsala NLP at SemEval-2021 Task 2: Multilingual Language Models for Fine-tuning and Feature Extraction in Word-in-Context Disambiguation</i>	
Huiling You, Xingran Zhu and Sara Stymne . . . . .	150

<i>SkoltechNLP at SemEval-2021 Task 2: Generating Cross-Lingual Training Data for the Word-in-Context Task</i>	
Anton Razzhigaev, Nikolay Arefyev and Alexander Panchenko . . . . .	157
<i>Zhestyatsky at SemEval-2021 Task 2: ReLU over Cosine Similarity for BERT Fine-tuning</i>	
Boris Zhestiankin and Maria Ponomareva . . . . .	163
<i>SzegedAI at SemEval-2021 Task 2: Zero-shot Approach for Multilingual and Cross-lingual Word-in-Context Disambiguation</i>	
Gábor Berend . . . . .	169
<i>ReCAM@IITK at SemEval-2021 Task 4: BERT and ALBERT based Ensemble for Abstract Word Prediction</i>	
Abhishek Mittal and Ashutosh Modi . . . . .	175
<i>ECNU_JCA_1 SemEval-2021 Task 4: Leveraging Knowledge-enhanced Graph Attention Networks for Reading Comprehension of Abstract Meaning</i>	
Pingsheng Liu, Linlin Wang, Qian Zhao, Hao Chen, Yuxi Feng, Xin Lin and liang he . . . . .	183
<i>LRG at SemEval-2021 Task 4: Improving Reading Comprehension with Abstract Words using Augmentation, Linguistic Features and Voting</i>	
Abheesht Sharma, Harshit Pandey, Gunjan Chhablani, Yash Bhartia and Tirtharaj Dash . . . . .	189
<i>IIE-NLP-Eyas at SemEval-2021 Task 4: Enhancing PLM for ReCAM with Special Tokens, Re-Ranking, Siamese Encoders and Back Translation</i>	
Yuqiang Xie, Luxi Xing, Wei Peng and Yue Hu . . . . .	199
<i>NLP-IIS@UT at SemEval-2021 Task 4: Machine Reading Comprehension using the Long Document Transformer</i>	
Hossein Basafa, Sajad Movahedi, Ali Ebrahimi, Azadeh Shakery and Hesham Faili . . . . .	205
<i>IITK@Detox at SemEval-2021 Task 5: Semi-Supervised Learning and Dice Loss for Toxic Spans Detection</i>	
Archit Bansal, Abhay Kaushik and Ashutosh Modi . . . . .	211
<i>UniParma at SemEval-2021 Task 5: Toxic Spans Detection Using CharacterBERT and Bag-of-Words Model</i>	
Akbar Karimi, Leonardo Rossi and Andrea Prati . . . . .	220
<i>UPB at SemEval-2021 Task 5: Virtual Adversarial Training for Toxic Spans Detection</i>	
Andrei Paraschiv, Dumitru-Clementin Cercel and Mihai Dascalu . . . . .	225
<i>NLRG at SemEval-2021 Task 5: Toxic Spans Detection Leveraging BERT-based Token Classification and Span Prediction Techniques</i>	
Gunjan Chhablani, Abheesht Sharma, Harshit Pandey, Yash Bhartia and Shan Suthaharan . . . . .	233
<i>UoB at SemEval-2021 Task 5: Extending Pre-Trained Language Models to Include Task and Domain-Specific Information for Toxic Span Prediction</i>	
Erik Yan and Harish Tayyar Madabushi . . . . .	243
<i>Cisco at SemEval-2021 Task 5: What's Toxic?: Leveraging Transformers for Multiple Toxic Span Extraction from Online Comments</i>	
Sreyan Ghosh and Sonal Kumar . . . . .	249

<i>MedAI at SemEval-2021 Task 5: Start-to-end Tagging Framework for Toxic Spans Detection</i>	
Zhen Wang, Hongjie Fan and Junfei Liu .....	258
<i>HamiltonDinggg at SemEval-2021 Task 5: Investigating Toxic Span Detection using RoBERTa Pre-training</i>	
Huiyang Ding and David Jurgens.....	263
<i>WVOQ at SemEval-2021 Task 6: BART for Span Detection and Classification</i>	
Cees Roele.....	270
<i>HumorHunter at SemEval-2021 Task 7: Humor and Offense Recognition with Disentangled Attention</i>	
Yubo Xie, Junze Li and Pearl Pu .....	275
<i>Grenzlinie at SemEval-2021 Task 7: Detecting and Rating Humor and Offense</i>	
Renyuan Liu and Xiaobing Zhou .....	281
<i>abcbpc at SemEval-2021 Task 7: ERNIE-based Multi-task Model for Detecting and Rating Humor and Offense</i>	
Chao Pang, Xiaoran Fan, Weiyue Su, Xuyi Chen, Shuohuan Wang, Jiayang Liu, Xuan Ouyang, Shikun Feng and Yu Sun .....	286
<i>Humor@IITK at SemEval-2021 Task 7: Large Language Models for Quantifying Humor and Offensiveness</i>	
Aishwarya Gupta, Avik Pal, Bholeshwar Khurana, Lakshay Tyagi and Ashutosh Modi.....	290
<i>RoMa at SemEval-2021 Task 7: A Transformer-based Approach for Detecting and Rating Humor and Offense</i>	
Roberto Labadie, Mariano Jason Rodriguez, Reynier Ortega and Paolo Rosso .....	297
<i>SemEval-2021 Task 8: MeasEval – Extracting Counts and Measurements and their Related Contexts</i>	
Corey Harper, Jessica Cox, Curt Kohler, Antony Scerri, Ron Daniel Jr. and Paul Groth .....	306
<i>SemEval-2021 Task 9: Fact Verification and Evidence Finding for Tabular Data in Scientific Documents (SEM-TAB-FACTS)</i>	
Nancy X. R. Wang, Diwakar Mahajan, Marina Danilevsky and Sara Rosenthal.....	317
<i>BreakingBERT@IITK at SemEval-2021 Task 9: Statement Verification and Evidence Finding with Tables</i>	
Aditya Jindal, Ankur Gupta, Jaya Srivastava, Preeti Menghwani, Vijit Malik, Vishesh Kaushik and Ashutosh Modi .....	327
<i>SemEval-2021 Task 12: Learning with Disagreements</i>	
Alexandra Uma, Tommaso Fornaciari, Anca Dumitrache, Tristan Miller, Jon Chamberlain, Barbara Plank, Edwin Simpson and Massimo Poesio .....	338
<i>SemEval-2021 Task 10: Source-Free Domain Adaptation for Semantic Processing</i>	
Egoitz Laparra, Xin Su, Yiyun Zhao, Özlem Uzuner, Timothy Miller and Steven Bethard .....	348
<i>BLCUFIGHT at SemEval-2021 Task 10: Novel Unsupervised Frameworks For Source-Free Domain Adaptation</i>	
Weikang Wang, Yi Wu, Yixiang Liu and Pengyuan Liu .....	357
<i>SemEval-2021 Task 11: NLPContributionGraph - Structuring Scholarly NLP Contributions for a Research Knowledge Graph</i>	
Jennifer D’Souza, Sören Auer and Ted Pedersen .....	364

<i>UIUC_BioNLP at SemEval-2021 Task 11: A Cascade of Neural Models for Structuring Scholarly NLP Contributions</i>	
Haoyang Liu, M. Janina Sarol and Halil Kilicoglu .....	377
<i>KGP at SemEval-2021 Task 8: Leveraging Multi-Staged Language Models for Extracting Measurements, their Attributes and Relations</i>	
Neel Karia, Ayush Kaushal and Faraaz Mallick .....	387
<i>DPR at SemEval-2021 Task 8: Dynamic Path Reasoning for Measurement Relation Extraction</i>	
Amir Pouran Ben Veyseh, Franck Dernoncourt and Thien Huu Nguyen .....	397
<i>CLaC-np at SemEval-2021 Task 8: Dependency DGCNN</i>	
Nihatha Lathiff, Pavel PK Khloponin and Sabine Bergler .....	404
<i>CLaC-BP at SemEval-2021 Task 8: SciBERT Plus Rules for MeasEval</i>	
Benjamin Therien, Parsa Bagherzadeh and Sabine Bergler .....	410
<i>THiFly_Queens at SemEval-2021 Task 9: Two-stage Statement Verification with Adaptive Ensembling and Slot-based Operation</i>	
Yuxuan Zhou, Kaiyin Zhou, Xien Liu, Ji Wu and Xiaodan Zhu .....	416
<i>TAPAS at SemEval-2021 Task 9: Reasoning over tables with intermediate pre-training</i>	
Thomas Müller, Julian Eisenschlos and Syrine Krichene .....	423
<i>BOUN at SemEval-2021 Task 9: Text Augmentation Techniques for Fact Verification in Tabular Data</i>	
Abdullatif Köksal, Yusuf Yüksel, Bekir Yıldırım and Arzucan Özgür .....	431
<i>IITK at SemEval-2021 Task 10: Source-Free Unsupervised Domain Adaptation using Class Prototypes</i>	
Harshit Kumar, Jinang Shah, Nidhi Hegde, Priyanshu Gupta, Vaibhav Jindal and Ashutosh Modi	438
<i>PTST-UoM at SemEval-2021 Task 10: Parsimonious Transfer for Sequence Tagging</i>	
Kemal Kurniawan, Lea Frermann, Philip Schulz and Trevor Cohn .....	445
<i>Self-Adapter at SemEval-2021 Task 10: Entropy-based Pseudo-Labeler for Source-free Domain Adaptation</i>	
Sangwon Yoon, Yanghoon Kim and Kyomin Jung .....	452
<i>The University of Arizona at SemEval-2021 Task 10: Applying Self-training, Active Learning and Data Augmentation to Source-free Domain Adaptation</i>	
Xin Su, Yiyun Zhao and Steven Bethard .....	458
<i>KnowGraph@IITK at SemEval-2021 Task 11: Building Knowledge Graph for NLP Research</i>	
Shashank Shailabh, Sajal Chaurasia and Ashutosh Modi .....	467
<i>YNU-HPCC at SemEval-2021 Task 11: Using a BERT Model to Extract Contributions from NLP Scholarly Articles</i>	
Xinge Ma, Jin Wang and Xuejie Zhang .....	478
<i>ITNLP at SemEval-2021 Task 11: Boosting BERT with Sampling and Adversarial Training for Knowledge Extraction</i>	
Genyu Zhang, Yu Su, Changhong He, Lei Lin, Chengjie Sun and Lili Shan .....	485

<i>Duluth at SemEval-2021 Task 11: Applying DeBERTa to Contributing Sentence Selection and Dependency Parsing for Entity Extraction</i>	
Anna Martin and Ted Pedersen . . . . .	490
<i>INNOVATORS at SemEval-2021 Task-11: A Dependency Parsing and BERT-based model for Extracting Contribution Knowledge from Scientific Papers</i>	
Hardik Arora, Tirthankar Ghosal, Sandeep Kumar, Suraj Patwal and Phil Gooch . . . . .	502
<i>MCL@IITK at SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation using Augmented Data, Signals, and Transformers</i>	
Rohan Gupta, Jay Mundra, Deepak Mahajan and Ashutosh Modi . . . . .	511
<i>HITSZ-HLT at SemEval-2021 Task 5: Ensemble Sequence Labeling and Span Boundary Detection for Toxic Span Detection</i>	
Qinglin Zhu, Zijie Lin, Yice Zhang, Jingyi Sun, Xiang Li, Qihui Lin, Yixue Dang and Ruifeng Xu	521
<i>SarcasmDet at SemEval-2021 Task 7: Detect Humor and Offensive based on Demographic Factors using RoBERTa Pre-trained Model</i>	
Dalya Faraj and Malak Abdullah . . . . .	527
<i>UPB at SemEval-2021 Task 8: Extracting Semantic Information on Measurements as Multi-Turn Question Answering</i>	
Andrei-Marius Avram, George-Eduard Zaharia, Dumitru-Clementin Cercel and Mihai Dascalu	534
<i>IITK@LCP at SemEval-2021 Task 1: Classification for Lexical Complexity Regression Task</i>	
Neil Shirude, Sagnik Mukherjee, Tushar Shandhilya, Ananta Mukherjee and Ashutosh Modi . .	541
<i>LCP-RIT at SemEval-2021 Task 1: Exploring Linguistic Features for Lexical Complexity Prediction</i>	
Abhinandan Tejalkumar Desai, Kai North, Marcos Zampieri and Christopher Homan . . . . .	548
<i>Alejandro Mosquera at SemEval-2021 Task 1: Exploring Sentence and Word Features for Lexical Complexity Prediction</i>	
Alejandro Mosquera . . . . .	554
<i>CompNA at SemEval-2021 Task 1: Prediction of lexical complexity analyzing heterogeneous features</i>	
Giuseppe Vettigli and Antonio Sorgente . . . . .	560
<i>PolyU CBS-Comp at SemEval-2021 Task 1: Lexical Complexity Prediction (LCP)</i>	
Rong Xiang, Jinghang Gu, Emmanuele Chersoni, Wenjie Li, Qin Lu and Chu-Ren Huang . . . .	565
<i>LAST at SemEval-2021 Task 1: Improving Multi-Word Complexity Prediction Using Bigram Association Measures</i>	
Yves Bestgen . . . . .	571
<i>DeepBlueAI at SemEval-2021 Task 1: Lexical Complexity Prediction with A Deep Ensemble Approach</i>	
Chunguang Pan, Bingyan Song, Shengguang Wang and Zhipeng Luo . . . . .	578
<i>CS-UM6P at SemEval-2021 Task 1: A Deep Learning Model-based Pre-trained Transformer Encoder for Lexical Complexity</i>	
Nabil El Mamoun, Abdelkader El Mahdaouy, Abdellah El Mekki, Kabil Essefar and Ismail Berrada	585

<i>Cambridge at SemEval-2021 Task 1: An Ensemble of Feature-Based and Neural Models for Lexical Complexity Prediction</i>	
Zheng Yuan, Gladys Tyen and David Strohmaier . . . . .	590
<i>hub at SemEval-2021 Task 1: Fusion of Sentence and Word Frequency to Predict Lexical Complexity</i>	
Bo Huang, Yang Bai and Xiaobing Zhou . . . . .	598
<i>Manchester Metropolitan at SemEval-2021 Task 1: Convolutional Networks for Complex Word Identification</i>	
Robert Flynn and Matthew Shardlow . . . . .	603
<i>UPB at SemEval-2021 Task 1: Combining Deep Learning and Hand-Crafted Features for Lexical Complexity Prediction</i>	
George-Eduard Zaharia, Dumitru-Clementin Cercel and Mihai Dascalu . . . . .	609
<i>UTFPR at SemEval-2021 Task 1: Complexity Prediction by Combining BERT Vectors and Classic Features</i>	
Gustavo Henrique Paetzold . . . . .	617
<i>RG PA at SemEval-2021 Task 1: A Contextual Attention-based Model with RoBERTa for Lexical Complexity Prediction</i>	
Gang Rao, Maochang Li, Xiaolong Hou, Lianxin Jiang, Yang Mo and Jianping Shen . . . . .	623
<i>CSECU-DSG at SemEval-2021 Task 1: Fusion of Transformer Models for Lexical Complexity Prediction</i>	
Abdul Aziz, MD. Akram Hossain and Abu Nowshed Chy . . . . .	627
<i>CLULEX at SemEval-2021 Task 1: A Simple System Goes a Long Way</i>	
Greta Smolenska, Peter Kolb, Sinan Tang, Mironas Bitinis, Héctor Hernández and Elin Asklöv	632
<i>RS_GV at SemEval-2021 Task 1: Sense Relative Lexical Complexity Prediction</i>	
Regina Stodden and Gayatri Venugopal . . . . .	640
<i>UNBNLP at SemEval-2021 Task 1: Predicting lexical complexity with masked language models and character-level encoders</i>	
Milton King, Ali Hakimi Parizi, Samin Fakharian and Paul Cook . . . . .	650
<i>ANDI at SemEval-2021 Task 1: Predicting complexity in context using distributional models, behavioural norms, and lexical resources</i>	
Armand Rotaru . . . . .	655
<i>JUST-BLUE at SemEval-2021 Task 1: Predicting Lexical Complexity using BERT and RoBERTa Pre-trained Language Models</i>	
Tuqa Bani Yaseen, Qusai Ismail, Sarah Al-Omari, Eslam Al-Sobh and Malak Abdullah . . . . .	661
<i>BigGreen at SemEval-2021 Task 1: Lexical Complexity Prediction with Assembly Models</i>	
Aadil Islam, Weicheng Ma and Soroush Vosoughi . . . . .	667
<i>cs60075_team2 at SemEval-2021 Task 1 : Lexical Complexity Prediction using Transformer-based Language Models pre-trained on various text corpora</i>	
Abhilash Nandy, Sayantan Adak, Tanurima Halder and Sai Mahesh Pokala . . . . .	678
<i>C3SL at SemEval-2021 Task 1: Predicting Lexical Complexity of Words in Specific Contexts with Sentence Embeddings</i>	
Raul Almeida, Hegler Tissot and Marcos Didonet Del Fabro . . . . .	683

<i>Stanford MLab at SemEval-2021 Task 1: Tree-Based Modelling of Lexical Complexity using Word Embeddings</i>	
Erik Rozi, Niveditha Iyer, Gordon Chi, Enok Choe, Kathy J. Lee, Kevin Liu, Patrick Liu, Zander Lack, Jillian Tang and Ethan A. Chi .....	688
<i>archer at SemEval-2021 Task 1: Contextualising Lexical Complexity</i>	
Irene Russo .....	694
<i>katildakat at SemEval-2021 Task 1: Lexical Complexity Prediction of Single Words and Multi-Word Expressions in English</i>

<i>GX at SemEval-2021 Task 2: BERT with Lemma Information for MCL-WiC Task</i>	
Wanying Xie .....	706
<i>PALI at SemEval-2021 Task 2: Fine-Tune XLM-RoBERTa for Word in Context Disambiguation</i>	
Shuyi Xie, Jian Ma, Haiqin Yang, Lianxin Jiang, Yang Mo and Jianping Shen .....	713
<i>hub at SemEval-2021 Task 2: Word Meaning Similarity Prediction Model Based on RoBERTa and Word Frequency</i>	
Bo Huang, Yang Bai and Xiaobing Zhou .....	719
<i>Lotus at SemEval-2021 Task 2: Combination of BERT and Paraphrasing for English Word Sense Disambiguation</i>	
Niloofer Ranjbar and Hossein Zeinali .....	724
<i>Cambridge at SemEval-2021 Task 2: Neural WiC-Model with Data Augmentation and Exploration of Representation</i>	
Zheng Yuan and David Strohmaier .....	730
<i>UoB_UK at SemEval 2021 Task 2: Zero-Shot and Few-Shot Learning for Multi-lingual and Cross-lingual Word Sense Disambiguation.</i>	
Wei Li, Harish Tayyar Madabushi and Mark Lee .....	738
<i>PAW at SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation : Exploring Cross Lingual Transfer, Augmentations and Adversarial Training</i>	
Harsh Goyal, Aadarsh Singh and Priyanshu Kumar .....	743
<i>LU-BZU at SemEval-2021 Task 2: Word2Vec and Lemma2Vec performance in Arabic Word-in-Context disambiguation</i>	
Moustafa Al-Hajj and Mustafa Jarrar .....	748
<i>GlossReader at SemEval-2021 Task 2: Reading Definitions Improves Contextualized Word Embeddings</i>	
Maxim Rachinskiy and Nikolay Arefyev .....	756
<i>UALberta at SemEval-2021 Task 2: Determining Sense Synonymy via Translations</i>	
Bradley Hauer, Hongchang Bao, Arnob Mallik and Grzegorz Kondrak .....	763
<i>TransWiC at SemEval-2021 Task 2: Transformer-based Multilingual and Cross-lingual Word-in-Context Disambiguation</i>	
Hansi Hettiarachchi and Tharindu Ranasinghe .....	771
<i>LIORI at SemEval-2021 Task 2: Span Prediction and Binary Classification approaches to Word-in-Context Disambiguation</i>	
Adis Davletov, Nikolay Arefyev, Denis Gordeev and Alexey Rey .....	780

<i>FII_CROSS at SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation</i> Ciprian Bodnar, Andrada Tapuc, Cosmin Pintilie, Daniela Gifu and Diana Trandabat . . . . .	787
<i>XRJL-HKUST at SemEval-2021 Task 4: WordNet-Enhanced Dual Multi-head Co-Attention for Reading Comprehension of Abstract Meaning</i> Yuxin Jiang, Ziyi Shou, Qijun Wang, Hao Wu and Fangzhen Lin . . . . .	793
<i>UoR at SemEval-2021 Task 4: Using Pre-trained BERT Token Embeddings for Question Answering of Abstract Meaning</i> Thanet Markchom and Huizhi Liang . . . . .	799
<i>Noobs at Semeval-2021 Task 4: Masked Language Modeling for abstract answer prediction</i> Shikhar Shukla, Sarthak Sarthak and Karm Veer Arya . . . . .	805
<i>ZJUKLAB at SemEval-2021 Task 4: Negative Augmentation with Language Model for Reading Comprehension of Abstract Meaning</i> Xin Xie, Xiangnan Chen, Xiang Chen, Yong Wang, Ningyu Zhang, Shumin Deng and Huajun Chen . . . . .	810
<i>PINGAN Omini-Sinitic at SemEval-2021 Task 4: Reading Comprehension of Abstract Meaning</i> Ye Wang, Yanmeng Wang, Haijun Zhu, Bo Zeng, Zhenghong Hao, Shaojun Wang and Jing Xiao . . . . .	820
<i>NEUer at SemEval-2021 Task 4: Complete Summary Representation by Filling Answers into Question for Matching Reading Comprehension</i> Zhixiang Chen, yikun lei, Pai Liu and Guibing Guo . . . . .	827
<i>WLV-RIT at SemEval-2021 Task 5: A Neural Transformer Framework for Detecting Toxic Spans</i> Tharindu Ranasinghe, Diptanu Sarkar, Marcos Zampieri and Alexander Ororbia . . . . .	833
<i>YNU-HPCC at SemEval-2021 Task 5: Using a Transformer-based Model with Auxiliary Information for Toxic Span Detection</i> Ruijun Chen, Jin Wang and Xuejie Zhang . . . . .	841
<i>UIT-ISE-NLP at SemEval-2021 Task 5: Toxic Spans Detection with BiLSTM-CRF and ToxicBERT Comment Classification</i> Son T. Luu and Ngan Nguyen . . . . .	846
<i>GHOST at SemEval-2021 Task 5: Is explanation all you need?</i> Kamil Pluciński and Hanna Klimczak . . . . .	852
<i>GoldenWind at SemEval-2021 Task 5: Orthrus - An Ensemble Approach to Identify Toxicity</i> Marco Palomino, Dawid Grad and James Bedwell . . . . .	860
<i>LISAC FSDM USMBA at SemEval-2021 Task 5: Tackling Toxic Spans Detection Challenge with Supervised SpanBERT-based Model and Unsupervised LIME-based Model</i> Abdessamad Benlahbib, Ahmed Alami and Hamza Alami . . . . .	865
<i>HITMI&amp;T at SemEval-2021 Task 5: Integrating Transformer and CRF for Toxic Spans Detection</i> Chenyi Wang, Tianshu Liu and Tiejun Zhao . . . . .	870
<i>AStarTwice at SemEval-2021 Task 5: Toxic Span Detection Using RoBERTa-CRF, Domain Specific Pre-Training and Self-Training</i> Thakur Ashutosh Suman and Abhinav Jain . . . . .	875

<i>NLP_UIOWA at Semeval-2021 Task 5: Transferring Toxic Sets to Tag Toxic Spans</i> Jonathan Rusert .....	881
<i>S-NLP at SemEval-2021 Task 5: An Analysis of Dual Networks for Sequence Tagging</i> Viet Anh Nguyen, Tam Minh Nguyen, Huy Quang Dao and Quang Huu Pham .....	888
<i>UAntwerp at SemEval-2021 Task 5: Spans are Spans, stacking a binary word level approach to toxic span detection</i> Ben Burtenshaw and Mike Kestemont .....	898
<i>hub at SemEval-2021 Task 5: Toxic Span Detection Based on Word-Level Classification</i> Bo Huang, Yang Bai and Xiaobing Zhou .....	904
<i>Sefamerve ARGE at SemEval-2021 Task 5: Toxic Spans Detection Using Segmentation Based 1-D Convolutional Neural Network Model</i> Selman Delil, Birol Kuyumcu and Cüneyt Aksakallı .....	909
<i>MIPT-NSU-UTMN at SemEval-2021 Task 5: Ensembling Learning with Pre-trained Language Models for Toxic Spans Detection</i> Mikhail Kotyushev, Anna Glazkova and Dmitry Morozov .....	913
<i>UIT-E10dot3 at SemEval-2021 Task 5: Toxic Spans Detection with Named Entity Recognition and Question-Answering Approaches</i> Phu Gia Hoang, Luan Thanh Nguyen and Kiet Nguyen .....	919
<i>SkoltechNLP at SemEval-2021 Task 5: Leveraging Sentence-level Pre-training for Toxic Span Detection</i> David Dale, Igor Markov, Varvara Logacheva, Olga Kozlova, Nikita Semenov and Alexander Panchenko .....	927
<i>Entity at SemEval-2021 Task 5: Weakly Supervised Token Labelling for Toxic Spans Detection</i> Vaibhav Jain and Mina Naghshnejad .....	935
<i>BennettNLP at SemEval-2021 Task 5: Toxic Spans Detection using Stacked Embedding Powered Toxic Entity Recognizer</i> Harsh Kataria, Ambuje Gupta and Vipul Mishra .....	941
<i>UoT-UWF-PartAI at SemEval-2021 Task 5: Self Attention Based Bi-GRU with Multi-Embedding Representation for Toxicity Highlighter</i> Hamed Babaei Giglou, Taher Rahgooy, Mostafa Rahgouy and Jafar Razmara .....	948
<i>YoungSheldon at SemEval-2021 Task 5: Fine-tuning Pre-trained Language Models for Toxic Spans Detection using Token classification Objective</i> Mayukh Sharma, Ilanthenral Kandasamy and W.B. Vasantha .....	953
<i>HLE-UPC at SemEval-2021 Task 5: Multi-Depth DistilBERT for Toxic Spans Detection</i> Rafel Palliser-Sans and Albert Rial-Farràs .....	960
<i>Lone Pine at SemEval-2021 Task 5: Fine-Grained Detection of Hate Speech Using BERToxic</i> Yakoob Khan, Weicheng Ma and Soroush Vosoughi .....	967
<i>SRPOL DIALOGUE SYSTEMS at SemEval-2021 Task 5: Automatic Generation of Training Data for Toxic Spans Detection</i> Michał Satława, Katarzyna Zamłyńska, Jarosław Piersa, Joanna Kolis, Klaudia Firląg, Katarzyna Beksa, Zuzanna Bordzicka, Christian Goltz, Paweł Bujnowski and Piotr Andruszkiewicz .....	974

<i>SINAI at SemEval-2021 Task 5: Combining Embeddings in a BiLSTM-CRF model for Toxic Spans Detection</i>	
Flor Miriam Plaza-del-Arco, Pilar López-Úbeda, L. Alfonso Ureña-López and M. Teresa Martín-Valdivia .....	984
<i>CSECU-DSG at SemEval-2021 Task 5: Leveraging Ensemble of Sequence Tagging Models for Toxic Spans Detection</i>	
Tashin Hossain, Jannatun Naim, Fareen Tasneem, Radiathun Tasnia and Abu Nowshed Chy ...	990
<i>UTNLP at SemEval-2021 Task 5: A Comparative Analysis of Toxic Span Detection using Attention-based, Named Entity Recognition, and Ensemble Models</i>	
Alireza Salemi, Nazanin Sabri, Emad Kebriaei, Behnam Bahrak and Azadeh Shakery .....	995
<i>macech at SemEval-2021 Task 5: Toxic Spans Detection</i>	
Maggie Cech .....	1003
<i>LZ1904 at SemEval-2021 Task 5: Bi-LSTM-CRF for Toxic Span Detection using Pretrained Word Embedding</i>	
Liang Zou and Wen Li .....	1009
<i>LIIR at SemEval-2021 task 6: Detection of Persuasion Techniques In Texts and Images using CLIP features</i>	
Erfan Ghadery, Damien Sileo and Marie-Francine Moens .....	1015
<i>AIMH at SemEval-2021 Task 6: Multimodal Classification Using an Ensemble of Transformer Models</i>	
Nicola Messina, Fabrizio Falchi, Claudio Gennaro and Giuseppe Amato .....	1020
<i>HOMADOS at SemEval-2021 Task 6: Multi-Task Learning for Propaganda Detection</i>	
Konrad Kaczyński and Piotr Przybyła .....	1027
<i>1213Li at SemEval-2021 Task 6: Detection of Propaganda with Multi-modal Attention and Pre-trained Models</i>	
Peiguang Li, Xuan Li and Xian Sun .....	1032
<i>NlyticsFKIE at SemEval-2021 Task 6: Detection of Persuasion Techniques In Texts And Images</i>	
Albert Pritzkau .....	1037
<i>YNU-HPCC at SemEval-2021 Task 6: Combining ALBERT and Text-CNN for Persuasion Detection in Texts and Images</i>	
Xingyu Zhu, Jin Wang and Xuejie Zhang .....	1045
<i>LT3 at SemEval-2021 Task 6: Using Multi-Modal Compact Bilinear Pooling to Combine Visual and Textual Understanding in Memes</i>	
Pranaydeep Singh and Els Lefever .....	1051
<i>FPAI at SemEval-2021 Task 6: BERT-MRC for Propaganda Techniques Detection</i>	
Xiaolong Hou, Junsong Ren, Gang Rao, Lianxin Lian, Zhihao Ruan, Yang Mo and Jianping Shen	1056
<i>NLPITR at SemEval-2021 Task 6: RoBERTa Model with Data Augmentation for Persuasion Techniques Detection</i>	
Vansh Gupta and Raksha Sharma .....	1061

<i>LeCun at SemEval-2021 Task 6: Detecting Persuasion Techniques in Text Using Ensembled Pretrained Transformers and Data Augmentation</i>	
Dia Abujaber, Ahmed Qarqaz and Malak A. Abdullah . . . . .	1068
<i>Volta at SemEval-2021 Task 6: Towards Detecting Persuasive Texts and Images using Textual and Multimodal Ensemble</i>	
Kshitij Gupta, Devansh Gautam and Radhika Mamidi . . . . .	1075
<i>MinD at SemEval-2021 Task 6: Propaganda Detection using Transfer Learning and Multimodal Fusion</i>	
Junfeng Tian, Min Gui, Chenliang Li, Ming Yan and Wenming Xiao . . . . .	1082
<i>CSECU-DSG at SemEval-2021 Task 6: Orchestrating Multimodal Neural Architectures for Identifying Persuasion Techniques in Texts and Images</i>	
Tashin Hossain, Jannatun Naim, Fareen Tasneem, Radiathun Tasnia and Abu Nowshed Chy .	1088
<i>UMUTeam at SemEval-2021 Task 7: Detecting and Rating Humor and Offense with Linguistic Features and Word Embeddings</i>	
José Antonio García-Díaz and Rafael Valencia-García . . . . .	1096
<i>ES-JUST at SemEval-2021 Task 7: Detecting and Rating Humor and Offensive Text Using Deep Learning</i>	
Emran Al Bashabsheh and Sanaa Abu Alasal . . . . .	1102
<i>Tsia at SemEval-2021 Task 7: Detecting and Rating Humor and Offense</i>	
Zhengyi Guan and Xiaobing ZXB Zhou . . . . .	1108
<i>DLJUST at SemEval-2021 Task 7: Hahackathon: Linking Humor and Offense</i>	
Hani Al-Omari, Isra'a AbedulNabi and Rehab Duwairi . . . . .	1114
<i>Gulu at SemEval-2021 Task 7: Detecting and Rating Humor and Offense</i>	
Maoqin Yang . . . . .	1120
<i>DUTH at SemEval-2021 Task 7: Is Conventional Machine Learning for Humorous and Offensive Tasks enough in 2021?</i>	
Alexandros Karasakalidis, Dimitrios Effrosynidis and Avi Arampatzis . . . . .	1125
<i>DeepBlueAI at SemEval-2021 Task 7: Detecting and Rating Humor and Offense with Stacking Diverse Language Model-Based Methods</i>	
Bingyan Song, Chunguang Pan, Shengguang Wang and Zhipeng Luo . . . . .	1130
<i>CS-UM6P at SemEval-2021 Task 7: Deep Multi-Task Learning Model for Detecting and Rating Humor and Offense</i>	
Kabil Essefar, Abdellah El Mekki, Abdelkader El Mahdaouy, Nabil El Mamoun and Ismail Berrada	1135
<i>hub at SemEval-2021 Task 7: Fusion of ALBERT and Word Frequency Information Detecting and Rating Humor and Offense</i>	
Bo Huang and Yang Bai . . . . .	1141
<i>YoungSheldon at SemEval-2021 Task 7: Fine-tuning Is All You Need</i>	
Mayukh Sharma, Ilanthenral Kandasamy and W.B. Vasantha . . . . .	1146
<i>MagicPai at SemEval-2021 Task 7: Method for Detecting and Rating Humor Based on Multi-Task Adversarial Training</i>	
Jian Ma, Shuyi Xie, Haiqin Yang, Lianxin Jiang, Mengyuan Zhou, Xiaoyi Ruan and Yang Mo	1153

<i>UPB at SemEval-2021 Task 7: Adversarial Multi-Task Learning for Detecting and Rating Humor and Offense</i>	
Răzvan-Alexandru Smădu, Dumitru-Clementin Cercel and Mihai Dascalu	1160
<i>Team_KGP at SemEval-2021 Task 7: A Deep Neural System to Detect Humor and Offense with Their Ratings in the Text Data</i>	
Anik Mondal and Raksha Sharma	1169
<i>ZYJ at SemEval-2021 Task 7: HaHackathon: Detecting and Rating Humor and Offense with ALBERT-Based Model</i>	
Yingjia Zhao and Xin Tao	1175
<i>UoR at SemEval-2021 Task 7: Utilizing Pre-trained DistilBERT Model and Multi-scale CNN for Humor Detection</i>	
Zehao Liu, Carl Haines and Huizhi Liang	1179
<i>TECHSSN at SemEval-2021 Task 7: Humor and Offense detection and classification using ColBERT embeddings</i>	
Rajalakshmi Sivanaiah, Angel Deborah S, S Milton Rajendram, Mirnalinee TT, Abrit Pal Singh, Aviansh Gupta and Ayush Nanda	1185
<i>Amherst685 at SemEval-2021 Task 7: Joint Modeling of Classification and Regression for Humor and Offense</i>	
Brian Zyllich, Akshay Gugnani, Gabriel Brookman and Nicholas Samoray	1190
<i>DuluthNLP at SemEval-2021 Task 7: Fine-Tuning RoBERTa Model for Humor Detection and Offense Rating</i>	
Samuel Akrah	1196
<i>CSECU-DSG at SemEval-2021 Task 7: Detecting and Rating Humor and Offense Employing Transformers</i>	
Afrin Sultana, Nabila Ayman and Abu Nowshed Chy	1204
<i>RedwoodNLP at SemEval-2021 Task 7: Ensembled Pretrained and Lightweight Models for Humor Detection</i>	
Nathan Chi and Ryan Chi	1209
<i>EndTimes at SemEval-2021 Task 7: Detecting and Rating Humor and Offense with BERT and Ensembles</i>	
Chandan Kumar Pandey, Chirag Singh and Karan Mangla	1215
<i>IITH at SemEval-2021 Task 7: Leveraging transformer-based humorous and offensive text detection architectures using lexical and hurtlex features and task adaptive pretraining</i>	
Tathagata Raha, Ishan Sanjeev Upadhyay, Radhika Mamidi and Vasudeva Varma	1221
<i>FII FUNNY at SemEval-2021 Task 7: HaHackathon: Detecting and rating Humor and Offense</i>	
Mihai Samson and Daniela Gifu	1226
<i>Counts@IITK at SemEval-2021 Task 8: SciBERT Based Entity And Semantic Relation Extraction For Scientific Data</i>	
Akash Gangwar, Sabhay Jain, Shubham Sourav and Ashutosh Modi	1232
<i>CONNER: A Cascade Count and Measurement Extraction Tool for Scientific Discourse</i>	
Jiarun Cao, Yuejia Xiang, Yunyan Zhang, Zhiyuan Qi, Xi Chen and Yefeng Zheng	1239

<i>Stanford MLab at SemEval-2021 Task 8: 48 Hours Is All You Need</i>	
Patrick Liu, Niveditha Iyer, Erik Rozi and Ethan A. Chi .....	1245
<i>LIORI at SemEval-2021 Task 8: Ask Transformer for measurements</i>	
Adis Davletov, Denis Gordeev, Nikolay Arefyev and Emil Davletov .....	1249
<i>Sattiy at SemEval-2021 Task 9: An Ensemble Solution for Statement Verification and Evidence Finding with Tables</i>	
Xiaoyi Ruan, Meizhi Jin, Jian Ma, Haiqin Yang, Lianxin Jiang, Yang Mo and Mengyuan Zhou	1255
<i>Volta at SemEval-2021 Task 9: Statement Verification and Evidence Finding with Tables using TAPAS and Transfer Learning</i>	
Devansh Gautam, Kshitij Gupta and Manish Shrivastava .....	1262
<i>KaushikAcharya at SemEval-2021 Task 9: Candidate Generation for Fact Verification over Tables</i>	
Kaushik Acharya .....	1271
<i>AttesTable at SemEval-2021 Task 9: Extending Statement Verification with Tables for Unknown Class, and Semantic Evidence Finding</i>	
Harshit Varma, Aadish Jain, Pratik Ratadiya and Abhishek Rathi .....	1276
<i>MedAI at SemEval-2021 Task 10: Negation-aware Pre-training for Source-free Negation Detection Domain Adaptation</i>	
Jinquan Sun, Qi Zhang, Yu Wang and Lei Zhang .....	1283
<i>YNU-HPCC at SemEval-2021 Task 10: Using a Transformer-based Source-Free Domain Adaptation Model for Semantic Processing</i>	
Zhewen Yu, Jin Wang and Xuejie Zhang .....	1289
<i>ECNUICA at SemEval-2021 Task 11: Rule based Information Extraction Pipeline</i>	
Jiaju Lin, Jing Ling, Zhiwei Wang, Jiawei Liu, Qin Chen and Liang He .....	1295
<i>UOR at SemEval-2021 Task 12: On Crowd Annotations; Learning with Disagreements to optimise crowd truth</i>	
Emmanuel Osei-Brefo, Thanet Markchom and Huizhi Liang .....	1303

# Conference Program

*All times are UTC.*

## **5 August 2021**

### **14:00–15:00 Invited Talk**

*Seven Social Factors in Natural Language Processing: Theory and Practice*  
Diyi Yang

### **15:00–15:25 Plenary session: Tasks 1, 2, 4**

#### *SemEval-2021 Task 1: Lexical Complexity Prediction*

Matthew Shardlow, Richard Evans, Gustavo Henrique Paetzold and Marcos Zampieri

#### *OCHADAI-KYOTO at SemEval-2021 Task 1: Enhancing Model Generalization and Robustness for Lexical Complexity Prediction*

Yuki Taya, Lis Kanashiro Pereira, Fei Cheng and Ichiro Kobayashi

#### *SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation (MCL-WiC)*

Federico Martelli, Najla Kalach, Gabriele Tola and Roberto Navigli

#### *SemEval-2021 Task 4: Reading Comprehension of Abstract Meaning*

Boyuan Zheng, Xiaoyu Yang, Yu-Ping Ruan, Zhenhua Ling, Quan Liu, Si Wei and Xiaodan Zhu

#### *TA-MAMC at SemEval-2021 Task 4: Task-adaptive Pretraining and Multi-head Attention for Abstract Meaning Reading Comprehension*

Jing Zhang, Yimeng Zhuang and Yinpei Su

**5 August 2021 (continued)**

**15:25–15:50 Plenary session: Tasks 5, 6, 7**

*SemEval-2021 Task 5: Toxic Spans Detection*

John Pavlopoulos, Jeffrey Sorensen, Léo Laugier and Ion Androutsopoulos

*SemEval-2021 Task 6: Detection of Persuasion Techniques in Texts and Images*

Dimitar Dimitrov, Bishr Bin Ali, Shaden Shaar, Firoj Alam, Fabrizio Silvestri, Hamed Firooz, Preslav Nakov and Giovanni Da San Martino

*Alpha at SemEval-2021 Task 6: Transformer Based Propaganda Classification*

Zhida Feng, Jiji Tang, Jiayang Liu, Weichong Yin, Shikun Feng, Yu Sun and Li Chen

*SemEval 2021 Task 7: HaHackathon, Detecting and Rating Humor and Offense*

J. A. Meaney, Steven Wilson, Luis Chiruzzo, Adam Lopez and Walid Magdy

**15:50–16:00 Announcement of Best Paper Awards & General Discussion**

**16:30–17:30 Poster session: Tasks 1, 2, 4**

+ *This poster session will also be held at 02:00–03:00 and at 11:30–12:30.*

*LangResearchLab NC at SemEval-2021 Task 1: Linguistic Feature Based Modelling for Lexical Complexity*

Raksha Agarwal and Niladri Chatterjee

*Complex words identification using word-level features for SemEval-2020 Task 1*

Jenny A. Ortiz-Zambrano and Arturo Montejo-Ráez

*TUDA-CCL at SemEval-2021 Task 1: Using Gradient-boosted Regression Tree Ensembles Trained on a Heterogeneous Feature Set for Predicting Lexical Complexity*

Sebastian Gombert and Sabine Bartsch

*JCT at SemEval-2021 Task 1: Context-aware Representation for Lexical Complexity Prediction*

Chaya Liebeskind, Otniel Elkayam and Shmuel Liebeskind

**5 August 2021 (continued)**

*IAPUCP at SemEval-2021 Task 1: Stacking Fine-Tuned Transformers is Almost All You Need for Lexical Complexity Prediction*

Kervy Rivas Rojas and Fernando Alva-Manchego

*Uppsala NLP at SemEval-2021 Task 2: Multilingual Language Models for Fine-tuning and Feature Extraction in Word-in-Context Disambiguation*

Huiling You, Xingran Zhu and Sara Stymne

*SkoltechNLP at SemEval-2021 Task 2: Generating Cross-Lingual Training Data for the Word-in-Context Task*

Anton Razzhigaev, Nikolay Arefyev and Alexander Panchenko

*Zhestyatsky at SemEval-2021 Task 2: ReLU over Cosine Similarity for BERT Fine-tuning*

Boris Zhestiankin and Maria Ponomareva

*SzegedAI at SemEval-2021 Task 2: Zero-shot Approach for Multilingual and Cross-lingual Word-in-Context Disambiguation*

Gábor Berend

*ReCAM@IITK at SemEval-2021 Task 4: BERT and ALBERT based Ensemble for Abstract Word Prediction*

Abhishek Mittal and Ashutosh Modi

*ECNU\_ICA\_1 SemEval-2021 Task 4: Leveraging Knowledge-enhanced Graph Attention Networks for Reading Comprehension of Abstract Meaning*

Pingsheng Liu, Linlin Wang, Qian Zhao, Hao Chen, Yuxi Feng, Xin Lin and liang he

*LRG at SemEval-2021 Task 4: Improving Reading Comprehension with Abstract Words using Augmentation, Linguistic Features and Voting*

Abheesht Sharma, Harshit Pandey, Gunjan Chhablani, Yash Bhartia and Tirtharaj Dash

*IIE-NLP-Eyas at SemEval-2021 Task 4: Enhancing PLM for ReCAM with Special Tokens, Re-Ranking, Siamese Encoders and Back Translation*

Yuqiang Xie, Luxi Xing, Wei Peng and Yue Hu

*NLP-IIS@UT at SemEval-2021 Task 4: Machine Reading Comprehension using the Long Document Transformer*

Hossein Basafa, Sajad Movahedi, Ali Ebrahimi, Azadeh Shakery and Hesham Faili

**5 August 2021 (continued)**

**17:30–18:30** Poster session: Tasks 5, 6, 7

+ *This poster session will also be held at 03:00–04:00 and at 12:30–13:30.*

*IITK@Detox at SemEval-2021 Task 5: Semi-Supervised Learning and Dice Loss for Toxic Spans Detection*

Archit Bansal, Abhay Kaushik and Ashutosh Modi

*UniParma at SemEval-2021 Task 5: Toxic Spans Detection Using CharacterBERT and Bag-of-Words Model*

Akbar Karimi, Leonardo Rossi and Andrea Prati

*UPB at SemEval-2021 Task 5: Virtual Adversarial Training for Toxic Spans Detection*

Andrei Paraschiv, Dumitru-Clementin Cercel and Mihai Dascalu

*NLRG at SemEval-2021 Task 5: Toxic Spans Detection Leveraging BERT-based Token Classification and Span Prediction Techniques*

Gunjan Chhablani, Abheesht Sharma, Harshit Pandey, Yash Bhartia and Shan Suthaharan

*UoB at SemEval-2021 Task 5: Extending Pre-Trained Language Models to Include Task and Domain-Specific Information for Toxic Span Prediction*

Erik Yan and Harish Tayyar Madabushi

*Cisco at SemEval-2021 Task 5: What's Toxic?: Leveraging Transformers for Multiple Toxic Span Extraction from Online Comments*

Sreyan Ghosh and Sonal Kumar

*MedAI at SemEval-2021 Task 5: Start-to-end Tagging Framework for Toxic Spans Detection*

Zhen Wang, Hongjie Fan and Junfei Liu

*HamiltonDinggg at SemEval-2021 Task 5: Investigating Toxic Span Detection using RoBERTa Pre-training*

Huiyang Ding and David Jurgens

*WVOQ at SemEval-2021 Task 6: BART for Span Detection and Classification*

Cees Roele

*HumorHunter at SemEval-2021 Task 7: Humor and Offense Recognition with Disentangled Attention*

Yubo Xie, Junze Li and Pearl Pu

## 5 August 2021 (continued)

*Grenzlinie at SemEval-2021 Task 7: Detecting and Rating Humor and Offense*

Renyuan Liu and Xiaobing Zhou

*abcbbc at SemEval-2021 Task 7: ERNIE-based Multi-task Model for Detecting and Rating Humor and Offense*

Chao Pang, Xiaoran Fan, Weiyue Su, Xuyi Chen, Shuohuan Wang, Jiaxiang Liu, Xuan Ouyang, Shikun Feng and Yu Sun

*Humor@IITK at SemEval-2021 Task 7: Large Language Models for Quantifying Humor and Offensiveness*

Aishwarya Gupta, Avik Pal, Bholeshwar Khurana, Lakshay Tyagi and Ashutosh Modi

*RoMa at SemEval-2021 Task 7: A Transformer-based Approach for Detecting and Rating Humor and Offense*

Roberto Labadie, Mariano Jason Rodriguez, Reynier Ortega and Paolo Rosso

## 6 August 2021

### 14:00–15:00 Invited Talk

*Predictability and Informativity in Communication*

Hannah Rohde

### 15:00–15:25 Plenary session: Tasks 8, 9, 12

*SemEval-2021 Task 8: MeasEval – Extracting Counts and Measurements and their Related Contexts*

Corey Harper, Jessica Cox, Curt Kohler, Antony Scerri, Ron Daniel Jr. and Paul Groth

*SemEval-2021 Task 9: Fact Verification and Evidence Finding for Tabular Data in Scientific Documents (SEM-TAB-FACTS)*

Nancy X. R. Wang, Diwakar Mahajan, Marina Danilevsky and Sara Rosenthal

*BreakingBERT@IITK at SemEval-2021 Task 9: Statement Verification and Evidence Finding with Tables*

Aditya Jindal, Ankur Gupta, Jaya Srivastava, Preeti Menghwani, Vijit Malik, Vishesh Kaushik and Ashutosh Modi

*SemEval-2021 Task 12: Learning with Disagreements*

Alexandra Uma, Tommaso Fornaciari, Anca Dumitrache, Tristan Miller, Jon Chamberlain, Barbara Plank, Edwin Simpson and Massimo Poesio

**6 August 2021 (continued)**

**15:25–15:50 Plenary session: Tasks 10, 11**

*SemEval-2021 Task 10: Source-Free Domain Adaptation for Semantic Processing*  
Egoitz Laparra, Xin Su, Yiyun Zhao, Özlem Uzuner, Timothy Miller and Steven Bethard

*BLCUFIGHT at SemEval-2021 Task 10: Novel Unsupervised Frameworks For Source-Free Domain Adaptation*  
Weikang Wang, Yi Wu, Yixiang Liu and Pengyuan Liu

*SemEval-2021 Task 11: NLPContributionGraph - Structuring Scholarly NLP Contributions for a Research Knowledge Graph*  
Jennifer D’Souza, Sören Auer and Ted Pedersen

*UIUC\_BioNLP at SemEval-2021 Task 11: A Cascade of Neural Models for Structuring Scholarly NLP Contributions*  
Haoyang Liu, M. Janina Sarol and Halil Kilicoglu

**15:50–16:00 Announcement of SemEval-2022 Tasks & Closing Remarks**

**16:30–17:30 Poster session: Tasks 8, 9, 12**

+ *This poster session will also be held at 02:00–03:00 and at 11:30–12:30.*

*KGP at SemEval-2021 Task 8: Leveraging Multi-Staged Language Models for Extracting Measurements, their Attributes and Relations*  
Neel Karia, Ayush Kaushal and Faraaz Mallick

*DPR at SemEval-2021 Task 8: Dynamic Path Reasoning for Measurement Relation Extraction*  
Amir Pouran Ben Veysheh, Franck Dernoncourt and Thien Huu Nguyen

*CLaC-np at SemEval-2021 Task 8: Dependency DGCNN*  
Nihatha Lathiff, Pavel PK Khloponin and Sabine Bergler

*CLaC-BP at SemEval-2021 Task 8: SciBERT Plus Rules for MeasEval*  
Benjamin Therien, Parsa Bagherzadeh and Sabine Bergler

**6 August 2021 (continued)**

*THiFly\_Queens at SemEval-2021 Task 9: Two-stage Statement Verification with Adaptive Ensembling and Slot-based Operation*

Yuxuan Zhou, Kaiyin Zhou, Xien Liu, Ji Wu and Xiaodan Zhu

*TAPAS at SemEval-2021 Task 9: Reasoning over tables with intermediate pre-training*

Thomas Müller, Julian Eisenschlos and Syrine Krichene

*BOUN at SemEval-2021 Task 9: Text Augmentation Techniques for Fact Verification in Tabular Data*

Abdullatif Köksal, Yusuf Yüksel, Bekir Yıldırım and Arzucan Özgür

**17:30–18:30 Poster session: Tasks 10, 11**

**+ *This poster session will also be held at 03:00–04:00 and at 12:30–13:30.***

*IITK at SemEval-2021 Task 10: Source-Free Unsupervised Domain Adaptation using Class Prototypes*

Harshit Kumar, Jinang Shah, Nidhi Hegde, Priyanshu Gupta, Vaibhav Jindal and Ashutosh Modi

*PTST-UoM at SemEval-2021 Task 10: Parsimonious Transfer for Sequence Tagging*

Kemal Kurniawan, Lea Frermann, Philip Schulz and Trevor Cohn

*Self-Adapter at SemEval-2021 Task 10: Entropy-based Pseudo-Labeler for Source-free Domain Adaptation*

Sangwon Yoon, Yanghoon Kim and Kyomin Jung

*The University of Arizona at SemEval-2021 Task 10: Applying Self-training, Active Learning and Data Augmentation to Source-free Domain Adaptation*

Xin Su, Yiyun Zhao and Steven Bethard

*KnowGraph@IITK at SemEval-2021 Task 11: Building Knowledge Graph for NLP Research*

Shashank Shailabh, Sajal Chaurasia and Ashutosh Modi

*YNU-HPCC at SemEval-2021 Task 11: Using a BERT Model to Extract Contributions from NLP Scholarly Articles*

Xinge Ma, Jin Wang and Xuejie Zhang

*ITNLP at SemEval-2021 Task 11: Boosting BERT with Sampling and Adversarial Training for Knowledge Extraction*

Genyu Zhang, Yu Su, Changhong He, Lei Lin, Chengjie Sun and Lili Shan

**6 August 2021 (continued)**

*Duluth at SemEval-2021 Task 11: Applying DeBERTa to Contributing Sentence Selection and Dependency Parsing for Entity Extraction*

Anna Martin and Ted Pedersen

*INNOVATORS at SemEval-2021 Task-11: A Dependency Parsing and BERT-based model for Extracting Contribution Knowledge from Scientific Papers*

Hardik Arora, Tirthankar Ghosal, Sandeep Kumar, Suraj Patwal and Phil Goch

# SemEval-2021 Task 1: Lexical Complexity Prediction

## Abstract

This paper presents the results and main findings of SemEval-2021 Task 1 - Lexical Complexity Prediction. We provided participants with an augmented version of the CompLex Corpus (Shardlow et al., 2020). CompLex is an English multi-domain corpus in which words and multi-word expressions (MWEs) were annotated with respect to their complexity using a five point Likert scale. SemEval-2021 Task 1 featured two Sub-tasks: Sub-task 1 focused on single words and Sub-task 2 focused on MWEs. The competition attracted 198 teams in total, of which 54 teams submitted official runs on the test data to Sub-task 1 and 37 to Sub-task 2.

## 1 Introduction

The occurrence of an unknown word in a sentence can adversely affect its comprehension by readers. Either they give up, misinterpret, or plough on without understanding. A committed reader may take the time to look up a word and expand their vocabulary, but even in this case they must leave the text, undermining their concentration. The natural language processing solution is to identify candidate words in a text that may be too difficult for a reader (Shardlow, 2013; Paetzold and Specia, 2016a). Each potential word is assigned a judgment by a system to determine if it was deemed ‘complex’ or not. These scores indicate which words are likely to cause problems for a reader. The words that are identified as problematic can be the subject of numerous types of intervention, such as direct replacement in the setting of lexical simplification (Gooding and Kochmar, 2019), or extra information being given in the context of explanation generation (Rello et al., 2015).

Whereas previous solutions to this task have typically considered the Complex Word Identification (CWI) task (Paetzold and Specia, 2016a; Yimam et al., 2018) in which a binary judgment of a word’s

complexity is given (i.e., is a word complex or not?), we instead focus on the Lexical Complexity Prediction (LCP) task (Shardlow et al., 2020) in which a value is assigned from a continuous scale to identify a word’s complexity (i.e., how complex is this word?). We ask multiple annotators to give a judgment on each instance in our corpus and take the average prediction as our complexity label. The former task (CWI) forces each user to make a subjective judgment about the nature of the word that models their personal vocabulary. Many factors may affect the annotator’s judgment including their education level, first language, specialism or familiarity with the text at hand. The annotators may also disagree on the level of difficulty at which to label a word as complex. One annotator may label every word they feel is above average difficulty, another may label words that they feel unfamiliar with, but understand from the context, whereas another annotator may only label those words that they find totally incomprehensible, even in context. Our introduction of the LCP task seeks to address this annotator confusion by giving annotators a Likert scale to provide their judgments. Whilst annotators must still give a subjective judgment depending on their own understanding, familiarity and vocabulary — they do so in a way that better captures the meaning behind each judgment they have given. By aggregating these judgments we have developed a dataset that contains continuous labels in the range of 0–1 for each instance. This means that rather than a system predicting whether a word is complex or not (0 or 1), instead a system must now predict where, on our continuous scale, a word falls (0–1).

Consider the following sentence taken from a biomedical source, where the target word ‘observation’ has been highlighted:

- (1) The **observation** of unequal expression leads to a number of questions.

In the binary annotation setting of CWI some annotators may rightly consider this term non-complex, whereas others may rightly consider it to be complex. Whilst the meaning of the word is reasonably clear to someone with scientific training, the context in which it is used is unfamiliar for a lay reader and will likely lead to them considering it complex. In our new LCP setting, we are able to ask annotators to mark the word on a scale from very easy to very difficult. Each user can give their subjective interpretation on this scale indicating how difficult they found the word. Whilst annotators will inevitably disagree (some finding it more or less difficult), this is captured and quantified as part of our annotations, with a word of this type likely to lead to a medium complexity value.

LCP is useful as part of the wider task of lexical simplification (Devlin and Tait, 1998), where it can be used to both identify candidate words for simplification (Shardlow, 2013) and rank potential words as replacements (Paetzold and Specia, 2017). LCP is also relevant to the field of readability assessment, where knowing the proportion of complex words in a text helps to identify the overall complexity of the text (Dale and Chall., 1948).

This paper presents SemEval-2021 Task 1: Lexical Complexity Prediction. In this task we developed a new dataset for complexity prediction based on the previously published CompLex dataset. Our dataset covers 10,800 instances spanning 3 genres and containing unigrams and bigrams as targets for complexity prediction. We solicited participants in our task and released a trial, training and test split in accordance with the SemEval schedule. We accepted submissions in two separate Sub-tasks, the first being single words only and the second taking single words and multi-word expressions (modelled by our bigrams). In total 55 teams participated across the two Sub-tasks.

The rest of this paper is structured as follows: In Section 2 we discuss the previous two iterations of the CWI task. In Section 3, we present the CompLex 2.0 dataset that we have used for our task, including the methodology we used to produce trial, test and training splits. In Section 5, we show the results of the participating systems and compare the features that were used by each system. We finally discuss the nature of LCP in Section 7 and give concluding remarks in Section 8

## 2 Related Tasks

**CWI 2016 at SemEval** The CWI shared task was organized at SemEval 2016 (Paetzold and Specia, 2016a). The CWI 2016 organizers introduced a new CWI dataset and reported the results of 42 CWI systems developed by 21 teams. Words in their dataset were considered complex if they were difficult to understand for non-native English speakers according to a binary labelling protocol. A word was considered complex if at least one of the annotators found it to be difficult. The training dataset consisted of 2,237 instances, each labelled by 20 annotators and the test dataset had 88,221 instances, each labelled by 1 annotator (Paetzold and Specia, 2016a).

The participating systems leveraged lexical features (Choubey and Pateria, 2016; Bingel et al., 2016; Quijada and Medero, 2016) and word embeddings (Kuru, 2016; S.P et al., 2016; Gillin, 2016), as well as finding that frequency features, such as those taken from Wikipedia (Konkol, 2016; Wróbel, 2016) were useful. Systems used binary classifiers such as SVMs (Kuru, 2016; S.P et al., 2016; Choubey and Pateria, 2016), Decision Trees (Choubey and Pateria, 2016; Quijada and Medero, 2016; Malmasi et al., 2016), Random Forests (Ronzano et al., 2016; Brooke et al., 2016; Zampieri et al., 2016; Mukherjee et al., 2016) and threshold-based metrics (Kauchak, 2016; Wróbel, 2016) to predict the complexity labels. The winning system made use of threshold-based methods and features extracted from Simple Wikipedia (Paetzold and Specia, 2016b).

A post-competition analysis (Zampieri et al., 2017) with oracle and ensemble methods showed that most systems performed poorly due mostly to the way in which the data was annotated and the the small size of the training dataset.

**CWI 2018 at BEA** The second CWI Shared Task was organized at the BEA workshop 2018 (Yimam et al., 2018). Unlike the first task, this second task had two objectives. The first objective was the binary complex or non-complex classification of target words. The second objective was regression or probabilistic classification in which 13 teams were asked to assign the probability of a target word being considered complex by a set of language learners. A major difference in this second task was that datasets of differing genres: (TEXT GENRES) as well as English, German and Spanish datasets

for monolingual speakers and a French dataset for multilingual speakers were provided (Yimam et al., 2018).

Similar to 2016, systems made use of a variety of lexical features including word length (Wani et al., 2018; De Hertog and Tack, 2018; AbuRa’ed and Saggion, 2018; Hartmann and dos Santos, 2018; Alfter and Pilán, 2018; Kajiwara and Komachi, 2018), frequency (De Hertog and Tack, 2018; Aroyehun et al., 2018; Alfter and Pilán, 2018; Kajiwara and Komachi, 2018), N-gram features (Gooding and Kochmar, 2018; Popović, 2018; Hartmann and dos Santos, 2018; Alfter and Pilán, 2018; Butnaru and Ionescu, 2018) and word embeddings (De Hertog and Tack, 2018; AbuRa’ed and Saggion, 2018; Aroyehun et al., 2018; Butnaru and Ionescu, 2018). A variety of classifiers were used ranging from traditional machine learning classifiers (Gooding and Kochmar, 2018; Popović, 2018; AbuRa’ed and Saggion, 2018), to Neural Networks (De Hertog and Tack, 2018; Aroyehun et al., 2018). The winning system made use of Adaboost with WordNet features, POS tags, dependency parsing relations and psycholinguistic features (Gooding and Kochmar, 2018).

### 3 Data

We previously reported on the annotation of the CompLex dataset (Shardlow et al., 2020) (hereafter referred to as CompLex 1.0), in which we annotated around 10,000 instances for lexical complexity using the Figure Eight platform. The instances spanned three genres: **Europarl**, taken from the proceedings of the European Parliament (Koehn, 2005); **The Bible**, taken from an electronic distribution of the World English Bible translation (Christodouloupoulos and Steedman, 2015) and **Biomedical** literature, taken from the CRAFT corpus (Bada et al., 2012). We limited our annotations to focus only on nouns and multi-word expressions following a Noun-Noun or Adjective-Noun pattern, using the POS tagger from Stanford CoreNLP (Manning et al., 2014) to identify these patterns.

Whilst these annotations allowed us to report on the dataset and to show some trends, the overall quality of the annotations we received was poor and we ended up discarding a large number of the annotations. For CompLex 1.0 we retained only instances with four or more annotations and the low number of annotations (average number of annotators = 7) led to the overall dataset being less

reliable than initially expected

For the Shared Task we chose to boost the number of annotations on the same data as used for CompLex 1.0 using Amazon’s Mechanical Turk platform. We requested a further 10 annotations on each data instance bringing up the average number of annotators per instance. Annotators were presented with the same task layout as in the annotation of CompLex 1.0 and we defined the Likert Scale points as previously:

**Very Easy:** Words which were very familiar to an annotator.

**Easy:** Words with which an annotator was aware of the meaning.

**Neutral:** A word which was neither difficult nor easy.

**Difficult:** Words which an annotator was unclear of the meaning, but may have been able to infer the meaning from the sentence.

**Very Difficult:** Words that an annotator had never seen before, or were very unclear.

These annotations were aggregated with the retained annotations of CompLex 1.0 to give our new dataset, CompLex 2.0, covering 10,800 instances across single and multi-words and across 3 genres.

The features that make our corpus distinct from other corpora which focus on the CWI and LCP tasks are described below:

**Continuous Annotations:** We have annotated our data using a 5-point Likert Scale. Each instance has been annotated multiple times and we have taken the mean average of these annotations as the label for each data instance. To calculate this average we converted the Likert Scale points to a continuous scale as follows: Very Easy  $\rightarrow$  0, Easy  $\rightarrow$  0.25, Neutral  $\rightarrow$  0.5, Difficult  $\rightarrow$  0.75, Very Difficult  $\rightarrow$  1.0.

**Contextual Annotations:** Each instance in the corpus is presented with its enclosing sentence as context. This ensures that the sense of a word can be identified when assigning it a complexity value. Whereas previous work has reannotated the data from the CWI–2018 shared task with word senses (Strohmaier et al., 2020), we do not make explicit sense distinctions between our tokens, instead leaving this task up to participants.

**Repeated Token Instances:** We provide more than one context for each token (up to a maximum of five contexts per genre). These words were annotated separately during annotation, with the expectation that tokens in different contexts would receive differing complexity values. This deliberately penalises systems that do not take the context of a word into account.

**Multi-word Expressions:** In our corpus we have provided 1,800 instances of multi-word expressions (split across our 3 sub-corpora). Each MWE is modelled as a Noun-Noun or Adjective-Noun pattern followed by any POS tag which is not a noun. This avoids selecting the first portion of complex noun phrases. There is no guarantee that these will correspond to true MWEs that take on a meaning beyond the sum of their parts, and further investigation into the types of MWEs present in the corpus would be informative.

**Aggregated Annotations:** By aggregating the Likert scale labels we have generated crowd-sourced complexity labels for each instance in our corpus. We are assuming that, although there is inevitably some noise in any large annotation project (and especially so in crowd-sourcing), this will even out in the averaging process to give a mean value reflecting the appropriate complexity for each instance. By taking the mean average we are assuming unimodal distributions in our annotations.

**Varied Genres:** We have selected for diverse genres as mentioned above. Previous CWI datasets have focused on informal text such as Wikipedia and multi-genre text, such as news. By focusing on specific texts we force systems to learn generalised complexity annotations that are appropriate in a cross-genre setting.

We have presented summary statistics for CompLex 2.0 in Table 1. In total, 5,617 unique words are split across 10,800 contexts, with an average complexity across our entire dataset of 0.321. Each genre has 3,600 contexts, with each split between 3,000 single words and 600 multi-word expressions. Whereas single words are slightly below the average complexity of the dataset at 0.302, multi-word expressions are much more complex at 0.419,

indicating that annotators found these more difficult to understand. Similarly Europarl and the Bible were less complex than the corpus average, whereas the Biomedical articles were more complex. The number of unique tokens varies from one genre to another as the tokens were selected at random and discarded if there were already more than 5 occurrences of the given token already in the dataset. This stochastic selection process led to a varied dataset with some tokens only having one context, whereas others have as many as five in a given genre. On average each token has around 2 contexts.

## 4 Data Splits

In order to run the shared task we partitioned our dataset into Trial, Train and Test splits and distributed these according to the SemEval schedule. A criticism of previous CWI shared tasks is that the training data did not accurately reflect the distribution of instances in the testing data. We sought to avoid this by stratifying our selection process for a number of factors. The first factor we considered was genre. We ensured that an even number of instances from each genre was present in each split. We also stratified for complexity, ensuring that each split had a similar distribution of complexities. Finally we also stratified the splits by token, ensuring that multiple instances containing the same token occurred in only one split. This last criterion ensures that systems do not overfit to the test data by learning the complexities of specific tokens in the training data.

Performing a robust stratification of a dataset according to multiple features is a non-trivial optimisation problem. We solved this by first grouping all instances in a genre by token and sorting these groups by the complexity of the least complex instance in the group. For each genre, we passed through this sorted list and for each set of 20 groups we put the first group in the trial set, the next two groups in the test set and the remaining 17 groups in the training data. This allowed us to get a rough 5-85-10 split between trial, training and test data. The trial and training data were released in this ordered format, however to prevent systems from guessing the labels based on the data ordering we randomised the order of the instances in the test data prior to release. The splits that we used for the Shared Task are available via GitHub<sup>1</sup>.

## 5 Results

The full results of our task can be seen in Appendix A. We had 55 teams participate in our 2 Sub-tasks, with 19 participating in Sub-task 1 only, 1 participating in Sub-task 2 only and 36 participating in both Sub-tasks. We have used Pearson’s correlation for our final ranking of participants, but we have also included other metrics that are appropriate for evaluating continuous and ranked data and provided secondary rankings of these.

Sub-task 1 asked participants to assign complexity values to each of the single words instances in our corpus. For Sub-task 2, we asked participants to submit results on both single words and MWEs. We did not rank participants on MWE-only submis-

sions due to the relatively small number of MWEs in our corpus (184 in the test set).

The metrics we chose for ranking were as follows:

**Pearson’s Correlation:** We chose this metric as our primary method of ranking as it is well known and understood, especially in the context of evaluating systems with continuous outputs. Pearson’s correlation is robust to changes in scale and measures how the input variables change with each other.

**Spearman’s Rank:** This metric does not consider the values output by a system, or in the test labels, only the order of those labels. It was chosen as a secondary metric as it is more robust to outliers than Pearson’s correlation.

**Mean Absolute Error (MAE):** Typically used for the evaluation of regression tasks, we included MAE as it gives an indication of how close the predicted labels were to the gold labels for our task.

**Mean Squared Error (MSE):** There is little difference in the calculation of MSE vs. MAE, however we also include this metric for completeness.

**R2:** This measures the proportion of variance of the original labels captured by the predicted labels. It is possible to do well on all the other metrics, yet do poorly on R2 if a system produces annotations with a different distribution than those in the original labels.

In Table 3 we show the scores of the top 10 systems across our 2 Sub-tasks according to Pearson’s

Team	Task 1	
	Pearson	R2
JUST BLUE	0.7886 (1)	0.6172 (2)
DeepBlueAI	0.7882 (2)	0.6210 (1)
Alejandro Mosquera	0.7790 (3)	0.6062 (3)
Andi	0.7782 (4)	0.6036 (4)
CS-UM6P	0.7779 (5)	0.3813 (47)
tuqa	0.7772 (6)	0.5771 (12)
OCHADAI-KYOTO	0.7772 (7)	0.6015 (5)
BigGreen	0.7749 (8)	0.5983 (6)
CSECU-DSC	0.7716 (9)	0.5909 (8)
IA PUCP	0.7704 (10)	0.5929 (7)
<i>Frequency Baseline</i>	0.5287	0.2779
Task 2		
DeepBlueAI	0.8612 (1)	0.7389 (1)
rg_pa	0.8575 (2)	0.7035 (5)
xiang_wen_tian	0.8571 (3)	0.7012 (7)

CS-UM6P	0.8489 (7)	0.6380 (17)
OCHADAI-KYOTO	0.8438 (8)	0.7103 (3)
LAST	0.8417 (9)	0.7030 (6)
KFU	0.8406 (10)	0.6967 (9)
<i>Frequency Baseline</i>	0.6571	0.4030

Table 3: The top 10 systems for each task according to Pearson’s correlation. We have also included R2 score to help interpret the former. For full rankings, see Appendix A

Correlation. We have only reported on Pearson’s correlation and R2 in these tables, but the full results with all metrics are available in Appendix A. We have included a Frequency Baseline produced using log-frequency from the Google Web1T and linear regression, which was beaten by the majority of our systems. From these results we can see that systems were able to attain reasonably high scores on our dataset, with the winning systems reporting Pearson’s Correlation of 0.7886 for Sub-task 1 and 0.8612 for Sub-task 2, as well as high R2 scores of 0.6210 for Sub-task 1 and 0.7389 for Sub-task 2. The rankings remained stable across Spearman’s rank, MAE and MSE, with some small variations. Scores were generally higher on Sub-task 2 than on Sub-task 1, and this is likely to be because of the different groups of token-types (single words and MWEs). MWEs are known to be more complex than single words and so this fact may have implicitly helped systems to better model the variance of complexities between the two groups.

## 6 Participating Systems

In this section we have analysed the participating systems in our task. System Description papers were submitted by 32 teams. In the subsections below, we have first given brief summaries of some of the top systems according to Pearson’s correlation for each task for which we had a description. We then discuss the features used across different systems, as well as the approaches to the task that different teams chose to take. We have prepared a comprehensive table comparing the features and approaches of all systems for which we have the relevant information in Appendix B.

### 6.1 System Summaries

**DeepBlueAI:** This system attained the highest Pearson’s Correlation on Sub-task 2 and the second highest Pearson’s Correlation on Sub-task 1. It also attained the highest R2 score across both tasks. The system used an ensemble of pre-trained language models fine-tuned for the task with Pseudo Labelling, Data Augmentation, Stacked Training Models and Multi-Sample Dropout. The data was encoded for the transformer models using the genre and token as a query string and the given context as a supplementary input.

**JUST BLUE:** This system attained the highest Pearson’s Correlation for Sub-task 1. The system did not participate in Sub-task 2. This system makes use of an ensemble of BERT and RoBERTa. Separate models are fine-tuned for context and token prediction and these are weighted 20-80 respectively. The average of the BERT models and RoBERTa models is taken to give a final score.

**RG PA:** This system attained the second highest Pearson’s Correlation for Sub-task 2. The system uses a fine-tuned RoBERTa model and boosts the training data for the second task by identifying similar examples from the single-word portion of the dataset to train the multi-word classifier. They use an ensemble of RoBERTa models in their final classification, averaging the outputs to enhance performance.

**Alejandro Mosquera:** This system attained the third highest Pearson’s Correlation for Sub-task 1. The system used a feature-based approach, incorporating length, frequency, semantic features from WordNet and sentence level readability features. These were passed through a Gradient Boosted Regression.

**Andi:** This system attained the fourth highest Pearson’s Correlation for Sub-task 1. They combine a traditional feature based approach with features from pre-trained language models. They use psycholinguistic features, as well as GLoVE and Word2Vec Embeddings. They also take features from an ensemble of Language models: BERT, RoBERTa, ELECTRA, ALBERT, DeBERTa. All features are passed through Gradient Boosted Regression to give the final output score.

**CS-UM6P:** This system attained the fifth highest Pearson’s Correlation for Sub-task 1 and the seventh highest Pearson’s Correlation for Sub-task 2. The system uses BERT and RoBERTa and encodes the context and token for the language models to learn from. Interestingly, whilst this system scored highly for Pearson’s correlation the R2 metric is much lower on both Sub-tasks. This may indicate the presence of significant outliers in the system’s output.

**OCHADAI-KYOTO:** This system attained the seventh highest Pearson’s Correlation on Sub-task 1 and the eight highest Pearson’s Correlation on Sub-task 2. The system used a fine-tuned BERT and RoBERTa model with the token and context encoded. They employed multiple training strategies to boost performance.

## 6.2 Approaches

There are three main types of systems that were submitted to our task. In line with the state of the art in modern NLP, these can be categorised as: Feature-based systems, Deep Learning Systems and Systems which use a hybrid of the former two approaches. Although Deep Learning Based systems have attained the highest Pearson’s Correlation on both Sub-tasks, occupying the first two places in each task, Feature based systems are not far behind, attaining the third and fourth spots on Sub-task 1 with a similar score to the top systems. We have described each approach as applied to our task below.

Feature-based systems use a variety of features known to be useful for lexical complexity. In particular, lexical frequency and word length feature heavily with many different ways of calculating these metrics such as looking at various corpora and investigating syllable or morpheme length. Psycholinguistic features which model people’s perception of words are understandably popular for this task as complexity is a perceived phenomenon.

Semantic features taken from WordNet modelling the sense of the word and it’s ambiguity or abstractness have been used widely, as well as sentence level features aiming to model the context around the target words. Some systems chose to identify named entities, as these may be innately more difficult for a reader. Word inclusion lists were also a popular feature, denoting whether a word was found on a given list of easy to read vocabulary. Finally, word embeddings are a popular feature, coming from static resources such as GLoVE or Word2Vec, but also being derived through the use of Transformer models such as BERT, RoBERTa, XLNet or GPT-2, which provide context dependent embeddings suitable for our task.

These features are passed through a regression system, with Gradient Boosted Regression and Random Forest Regression being two popular approaches amongst participants for this task. Both apply scale invariance meaning that less pre-processing of inputs is necessary.

Deep Learning Based systems invariably rely on a pre-trained language model and fine-tune this using transfer learning to attain strong scores on the task. BERT and RoBERTa were used widely in our task, with some participants also opting for ALBERT, ERNIE, or other such language models. To prepare data for these language models, most participants following this approach concatenated the token with the context, separated by a special token ( $\langle SEP \rangle$ ). The Language Model was then trained and the embedding of the  $\langle CLS \rangle$  token extracted and passed through a further fine-tuned network for complexity prediction. Adaptations to this methodology include applying training strategies such as adversarial training, multi-task learning, dummy annotation generation and capsule networks.

Finally, hybrid approaches use a mixture of Deep Learning by fine-tuning a neural network alongside feature-based approaches. The features may be concatenated to the input embeddings, or may be concatenated at the output prior to further training. Whilst this strategy appears to be the best of both worlds, uniting linguistic knowledge with the power of pre-trained language models, the hybrid systems do not tend to perform as well as either feature based or deep learning systems.

## 6.3 MWEs

For Sub-task 2 we asked participants to submit both predictions for single words and multi-words

from our corpus. We hoped this would encourage participants to consider models that adapted single word lexical complexity to multi-word lexical complexity. We observed a number of strategies that participants employed to create the annotations for this secondary portion of our data.

For systems that employed a deep learning approach, it was relatively simple to incorporate MWEs as part of their training procedure. These systems encoded the input using a query and context, separated by a  $\langle SEP \rangle$  token. The number of tokens prior to the  $\langle SEP \rangle$  token did not matter and either one or two tokens could be placed there to handle single and multi-word instances simultaneously.

However, feature based systems could not employ this trick and needed to devise more imaginative strategies for handling MWEs. Some systems handled them by averaging the features of both tokens in the MWE, or by predicting scores for each token and then averaging these scores. Other systems doubled their feature space for MWEs and trained a new model which took the features of both words into account.

## 7 Discussion

In this paper we have posited the new task of Lexical Complexity Prediction. This builds on previous work on Complex Word Identification, specifically by providing annotations which are continuous rather than binary or probabilistic as in previous tasks. Additionally, we provided a dataset with annotations in context, covering three diverse genres and incorporating MWEs, as well as single tokens. We have moved towards this task, rather than rerunning another CWI task as the outputs of the models are more useful for a diverse range of follow-on tasks. For example, whereas CWI is particularly useful as a preprocessing step for Lexical simplification (identifying which words should be transformed), LCP may also be useful for readability assessment or as a rich feature in other downstream NLP tasks. A continuous annotation allows a ranking to be given over words, rather than binary categories, meaning that we can not only tell whether a word is likely to be difficult for a reader, but also how difficult that word is likely to be. If a system requires binary complexity (as in the case of lexical simplification) it is easy to transform our continuous complexity values into a binary value by placing a threshold on the complex-

ity scale. The value of the threshold to be selected will likely depend on the target audience, with more competent speakers requiring a higher threshold. When selecting a threshold, the categories we used for annotation should be taken into account, so for example a threshold of 0.5 would indicate all words that were rated as neutral or above.

To create our annotated dataset, we employed crowdsourcing with a Likert scale and aggregated the categorical judgments on this scale to give a continuous annotation. It should be noted that this is not the same as giving a truly continuous judgment (i.e., asking each annotator to give a value between 0 and 1). We selected this protocol as the Likert Scale is familiar to annotators and allows them to select according to defined points (we provided the definitions given earlier at annotation time). The annotation points that we gave were not intended to give an even distribution of annotations and it was our expectation that most words would be familiar to some degree, falling in the very easy or easy categories. We pre-selected for harder words to ensure that there were also words in the difficult and very difficult categories. As such, the corpus we have presented is not designed to be representative of the distribution of words across the English language. To create such a corpus, one would need to annotate all words according to our scale with no filtering. The general distribution of annotations in our corpus is towards the easier end of the Likert scale.

A criticism of the approach we have employed is that it allows for subjectivity in the annotation process. Certainly one annotator’s perception of complexity will be different to another’s. Giving fixed values of complexity for every word will not reflect the specific difficulties that one reader, or one reader group will face. The annotations we have provided are averaged values of the annotations given by our annotators, we chose to keep all instances, rather than filtering out those where annotators gave a wide spread of complexity annotations. Further work may be undertaken to give interesting insights into the nature of subjectivity in annotations. For example, some words may be rated as easy or difficult by all annotators, whereas others may receive both easy and difficult annotations, indicating that the perceived complexity of the instance is more subjective. We did not make the individual annotations available as part of the shared task data, to encourage systems to focus

primarily on the prediction of complexity.

An issue with the previous shared tasks is that scores were typically low and that systems tended to struggle to beat reasonable baselines, such as those based on lexical frequency. We were pleased to see that systems participating in our task returned scores that indicated that they had learnt to model the problem well (Pearson’s Correlation of 0.7886 on Task 1 and 0.8612 on Task 2). MWEs are typically more complex than single words and it may be the case that these exhibited a lower variance, and were thus easier to predict for the systems. The strong Pearson’s Correlation is backed up by a high R2 score (0.6172 for Task 1 and 0.7389 for Task 2), which indicates that the variance in the data is captured accurately by the models’ predictions. These models strongly outperformed a reasonable baseline based on word frequency as shown in Table 3.

Whilst we have chosen in this report to rank systems based on their score on Pearson’s correlation, giving a final ranking over all systems, it should be noted that there is very little variation in score between the top systems and all other systems. For Task 1 there are 0.0182 points of Pearson’s Correlation separating the systems at ranks 1 and 10. For Task 2 a similar difference of 0.021 points of Pearson’s Correlation separates the systems at ranks 1 and 10. These are small differences and it may be the case that had we selected a different random split in our dataset this would have led to a different ordering in our results (Gorman and Bedrick, 2019; Søgaard et al., 2020). This is not unique to our task and is something for the SemEval community to ruminate on as the focus of NLP tasks continues to move towards better evaluation rather than better systems.

An analysis of the systems that participated in our task showed that there was little variation between Deep Learning approaches and Feature Based approaches, although Deep Learning approaches ultimately attained the highest scores on our data. Generally the Deep Learning and Feature Based approaches are interleaved in our results table, showing that both approaches are still relevant for LCP. One factor that did appear to affect system output was the inclusion of context, whether that was in a deep learning setting or a feature based setting. Systems which reported using no context appeared to perform worse in the overall rankings. Another feature that may have helped performance

is the inclusion of previous CWI datasets (Yimam et al., 2017; Maddela and Xu, 2018). We were aware of these when developing the corpus and attempted to make our data sufficiently distinct in style to prevent direct reuse of these resources.

A limitation of our task is that it focuses solely on LCP for the English Language. Previous CWI shared tasks (Yimam et al., 2018) and simplification efforts (Saggion et al., 2015; Aluísio and Gasperin, 2010) have focused on languages other than English and we hope to extend this task in the future to other languages.

## 8 Conclusion

We have presented the SemEval-2021 Task 1 on Lexical Complexity Prediction. We developed a new dataset focusing on continuous annotations in context across three genres. We solicited participants via SemEval and 55 teams submitted results across our two Sub-tasks. We have shown the results of these systems and discussed the factors that helped systems to perform well. We have analysed all the systems that participated and categorised their findings to help future researchers understand which approaches are suitable for LCP.

## Abstract

We propose an ensemble model for predicting the lexical complexity of words and multiword expressions (MWEs). The model receives as input a sentence with a target word or MWE and outputs its complexity score. Given that a key challenge with this task is the limited size of annotated data, our model relies on pretrained contextual representations from different state-of-the-art transformer-based language models (i.e., BERT and RoBERTa), and on a variety of training methods for further enhancing model generalization and robustness: multi-step fine-tuning and multi-task learning, and adversarial training. Additionally, we propose to enrich contextual representations by adding hand-crafted features during training. Our model achieved competitive results and ranked among the top-10 systems in both subtasks.

## 1 Introduction

Predicting the difficulty of a word in a given context is useful in many natural language processing (NLP) applications such as lexical simplification. Previous efforts (Paetzold and Specia, 2016; Yimam et al., 2018; Zampieri et al., 2017) have focused on framing this as a binary classification task, which might not be ideal, since a word close to the decision boundary is assumed to be just as complex as one further away (Shardlow et al., 2020). To alleviate this issue, SemEval-2021 Task 1 (Shardlow et al., 2021a) formulates this task as a regression task, where a model should predict the complexity value of words (Subtask 1) and MWEs (Subtask 2) in context.

This paper describes the system developed by the Ochadai-Kyoto team for SemEval-2021 Task 1. Given that a key challenge in this task is the limited size of annotated data, we follow best practices from recent work on enhancing model generalization and robustness, and propose a model

Task	Domain	Train	Trial	Test
Subtask 1 (single-word)	Europarl	2512	143	345
	Biomed	2576	135	289
	Bible	2574	143	283
	All	7662	421	917
Subtask 2 (MWE)	Europarl	498	37	65
	Biomed	514	33	53
	Bible	505	29	66
	All	1517	99	184

Table 1: Summary of the Complex dataset.

ensemble that leverages pretrained representations (i.e. BERT and RoBERTa), multi-step fine-tuning, multi-task learning and adversarial training. Additionally, we propose to enrich contextual representations by incorporating hand-crafted features during training. Our model ranked 7th out of 54 participating teams on Subtask 1, and 8th out of 37 teams on Subtask 2, obtaining Pearson correlation scores of 0.7772 and 0.8438, respectively.

## 2 Task Description

SemEval-2021 Task 1 provides participants with an augmented version of the CompLex dataset (Shardlow et al., 2020), a multi-domain English dataset with sentences containing words and MWEs annotated on a continuum scale of complexity, in the range of [0,1]. Easier words and MWEs are assigned lower complexity scores, while the more challenging ones are assigned higher scores. This corpus contains a balanced number of sentences from three different domains: Bible (Christodouloupoulos and Steedman, 2015), Europarl (Koehn, 2005) and Biomedical (Bada et al., 2012). The task is to predict the complexity value of single words (Subtask 1) and MWEs (Subtask 2) in context. The statistics of the corpus are presented in Table 1. Our team participated in both subtasks, and the next section outlines the overview of our model.

### 3 System Overview

We focus on exploring different training techniques using BERT and RoBERTa, given their superior performance on a wide range of NLP tasks. Each text encoder and training method used in our model are detailed below.

#### 3.1 Text Encoders

**BERT** (Devlin et al., 2019): We use the BERT<sub>BASE</sub> model released by the authors. It consists of 12 transformer layers, 12 self-attention heads per layer, and a hidden size of 768.

**RoBERTa** (Liu et al., 2019b): We use both the RoBERTa<sub>BASE</sub> and RoBERTa<sub>LARGE</sub> models released by the authors. Similar to BERT, RoBERTa<sub>BASE</sub> consists of 12 transformer layers, 12 self-attention heads per layer, and a hidden size of 768. RoBERTa<sub>LARGE</sub> consists of 24 transformer layers, 16 self-attention heads per layer, and a hidden size of 1024.

#### 3.2 Training Procedures

**Standard fine-tuning:** This is the standard fine-tuning procedure where we fine-tune BERT and RoBERTa on each subtask-specific data.

**Feature-enriched fine-tuning (FEAT):** During training, we enrich BERT and RoBERTa representations with word frequency information of the target word or MWE. We compute the log frequency values using the Wiki40B corpus (Guo et al., 2020). For MWEs, we compute the log of the average of the frequency of each component word. After applying the min-max normalization to this feature, we concatenate it to the CLS token vector obtained from the last layer of BERT and RoBERTa.

**Multi-step fine-tuning (MSFT):** Multi-step fine-tuning works by performing a second stage of pre-training with data-rich related supervised tasks. It has been shown to improve model robustness and performance, especially for data-constrained scenarios (Phang et al., 2018; Camburu et al., 2019). Due to the limited size of the data provided for Subtask 2, we first fine-tune BERT and RoBERTa on the Subtask 1 dataset. This model’s parameters are further refined by fine-tuning on the Subtask 2 dataset.

**Multi-task learning (MTL):** Multi-task learning is an effective training paradigm to promote model generalization ability and performance (Caruana, 1997; Liu et al., 2015, 2019a; Ruder, 2017; Collobert et al., 2011). It works by leveraging data

from many (related) tasks. In our experiments, we use the MT-DNN framework (Liu et al., 2019a, 2020b), which incorporates BERT and RoBERTa as the shared text encoding layers (shared across all tasks), while the top layers are task-specific. We used the pre-trained BERT and RoBERTa models to initialize its shared layers and refined them via MTL on both subtasks (i.e. Subtask 1 and Subtask 2).

**Adversarial training (ADV):** Adversarial training has proven effective in improving model generalization and robustness in computer vision (Madry et al., 2017; Goodfellow et al., 2014) and more recently in NLP (Zhu et al., 2019; Jiang et al., 2019; Cheng et al., 2019; Liu et al., 2020a; Pereira et al., 2020). It works by augmenting the input with a small perturbation that maximizes the adversarial loss:

$$\min_{\theta} \mathbb{E}_{(x,y) \sim D} [\max_{\delta} l(f(x + \delta; \theta), y)] \quad (1)$$

where the inner maximization can be solved by projected gradient descent (Madry et al., 2017). Recently, adversarial training has been successfully applied to NLP as well (Zhu et al., 2019; Jiang et al., 2019; Pereira et al., 2020). In our experiments, we use SMART (Jiang et al., 2019), which instead regularizes the standard training objective using *virtual adversarial training* (Miyato et al., 2018):

$$\min_{\theta} \mathbb{E}_{(x,y) \sim D} [l(f(x; \theta), y) + \alpha \max_{\delta} l(f(x + \delta; \theta), f(x; \theta))] \quad (2)$$

Effectively, the adversarial term encourages smoothness in the input neighborhood, and  $\alpha$  is a hyperparameter that controls the trade-off between standard errors and adversarial errors.

#### 3.3 Ensemble Model

Ensemble of deep learning models has proven effective in improving test accuracy (Allen-Zhu and Li, 2020). We built different ensemble models by taking an unweighted average of the outputs of a few independently trained models. Each single model was trained on standard fine-tuning, multi-step fine-tuning, multi-task learning, or adversarial training, using different text encoders (i.e. BERT or RoBERTa).

## 4 Experiments

### 4.1 Implementation Details

Our model implementation is based on the MT-DNN framework (Liu et al., 2019a, 2020b). We

use BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019b) as the text encoders. We used ADAM (Kingma and Ba, 2015) as our optimizer with a learning rate in the range  $\in \{8 \times 10^{-6}, 9 \times 10^{-6}, 1 \times 10^{-5}\}$  and a batch size  $\in \{8, 16, 32\}$ . The maximum number of epochs was set to 10. A linear learning rate decay schedule with warm-up over 0.1 was used, unless stated otherwise. To avoid gradient exploding, we clipped the gradient norm within 1. All the texts were tokenized using wordpieces and were chopped to spans no longer than 512 tokens. During adversarial training, we follow (Jiang et al., 2019) and set the perturbation size to  $1 \times 10^{-5}$ , the step size to  $1 \times 10^{-3}$ , and to  $1 \times 10^{-5}$  the variance for initializing the perturbation. The number of projected gradient steps and the  $\alpha$  parameter (Equation 2) were both set to 1.

We follow (Devlin et al., 2019), and set the first token as the [CLS] token when encoding the input. For Subtask 1, we separate the input sentence and the target token with the special token [SEP]. e.g. [CLS] This was the *length* of Sarah’s life [SEP] *length* [SEP]. For Subtask 2, such encoding led to lower performance of our system. Therefore, we consider only the target MWE when encoding the input, e.g. [CLS] *financial world* [SEP].

For each subtask, we used the trial dataset released by organizers as development set (see Table 1). We select the best epoch and the best hyper-parameters using performance (measured in terms of Pearson correlation score) on this development set. We also experimented on saving the best epoch and best hyper-parameters for each domain (Bible, Biomedical and Europarl).

## 4.2 Main Results

Submitted systems were evaluated on five metrics: Pearson correlation (R), Spearman correlation (Rho), Mean Absolute Error (MAE), Mean Squared Error (MSE), and R-squared (R2). The systems were ranked from highest Pearson correlation score to lowest. We built several models that use different text encoders and different training methods, as described in Section 3. See Table 2 for the results. First, we observe that ensembling different single models yield better performance on both tasks. Furthermore, models that use feature-enriched representations, multi-task learning, multi-step fine-tuning and adversarial training surpass models that use the standard fine-tuning approach. We detail next the results for each subtask.

For Subtask 1, the single models that used RoBERTa, adversarial training, multi-task learning and feature-enriched representations performed best on the development set. Moreover, saving the best epoch and hyper-parameters for each domain performed better than saving the best epoch and hyper-parameters without domain distinction. Among the single models, the model that performed best on the development set was the model that uses RoBERTa<sub>LARGE</sub> and adversarial training (RoBERTa<sub>LARGE</sub>(ADV)<sub>domain</sub> model, with a Pearson score of 0.8441). The second best single model was the model that uses RoBERTa<sub>BASE</sub> and feature-enriched contextual representations (RoBERTa<sub>BASE</sub>(FEAT)<sub>domain</sub> model, with a Pearson score of 0.8391). The third best single model was the model that uses RoBERTa<sub>LARGE</sub> and multi-task learning (RoBERTa<sub>LARGE</sub>(MTL)<sub>domain</sub> model, with a Pearson score of 0.8371). Thus, we ensemble these three single models in different ways when making our submissions. The ensemble model that performed best on the test set (Ensemble  $2_{\text{single\_word}}$ ) was the model that combined feature-enriched contextual representations (RoBERTa<sub>BASE</sub>(FEAT)<sub>domain</sub>), adversarial training (RoBERTa<sub>LARGE</sub>(ADV)<sub>domain</sub>), and multi-task learning (RoBERTa<sub>LARGE</sub>(MTL)<sub>domain</sub>). This ensemble model obtained development and test set Pearson scores of 0.8570 and 0.7772, respectively.

For Subtask 2, the single models that use BERT<sub>BASE</sub> outperformed models that use RoBERTa, on the development set. Moreover, we noted that using the Subtask 1 dataset as auxiliary dataset by performing multi-step fine-tuning and multi-task learning greatly help to improve the performance. For instance, the BERT<sub>BASE</sub>(MSFT) outperformed the BERT<sub>BASE</sub> model by 0.0405 Pearson correlation points (0.7965 vs 0.8370). The ensemble model that performed best on the test set (Ensemble  $1_{\text{MWE}}$ ) was the model that combined multi-step fine-tuning and multi-task learning using BERT, i.e. BERT<sub>BASE</sub>(MSFT) and BERT<sub>BASE</sub>(MTL) models, respectively, and multi-task learning using RoBERTa (RoBERTa<sub>LARGE</sub>(MTL) model). This ensemble model obtained development and test set Pearson scores of 0.8461 and 0.8438, respectively. Different from Subtask 1, we observe that saving the best epoch and hyper-parameters for each domain on the development set performed worse than saving the best epoch and hyper-parameters without do-

Table 2: Comparison of different text encoders and different training methods on the single word lexical complexity prediction task (Subtask 1) and on the MWE lexical complexity prediction task (Subtask 2). Best results for single and ensemble models are highlighted in **bold**. † indicates that we consider the full context surrounding the MWE when encoding the input. In the other models for Subtask 2, we consider only the target MWE. \* indicates results obtained from the Task’s official leaderboard: (<https://competitions.codalab.org/competitions/27420#results>). ✓ indicates each single model that was used in the ensemble, indicated in each column by ○.

main distinction. We hypothesize that, due to the small size of the data provided for Subtask 2, saving the best epoch and hyper-parameters without domain distinction might avoid overfitting.

## 5 Analysis

We briefly analyse our best models’ results on the test set for each subtask. Figure 1 (top) shows a comparison between our best ensemble model’s

predictions for Subtask 1 (Ensemble 2<sub>single\_word</sub>) and the gold answers. We observe that our model often fails to predict correctly in the range where samples have a complexity score below 0.2. We hypothesize this might be due to the skewed distribution of the golden complexity scores for each domain, as shown in Table 4. A possible solution might be to build domain-specific models.

Figure 1 (bottom) shows a comparison between the best ensemble model’s predictions for Subtask

Domain	Sentence	Target	Prediction	Label
<b>Sub-task 1</b>				
Europarl	The Swedish Presidency aims to maintain the debate on animal welfare and good animal <i>husbandry</i> .	<i>husbandry</i>	0.3270	0.53143
Biomed	We adopted the same strategy to investigate the relative contribution of the 129 <i>Chromosome 1</i> segment and the Apes gene to each disease trait.	<i>Chromosome</i>	0.4865	0.2237
Bible	God has gone up with a <i>shout</i> , Yahweh with the sound of a trumpet.	<i>shout</i>	<b>0.2032</b>	<b>0.2031</b>
<b>Sub-task 2</b>				
Biomed	These studies strongly suggest that the hsp family of proteins has <i>other functions</i> in addition to protecting proteins and cells during stress.	<i>other functions</i>	0.2564	0.4167

Bible	In the <i>dry season</i> , they vanish.	<i>dry season</i>	<b>0.2832</b>	<b>0.2857</b>

Table 3: Examples of successful and poor predictions on the test set by the best ensemble models submitted for each subtask (Ensemble  $2_{\text{single\_word}}$  and Ensemble  $1_{\text{MWE}}$  models). Successful predictions are highlighted in **bold**.

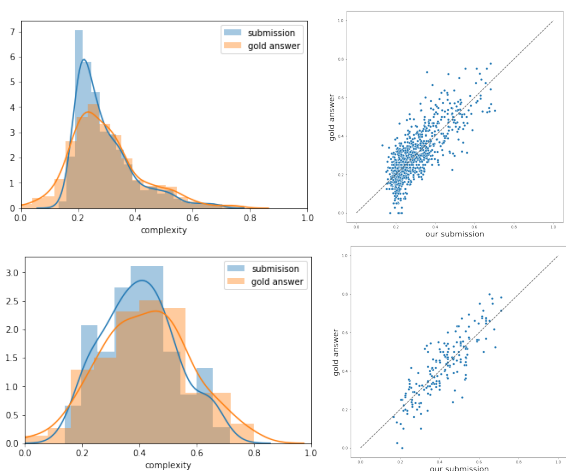

Figure 1: Comparison between the Ensemble  $2_{\text{single\_word}}$  and Ensemble  $1_{\text{MWE}}$  models' predictions submitted for Sub-task 1 (top) and Sub-task 2 (bottom), respectively, and the gold answers. On the left, we show the distribution of the correct complexity score and our submission. On the right, we show a scatter plot where the x-axis corresponds to our model's predictions and the y-axis corresponds to the gold answers.

2 (Ensemble  $1_{\text{MWE}}$ ), and the gold answers. Compared to Subtask 1, the data distribution of the development and test sets of Subtask 2 look more similar, hence a possible reason why the development and test set scores were closer than in Subtask 1 (the best ensemble models obtained development and test set scores of 0.8570 and 0.7772, respectively, in Subtask 1, and 0.8461 and 0.8438, respectively, in Subtask 2). Table 3 shows examples of successful and poor predictions made by Ensemble  $2_{\text{single\_word}}$  and Ensemble  $1_{\text{MWE}}$  models. Table 4 shows how the performance of these models varies across domains. The Biomedical domain obtained the highest Pearson correlation scores on both subtasks, which indicates that

	Bible	Europarl	Biomed
<b>Sub-task 1</b>			
<b>MAE</b>	0.0679	0.0549	0.0638
<b>R</b>	0.7329	0.7213	0.8358
<b>Sub-task 2</b>			
<b>MAE</b>	0.0721	0.0592	0.0667
<b>R</b>	0.8114	0.6374	0.9104

Table 4: Performance of Ensemble  $2_{\text{single\_word}}$  and Ensemble  $1_{\text{MWE}}$  models on each domain and subtask.

might be a sharper difference between simple and complex words in this corpus (Shardlow et al., 2021b).

## 6 Conclusion

In this paper, we have presented the implementation of the Ochadai-Kyoto system submitted to the SemEval-2021 Task 1. Our model ranked 7th out of 54 participating teams on Subtask 1, and 8th out of 37 teams on Subtask 2. We proposed an ensemble model that leverages pretrained representations, multi-step fine-tuning, multi-task learning and adversarial training. We also proposed to enrich contextual representations by incorporating hand-crafted features during training. In future efforts, we plan to further improve our model to better handle data-constraint and domain-shift scenarios.

## Abstract

In this paper, we introduce the first SemEval task on Multilingual and Cross-Lingual Word-in-Context disambiguation (MCL-WiC). This task allows the largely under-investigated inherent ability of systems to discriminate between word senses within and across languages to be evaluated, dropping the requirement of a fixed sense inventory. Framed as a binary classification, our task is divided into two parts. In the multilingual sub-task, participating systems are required to determine whether two target words, each occurring in a different context within the same language, express the same meaning or not. Instead, in the cross-lingual part, systems are asked to perform the task in a cross-lingual scenario, in which the two target words and their corresponding contexts are provided in two different languages. We illustrate our task, as well as the construction of our manually-created dataset including five languages, namely Arabic, Chinese, English, French and Russian, and the results of the participating systems. Datasets and results are available at: <https://github.com/SapienzaNLP/mcl-wic>.

## 1 Introduction

During recent decades, the field of Natural Language Processing (NLP) has witnessed the development of an increasing number of neural approaches to representing words and their meanings. Word embeddings encode a target word type with one single vector based on co-occurrence information. However, word embeddings conflate different meanings of a single target word into the same representation, thus they fail to capture the polysemous nature of words. To address this limitation, more sophisticated representations such as multi-prototype and contextualized embeddings have been put forward. Multi-prototype embeddings concentrate on the semantics which underlie

a target word by clustering occurrences based on their context similarities (Neelakantan et al., 2015; Pelevina et al., 2016). In an effort to exploit the knowledge derived from lexical-knowledge bases, Iacobacci et al. (2015) introduced a new approach which allows sense representations to be linked to a predefined sense inventory. More recently, contextualized embeddings were proposed. These representations are obtained by means of neural language modeling, e.g. using LSTMs (Melamud et al., 2016) or the Transformer architecture (Devlin et al., 2019; Conneau et al., 2020), and are capable of representing words based on the context in which they occur. Contextualized representations have also been used to obtain effective sense embeddings (Loureiro and Jorge, 2019; Scarlini et al., 2020a,b; Calabrese et al., 2020).

Although virtually all the above approaches can be evaluated in downstream applications, the inherent ability of the various embeddings to capture meaning distinctions still remains largely under-investigated. While Word Sense Disambiguation (WSD), i.e. the task of determining the meaning of a word in a given context (Navigli, 2009), has long explored the aforementioned ability, the task does not make it easy to test approaches that are not explicitly linked to existing sense inventories, such as WordNet (Miller et al., 1990) and BabelNet (Navigli and Ponzetto, 2010). This has two major drawbacks. First, sense inventories are not always available, especially for rare languages. Second, such requirement limits the evaluation of word and sense representations which are not bound to a sense inventory. To tackle this limitation, some benchmarks have recently been proposed. The CoSimLex dataset (Armendariz et al.) and the related SemEval-2020 Task 3 (Armendariz et al., 2020) focus on evaluating the similarity of word pairs which occur in the same context. More recently, the Word-in-Context (WiC) task (Pilehvar

and Camacho-Collados, 2019), included in the SuperGLUE benchmark for Natural Language Understanding (NLU) systems (Wang et al., 2019) and its multilingual extension XL-WiC (Raganato et al., 2020), require systems to determine whether a word occurring in two different sentences is used with the same meaning, without relying on a pre-defined sense inventory. For instance, given the following sentence pair:

- the *mouse* eats the cheese,
- click the right *mouse* button,

the ideal system should establish that the target word *mouse* is used with two different meanings.

Despite the steps forward made in this promising research direction, existing benchmarks suffer from the following shortcomings: i) they are mostly automatically retrieved; ii) they do not enable cross-lingual evaluation scenarios in which systems are tested in different languages at the same time; iii) they do not cover all open-class parts of speech.

In order to address the aforementioned drawbacks, we propose the first SemEval task on Multilingual and Cross-Lingual Word-in-Context disambiguation (MCL-WiC) and present the first entirely manually-annotated dataset for the task. Importantly, MCL-WiC enables new cross-lingual evaluation scenarios covering all open-class parts of speech, as well as a wide range of domains and genres. The dataset is available in five European and non-European languages, i.e. Arabic (Ar), Chinese (Zh), English (En), French (Fr) and Russian (Ru).

## 2 Related Work

Several different tasks have been put forward which go beyond traditional WSD and drop the requirement of fixed sense inventories. Among the first alternatives we cite monolingual and cross-lingual Lexical Substitution (McCarthy and Navigli, 2007; Mihalcea et al., 2010). Word-in-context similarity has also been proposed as a way to capture the dynamic nature of word meanings: the Stanford Contextual Word Similarities (SCWS) dataset, proposed by Huang et al. (2012), contains human judgements on pairs of words in context. Along these same lines, Armendariz et al. introduced CoSimLex, a dataset designed to evaluate the ability of models to capture word similarity judgements provided by humans.

MCL-WiC				
Sub-task	Dataset	Train	Dev	Test
Multilingual	Ar-Ar	-	500	500
	En-En	4000	500	500
	Fr-Fr	-	500	500
	Ru-Ru	-	500	500
	Zh-Zh	-	500	500
Cross-lingual	En-Ar	-	-	500
	En-Fr	-	-	500
	En-Ru	-	-	500
	En-Zh	-	-	500

Table 1: The MCL-WiC dataset: number of unique lexemes divided by sub-task and dataset. The second column (Dataset) indicates the available language combination.

More recently, Pilehvar and Camacho-Collados (2019) presented the Word-in-Context (WiC) dataset. Framed as a binary classification task, WiC is a benchmark for the evaluation of context-dependent embeddings. However, WiC covers only one language, i.e. English, and two parts of speech, namely nouns and verbs. To enable evaluation in languages other than English, Raganato et al. (2020) proposed XL-WiC, an extension of the WiC dataset which covers different European and non-European languages, thus allowing for zero-shot settings. Despite their effectiveness, both the WiC and XL-WiC datasets are not manually created and do not cover all open-class parts of speech. Moreover, they do not consider cross-lingual evaluation scenarios in which systems are tested in more than one language at the same time, thus highlighting the need for a new evaluation benchmark.

## 3 The Multilingual and Cross-lingual Word-in-Context Task

In this Section, we present our SemEval task and describe a new dataset called Multilingual and Cross-lingual Word-in-Context (MCL-WiC). The task is divided into a multilingual and a cross-lingual sub-task, each containing different datasets divided according to language combination. Each dataset instance is focused on a given lexeme<sup>1</sup> and is composed of a unique ID, a target lemma, its part of speech, two sentential contexts in which the target lemma occurs, and positional indices for retrieving the target words in each sentence. In

<sup>1</sup>Each lexeme corresponds to a lemma and its part of speech.

ID	Lemma	POS	Start	End	Sentence
training.en-en.624	leave	VERB	47	51	As mentioned, it was clear that people usually <b>left</b> their homelands in search of a better life.
			13	17	It should be <b>left</b> entirely to the parties to a dispute to choose the modalities of settlement they deemed most appropriate.
training.en-en.625	leave	VERB	47	51	As mentioned, it was clear that people usually <b>left</b> heir homelands in search of a better life.
			80	87	However, no hasty conclusion should be drawn that the Republic of Macedonia was <b>leaving</b> no room for future improvement.

Table 2: Excerpt from the multilingual dataset (En-En): two sentence pairs sharing the same first sentence are shown, with the target word occurrence in bold type.

ID	Tag
training.en-en.624	F
training.en-en.625	F

Table 3: Example of gold file.

both sub-tasks, for each lexeme, we provide two different instances which share one sentence<sup>2</sup>. We provide training and development data only for the multilingual sub-task, whereas test data is provided for both sub-tasks. While training data is produced only in English, both the development and the test data are available in other languages as well. Table 1 provides an overview of the composition of the dataset, which we detail further in the remainder of this paper. Compared to existing datasets, MCL-WiC makes it possible to perform a thorough, high-quality evaluation of a multitude of approaches, ranging from architectures based on pre-trained language models to traditional WSD systems.

In the following, we introduce the multilingual and cross-lingual sub-tasks. Then, we describe the data sources, the selection of the target lexemes and sentence pairs and, finally, the annotation process.

### 3.1 Multilingual sub-task

This sub-task allows systems to be evaluated in a scenario in which only one language at a time is considered. To this end, we manually select sentence pairs in the following language combinations:

<sup>2</sup>To speed up the annotation process, for each lexeme, we selected a fixed sentence and annotated two other sentences so as to obtain two instances.

Ar-Ar, En-En, Fr-Fr, Ru-Ru and Zh-Zh. The multilingual sub-task includes training, development and test splits as reported in Table 1 (top). The training data, available only in English, contains 4000 unique lexemes and 8000 sentence pairs. Instead, both the development and test data splits include 500 unique lexemes and 1000 sentence pairs for each of the aforementioned language combinations. To avoid any bias, each dataset contains a balanced number of tags, i.e. 50% True (T) and 50% False (F).

In Table 2,<sup>3</sup> we report two instances derived from En-En, which share the first sentence. Given the target lemma *leave*, its part of speech (verb) and two sentences in which two occurrences of *leave* are contained, participating systems are required to determine whether the target occurrences (shown in bold type in the Table) share the same meaning (T) or not (F). Since the senses of the target occurrences differ in both sentence pairs, they are both tagged with F in the gold file, as shown in Table 3. Note that, in MCL-WiC, target occurrences can be inflected forms of the target lemma.

### 3.2 Cross-lingual sub-task

The cross-lingual sub-task allows systems to be tested and compared in a cross-lingual scenario. Here, sentence pairs are composed of a sentence in English and a sentence in one of the other MCL-WiC languages, including the following language combinations: En-Ar, En-Fr, En-Ru and En-Zh. It is worth mentioning that, in contrast to past efforts,

<sup>3</sup>Due to space limits we removed some words from the sentences reported in Table 2 and 4.

ID	Lemma	POS	Start	End	Sentence
test.en-ru.18	light	NOUN	46	51	Using a technique for concentrating the solar <b>light</b> , resulted in an overall efficiency of 20%.
			39	50	Каждый представитель может выступать в <b>зависимости</b> от полученных указаний.
test.en-ru.19	light	NOUN	46	51	Using a technique for concentrating the solar <b>light</b> , resulted in an overall efficiency of 20%.
			2	8	С <b>учетом</b> работы, оратор считает целесообразным изложить принципы.

Table 4: Excerpt from the cross-lingual dataset (En-Ru): two sentence pairs sharing the same first sentence are shown, with the target word occurrence in bold type.

all sentences are manually selected and annotated, and that Arabic and Russian are included in a Word-in-Context dataset for the first time.

We report two cross-lingual instances (sentence pairs) in Table 4 for the En-Ru language combination, which share the first sentence. Given the English lemma *light*, its part of speech (noun), and two sentences, one in English where *light* occurs and one in Russian where a translation of *light* appears, participants are asked to determine whether the target occurrence (in bold in the Table) of *light* and its translations into Russian *зависимости* and *учетом* share the same meaning or not. Importantly, translations are allowed to be multi-word expressions and periphrases.

The cross-lingual sub-task comprises test data only and includes 500 unique English lexemes and 1000 sentence pairs for each language combination as reported in Table 1 (bottom). Note that, in this case, all cross-lingual datasets share the same English target lexemes. Similarly to its multilingual counterpart, the data in this sub-task contains a balanced number of T (50%) and F (50%) tags.

### 3.3 Selection of the data and annotation

**Sources of the data** In order to construct MCL-WiC, we leveraged three resources. First, we used the BabelNet<sup>4</sup> multilingual semantic network (Navigli and Ponzetto, 2010) to obtain a set of lexemes in all languages of interest. Subsequently, we extracted sentence pairs containing occurrences of such lexemes from two corpora, namely the United Nations Parallel Corpus (Ziemski et al., 2016, UNPC)<sup>5</sup> and Wikipedia<sup>6</sup>. UNPC is a collection of official records and parliamentary docu-

ments of the United Nations available in the six UN languages<sup>7</sup>, whereas Wikipedia is a wide-coverage multilingual collaborative encyclopedia. These corpora were selected due to their wide coverage in terms of domains and languages. In fact, such heterogeneity allowed for the creation of a new competitive benchmark capable of evaluating the generalization ability of a system in discriminating senses in different domains and across languages. With this aim in view, we derived 50% of the selected sentence pairs from UNPC and the remaining 50% from Wikipedia.

**Selection of lexemes** Starting from BabelNet, we extracted a set of 5250 unique ambiguous lexemes in English and 1000 unique lexemes for each of the following languages: Arabic, Chinese, French and Russian. The selected pairs in English were distributed as follows: 4000 for the training data, 500 for the development data and 750 for the test data (500 for the multilingual sub-task and 250 for the cross-lingual sub-task<sup>8</sup>; we enriched the latter with additional 250 pairs derived from the multilingual test data). Instead, the selected pairs in languages other than English were included in the multilingual sub-task only and distributed as follows: 500 for the development data and 500 for the test data. We selected the target lexemes starting from basic vocabulary words and such that they had at least three senses in BabelNet. A key goal was to cover all open-class parts of speech, namely nouns, verbs, adjectives and adverbs, whose distribution in MCL-WiC is shown in Table 5. The target lexemes were chosen so as to avoid phrasal verbs and multi-word expressions.

<sup>4</sup><https://babelnet.org/>

<sup>5</sup><https://conferences.unite.un.org/uncorpus/>

<sup>6</sup><https://wikipedia.org>

<sup>7</sup>Arabic, Chinese, English, French, Spanish and Russian.

<sup>8</sup>We recall that, in the cross-lingual sub-task, the target lexemes are provided in English and shared across all datasets.

	En-En			Ar-Ar		Fr-Fr		Ru-Ru		Zh-Zh		En-*

Table 5: Part-of-speech distribution in MCL-WiC. \* indicates all languages supported in MCL-WiC other than English.

**Selection and annotation of sentence pairs** For each of the target lexemes, we annotated two sentence pairs from either UNPC or Wikipedia. All selected sentences were well-formatted and, most importantly, provided a sufficient semantic context to determine the meaning of the target occurrences unequivocally. Subsequently, each sentence pair was associated with a tag, depending on whether the target words in the two contexts are used with the same meaning (T) or not (F). To perform both the selection of the data as well as the annotation, we employed eight annotators with a high level of education and linguistic proficiency in the corresponding language; the annotation work required approximately six months. Importantly, all annotators followed specific criteria which we describe in the following paragraph.

**Annotation criteria** We provided each annotator with general annotation guidelines. Besides general criteria, each annotation team<sup>9</sup> established ad-hoc guidelines for specific linguistic issues, some of which will be briefly illustrated in Section 4, below.

General annotation criteria can be broadly divided into grammatical and lexicographic-semantic criteria. The former refer to the format and the grammatical correctness of the sentences to be selected: annotators were asked to choose well-written sentences only, i.e. sentences with a clear structure, ending with a full stop and containing a main clause. Instead, lexicographic-semantic criteria refer to the attribution of the labels. To determine whether two occurrences were used with the same meaning or not, annotators were asked to use multiple reputable dictionaries (e.g. for English we used the Merriam-Webster, Oxford Dictionary of English and English Collins dictionaries). Moreover, to avoid misperceptions in the same-sense tagging annotations, we asked annotators to justify

<sup>9</sup>An annotation team is made up of annotators working on the same language.

their choices by providing substitutes for the target occurrences with synonyms, hypernyms, paraphrases or the like. Contrary to what was done in WiC and XL-WiC, we argue that, for the purposes of this task, annotating according to lexicographic motivations, i.e. by using reliable dictionaries, contributes significantly to minimizing the impact of subjectivity, thus producing more adequate and consistent data. Finally, lexicographic-semantic criteria also provided concrete indications and examples regarding the attribution of tags. For instance, T was used if and only if the two target occurrences were used with exactly the same meaning or, in other words, if, using a dictionary, the definition of the two target words was the same.

**Inter-annotator agreement** In order to determine the degree of uncertainty encountered during the annotation process, we computed the inter-annotator agreement. To this end, we randomly selected a sample of 500 sentence pairs from each of the En-En and Ru-Ru multilingual datasets, and 200 sentence pairs from the En-Ar and En-Zh cross-lingual datasets. Validators were provided with the same guidelines used during the annotation process. We calculated the agreement between two different annotators using the Cohen’s kappa, obtaining  $\kappa=0.968$  in En-En, 0.952 in Ru-Ru, 0.94 in En-Ar and 0.91 in En-Zh, which is interpreted as almost perfect agreement.

**Data format** For each sub-task, we provide two types of file (.data and .gold) in JSON format. The .data files contain the following information: a unique ID, the lemma, its part of speech, the two sentences and the positional indices to identify the target occurrences to be considered (see Tables 2 and 4). Instead, the .gold files include the gold answers, i.e. the corresponding ID and tag, as shown in Table 3.

## 4 Linguistic Issues

In this section, we describe interesting language-specific issues which required additional guidelines. Due to space limits, we focus on languages which do not use the Latin alphabet, i.e. Arabic, Chinese and Russian, illustrating only the most significant issues encountered.

**Arabic** From a WSD perspective, compared to other languages, written Arabic poses bigger challenges due to the omission of vocalization, which increases the degree of semantic ambiguity. In fact, the vocalization, expressed by diacritics placed above or below consonants, contributes significantly to determining the right interpretation and thus the meaning of words. For instance, the unvocalized word form *b-r-d* could be interpreted as *bard* (“cold”), *burd* (“garment”) or *barad* (“hail”). Of course, in Arabic, polysemy also affects vocalized words, which can have multiple meanings, e.g. *ummiyy* means “maternal”, but also “illiterate”. For the purposes of MCL-WiC, we chose to keep the sentences as they are found in UNPC and Wikipedia, i.e. unvocalized in the vast majority of cases, while – instead – providing the target lemmas in the vocalized form. This was done in order to avoid lexical ambiguity deriving from lemmas which share the same word form but are vocalized in a different way. Furthermore, this choice facilitated the selection and annotation of sentence pairs in which a given target lemma occurs.

**Chinese** Since Chinese does not adopt an alphabet, the semantic ambiguity that can be found in English homographs is basically lost. In Chinese, if two unrelated words are pronounced in the same way, such as “plane” (the airplane) and “plane” (the surface), they are not usually written in the same way. By way of illustration, 沉默, meaning “silent; to be silent” and 沉没, “to sink”, are both pronounced as *chénmò*, but, because they are written with different characters, they cannot be considered ambiguous words. Analogously, some characters have an extremely high semantic ambiguity themselves, but since they appear most frequently in polysyllabic words, their ambiguity is lost. For example, the character *guǒ* 果 has at least two meanings, “fruit” and “result”, but this character almost never stands as a word on its own in contemporary Chinese. In the current lexicon most of the Chinese words are composed of two or more characters; when it appears in actual texts, *guǒ* is al-

most always connected to other characters, and the word thus formed is no longer semantically ambiguous. Finally, similarly to the cross-lingual sub-task, some ambiguity had to be discarded in translation, as in the case of Chinese classifiers which have a marked potential for semantic ambiguity. For example, *dào* 道 is, among others, the classifier for long and narrow objects, as in *yī dào hé* 一道河, a river (one+classifier+river), or for doors, walls and similar objects with an entry and an exit, as in *yī dào mén* 一道门, a door (one+classifier+door). However, since classifiers are virtually absent in European languages, they could not be applied in the cross-lingual sub-task and were discarded.

**Russian** A noteworthy issue encountered by Russian annotators concerned the verbal aspects which can be viewed as one of the most challenging features of the Russian language especially for L2-learners<sup>10</sup> with no Slavic background. In Russian, a verb can be perfective, imperfective or both. Normally, a perfective verb has one or more imperfective counterparts and vice versa. Broadly speaking, perfective verbs are typically used to express non-repetitive actions completed in the past, or actions which will certainly be carried out in the future, and also in general for past or future actions for which the speaker intends to emphasize the result that was or will be achieved. Conversely, imperfective verbs are used to express actions which are incomplete, habitual, in progress, or actions for which the speaker does not stress the result to be attained. In MCL-WiC, given a verbal target lexeme, we decided to choose sentences in which the target words occurring in the selected sentences and the target lemma shared the same aspect. In fact, in Russian, although pairs of perfective and imperfective verbs such as *делать, сделать* (to do) or *спрашивать, спросить* (to ask) show a high degree of morphological relatedness, they tend to be considered as distinct lemmas.

Another interesting issue regards participles. In some cases, annotators raised issues concerning the part of speech of participles occurring as target words in the selected sentences. In fact, Russian participles derive from verbs, but are declined and can behave as adjectives. Since the target lexemes and the corresponding occurrences must share the same part of speech, we decided to discard sentences in which the part of speech of the target

<sup>10</sup>In language teaching, L2 indicates a language which is not the native language of the speaker.

words could not be determined unequivocally.

## 5 Participating Systems

This Section is devoted to the participating systems. First, we briefly describe the rules of the competition. Subsequently, we provide an overview of the data and approaches used by participants. Then, we focus on some of the best-scoring systems and provide a breakdown of the techniques adopted. We report the three best-performing teams for each sub-task and language combination in Tables 6 and 7. All results are publicly available on the official MCL-WiC page on GitHub<sup>11</sup>. For each winning team, we show only the best performance in the corresponding category.

### 5.1 Rules of the competition

Participants were given no constraints as far as data was concerned; for instance, the development data could be used for training or it was allowed to enrich the provided data by constructing new datasets in an automatic or semi-automatic fashion. Furthermore, we allowed more than one participant for each team. Participating teams could upload up to five submissions, each including up to 9 language combinations for the two sub-tasks.

### 5.2 Data

**Multilingual sub-task** As far as English is concerned, the majority of participating systems used the MCL-WiC training and development data. Some participants also used the data derived from WiC and XL-WiC. Furthermore, automatically-constructed WiC-like datasets were obtained by some participants, starting from semantic resources such as SemCor (Miller et al., 1993), WordNet and the Princeton WordNet Gloss Corpus (PWNG)<sup>12</sup>, or by automatically translating available datasets into English. The available data was also enriched via sentence reversal augmentation (given a sentence pair, the two sentences were swapped). In some cases, the development and trial<sup>13</sup> data was used to enrich the training data.

As regards languages other than English, most participants used XL-WiC data, or new training and development datasets were obtained by splitting the MCL-WiC language-specific development

data. Alternatively, in zero-shot scenarios, participants trained their models using the English training data. Furthermore, some participants augmented the training and development data by including the trial data. Also in this case, training and development splits were augmented via sentence reversal.

**Cross-lingual sub-task** In the cross-lingual sub-task, most participants used the MCL-WiC English training and development data in zero-shot settings. A smaller group of participants used WiC and XL-WiC data. Some participants created additional training and development data from other resources such as the Open Multilingual WordNet and PWNG. Additional training and development data was produced via Machine Translation.

### 5.3 Approaches

**Multilingual sub-task** Most participants used XLM-RoBERTa (Conneau et al., 2020) as pre-trained language model to obtain contextual representations of the target occurrences. Other models frequently used by participants were mBERT, RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2019), ELECTRA (Clark et al., 2019) and ERNIE (Sun et al., 2020). The majority of participants made use of fine-tuned contextualized embeddings and used logistic regression to perform binary classification. Some participants used ensembles and majority voting.

**Cross-lingual sub-task** Also in this sub-task, XLM-RoBERTa was the most used multilingual language model. Again, the majority of systems obtained contextualized embeddings, passing them to a logistic regression unit. In this case, participants mainly explored zero-shot approaches. Some participants made use of ensembles, adversarial training, pseudo-labelling (Wu and Prasad, 2017) and cross-validation techniques.

### 5.4 Competition and best-scoring systems

The MCL-WiC competition took place on the CodaLab<sup>14</sup> open Web-based platform and reported 170 participants, out of which 48 uploaded one or more datasets. Overall, 170 submissions were received, the majority of which were focused on the multilingual sub-task and specifically on the En-En dataset. As far as the evaluation metric was concerned, systems were tested using the accuracy

score. In what follows, we provide insights regarding the approaches adopted by some of the best-performing participating systems, based on the information we received.

**Cam** The Cam team (Yuan and Strohmaier, 2021) made use of the WiC and XL-WiC datasets in addition to the MCL-WiC data. Furthermore, examples from the Sense Complexity Dataset (Strohmaier et al., 2020, SeCoDa) and the Cambridge Advanced Learner’s Dictionary (CALD) were extracted. Cam used pre-trained XLM-RoBERTa as underlying language model and added two additional layers on top to perform binary classification with tanh and sigmoid activation, respectively. As input, the following items were concatenated: the representation corresponding to the first token of the sequence, the representations of the target words in both sentences, as well as the absolute difference, cosine similarity and pairwise distance between the two vectors. When the target word was split into multiple sub-tokens, Cam took the average representation rather than the first sub-token. Finally, a two-step training strategy was applied: 1) pre-training the system using out-of-domain data, i.e. WiC, XL-WiC, SeCoDa and CALD; 2) fine-tuning the system on MCL-WiC data.

**godzilla** godzilla enriched the MCL-WiC training data by automatically constructing a dataset starting from WordNet and using Machine Translation. Different types of pre-trained models, such

as RoBERTa and XLM-RoBERTa, were adopted. godzilla highlighted the target words by surrounding them with special markings on both sides and appending the target words to the end of each sentence. As architecture, this system used the next sentence prediction models from the hugging face<sup>15</sup> library. Given the strong connection between En-Ar, En-Fr, En-Ru, En-Zh test datasets, pseudo-tagging was used for each language combination. Finally, godzilla applied label smoothing and model merging.

**LIORI** The LIORI<sup>16</sup> team (Davletov et al., 2021) used the datasets provided in the MCL-WiC competition. Specifically, the training data was enriched with 70% of the development data for Arabic, Chinese, French and Russian, and the whole trial data. Optionally, data augmentation was performed by swapping sentences in each example. LIORI fine-tuned XLM-RoBERTa on a binary classification task and used a 2-layered feed-forward neural network on top of the language model with dropout and the tanh activation function. Sentences in each pair were concatenated by the special token "</s>" and fed to XLM-RoBERTa. As input, the model took the concatenation of the contextualized embeddings of the target words, aggregating over sub-tokens either by max pooling, or just by taking the first sub-token. LIORI used a voting ensemble composed of three models: the first model trained with data augmentation, using the concatenations of the first sub-tokens of the target words; the second trained with data augmentation using max-pooling over sub-tokens; finally, the third trained without data augmentation and using concatenations of the first sub-tokens.

**stce** stce used the MCL-WiC datasets and built additional training data using HowNet (Dong and Dong, 2003). Furthermore, the training data was enriched by pseudo-labelling the test datasets. Data cleaning was performed and target words were surrounded by special markings. The main language model used was XLM-RoBERTa-large. During the training process, dynamic negative sampling was performed for each batch of data fed to the model. At the same time, stce adopted the Fast Gradient Method and added disturbance to the embedding layer to obtain more stable word representations.

Table 7: Cross-lingual sub-task: three best-scoring systems by language combination.

**zhestyatsky** Zhestiankin and Ponomareva (2021) augmented the English MCL-WiC training and development data with WiC. Training and development data were split randomly to create a larger training sample which included 97.5% of the data, while leaving only 2.5% for the new development dataset. Then, bert-large-cased embeddings were fine-tuned using AdamW as optimizer with a learning rate equal to  $1e-5$ . Each sentence was split by BertTokenizerFast into 118 tokens maximum. The model was trained for 4.5 epochs and stopped by Early Stopping with patience equal to 2. For each sentence, zhestyatsky took the embeddings of all sub-tokens corresponding to the target word and max pooled them into one embedding. Subsequently, zhestyatsky evaluated the cosine similarity of these embeddings and activated this value through ReLU.

**MCL@IITK** First, the MCL@IITK<sup>17</sup> team (Gupta et al., 2021) pre-processed the sentences by adding a signal, either double quotes on both sides of the target word, or the target word itself appended to the end of the sentence. For En-En, MCL@IITK enriched the MCL-WiC training data using sentence reversal augmentation, WiC and SemCor. MCL@IITK obtained embeddings of the target words using the last hidden layer, and passed them to a logistic regression unit. MCL@IITK used ELECTRA, ALBERT, and XLM-RoBERTa as language models and submitted probability sum ensembles. For the non-English multilingual sub-task, MCL@IITK used XLM-RoBERTa only and

<sup>17</sup>The following members of the MCL@IITK team took part in the competition: jaymundra, rohangpt and dipakam.

tackled all four language pairs jointly. A 9:1 train-dev split with sentence reversal augmentation was used on the non-English dev data, in addition to En-En train data and XL-WiC with an ensemble model. For the cross-lingual subtask, ELECTRA embeddings were used. The models were trained on partly back-translated En-En train set and validated on back-translated En-En development set.

**PALI** The PALI<sup>18</sup> team (Xie et al., 2021) enriched the MCL-WiC data using WordNet while keeping the original cross-lingual data to maintain the target words in the cross-lingual data. After text pre-processing, task-adaptive pre-training was performed using the MCL-WiC data. The target words were surrounded by special symbols. PALI used XLM-RoBERTa as main language model and took its final output layer, concatenating the [CLS] token with the embeddings of the target occurrences in each sentence pair. To increase the training data, PALI exchanged the order of 20% of the sentence pairs. During training, lookahead (AdamW) was used together with adversarial training implemented by the Fast Gradient Method to obtain more stable word representations. Hyperparameters were tuned through trial-and-errors. The models of stratified 5-fold cross-validation were averaged to yield the final prediction results.

## 6 Baselines

Following Raganato et al. (2020), we used a baseline transformer-based binary classifier. Thus, first, given a sentence pair, a dense representation is obtained for each target occurrence. As indicated in Devlin et al. (2019), in the case that a target occurrence is split into multiple sub-tokens, the first sub-token is selected. The resulting representations are then given as input to a binary classifier implemented following Wang et al. (2019). We selected the Adam optimizer (Kingma and Ba, 2015) with learning rate and weight decay equal to  $1e-5$  and 0, respectively, and trained for 10 epochs.

We experimented with two different contextualized embedding models: BERT (base-multilingual-cased) and XLM-RoBERTa (base). As for the data, in contrast to most participants, we made use of the data provided for the task only. We used En-En as training and development data for English. As for other language combinations, we trained on En-En and validated both on En-En or and on the other

language multilingual development data. Table 8 reports the best training results according to the corresponding validation.

## 7 Results and Discussion

In this section, we discuss the results achieved in our competition. Overall, the MCL-WiC dataset allows systems to attain high performances, in the 85-93% accuracy range. This leads us to hypothesize that, in general, systems were able to develop a good ability in capturing sense distinctions without relying on a fixed sense inventory.

When compared to the proposed baselines, we observe that best-performing systems were able to achieve an absolute improvement of up to 27.1 points over the corresponding baselines (e.g. on En-Ar, cf. Tables 7 and 8). Both our baselines and the systems developed by participants confirm that, in this task, XLM-RoBERTa outperforms BERT in most language combinations. The highest score was obtained in En-En, with the best system achieving 93.3% accuracy. Note that our baselines were also able to attain good performances in En-En, i.e. 84.0% using BERT and 86.6% with XLM-RoBERTa, without benefiting from additional training and development data. Interestingly, Chinese was the language which achieved the second-best results, both in Zh-Zh and En-Zh, attaining on average results which were considerably higher. Instead, Arabic seems to have been the most difficult language for participants, especially in Ar-Ar. A reason for this result, deserving further exploration, could lie in morpho-semantic features inherent in Arabic, which we briefly outlined in Section 4.

Zero-shot approaches differ in the performances achieved by participants in the two sub-tasks: in the cross-lingual sub-task participants were able to achieve slightly better performances than those in the multilingual setting, most probably thanks to the presence of English in both the training and

the test data, and, more in general, to the availability of English WiC-style datasets which could be used to enrich the already provided data. With the exception of Chinese, instead, on the multilingual sub-task we observe a performance drop between 1.6 and 4.3%.

Finally, we note that performance boosts were observed across the board when using data augmentation, especially by swapping the two sentences within a pair or by coupling the second sentences of two pairs sharing the same first sentence and the same meaning. Another consistent performance increase, observed both in the multilingual and in the cross-lingual sub-task, was obtained when adding a signal on both sides of the target occurrences.

## 8 Conclusions

In this paper, we described the SemEval-2021 Task 2 and introduced Multilingual and Cross-lingual Word-in-Context (MCL-WiC), the first entirely manually-curated WiC-style dataset in five European and non-European languages, namely Arabic, Chinese, English, French and Russian. MCL-WiC allows the inherent ability of systems to discriminate between word senses within the same language to be tested, and also, interestingly, within cross-lingual scenarios in which a system is evaluated in two languages at the same time, namely English and one of the remaining MCL-WiC languages.

While current Word-in-Context datasets focus primarily on single tokens, as a suggestion for future work we would like to further explore the integration of multi-word expressions and idiomatic phrases into a Word-in-Context task. This would allow us to investigate the intrinsic ability of a system to correctly discriminate the semantics of such linguistic constructs, especially those whose meaning is not compositional, i.e. it cannot be derived by combining the meaning of each of their individual components.

## Acknowledgments

The authors gratefully acknowledge the support of the ERC Consolidator Grant MOUSSE No. 726487 and the

ELEXIS project No. 731015 under the European Union’s Horizon 2020 research and innovation programme.

We gratefully thank Luisa Borchio, Ibraam Abdelsayed, Anna Guseva, Zhihao Lyu and Beatrice Buselli for their valuable annotation work.

## Abstract

This paper introduces the SemEval-2021 shared task 4: Reading Comprehension of Abstract Meaning (ReCAM). This shared task is designed to help evaluate the ability of machines in representing and understanding abstract concepts. Given a passage and the corresponding question, a participating system is expected to choose the correct answer from five candidates of abstract concepts in a cloze-style machine reading comprehension setup. Based on two typical definitions of *abstractness*, i.e., the *imperceptibility* and *nonspecificity*, our task provides three subtasks to evaluate the participating models. Specifically, Subtask 1 aims to evaluate how well a system can model concepts that cannot be directly perceived in the physical world. Subtask 2 focuses on models’ ability in comprehending *nonspecific* concepts located high in a hypernym hierarchy given the context of a passage. Subtask 3 aims to provide some insights into models’ generalizability over the two types of abstractness. During the SemEval-2021 official evaluation period, we received 23 submissions to Subtask 1 and 28 to Subtask 2. The participating teams additionally made 29 submissions to Subtask 3. The leaderboard and competition website can be found at <https://competitions.codalab.org/competitions/26153>. The data and baseline code are available at <https://github.com/boyuanzheng010/SemEval2021-Reading-Comprehension-of-Abstract-Meaning>.

## 1 Introduction

Humans use words with abstract meaning in their daily life. In the past, research efforts have been exerted to better understand and model abstract meaning (Turney et al., 2011; Theijssen et al.,

\* This work was performed when Boyuan Zheng visited Queen’s University.

2011; Changizi, 2008; Spreen and Schulz, 1966). Modelling abstract meaning is closely related to many other NLP tasks such as reading comprehension, metaphor modelling, sentiment analysis, summarization, and word sense disambiguation.

In the past decade, significant advancement has been seen in developing computational models for semantics, based on deep neural networks. In this shared task, we aim to help assess the capability of the state-of-the-art deep learning models on representing and modelling abstract concepts in a specific reading comprehension setup.

We introduce SemEval-2021 Task 4, Reading Comprehension of Abstract Meaning (**ReCAM**). Specifically, we design this shared task by following the machine reading comprehension framework (Hermann et al., 2015; Onishi et al., 2016; Hill et al., 2016), in which computers are given a passage  $D_i$  as well as a human summary  $S_i$  to comprehend. If a model can digest the passage as humans do, we expect it to predict the abstract word used in the summary, if the abstract word is masked. Unlike the previous work that requires computers to predict concrete concepts, e.g., named entities, in our task we ask models to fill in abstract words removed from human summaries. During the SemEval-2021 official evaluation period, we received 23 submissions to Subtask 1 and 28 submissions to Subtask 2. The participating teams additionally made 29 submissions to Subtask 3. In this paper, we induce the shared task and provide a summary for the evaluation.

## 2 Task Description

We organize our shared task based on two typical definitions of *abstractness*, named as *imperceptibility* and *nonspecificity* in this paper, implemented in Subtask 1 and Subtask 2, respectively. Subtask 3 further evaluates models’ generalizability over the two definitions of abstractness.

<b>Passage</b>	... Observers have even named it after him, “Abenomics”. It is based on three key pillars of monetary policy to ensure long-term sustainable growth in the world’s third-largest economy, with fiscal stimulus and structural reforms. In this weekend’s upper house elections, ...
<b>Question</b>	Abenomics: The <i>@placeholder</i> and the risk.
<b>Answer</b>	(A) chance (B) prospective (C) government (D) <b>objective</b> (E) threat

Table 1: An example for Subtask 1. The correct answer to the question is *objective*.

## 2.1 Subtask 1: ReCAM-Imperceptibility

In one definition (Turney et al., 2011; Theijssen et al., 2011; Spreen and Schulz, 1966), concrete words refer to things, events, and properties that humans can directly perceive with their senses, e.g., *trees* and *flowers*. In contrast, abstract words refer to “ideas and concepts that are distant from immediate perception”, e.g., *objective*, *culture*, and *economy*. In Subtask 1, we perform reading comprehension on *imperceptible* abstract concepts, named as **ReCAM-ImPerceptibility**. Table 1 shows an example.

## 2.2 Subtask 2: ReCAM-NonSpecificity

The second typical definition of abstractness is based on *nonspecific* concepts (Theijssen et al., 2011; Spreen and Schulz, 1966). Compared to specific concepts such as *groundhog* and *whale*, words such as *vertebrate* are regarded as more *abstract*. Our Subtask 2, named as **ReCAM-NonSpecificity**, is designed based on this viewpoint. We will discuss how the datasets are constructed in Section 3.

## 2.3 Subtask 3: ReCAM-Cross

In this subtask, participants are asked to submit their predictions on the test data of Subtask 2, using models trained on the training data of Subtask 1, and vice versa. This subtask aims to demonstrate models’ generalizability between modelling the two typical definitions of abstractness.

## 3 Data Construction

We develop our multi-choice machine reading comprehension datasets based on the XSum summarization dataset (Narayan et al., 2018). We first locate words with abstract meaning using our abstractness scorers. Then we perform data filtering to select our target words to construct our datasets.

## 3.1 The XSum Data

By collecting online articles from the British Broadcasting Corporation (BBC), Narayan et al. (2018) developed a large-scale text summarization dataset, XSum, in which each article has a single sentence summary. We developed our ReCAM dataset based on XSum.

## 3.2 Finding Imperceptible Concepts

**Abstractness Scorer for Imperceptibility** Following Turney et al. (2011), we use the MRC Psycholinguistic Database (Coltheart, 1981), which includes 4,295 words rated with a degree of abstractness by human subjects, to train our abstractness scorer for *imperceptibility*. The rating of the words in the MRC Psycholinguistic Database ranges from 158 (highly abstract) to 670 (highly concrete). We linearly scale the rating to the range of 0 (highly abstract) to 1 (highly concrete). The neural regression model accepts fixed Glove embedding (Pennington et al., 2014) as input and predicts the abstractness rating score between 0 and 1. Our regression model is a three-layer network that consists of two non-linear hidden layers with the ReLU activation and a sigmoid output layer. The mean square error (MSE) is used as the training loss.

To test the regression model’s performance, we randomly split the MRC Psycholinguistic Database into train and test set with the size of 2,148 and 1,877, respectively. Table 2 shows the final performance of the neural regression model on the MRC database. We use the Pearson correlation between ratings predicted by models and original ratings from MRC as the evaluation metric. We can see that the regression model achieves high correlation coefficients (the higher, the better), i.e., 0.934 and 0.835, on the training and test set. The correlations are significant ( $p$ -values are smaller than  $10^{-5}$ ), reflecting the quality of our models in finding abstract words. Note that Turney et al. (2011) report a correlation score of 0.81 on their MRC test set. Their training-test split is unavailable, so we run cross-validation here in our experiment. The scorer can then be used to assign an *imperceptibility* score to a word that is not in the MRC Psycholinguistic Database.

Using the abstractness scorer described above, we assign an abstractness value to each word in summaries and select words with a value lower than 0.35 as the candidates for our *target words* (words that will be removed from the summaries

	#samples	Pearson $r$	$p$ -value
train	2,148	0.934	$p < 10^{-5}$
test	1,877	0.854	$p < 10^{-5}$

Table 2: Fitting performance of neural regression model on the MRC database.

to construct questions). We only consider content words as potential target words, i.e., nouns, verbs, adjectives, and adverbs. For this purpose, we use part-of-speech tagging model (?) implemented in Stanza (Qi et al., 2020).

### 3.3 Finding *Nonspecific* Concepts

**Nonspecificity Scorer** Following the work of Changizi (2008), we assign a *nonspecificity* score to a word token based on the hypernym hierarchy of WordNet (Miller, 1998). Specifically, the root of the hierarchy is at level 0 and regarded as the most abstract. The abstractness of a node in the hierarchy is measured by the maximal length of its path to the root. The hypernym level in WordNet is between 0 and 17. For each word token in summaries, we use Adapted Lesk Algorithm (Banerjee and Pedersen, 2002) to label the sense since the WordNet hypernym hierarchy works at the sense level. Since a summary sentence may be short, we concatenate each summary sentence with the corresponding passage for word sense disambiguation. Built on this, each token, which is labelled with a sense, receives an abstractness score based on the WordNet hierarchy.

Using the *nonspecificity* scorer, we assign an *nonspecificity* value to each word in summaries and select words with a value smaller than six as the candidate target words. The targets words will be nouns and verbs since the hypernym hierarchy in WordNet (?) consists of these two POS types.

### 3.4 Filtering

We aim to avoid developing simple questions. For example, if a target word also appears in the passage, it is likely that a model can easily find the answer without the need to understand the passage in depth.

**Filtering by Lemmas** We lemmatized passages and summaries. If a lemma appears both in a summary and the corresponding passage, the lexemes of the lemma will not be considered as target words. Note that a strict filter may exclude some good candidates for target words but helps avoid introducing

many simple questions.

**Filtering by Synonyms and Antonyms** For a word in a summary, if a synonym or antonym of the word appears in the corresponding passage, we will not consider this word to be our target word. We use WordNet (?) to derive synonyms and antonyms. Instead of using word sense disambiguation (WSD), for a word  $w_i$  in a summary, we use all senses of this word and add all synonyms and antonyms into a pool. Only if none of the words in the pool appear in the passage, we consider  $w_i$  as a candidate target word. Otherwise, we will not use  $w_i$  to construct a question for this passage-summary pair.

**Filtering by Similarity** We further filter words by similarity. For each candidate target word in a summary and each word in the passage, we calculate similarity and use that to perform further filtering.

We use 300-dimension GloVe word embedding trained on 840 billion tokens (Pennington et al., 2014). We calculate the cosine similarity between a candidate target word and a passage word. For contextual embedding, we embed each sentence in a passage as well as the summary into a context-aware representation matrix using the BERT-large uncased language model. Then, we calculate the similarity between each passage token and question token with the cosine similarity. If the similarity is higher than 0.85, we will not consider the involved summary words as candidate target words.

### 3.5 Constructing Multiple Choices

We train machine reading comprehension models using the data built so far to generate four choices for each question. Together with the ground-truth (the target word identified above and removed from the human summary), we have five choices/options for each question. In our work, we propose to use three models, Gated-Attention Reader (Hermann et al., 2015), Attentive Model and Attention Model with Word Gloss to generate the candidate options. Please find details of the models in Appendix B and Appendix C as well as the training details in Appendix D.

We adopt the idea of k-fold cross validation to train the above mentioned three models to generate candidate answer words. Specifically, we split the data into 4 folds. Each time, we train the baseline models on 3 folds of data and use the trained

	MRR	R@1	R@5	R@10
GARReader	0.245	0.175	0.314	0.378
AttReader	0.235	0.167	0.300	0.363
+gloss	0.179	0.123	0.227	0.276

Table 3: Three baseline models are used to generate candidate multiple choices for Subtask 1. The table shows their performance on the XSum dataset, evaluated with MRR (Craswell, 2009), Recall@1, Recall@5, and Recall@10.

	MRR	R@1	R@5	R@10
GARReader	0.343	0.268	0.422	0.484
AttReader	0.348	0.273	0.424	0.490
+gloss	0.228	0.166	0.286	0.345

Table 4: Three baseline models are used to generate candidate multiple choices for Subtask 2. The table shows their performance on the XSum dataset, evaluated with MRR, Recall@1, Recall@5, and Recall@10.

models to predict candidate words on the remaining 1-fold data. With 4-fold iteration, we obtain predication of each model on the entire data. The performance of the three baseline models are listed in Table 3 for Subtask 1 and Table 4 for Subtask 2, using several typical retrieval-based evaluation metrics.

For each target word that has been removed from the corresponding summary sentence (again, a question is a summary sentence containing a removed target word), we collect top-10 words predicted by each of the three models. In this way, we can collect a candidate word pool of 30 predicted word tokens for each removed target word. To avoid including multiple correct choices for each question, we adopt synonym and context similarity filtering methods described in Section 3.4. Specifically we first calculate similarity between the ground-truth target word and each word type in the pool. We exclude a word type from the multiple choices if its similarity to the ground-truth is higher than 0.85. In addition, we also exclude synonyms of the ground-truth target word. For the remaining word tokens in the pool, we select four most frequent word types (a word type may have multiple tokens in the pool). Together with the ground-truth word, we obtain five choices for each question.

### 3.6 Further Quality Control

We further make the following efforts to remove noise in the dataset and improve the datasets’ qual-

ity. We observe that up to now, there are mainly two kinds of noise in our dataset: 1) some target words cannot be inferred solely based on the corresponding passage; 2) more than one of the multiple choices are correct answers.

The first issue is mainly related to the property of the XSum dataset, in which the first sentence of a passage is used as the summary. The second type of problems are often caused by our automatic generation method. Although we have applied strict rules in Section 3.4 to handle this, among a small portion of the resulting data, multiple potentially correct answers still exist in candidate answers.

To further ensure the quality of our dataset, we invite workers in Amazon Mechanical Turk to perform further data selection. Each annotator needs to follow the procedure of Appendix A to answer the question and annotate relevant information, with which further data selection is applied. To ensure quality, we only include workers from English-speaking countries and only if their previous HITs’ approval rates are above 90%. To see more details about this process, please refer to Appendix E.

### 3.7 ReCAM Data Statistics

Table 5 lists the size of our ReCAM datasets, i.e., numbers of questions. For example, in total Subtask 2 has 6,186 questions, which are split into training/development/test subsets.

Dataset	Subtask 1	Subtask 2	Total
Train	3,227	3,318	6,545
Dev	837	851	1,688
Test	2,025	2,017	4,042
Total	6,089	6,186	12,275

Table 5: Size of the ReCAM Dataset.

## 4 Systems and Results

Our shared task received 23 submissions to Subtask 1, 28 submissions to Subtask 2, and 29 submissions to Subtask 3. We use *accuracy* as the evaluation metric for the three subtasks.

In general, most participating teams use pre-trained language models in their systems such as BERT (Devlin et al., 2019), ALBERT (Lan et al., 2020), DistilBERT (Sanh et al., 2019), RoBERTa (Liu et al., 2019), ELECTRA (Clark et al., 2020), DeBERTa (He et al., 2020), XLNet (Yang et al., 2019), T5 (Raffel et al., 2020). Data augmentation, external knowledge resources,

and/or transfer learning are additionally used by many teams to further enhance their model performance.

#### 4.1 Subtask 1: ReCAM-Imperceptibility

Table 6 shows all the official submissions and most of them outperform the baseline model. The baseline used for Subtask 1 is the Gated-Attention (GA) Reader (Dhingra et al., 2017). The GA Reader uses a multi-layer iterated architecture with a gated attention mechanism to derive better query-aware passage representation. The motivation behind using GA Reader is to have a simple comparison between our task and the CNN/Daily Mail reading comprehension dataset since GA Reader achieves reasonably good performance on the CNN/Daily Mail reading comprehension dataset.

Note that the last column of the table lists the accuracy (*Acc. Cross*) for models trained on the Subtask 2 training data and tested on the Subtask 1 testset. We will discuss those results later in Section 4.3.

The best result in Subtask 1 was achieved by team SRC-B-roc (Zhang et al., 2021) with an accuracy of 0.951. The system was built on a pre-trained ELECTRA discriminator and it further applied upper attention and auto-denoising mechanism to process long sequences. The second-placed system, PINGAN omini-Sinitic (Wang et al., 2021), adopted an ensemble of ELECTRA-based models with task-adaptive pre-training and a multi-head attention based multiple-choice classifier. ECNU-ICA-1 (Liu et al., 2021) ranked third in this subtask with a knowledge-enhanced Graph Attention Network and a semantic space transformation strategy.

Most teams in Subtask 1 utilize pre-trained language models (PLM), like BERT (Devlin et al., 2019), ALBERT (Lan et al., 2020), DistilBERT (Sanh et al., 2019), RoBERTa (Liu et al., 2019), ELECTRA (Clark et al., 2020), DeBERTa (He et al., 2020), XLNet (Yang et al., 2019), T5 (Raffel et al., 2020). SRC-B-roc (Zhang et al., 2021) conducted an ablation study regarding the performance discrepancy of different transformers-based pre-training models. They tested BERT, ALBERT, and ELECTRA by directly fine-tuning the pre-trained LMs on the ReCAM data. ELECTRA outperforms BERT and ALBERT by large margins, which may be due to the different learning objec-

Rank	Team	Acc	Acc. Cross
-	GA Reader	25.1	-
1	SRC-B-roc	95.1	91.8 (↓ 3.3)

Table 6: Official results of Subtask 1 and Subtask 3. *Acc* is the accuracy of the models trained on the Subtask 1 training data and tested on the Subtask 1 testset. *Acc. cross* is the accuracy of models trained on the Subtask 2 training data and tested on the Subtask 1 testset.

tives of these pre-trained models.

Most participating systems performed intermediate task pre-training (Pruksachatkun et al., 2020) for their language models. For example, CNN/Daily Mail dataset was selected by ZJUKLAB (Xie et al., 2021a) to further pre-train their language models. The CNN/Daily Mail dataset and Newsroom dataset boost model performance on both Subtask 1 and Subtask 2. Data augmentation methods are also popular among participants. ZJUKLAB (Xie et al., 2021a) performed negative data augmentation with a

language model to leverage misleading words. IIE-NLP-Eyas (Xie et al., 2021b) adopted template-based input reconstruction methods to augment their dataset and further fine-tuned their language models based on the dataset.

Most teams also used an ensemble of multiple pre-trained language models to further enhance model performance. SRC-B-roc (Zhang et al., 2021) applied Wrong Answer Ensemble (Kim and Fung, 2020) by training the model to learn the correct and wrong answer separately and ensembled them to obtain the final predictions. Stochastic Weight Averaging (Izmailov et al., 2018) was also performed across multiple checkpoints in the same run to achieve better generalization.

In addition, some interesting approaches were additionally used to tackle the task from different perspectives. PINGAN omini-Sinitic (Wang et al., 2021) turned the original multi-choice task into a masked-sentence classification task by adding each option to the placeholder. Noise detection methods and auto denoising methods were further proposed by adding a noise-tolerant loss. ZJUKLAB (Xie et al., 2021a) used label smoothing to encourage the activations of the penultimate layer. ECNU-ICA-1 (Liu et al., 2021) utilized a semantic space transformation strategy to convert ordinary semantic representations into abstract representations for classification.

Many teams used external knowledge resources to further improve model performance. WordNet (Fellbaum, 1998) was widely used to provide candidate word definitions. ECNU-ICA-1 (Liu et al., 2021) also used ConceptNet5 (Speer et al., 2016) and Graph Neural Network in their systems. To alleviate the noise induced by incorporating structured knowledge through unimportant edges, they propose a noise reduction strategy. owlmx used the MRC Psycholinguistic Database to obtain a measurement of *imperceptibility* abstractness.

Different pre-processing techniques were proposed in multiple systems. ZJUKLAB (Xie et al., 2021a) used a sliding window to limit input length in training. PINGAN Omini-Sinitic (Wang et al., 2021) used the cycle noisy label detection algorithm to make models more robust.

Much interesting analysis regarding the failure cases and data distribution was discussed in several system description papers. XRJL (Jiang et al., 2021) found that for a few questions, common

sense knowledge was further needed to help find the answer. They also pointed out that there were still a few questions in which multiple candidate choices may serve as appropriate answers.

## 4.2 Subtask 2: ReCAM-Nonspecificity

In Subtask 2, we received 28 submissions. Table 7 shows the official leaderboard. The best result in Subtask 2 was achieved by team PINGAN-omni-Sinitic (Wang et al., 2021) with an accuracy of 0.953, using a model similar to the team’s model in Subtask 1. The second-placed team SRC-B-roc (Zhang et al., 2021) also adopted the same model it used in Subtask 1 with a data augmentation method based on the hypernym hierarchy in WordNet.

In general, the participating teams in Subtask 2 used pre-trained language models and neural networks similar to those they used in Subtask 1. The main differences lie in how the participants performed data augmentation and leveraged external knowledge. For example, in addition to SRC-B-roc (Zhang et al., 2021), the IRG team (Sharma et al., 2021) also performed data augmentation using hypernyms from WordNet.

## 4.3 Subtask 3: Cross-task Performance

In this section, we explore models’ performance across the two types of definitions of abstractness. Specifically, in this subtask, participants train their models on the training set of one subtask and test on the testset of the other subtask. We received 29 submissions in total from the participants.

**Cross-task performance: Subtask 2-to-1 testing.** We asked participants to test their models trained on the Subtask 2 training data on the Subtask 1 test data. The results are shown in the last column of Table 6.

The results we received show that the performance of all systems drops substantially. For some systems ranking among top 10, the accuracy can decrease by 5 points (IIE-NLP-Eyas (Xie et al., 2021b) and XRJL (Jiang et al., 2021)), or even more (14 points for nxc). Some systems show good generalization ability in this Subtask 2-to-1 scenario; the performance of PINGAN-Omini-Sinitic (Wang et al., 2021) is only 1.3 point less, which may be due to the the data augmentation and task adaptive training used in the model.

**Cross-task Performance: Subtask 1-to-2 Testing.** Participants are asked to test their Subtask 1 systems on the Subtask 2 testset. Details of the results can be seen in the last column of Table 7. All systems’ performances drop. For example, among

the top-10 systems, the accuracy decreases by 5 points (IIE-NLP-Eyas (Xie et al., 2021b)) or 7 points (tt123).

However, ECNU-ICA-1 (Liu et al., 2021) shows a very good generalization ability in Subtask 1-to-2 testing. PINGAN-Omini-Sinitic (Wang et al., 2021), SRC-B-roc (Zhang et al., 2021) and XRJL (Jiang et al., 2021)’s systems are rather consistent in this Subtask 1-to-2 cross testing. Some algorithms they used may explain the models’ good generalization ability. ECNU-ICA-1’s algorithm of using knowledge-enhanced Graph Attention Network can provide external knowledge to the model. The Wrong Answer Ensemble algorithm (Kim and Fung, 2020) used in PINGAN-Omini-Sinitic (Wang et al., 2021) is a relatively simple but an effective way of improving model performance and generalization ability. Also, the Stochastic Weight Averaging algorithm across multiple checkpoints is effective for better generalization. XRJL (Jiang et al., 2021) retrieves the definitions of candidate answers from WordNet and feeds them to the model as extra inputs. We also think data augmentation methods contribute to the generalization ability.

## 5 Related Work

There have been tasks being proposed to evaluate machines’ ability on reading comprehension, which either require models to find an entity or text span from the source document as the answer (Hermann et al., 2015; Hill et al., 2016; Onishi et al., 2016; Rajpurkar et al., 2016; Trischler et al., 2017), or further generate an answer (Nguyen et al., 2016; He et al., 2018; Kočiský et al., 2018). The cloze-style MRC tasks (Hermann et al., 2015; Onishi et al., 2016; Hill et al., 2016) are most similar to ours, in which the missing words in the cloze questions are entities appearing in source documents. Unlike previous work, ReCAM questions specifically focus on abstract words unseen in the corresponding source documents.

In general, multi-choice questions have been widely used as a tool for language examination to test both humans and machines. In this paper, we follow the multiple-choice framework for our proposed ReCAM task to evaluate computers’ ability in comprehending abstract concepts, in which computers are asked to predict the missing abstract words in human-written summaries.

## 6 Summary

This shared task aims to study the ability of machines in representing and understanding abstract concepts, based on two definitions of abstractness, the *imperceptibility* and *nonspecificity*, in a specific machine reading comprehension setup. We provide three subtasks to evaluate models' ability in comprehending the two types of abstract meaning as well as their generalizability. In Subtask 1, the top system achieves an accuracy of 0.951, and in Subtask 2, an accuracy of 0.953, suggesting the current systems perform well in the specific setup of our share task. In Subtask 3, we found that in general the models' performances dropped in both Subtask 2-to-1 and Subtask 1-to-2 testing. However, some models generalize well, benefiting from technologies such as data augmentation and task adaptive training. We hope the shared task can help shed some light on modelling abstract concepts and help design more challenging tasks in the future.

## A Annotation Script

Please read the instruction before starting answering the question (about 2 minutes reading). The instruction will help you better understand the task. Here is a question with one word missing. Please pick one word to complete it.

**Question:** Wales are waiting to discover the **@placeholder** of the knee injury lock Jake Ball suffered in Scarlets ' 24 - 15 win over Treviso on Friday .

- Before reading the passage, please select one word to answer the question.

challenge    duties    extent    causes    future

**Passage:** Ball, 24, limped off towards the end of the Pro12 game at Parc Scarlets, a week before Wales face England in the Six Nations at Twickenham. "Jake took a knock to the knee at the stage when we scored the try," Scarlets head coach Wayne Pivac said. "It was sensible to get him off as well." Pivac added: "I think he'll be all right - he's thrown a bit of ice so we'll see what the medical boys say." Wales coach Warren Gatland released lock Ball and scrum-half Aled Davies to the region as the Welsh squad prepare for their Six Nations showdown with England on 12 March. Media playback is not supported on this device Pivac also revealed Davies, 23, had been struggling with a virus while Scotland forward John Barclay also suffered an injury during the victory over bottom side Treviso. "John just took a stinger and felt he was favouring one side so he was going to let the team down so it was the right decision and he came off but I'm pretty sure he'll be OK," Pivac added. "Aled Davies was crook for the last couple of days with a virus and had to get through the warm-up. He did that and started so he was always going to run out of petrol. "It was a matter of how long he'd last and he did well to get to where he did."

- After reading and understanding the passage, select one word to answer the question.

challenge    duties    extent    causes    future

- If you think there is another answer to this question, please pick your second choice.

Else, please pick the *"No Other Answer"* option.

challenge    duties    extent    causes    future    No Other Answer

- Which part of the passage supports your answer? Copy the text span to the line below:

Paste corresponding text span here: \_\_\_\_\_

- Does the answer summarize or paraphrase the text span?

Summarize    Paraphrase    Others

- Which part of the passage summarize the information included in the answer? Copy the text span to the line below:

Paste corresponding text span here: \_\_\_\_\_

- How difficult is this problem?

Easy    Medium    Difficult

## B Gated-Attention Reader

The Gated-Attention (GA) Reader (Dhingra et al., 2017), the state-of-art model on CNN/Daily Mail reading comprehension dataset (Hermann et al., 2015), is adapted here in our experiments. The GA Reader uses a multi-layer iterated architecture with a gated attention mechanism, which is based on multiplicative interactions between the query embedding and the intermediate states of a recurrent neural network document reader, to derive better query-aware passage representation. To apply GA Reader to our ARC task, we input the news passage  $p$  as the document and the processed summary  $s$  as the query to GA Reader.

Specifically, for an input passage  $p = [p_1, p_2, \dots, p_{l_p}]$  with  $l_p$  words and its corresponding summary  $s = [s_1, s_2, \dots, s_{l_s}]$  with  $l_s$  words, we first derive their corresponding word embedding sequence  $\mathbf{P} = [\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_{l_p}]$  and  $\mathbf{S} = [\mathbf{s}_1, \mathbf{s}_2, \dots, \mathbf{s}_{l_s}]$  respectively. Then the GA Reader accepts the  $\mathbf{P}$  and  $\mathbf{S}$  as inputs and return the hidden states  $\mathbf{H}_p = [\mathbf{h}_1^p, \mathbf{h}_2^p, \dots, \mathbf{h}_{l_p}^p]$  and  $\mathbf{H}_s = [\mathbf{h}_1^s, \mathbf{h}_2^s, \dots, \mathbf{h}_{l_s}^s]$  as the sequential representation for passage  $p$  and summary  $s$  respectively. As for the final prediction process, we do not adopt the operations in Dhingra et al. (2017) because in ARC the answer words are unseen in the corresponding passage, however, GA Reader in Dhingra et al. (2017) tries to select a entity word in the passage as the final prediction since their target answer word appears in the passage. So we redesign the part of prediction.

First, the corresponding representation of “@placeholder” in  $\mathbf{H}_s$ , denoted as  $\mathbf{h}_q^s$  ( $q$  is the position index of @placeholder in summary  $s$ ), is used as the final vector representation for summary  $s$ . For the final vector representation  $\mathbf{p}$  for passage  $p$ , a bilinear attention between  $\mathbf{h}_q^s$  and  $\mathbf{H}_p$  is used for its derivation:

$$e_i = \mathbf{h}_q^{sT} \mathbf{W}^{att} \mathbf{h}_i^p, \forall i \in [1, \dots, l_p] \quad (1)$$

$$\mathbf{p} = \sum_{i=1}^{l_p} \frac{\exp e_i}{\sum_{j=1}^{l_p} \exp e_j} \mathbf{h}_i^p, \quad (2)$$

We set a token embedding  $\mathbf{a}_t^e$  for each candidate abstractive word  $a_t$  ( $t \in [1, \dots, n_c]$ ,  $n_c$  is the size of candidate set). We first concatenate the  $\mathbf{h}_p^s$  and  $\mathbf{p}$ , then use the bilinear product and softmax to predict the probability distribution over all  $n_c$  candidate

abstractive words.

$$r_t = [\mathbf{h}_q^s; \mathbf{p}]^T \mathbf{W}_p \mathbf{a}_t^e, \forall t \in [1, \dots, n_c], \quad (3)$$

$$o_t = \text{softmax}_t(r_t), \forall t \in [1, \dots, n_c] \quad (4)$$

in which  $o_t$  represents the probability of predicting the candidate abstractive word  $a_t$  as the final answer.

## C Attentive Model

The word gloss, which defines a word sense meaning, has been mainly used in word sense disambiguation (WSD) task and its variants (Lesk, 1986; Moro et al., 2014). Since the goal of ARC is to predict a word that can summarize corresponding information from the source passage, which is an abstracting process, it may be helpful when the gloss, i.e., interpretation of candidate abstractive words, are provided.

We design an attentive model with word gloss (AMWG) as Figure 1 shows. Specifically, all the encoders are 1-layer bi-directional recurrent neural networks (RNNs) with Gated Recurrent Units (GRU) (Cho et al.). For an input news passage  $p = [p_1, p_2, \dots, p_{l_p}]$  with  $l_p$  words, we can derive its hidden states  $\mathbf{H}_p = [\mathbf{h}_1^p, \mathbf{h}_2^p, \dots, \mathbf{h}_{l_p}^p]$  by sending its word embedding sequence  $\mathbf{P} = [\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_{l_p}]$  to the *Passage Encoder*. Similarly, we can derive hidden states  $\mathbf{H}_s = [\mathbf{h}_1^s, \mathbf{h}_2^s, \dots, \mathbf{h}_{l_s}^s]$  for summary  $s$  by inputting its word embedding sequence  $\mathbf{S} = [\mathbf{s}_1, \mathbf{s}_2, \dots, \mathbf{s}_{l_s}]$  into the *Summary Encoder* and hidden states  $\mathbf{H}_{g_t} = [\mathbf{h}_1^{g_t}, \mathbf{h}_2^{g_t}, \dots, \mathbf{h}_{l_{g_t}}^{g_t}]$  for gloss  $g_t$  of the candidate word  $a_t$  by sending its word embedding sequence  $\mathbf{G}_t = [\mathbf{g}_1^t, \mathbf{g}_2^t, \dots, \mathbf{g}_{l_{g_t}}^t]$  to the *WordGloss Encoder*.

Similar to Section B, the corresponding representation of “@placeholder”, i.e.,  $\mathbf{h}_q^s$ , is used as the final vector representation for summary  $s$ . And an bilinear attention  $f_{att}^p(\bullet)$  is applied to  $\mathbf{h}_q^s$  and  $\mathbf{H}_p$  as follows:

$$e_i = \mathbf{h}_q^{sT} \mathbf{W}_{att}^p \mathbf{h}_i^p, \forall i \in [1, \dots, l_p] \quad (5)$$

$$\alpha_i = \frac{\exp e_i}{\sum_{j=1}^{l_p} \exp e_j}, \forall i \in [1, \dots, l_p] \quad (6)$$

Then  $\mathbf{p}$  is derived as the vector representation for passage  $p$  by the weighed sum of  $\mathbf{H}_p$ , which is further concatenated with the  $\mathbf{h}_q^s$  to form the final summarization vector  $\mathbf{v}$ :

$$\mathbf{p} = \sum_{i=1}^{l_p} \alpha_i \mathbf{h}_i^p, \quad (7)$$

$$\mathbf{v} = \text{concat}(\mathbf{p}, \mathbf{h}_q^s), \quad (8)$$

Figure 1: The model architecture of the attentive model with word gloss (AMWG) implemented in this paper.  $\oplus$  denotes the concatenation of input vectors. All the encoders are 1-layer bi-directional GRU-RNNs,  $\otimes$  denotes the weighted sum of vectors.

Another attention  $f_{att}^g(\bullet)$  is applied to  $\mathbf{v}$  and  $\mathbf{H}_{g_t}$ ,

$$e_j = \tanh(\mathbf{W}_{att}^g \mathbf{v} + \mathbf{b})^T \mathbf{h}_j^{g_t}, \forall j \in [1, \dots, l_{g_t}] \quad (9)$$

$$\beta_j = \frac{\exp e_j}{\sum_{i=1}^{l_{g_t}} \exp e_i}, \forall j \in [1, \dots, l_{g_t}], \quad (10)$$

The following weighted sum of  $\mathbf{H}_{g_t}$ , i.e.  $\mathbf{a}_t^g$ , is derived as the final vector representation for the gloss of candidate word  $a_t$ :

$$\mathbf{a}_t^g = \sum_{j=1}^{l_{g_t}} \beta_j \mathbf{h}_j^{g_t} \quad (11)$$

We also set a token embedding  $\mathbf{a}_t^e$  for each candidate word  $a_t$  ( $t \in [1, \dots, n_c]$ ,  $n_c$  is the size of candidate set), which is further concatenated with  $\mathbf{a}_t^g$  to build the final representation  $\mathbf{a}_t$  for candidate word  $a_t$ . For the final prediction, we input the summarization vector  $\mathbf{v}$  and candidate representation vector  $\mathbf{a}_t$  to  $f_{pred}(\bullet)$  and apply the softmax to derive the probability distribution over all  $n_c$  candidate abstractive words,

$$\mathbf{a}_t = \text{concat}(\mathbf{a}_t^g, \mathbf{a}_t^e), \quad (12)$$

$$r_t = \mathbf{v}^T \mathbf{W}_{pred} \mathbf{a}_t, \forall t \in [1, \dots, n_c], \quad (13)$$

$$o_t = \text{softmax}_t(r_t), \forall t \in [1, \dots, n_c] \quad (14)$$

in which  $o_t$  gives the probability of predicting the candidate word  $a_t$  as the final answer. The word gloss, which defines a word sense meaning, has been mainly used in word sense disambiguation (WSD) task and its variants (Lesk, 1986; Moro et al., 2014). Since the goal of ARC is to predict a word that can summarize corresponding information from the source passage, which is an abstracting process, it may be helpful when the gloss, i.e., interpretation of candidate abstractive words, are provided.

We design an attentive model with word gloss (AMWG) as Figure 1 shows. Specifically, all the encoders are 1-layer bi-directional recurrent neural networks (RNNs) with Gated Recurrent Units (GRU) (Cho et al.). For an input news passage  $p = [p_1, p_2, \dots, p_{l_p}]$  with  $l_p$  words, we can derive its hidden states  $\mathbf{H}_p = [\mathbf{h}_1^p, \mathbf{h}_2^p, \dots, \mathbf{h}_{l_p}^p]$  by sending its word embedding sequence  $\mathbf{P} = [\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_{l_p}]$  to the *Passage Encoder*. Similarly, we can derive hidden states  $\mathbf{H}_s = [\mathbf{h}_1^s, \mathbf{h}_2^s, \dots, \mathbf{h}_{l_s}^s]$  for summary  $s$  by inputting its word embedding sequence  $\mathbf{S} = [s_1, s_2, \dots, s_{l_s}]$  into the *Summary Encoder* and hidden states  $\mathbf{H}_{g_t} = [\mathbf{h}_1^{g_t}, \mathbf{h}_2^{g_t}, \dots, \mathbf{h}_{l_{g_t}}^{g_t}]$  for gloss  $g_t$  of the candidate word  $a_t$  by sending its word embedding sequence  $\mathbf{G}_t = [g_1^t, g_2^t, \dots, g_{l_{g_t}}^t]$  to the *WordGloss Encoder*.

Similar to Section B, the corresponding representation of “@placeholder”, i.e.,  $\mathbf{h}_q^s$ , is used as the final vector representation for summary  $s$ . And an bilinear attention  $f_{att}^p(\bullet)$  is applied to  $\mathbf{h}_q^s$  and  $\mathbf{H}_p$  as follows:

$$e_i = \mathbf{h}_q^{sT} \mathbf{W}_{att}^p \mathbf{h}_i^p, \forall i \in [1, \dots, l_p] \quad (15)$$

$$\alpha_i = \frac{\exp e_i}{\sum_{j=1}^{l_p} \exp e_j}, \forall i \in [1, \dots, l_p] \quad (16)$$

Then  $\mathbf{p}$  is derived as the vector representation for passage  $p$  by the weighed sum of  $\mathbf{H}_p$ , which is further concatenated with the  $\mathbf{h}_q^s$  to form the final summarization vector  $\mathbf{v}$ :

$$\mathbf{p} = \sum_{i=1}^{l_p} \alpha_i \mathbf{h}_i^p, \quad (17)$$

$$\mathbf{v} = \text{concat}(\mathbf{p}, \mathbf{h}_q^s), \quad (18)$$

Another attention  $f_{att}^g(\bullet)$  is applied to  $\mathbf{v}$  and  $\mathbf{H}_{g_t}$ ,

$$e_j = \tanh(\mathbf{W}_{att}^g \mathbf{v} + \mathbf{b})^T \mathbf{h}_j^{g_t}, \forall j \in [1, \dots, l_{g_t}] \quad (19)$$

$$\beta_j = \frac{\exp e_j}{\sum_{i=1}^{l_{g_t}} \exp e_i}, \forall j \in [1, \dots, l_{g_t}], \quad (20)$$

The following weighted sum of  $\mathbf{H}_{g_t}$ , i.e.  $\mathbf{a}_t^g$ , is derived as the final vector representation for the gloss of candidate word  $a_t$ :

$$\mathbf{a}_t^g = \sum_{j=1}^{l_{g_t}} \beta_j \mathbf{h}_j^{g_t} \quad (21)$$

We also set a token embedding  $\mathbf{a}_t^e$  for each candidate word  $a_t$  ( $t \in [1, \dots, n_c]$ ,  $n_c$  is the size of candidate set), which is further concatenated with  $\mathbf{a}_t^g$  to build the final representation  $\mathbf{a}_t$  for candidate word  $a_t$ . For the final prediction, we input the summarization vector  $\mathbf{v}$  and candidate representation vector  $\mathbf{a}_t$  to  $f_{pred}(\bullet)$  and apply the softmax to derive the probability distribution over all  $n_c$  candidate abstractive words,

$$\mathbf{a}_t = \text{concat}(\mathbf{a}_t^g, \mathbf{a}_t^e), \quad (22)$$

$$r_t = \mathbf{v}^T \mathbf{W}_{pred} \mathbf{a}_t, \forall t \in [1, \dots, n_c], \quad (23)$$

$$o_t = \text{softmax}_t(r_t), \forall t \in [1, \dots, n_c] \quad (24)$$

in which  $o_t$  gives the probability of predicting the candidate word  $a_t$  as the final answer.

## D Training Details

We train all models using the non-negative log-likelihood as the objective function. The gloss of candidate words are derived from *WordNet* using the NLTK tools (Bird and Loper, 2004). Specifically, we first lemmatize the candidate word and use the lemmatized word as the query word for the searching in *WordNet*. To cope with the semantic ambiguity of words, we just concatenate the gloss of the first sense in each retrieved POS for the query word with corresponding POS tag as the delimiter.

Models in our experiments are trained with the following hyperparameter settings: All word embeddings and token embeddings  $\mathbf{a}_t^e$  have 300 dimensions and are initialized with Glove (Pennington et al., 2014). The passage  $p$  and summary  $s$  share one set of word embeddings, which are fixed during training. The glosses  $\{g_t\}$  for candidate words  $\{a_t\}$  keep its own word embeddings.

The hidden state vectors of all bi-directional GRU-RNNs in all models have 150 dimensions. The number of attention hops in GA Reader is set to 3. The batch size is set to 32. The method of Adam (Kingma and Ba, 2015) is adopted for optimization with initial learning rate  $1e - 03$ . A dropout with rate 0.3 is applied to the input layers for all GRU-RNN encoders and the final summarization vector  $\mathbf{v}$ .

## E Annotation Selection

To ensure most of our annotation is valid, we select annotations satisfying the following criteria: a) the average accuracy is higher than 40%; b) both text spans should not be empty; c) if the difficulty level is rated as easy, then this data sample should be answered correctly.

# TA-MAMC at SemEval-2021 Task 4: Task-adaptive Pretraining and Multi-head Attention for Abstract Meaning Reading Comprehension

Jing Zhang, Yimeng Zhuang, Yinpei Su\*

Samsung Research China-Beijing (SRC-B)

{jing97.zhang, ym.zhuang, yinpei.su}@samsung.com

## Abstract

This paper describes our system used in the SemEval-2021 Task 4 Reading Comprehension of Abstract Meaning, achieving 1st for subtask 1 and 2nd for subtask 2 on the leaderboard. We propose an ensemble of ELECTRA-based models with task-adaptive pretraining and a multi-head attention multiple-choice classifier on top of the pre-trained model. The main contributions of our system are 1) revealing the performance discrepancy of different transformer-based pretraining models on the downstream task, 2) presentation of an efficient method to generate large task-adaptive corpora for pretraining. We also investigated several pretraining strategies and contrastive learning objectives. Our system achieves a test accuracy of 95.11 and 94.89 on subtask 1 and subtask 2 respectively.

## 1 Introduction

Machine reading comprehension (MRC) is one of the key tasks for measuring machines' ability of understanding human languages and reasoning, it can be used broadly in real world applications such as Q&A systems and dialogue systems. MRC often comes in a triplet style  $\{passage, question, answer\}$ , given a context passage, questions related with this passage is asked, and the machine is expected to give the answers. The question-answer form can be question-answer pair, where the answer text is to be provided by machines, or statement form where the answer is to be filled in as cloze or multiple choices selection. By the type of answer formation, MRC can be divided into extractive and generative MRC, the former takes segments from the passage as the answer and the latter requires answer text generation based on the understanding of the passage.

Contribution during Internship in Samsung Research China-Beijing.

Generative MRC is harder than extractive MRC, since it requires more on information integration and reasoning besides focusing on relevant information.

One of the classic MRC approach focuses on matching networks, various network structures have been proposed to capture the semantic interaction within passages/questions/answers. Recent years, pre-trained language models (LMs) have brought non-trivial progress to the performance on MRC, and there's a decline of complex matching networks (Zhang et al., 2020). Plugging matching networks on top of pre-trained LMs can see either improvements or degradation in performance (Zhang et al., 2020; Zhu et al., 2020). Multiple-choice MRC (MMRC) often lacks abundant training data for deep neural networks (this might be caused by the expensive human labelling cost) and it results in a limitation to take full advantage of the pre-trained LMs.

The SemEval-2021 task 4 Reading Comprehension of Abstract Meaning (Zheng et al., 2021), is a multiple-choice English MRC task, aiming at investigating the machine's ability to understand abstract concepts in two aspects: subtask 1, non-concrete concepts, e.g. service/economy compared with trees/red; subtask 2, generalized/summarized concepts, like vertebrate compared with monkey.

We propose an approach based on the pre-trained LM ELECTRA (Clark et al., 2020), with an ensemble of multi-head attention (Vaswani et al., 2017) multiple-choice classifier, and WAE (Kim and Fung, 2020) to get the final prediction. **First**, we conduct task-adaptive pretraining, which is transfer learning using in-domain data on the ELECTRA model. **Then** we fine-tune the ReCAM task using a multi-head attention multiple choice classifier (MAMC) on top of the ELECTRA model. **Finally** we enhance the system with WAE and ensemble them all to get the best generalization capability.

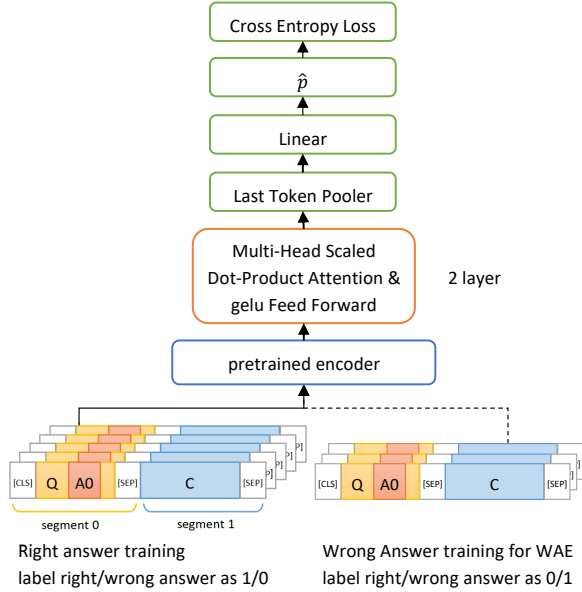

Figure 1: The overall architecture of our proposed system

In addition, we also investigated into transfer learning with natural language inference (NLI) tasks and contrastive learning objectives.

## 2 System Overview

Figure 1 illustrates the overall architecture of our system. The options are substituted into the query to form a complete context, rather than separate query/option segments, in order to get a less semantically ambiguous representation of the query and option. The option-filled query and context tokens are concatenated as in Figure 1, wrapped by [CLS] token and [SEP] tokens. Token embeddings are added up with segment embeddings and positional encodings to form the input for the pre-trained encoder. Then the representations from the encoder are put through a multi-head attention multiple choice classifier, which consists of 1) a 2 layer multi-head attention feed forward network to further capture the task specific query-context interactions, 2) a pooler and a linear transformation to get the final cross entropy loss. We first conduct task-adaptive pretraining on the system, and then fine-tune on the ReCAM dataset, the final model is an ensemble model by several generalization techniques including wrong answer ensemble.

### 2.1 Task-adaptive Pretraining

Pre-trained LMs and their downstream applications have definitely proved the power of transfer learning. The precondition of transfer learning is that the pretraining tasks have shared underlying sta-

tistical features with downstream tasks. Usually in-domain data brings more improvement on downstream tasks than out-of-domain data (Sun et al., 2019; Gururangan et al., 2020).

The genre of the ReCAM task dataset is news (confirmed by manual random checking), we argue that the task of news abstractive summarization provides high quality further pretraining dataset for ReCAM. The dataset comes in  $\{article, summary\}$  pairs, the articles are crawled from formal online news publishers and the summaries are generated by humans and contain abstractive key information of the articles. News abstractive summarization aims at teaching machines to grasp the key information of the whole context by letting machines to generate the summary text.

We regenerate the ReCAM style multiple-choice dataset from the original news abstractive summarization dataset. Letting the article/summary be the passage/question, the regeneration strategy mainly includes 2 steps: 1) identify the abstract concepts in the news dataset, 2) generate gold and pseudo options. In step 1, we count the part-of-speech (POS) tags of all gold labels on the ReCAM training data as shown in Figure 2 (nouns, adjectives and adverbs are the most frequent option tags), and use a similar POS tag distribution to randomly sample word in the summary text that does not appear in the corresponding news article as gold option. In step 2, the gold option in the summary is replaced by the mask token and fed into the pre-trained LM. The LM predicts the mask token and we select some of the top ranking ones as pseudo options. Specifically, setting a high ranking threshold (e.g. top 5) would get words too similar with the gold option, which would bring extra ambiguity to the model, some relaxation on the ranking threshold would ease the problem. This method is automatic, cheap to apply on large dataset, while the abstract concept approximation in step 1 would bring some noise, such as person’s names and geolocations are sometimes selected, but by our experiment result the overall pretraining performance is not hurt, the noisy samples should account for a small fraction.

In addition, it is reported that NLI task transfer

Figure 2: Subtask 1 (left) and subtask 2 (right) gold options POS Tag distribution

Dataset	# Passages	avg. doc len		avg. qry/smry len	
	training/dev/test	# words	# sent.	# words	# sent.
ReCAM subtask 1	3227/837/-	302.15	13.1	24.69	1
ReCAM subtask 2	3318/851/-	481.51	21.08	26.9	1
XSUM	20.3k/11.3k/1.1k	431.07	19.77	23.26	1
NEWSROOM	99.5k/-/-	658.6	-	26.7	-

Table 1: ReCAM/XSUM/NEWSROOM datasets statistics

learning performs well in several MMRC tasks (Jin et al., 2020). Therefore we also explored the MNLI (Williams et al., 2017) and RTE (Wang et al., 2018) tasks transfer learning for the ReCAM task, but it results in degradation. This indicates that NLI tasks are not generally fit for further pre-training in MMRC on pre-trained LMs.

## 2.2 Multi-head Attention Multiple Choice Classifier

The classifier takes the last layer hidden representations from the pre-trained encoder, applies the multi-head attention and feed forward non-linearity, each with a layer normalization (Vaswani et al., 2017). After that the last token is pooled, which is selecting the hidden vector from the hidden embeddings by the index of the last [SEP] token in the input, and then linearly transformed to get the probability of each  $\{query_{option\_filled}, context\}$  candidate pair.

In addition, we also explored the contrastive learning objective. When humans do MMRC, they usually compare the options according to the passage, exclude the wrong ones and then analyze further on the indeterminate ones. Inspired by this, we experimented with triplet loss (Weinberger et al., 2006) (among  $\{input_{non\_filled}, input_{gold}, input_{pseudo}\}$ ) and n-tuplet loss (Sohn, 2016) on all option-filled query and context within one sample. However the contrastive learning objective degrades the performance, suggesting these learning objectives are not as suitable for the ReCAM task as the MLE loss.

## 2.3 Wrong Answer Ensemble

Wrong Answer Ensemble (Kim and Fung, 2020) is a relatively simple yet effective method (Zhu et al., 2020). Kim proposed to train the model to learn the correct and the wrong answers separately and ensemble them to get the final prediction. In 2.2, the correct answer is labelled as 1 and wrong as 0 for correct answer training. Wrong answer training does the opposite labelling (correct/wrong answers

as 0/1) and fine tune the model with binary cross entropy loss as below:

$$loss_w = - \sum y \log \hat{y} + (1 - y) \log(1 - \hat{y}) \quad (1)$$

The two models’s output,  $p_c$  and  $p_w$  are linearly combined to give the final prediction. A simple linear regression is leveraged to find the best value of weight  $w$ .

$$\hat{p} = p_c - w \cdot p_w \quad (2)$$

## 3 Experimental Setup

### 3.1 Dataset

We leverage external news abstractive summarization datasets for transfer learning, and then fine tune our model on the ReCAM dataset.

**ReCAM.** Dataset for the SemEval-2021 Task 4, consisting of news articles (verified by manually random checking) and multiple-choice questions.

**XSUM.** XSUM (Narayan et al., 2018) consists of 227k BBC articles from 2010 to 2017 covering a wide variety of subjects along with professionally written single-sentence summaries.

**NEWSROOM.** NEWSROOM (Grusky et al., 2018) is a dataset of 1.3 million news articles and summaries written by authors and editors in newsrooms of 38 major news publications between 1998 and 2017. After a coarse selection (filtering out lengthy articles/summaries, summaries duplicate with news articles, articles with unqualified pseudo options), about 229k article/summary pairs are used.

The data statistics are listed in Table 1, the 3 news datasets share similar article and query lengths.

### 3.2 Training Details

We compare the baseline performance of 3 kinds of Transformer-based models, BERT/ALBERT/ELECTRA, and select ELECTRA as our encoder. We adopt most hyper parameter settings from the ELECTRA large model, specifically our learning rate is  $1e-5$ , batch size is 32 and gradient clip norm

Pre-trained model	subtask 1 dev acc.	subtask 2 dev acc.
BERT base	61.25	58.28
BERT large	66.31	67.33
ALBERT base	50.78	50.29
ALBERT large	80.88	79.08
ELECTRA base	76.82	76.97
ELECTRA large	90.20	90.13

Table 2: Baseline performance of different pre-trained Models

threshold is set to 1. In the task-adaptive data generation process, We set the threshold as top 10 for pseudo options selection, filtering out the word piece predictions(word pieces all start with a ”#” in the vocabulary) and randomly select 4 words as pseudo options. See the appendix for hyperparameter details. Training was done on NVidia V100 GPUs. All the performance data is on the dev set.

## 4 Results

### 4.1 Pre-trained LM Selection and Task-adaptive Pretraining

The baseline performance of BERT, ALBERT and ELECTRA is tested by directly fine-tuning the ReCAM data on the pre-trained LMs. The results are shown in Table 2. ELECTRA outperforms the other two models with large margins. This may be caused by the learning objective difference among the models. The BERT/ALBERT models learn to predict the masked word from the vocabulary, while the ELECTRA model learns to predict whether each of the token in the input is replaced or not, which learns more about unreasonable co-occurrence knowledge besides reasonable co-occurrences and may help in digging deeper implicit semantic relations for ReCAM. Therefore the ELECTRA large model is selected as the encoder for further experiments.

The XSUM/NEWSROOM regenerated data (denoted as XN) is used for in-domain pretraining on the encoder, and the subtask 1 is fine tuned after pretraining. The prediction accuracy grows with more data fed, as shown in Figure 3. In the end of the task-adaptive pretraining, subtask 1 achieves dev accuracy 92.73, 2.80% higher than directly fine-tuning on the encoder, subtask 2 gets 92.95, increased by 3.13%.

Besides the task-adaptive pretraining and fine-tuning, we also tried multitask learning with

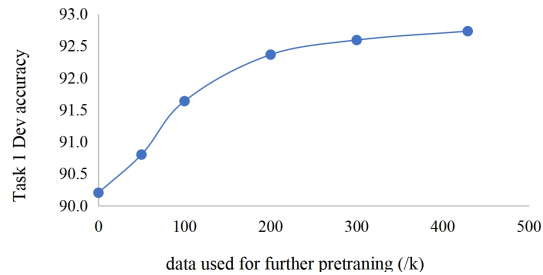

Figure 3: Subtask 1 fine-tuning performance increases with more data for further pretraining

Transfer learning setting	subtask 1	subtask 2
XN	92.73	92.95
ReCAM/ $XN_{multitask}$	92.35	92.36
MNLI	78.14	81.67
RTE	88.53	89.36

Table 3: Dev accuracy for different transfer learning settings

XSUM/NEWSROOM and the ReCAM data together (up sampling the ReCAM data as 3:7 with the news dataset). The results in Table 3 shows that this approach outperforms the encoder baseline, while slightly worse than the full news data pre-trained model, this model is used for ensemble. Using MNLI/RTE for further pretraining hurt the ReCAM fine-tuning performance, especially MNLI pretraining brings about 10% accuracy decrease than the baseline.

### 4.2 On-top Classifier and WAE

Adding MAMC on the top of the encoder helps increase accuracy on the ReCAM subtask 1 and subtask 2, the results are shown in Table 4. Further we applied the WAE to squeeze marginal increases on prediction accuracy. While option contrastive learning (OCL) does not bring performance improvement, worse than directly fine-tuning the encoder with multiple choice classifier.

Settings	subtask 1	subtask 2
Baseline	90.20	90.13
transfer learning	92.73	92.95
+ MAMC	93.64	93.79
+ WAE	93.94	94.07
OCL (triplet loss)	86.38	-
OCL (n-tuple loss)	85.32	-

Table 4: Dev accuracy on different transfer learning settings

Generalization Procedures	subtask1	subtask2
data repar. (3 sets)	93.72 94.01	93.65 94.48
task data aug.	93.82	94.36
	93.29	93.36

Table 5: Dev accuracy of subtask 1/2 over generalization procedures.

### 4.3 Improving Generalization

We mainly applied 3 procedures below for better generalization, and the ensemble of all the models have achieved test accuracy 95.11 on subtask 1 and 94.89 on subtask 2 on the ReCAM leaderboard.

1) Data repartitioning (mix the train/dev sets, and randomly split into new train/dev sets by 8:2 or 9:1) aims to smooth the distribution difference among different train/dev data partition. As is shown in the Table 5, the accuracy of different sets differs, with some higher than then original partition.

2) Augmenting the task data itself for fine-tuning, to mask different word than the original gold option (if there exists) using the method in 2.1. The accuracy remains almost the same after adding the task augmented data. This suggests that our automatic augmentation method makes lower quality samples than the labelling data, while not too noisy that it can contribute to the robustness of the model.

3) We also did Stochastic Weight Averaging (Izmailov et al., 2018) across multiple checkpoints in the same run to get better generalization (SWA dose not improve dev error but test error, so it’s not listed in Table 5).

### 4.4 Fail Cases Analysis

We manually checked and categorized the fail cases on subtask 1 and subtask 2 into 5 classes (given roughly 850 dev cases, the total fail cases is around 50 for both subtask 1 and subtask 2). The detailed examples for each class can be found in the appendix.

- EC0, easy case. In these cases, the answer can be inferred from the query/context, while the model fails to give the correct prediction
- EC1, complicated coreference. Such cases has complicated coreference relations, though the answer can be inferred, the coreferences hinder the model from understanding correctly
- EC2, complex reasoning. In these cases, either the information related with the answer

Figure 4: Subtask 1/2 fail case distribution

is sparse in the query/context, or the facets related with the answer is separated with intense unrelated noisy information

- EC3, external knowledge dependency. Only with the external knowledge can one give a correct answer
- EC4, ambiguity in sample cases. This category includes cases for which we think humans are not able to select the correct answer. Either the information is not enough to make a decision or there are more than one reasonable answers.

Figure 4 shows the ratios of each fail case class, the EC4 is the major class, 48.5% for subtask 1 and 75.0% for sutask 2. The following is EC3, 36.4% for subtask 1 and 6.3% for subtask 2. EC0 and EC1 are minor classes among all. With the system backbone being pre-trained LM with a matching network, it’s not a surprise to see EC1 and EC3 failures, while the few EC0 and EC2 failures shows that our system learns well to capture abstract concepts within the query/article pair.

## 5 Conclusion

Our system takes the large pre-trained LM ELECTRA, and enhance it with in-domain transfer learning and a multi-head multiple-choice classifier on top. We compared the benchmark performance of different pre-trained LMs (BERT, ALBERT and ELECTRA) on the SemEval-2021 task 4, the result shows that different pretraining objective/dataset can lead to different inclination of model knowledge and large performance discrepancy on the downstream task. Task-adaptive pretraining has contributed the main improvement, and multi-head multiple-choice classifier and WAE bring marginal improvement. We also investigated into option contrastive learning and multitask learning, the degradation of performance suggests that triplet and n-tuplet contrastive loss is not suitable for this task and NLI is not generally beneficial for MMRC tasks.

## Abstract

The Toxic Spans Detection task of SemEval-2021 required participants to predict the spans of toxic posts that were responsible for the toxic label of the posts. The task could be addressed as supervised sequence labeling, using training data with gold toxic spans provided by the organisers. It could also be treated as rationale extraction, using classifiers trained on potentially larger external datasets of posts manually annotated as toxic or not, without toxic span annotations. For the supervised sequence labeling approach and evaluation purposes, posts previously labeled as toxic were crowd-annotated for toxic spans. Participants submitted their predicted spans for a held-out test set, and were scored using character-based F1. This overview summarises the work of the 36 teams that provided system descriptions.

## 1 Introduction

Discussions online often host toxic posts, meaning posts that are rude, disrespectful, or unreasonable; and which can make users want to leave the conversation (Borkan et al., 2019a). Current toxicity detection systems classify whole posts as toxic or not (Schmidt and Wiegand, 2017; Pavlopoulos et al., 2017; Zampieri et al., 2019), often to assist human moderators, who may be required to review only posts classified as toxic, when reviewing all posts is infeasible. In such cases, human moderators could be assisted even more by automatically highlighting spans of the posts that made the system classify the posts as toxic. This would allow the moderators to more quickly identify objectionable parts of the posts, especially in long posts, and more easily approve or reject the decisions of the toxicity detection systems. As a first step along this direction, Task 5 of SemEval 2021 provided the participants with posts previously rated to be toxic, and required them to identify toxic spans,

i.e., spans that were responsible for the toxicity of the posts, when identifying such spans was possible. Note that a post may include no toxic span and still be marked as toxic. On the other hand, a non toxic post may comprise spans that are considered toxic in other toxic posts. We provided a dataset of English posts with gold annotations of toxic spans, and evaluated participating systems on a held-out test subset using character-based F1. The task could be addressed as supervised sequence labeling, training on the provided posts with gold toxic spans. It could also be treated as rationale extraction (Li et al., 2016; Ribeiro et al., 2016), using classifiers trained on larger external datasets of posts manually annotated as toxic or not, without toxic span annotations. There were almost 500 individual participants, and 36 out of the 92 teams that were formed submitted reports and results that we survey here. Most teams adopted the supervised sequence labeling approach. Hence, there is still scope for further work on the rationale extraction approach. We also discuss other possible improvements in the definition and data of the task.

## 2 Competition Dataset Creation

During 2015, when many publications were closing down comment sections due to moderation burdens, a start up named Civil Comments launched (Finley, 2016). Using a system of peer-based review and flagging, they hoped to crowd source the moderation responsibility. When this effort shut down in 2017 (Bogdanoff, 2017), they cited the financial constraints of the competitive publishing industry and the challenges of attaining the necessary scale.

The founders of Civil Comments, in collaboration with researchers from Google Jigsaw, undertook an effort to open source the collection of more than two million comments that had been collected. After filtering the comments to remove personally

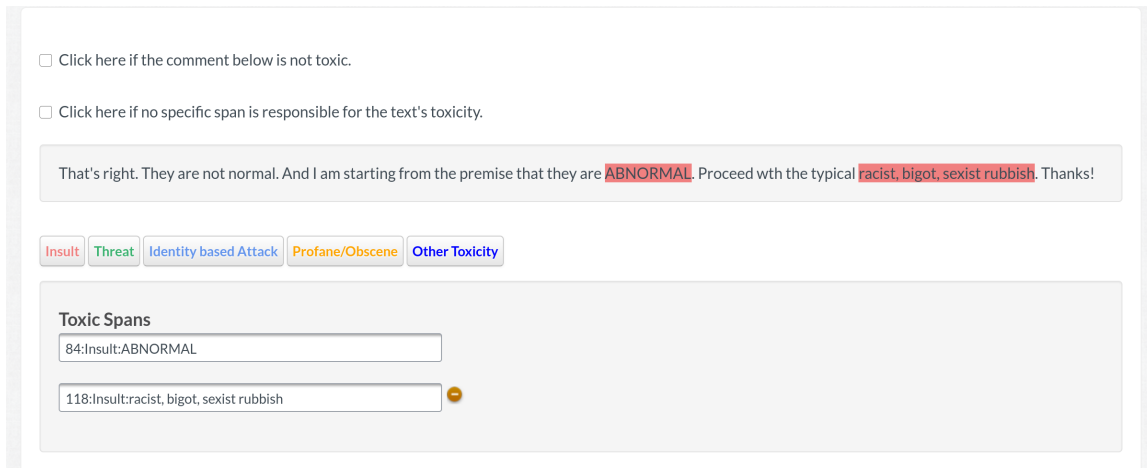

Figure 1: Screenshot of the Appen labeling interface that was used to annotate toxic spans.

identifiable information, a revised version of the annotation system of Wulczyn et al. (2017) was used on the Appen crowd rating platform to label the comments using a number of attributes including ‘toxicity’, ‘obscene’, ‘threat’ Borkan et al. (2019a). The complete dataset, partitioned into training, development, and test sets, was featured in a Kaggle competition,<sup>1</sup> with additional material, including individual rater decisions, published (Borkan et al., 2019b) after the close of the competition.

Civil Comments contains about 30k comments marked as toxic by a majority of at least three crowd raters. Toxic comments are *rare*, especially in fora that are not anonymous and where people have expectations that moderators will be watching and taking action. We undertook an effort to re-annotate this subset of comments at the span level, using the following instructions:

*For this task you will be viewing comments that a majority of annotators have already judged as toxic. We would like to know what parts of the comments are responsible for this.*

*Extract the toxic word sequences (spans) of the comment below, by highlighting each such span and then clicking the right button. If the comment is not toxic or if the whole comment should have been annotated, check the appropriate box and do not highlight any span.*

and a custom JavaScript based template,<sup>2</sup> which allowed selection and tagging of comment spans

<sup>1</sup>[www.kaggle.com/c/jigsaw-unintended-bias-in-toxicity-classification](http://www.kaggle.com/c/jigsaw-unintended-bias-in-toxicity-classification)

<sup>2</sup>[github.com/ipavlopoulos/toxic\\_spans](https://github.com/ipavlopoulos/toxic_spans)

(Fig. 1). While raters were asked to categorize each span as one of five different categories, this was primarily intended as a priming exercise and all of the highlighted spans were collapsed into a single category. The lengths of the highlighted spans were decided by the raters. Seven raters were employed per post, but there were posts where fewer were eventually assigned. On the test subset (Table 1), we verified that the number of raters per post varied from three to seven; on the trial and train subsets this number varied from two to seven. All raters were warned the content might be explicit, and only raters who allowed adult content were selected.<sup>3</sup>

## 2.1 Inter-annotator Agreement

We measured inter-annotator agreement, initially, on a small set of 35 posts and we found 0.61 average Cohen’s Kappa. That is, we computed the mean pairwise Kappa per post, by using character offsets as instances being classified in two classes, toxic and non-toxic. And then we averaged Kappa over the 35 posts. On later experiments with larger samples (up to 1,000 posts) we observed equally moderate agreement and always higher than 0.55. Given the highly subjective nature of the task we consider this agreement to be reasonably high.

## 2.2 Extracting the ground truth

Each post comprises sets of annotated spans, one per rater. Each span is assigned a binary (toxic, non-toxic) label, based on whether the respective rater

<sup>3</sup>The full dataset and annotations for ToxicSpans is released ([github.com/ipavlopoulos/toxic\\_spans](https://github.com/ipavlopoulos/toxic_spans)) with a CC0 licence. The previously released Civil Comments dataset, on which the new dataset is based, was filtered to remove any potential personally identifiable information.

	<b>Trial</b>	<b>Train</b>	<b>Test</b>
<b>Number of posts</b>	690	7,939	2,000
<b>Avg. post length</b>	199.47	204.57	186.41
<b>Avg. toxic span length</b>	10.78	13.11	7.89
<b>Avg. # of toxic spans</b>	1.43	1.39	0.92

Table 1: Statistics of the trial, training, and test subsets of the dataset. Lengths are calculated in characters.

found the span to be insulting, threatening, identity-based attack, profane/obscene, or otherwise toxic. If the span was annotated with any of those types, the span is considered toxic according to the rater, otherwise not. For each post, we extracted the character offsets of each toxic span of each rater. In each post, the ground truth considers a character offset as toxic if the majority of the raters included it in their toxic spans, otherwise the ground truth of the character offset is non-toxic. A toxic span (Table 1) in the ground truth of a post is a maximal sequence of contiguous toxic character-offsets.

### 2.3 Exploratory analysis

After discarding duplicates and posts used as quiz questions to check the reliability of candidate annotators, we split the data into trial, train, and test (Table 1). Compared to the trial and training sets, the test set comprises posts with fewer characters and spans, but also shorter spans on average.

When studying the toxicity subtypes, we find that the vast majority of posts are annotated as insulting. In the training set, more than 6,000 posts are annotated as insulting, and the same high fraction is observed in the trial and test sets. Most of the toxic spans in the training set are single-word terms. The most frequent of them, such as ‘stupid’ and ‘idiot’, occur hundreds of times and remain frequent in the trial and test sets. Multi-word terms, such as ‘white trash’, ‘mentally ill’, are less frequent and vary across the three sets.

In an analysis of the test set, Palomino et al. (2021) used an emotion classifier that returns five scores per post, one for each of the following emotions: *anger*, *happiness*, *sadness*, *surprise*, *fear*.<sup>4</sup> *Fear* and *sadness* were reported to be the emotions with the highest average scores, a finding that we verified by repeating the experiment (see Fig. 2).<sup>5</sup> Interestingly, the emotion with the highest average score after *sadness* and *fear* is *surprise*, not *anger*, and *happiness* has the lowest score.

<sup>4</sup>[pypi.org/project/text2emotion](https://pypi.org/project/text2emotion)

<sup>5</sup>A post with a high *sadness* score (100%) is the following: “Such thin skin. **Pathetic.**”; the toxic span shown in red.

Figure 2: Emotion scores of the test posts. Emotion scores were obtained using an off-the-shelf emotion classifier, following Palomino et al. (2021).

## 3 Task description

The objective of this task is the detection of the spans that make a post toxic, when detecting such spans is possible. Systems had to extract a list of toxic spans, or an empty list, per post. A toxic span was defined to be a sequence of words that attribute to the post’s toxicity. Although we defined the task at the word level, gold labels were provided at the character level counting from zero (see Table 2).

Figure 3: Number of submissions per evaluation day.

The evaluation period started on January 10, 2021 and finished on January 31, 2021. The first week, 10 submissions were allowed per day per team. The second week this number was reduced to 5, and it was reduced further to 1 during the final week. We chose to allow an extended evaluation period combined with multiple team submissions, to promote the competition. However, we also chose a decreasing submission limit to make it harder for participants to overfit the test set. As shown in Fig. 3, the number of submissions dropped over time, due to this constraint, but the interest was

OFFSETS	POST
{}	I will stand by my statement that liberalism is what smart looks like to stupid people. The letter posted yesterday states the real problem clearly enough. "It doesn't matter if it was protected by the First Amendment." I have legal news flash for the University of Oregon. Because the University is public and receives government tax dollars it is indeed bound to abide by the US constitution with ALL OF IT'S PROTECTION INCLUDED. Which should tell everyone right off the signatories are anti-American, and perhaps even anti-America in their twisted PC nonsense.
{}	Fits the despicable piece of trash like a glove.
{}	No he shot someone so he shouldn't be free. He should be locked up like He is for the next decade. You holla like its no big deal but what if it was your little brother who was shot? Then your dumb ass wouldnrht be screaming free ace g or whatever gay nickname he has. That is the lamest gangster name ever. Do you think that name scares people? Ace clown is what i will now call him.
{55, 56, 57, 58}	Time to give the opposition weapons and overthrow this <b>jerk</b> .
{31, ..., 39}	you are a paid liberal hack of <b>stupidity</b> shore living the liberal lie every day
{9, ..., 13}	Youre an <b>idiot</b> .
{7, 8, ..., 11, 14, 15, ..., 18}	what a <b>dummy, dummy</b> has no regard for the law. you cannot brutalize a suspect. he has complete lack of respect for any law and is acting like a dictator. he is trying to emulate putin.
{12, ..., 17, 94, ..., 102}	People make <b>stupid</b> decisions and then expect the gov't to bail them out. There is no cure for <b>stupidity</b> .
{14, ..., 20, 29, ..., 35}	Nah, the only <b>asshole</b> is the <b>asshole</b> firing a rifle within city limits.

Table 2: Examples of toxic test posts and their ground truth toxic spans (shown in red). The left column shows the character offsets of the toxic spans. The top three posts have no toxic spans, the next three have one each, while the remaining three posts have two toxic spans each.

continuous, and there were submissions until the last day. Despite the decreasing total number of submissions per day, the top daily score increased, reaching its maximum on the last day (see Fig. 4).

Figure 4: The evaluation score (character F1) of the best submission per day during the evaluation period.

## 4 Participation overview

We received 479 individual participation requests, 92 team formations, and 1,449 submissions. 91 teams submitted valid predictions (1,385 valid submissions in total) and were scored; out of these, only 36 submitted system descriptions.

### 4.1 The HITSZ-HLT submission

The best performing team (HITSZ-HLT) formulated the problem as a combination of token label-

ing and span extraction (Zhu et al., 2021).

For their token labeling approach, the team used two systems based on BERT (Devlin et al., 2019). Both systems had a Conditional Random Field (CRF) layer (Sutton and McCallum, 2006) on top, but one of the two also had an LSTM layer (Hochreiter and Schmidhuber, 1997) between BERT and the CRF layer. In both approaches, word-level BIO tags were used, i.e., words were labelled as B (beginning word of a toxic span), I (inside word of a toxic span), or O (outside of any toxic span).

For their span extraction approach, the team also used BERT. Roughly speaking, in this case BERT produces probabilities indicating how likely it is for each token to be the beginning or end of a toxic span. Then a heuristic search algorithm, originally developed for target extraction in sentiment analysis by Hu et al. (2019), selects the best combinations of candidate begin and end tokens, aiming to output the most likely set of toxic spans per post.

The character predictions of the three systems described above were combined with majority voting per character. That is, if any two systems considered a character to be part of a toxic span, then the ensemble classified the character as toxic, otherwise the ensemble classified it as non-toxic.

### 4.2 The S-NLP submission

The team with the second best performing system (S-NLP) consists of individual participants who grouped and submitted an ensemble of their sys-

tems (Nguyen et al., 2021). The ensemble combines two approaches, both of which are based on a RoBERTa model (Liu et al., 2019). The latter is first fine-tuned to classify posts as toxic or non-toxic, using three Kaggle toxicity datasets.<sup>6</sup> For toxic span detection, RoBERTa’s subword representations from three different layers (1, 6, 12) are summed to produce the corresponding word embeddings. A binary classifier on top of RoBERTa, operating on the word embeddings, predicts whether a word belongs to a toxic span or not.

For the first component of the ensemble, the word embeddings obtained from RoBERTa’s subword representations are concatenated with FLAIR (Akbik et al., 2019) and FastText (Bojanowski et al., 2017) embeddings.<sup>7</sup> The resulting embeddings are passed on to a two-layer stacked BiLSTM with a CRF layer on top to generate a BIO tag per word.

The second component of the ensemble used the RoBERTa model as a teacher to produce silver toxic spans for 30,000 unlabelled toxic posts (Borkan et al., 2019a). RoBERTa was then retrained as a student on the augmented dataset (30k posts with silver labels and the training posts provided by the organisers) to predict toxic offsets.

The ensemble returns the intersection of the toxic spans identified by the two components.

### 4.3 Additional interesting approaches

We now discuss some of the most interesting alternative approaches tried by the participants, even if they did not lead to high scores.

**Rationales** Some participants experimented with training toxicity classifiers on external datasets containing posts labeled as toxic or non-toxic; and then employing model-specific or model-agnostic rationale extraction mechanisms to produce toxic spans as explanations of the decisions of the classifier. The model-specific rationale mechanism of Rusert (2021) used the attention scores of an LSTM toxicity classifier to detect the toxic spans. Pluciński and Klimczak (2021) used the same approach, but also employed an orthogonalisation technique (Mohan Kumar et al., 2020). The model-agnostic rationale mechanism of Rusert (2021) combined an LSTM classifier with a token-masking approach that we call Input Erasure (IE), due to its similarities to the method of Li et al. (2016). The

<sup>6</sup>[github.com/unitaryai/detoxify](https://github.com/unitaryai/detoxify)

<sup>7</sup>In the latter case, in-vocabulary word embeddings were imported to Word2Vec for efficiency, and out of vocabulary words were handled with BPEs (Sennrich et al., 2016).

model-agnostic approach of Pluciński and Klimczak (2021) combined SHAP (Lundberg and Lee, 2017) with a fine-tuned BERT model. Ding and Jurgens (2021) and Benlahbib et al. (2021) also experimented with model-agnostic approaches, but they combined LIME (Ribeiro et al., 2016) with a Logistic Regression (LR) or with a linear Support Vector Machine (SVM) toxicity classifier. All the above mentioned approaches used a threshold to turn the explanation scores (e.g., attention or LIME scores) of the words into binary decisions (toxic/non-toxic words).

**Lexicon-based** No team relied on a purely lexicon-based approach, but few experimented with lexicon-based baselines (Zhu et al., 2021; Palomino et al., 2021) or used such components in ensembles (Ranasinghe et al., 2021). Three kinds of lexicon-based methods were used. First, the lexicon was handcrafted by domain experts (Smedt et al., 2020) and it was simply employed as a list of toxic words for lookup operations (Palomino et al., 2021). Second, the lexicon was compiled using the set of tokens labeled as toxic in our span-annotated training set and it was used as a lookup table (Burtenshaw and Kestemont, 2021), possibly also storing the frequency of each lexicon token in the training set (Zhu et al., 2021). The former two were also combined (Ranasinghe et al., 2021). Third, the least supervised lexicons were built with statistical analysis on the occurrences of tokens in a training set solely annotated at the comment level (toxic/non-toxic post) (Rusert, 2021). An added value of these approaches is that easy to use resources (toxicity lexicons) are built and shared publicly, such as the one suggested by Pluciński and Klimczak (2021).<sup>8</sup>

**Custom losses** Zhen Wang and Liu (2021) experimented with a new custom loss, which weighted false toxicity predictions based on their location in the text. If a false prediction was located near a ground truth toxic span, then it would contribute less to the overall loss for that post, compared to one located further away. The loss function used by Kuyumcu et al. (2021) to train their system is the Tversky Similarity Index (Tversky, 1977), a generalisation of the Sørensen–Dice coefficient and the Jaccard index, which was adjusted by the authors to weigh up false negatives.

**Data augmentation** The vast majority of the participating teams employed additional training data annotated at the post level. That is, either to

<sup>8</sup>[github.com/Orthrux-Lexicon/Toxic](https://github.com/Orthrux-Lexicon/Toxic)

build lexicons (Rusert, 2021), to leverage unsupervised rationale extraction methods (Rusert, 2021; Pluciński and Klimczak, 2021; Ding and Jurgens, 2021; Benlahbib et al., 2021), or to filter posts (Luu and Nguyen, 2021) that were not labeled as toxic by a toxicity classifier. Suman and Jain (2021) astutely produced silver data from external sources to augment the initial golden annotated dataset, training their model iteratively in a semi-supervised manner.

## 5 Evaluation

This section focuses on the evaluation framework of the task. First, the official measure that was used to evaluate the participating systems is described. Then, we discuss baseline models that were selected as benchmarks for comparison reasons. Finally, the results are presented.

### 5.1 Official evaluation measure

Following the work of Martino et al. (2019), systems were evaluated in terms of F1 computed on character offsets. For each system, we computed the F1 score per post, between the predicted and the ground truth character offsets. Then, we returned the macro-averaged (over test posts) score. When the ground truth set of character offsets was empty, we assigned a perfect score ( $F_1 = 1$ ) to the post in question if the predicted set of character offsets was also empty, and a zero score otherwise.<sup>9</sup>

### 5.2 Benchmarks

We report the results of some baselines, developed by us or the participants, to act as benchmarks.

BENCHMARK I was developed by Nguyen et al. (2021). It is based on a RoBERTa model, fine-tuned to predict if a post is toxic or not (Section 4.2) and further fine-tuned to predict toxic spans by using a CRF layer on top.

BENCHMARK II is a lexicon-based system, developed by Zhu et al. (2021), which extracts likely toxic words from the training data and simply tags them during inference. The lexicon comprises words that appear frequently inside ground truth toxic spans and not outside.

BENCHMARK III is a random baseline, which assigns a random label (toxic/non-toxic) per character offset (50% chance of being toxic).<sup>10</sup>

<sup>9</sup>The evaluation code can be found in our GitHub repository ([github.com/ipavlopoulos/toxic\\_spans](https://github.com/ipavlopoulos/toxic_spans)).

<sup>10</sup>The code of this baseline is also in the task’s repository.

Table 3: Official rank and F1 score (%) of the 36 participating teams that submitted system description papers. (There were 91 teams with submissions in total.) The median is shown in blue and benchmarks in red.

Table 3 shows the scores and ranks of all participating teams that described their approach, i.e., 36 out of 91 teams that participated. HITSZ-HLT (Section 4.1) was ranked first, followed by S-NLP (Section 4.2) that scored 0.06% lower. The rest of the teams followed with scores lower than 70%.

The score of the median is 67.58%, which is not far below the top scored team (-3.22 percent units), while it is far above the last two (+17.52 percent units). The standard deviation of system scores above the median is much lower (0.94) than that of the systems below the median (4.12). Most teams that were excluded from the table (because they did not describe their methods) score lower than

the median. However, there were also top scoring teams among those that were excluded, such as a team with a RoBERTa-based token-level ensemble that was ranked 4th.<sup>11</sup>

BENCHMARK I achieves a considerably high score and, hence, is very highly ranked. Combining BERT with a CRF or a span extraction method (two of the individual methods of the HITSZ-HLT ensemble, Section 4.1, not shown in Table 3) also performs well (Zhu et al., 2021), but these methods would be ranked two positions lower than BENCHMARK I. Nguyen et al. (2021) explored the benefits of further enhancing these word embeddings by concatenating them with FLAIR (Akbik et al., 2019) and FastText (Bojanowski et al., 2017) embeddings (Section 4.2). As shown in Fig. 5, the F1 score is slightly improved, reaching a maximum when both FLAIR and FastText embeddings are added.<sup>12</sup> We note that the same beneficial effect of enhancing the word embeddings was reported when using BERT as the base model (Sans and Farràs, 2021).

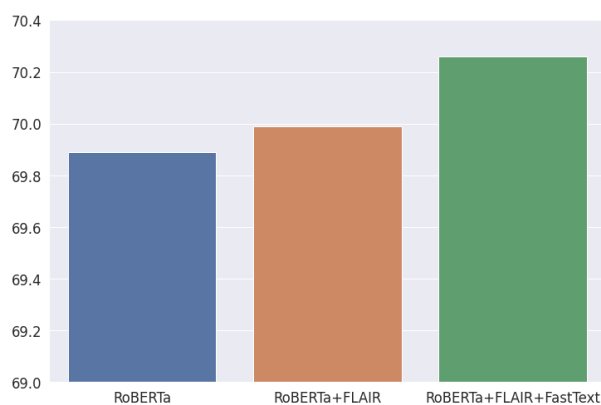

Figure 5: F1 of BENCHMARK I (Zhu et al., 2021) when FLAIR and FastText word embeddings are concatenated with the embeddings obtained from RoBERTa’s subword representations (from layers 1, 6, 12).

The lexicon-based BENCHMARK II and the random BENCHMARK III scored very low. The latter outperformed only one submission (MACECH), which sent the predictions in the wrong order. As noted in their report (Cech, 2021), if the predictions had been submitted in the correct order, the team’s score would have been 54%, and BENCHMARK III would have been the worst system in Table 3.

<sup>11</sup>We asked for details from participants that did not submit a description paper, but not all of them replied.

<sup>12</sup>Out of vocabulary words were tackled by using FastText embeddings of BPEs; consult Nguyen et al. (2021).

## 6 Analysis and discussion

Overall the organisers were happy to see the degree of involvement in this shared task, and the resulting diversity of approaches to this problem. We include some of our observations regarding the administration of the evaluation and what we have learned from the results.

### 6.1 Participation

The authors reached out to teams that decided not to submit a description paper and the vast majority were students who were time-limited. The fact that students participated in the task is promising and we plan to consider more ways to introduce SemEval tasks in classrooms. On the other hand, 60% of the participants chose not to describe their approach, which is problematic and should be addressed. A team could take advantage of such an option to create duplicate submissions and bypass any submission limits. More importantly, potentially interesting approaches are not discussed and properly compared to others.

It is also worth mentioning that the extended timeline allowed participants to join forces. For instance, a number of participants decided to combine their systems and form the 2nd ranked S-NLP. Their ensemble scored higher than all their standalone systems, though their best standalone system would still be ranked 2nd. In any case, we welcome the collaboration between participants, which may provide further insights regarding effective combinations of architectures.

### 6.2 General remarks on the approaches

Except for lexicon-based baselines, we observed that the vast majority of systems adopted the recent paradigm in NLP: fine-tuning large off-the-shelf Transformers (Vaswani et al., 2017) pre-trained on massive corpora. Non-Transformer based approaches, mostly LSTMs with pre-trained word embeddings were also used. The nature of the task, similar to the well-studied Named Entity Recognition (NER) task, led many competitors to use a CRF layer on top of the model (e.g., Transformers or LSTMs) of their choice.

### 6.3 Performance

The winning team (HITSZ-HLT) combined BERT with two approaches for their ensemble: a token labeling approach (two versions, with/without an LSTM between BERT and the CRF) and a span ex-

traction approach (Section 4.1). The comparison of the two showed that span extraction is slightly better on posts with a single span, but token labeling is clearly better on multi-span posts (Zhu et al., 2021). The complementary nature of the two approaches is probably what makes even a simple majority voting ensemble better than its competitors.

The system that was ranked second (S-NLP) also employed an ensemble, using a RoBERTa model initially fine-tuned to classify posts as toxic or non-toxic as the starting point (Nguyen et al., 2021). The ensemble combined (i) the resulting RoBERTa model, now fine-tuned to predict toxic spans, with additional FLAIR and FastText embeddings, and (ii) a RoBERTa model retrained as a student to predict toxic spans (Section 4.2). Although the two standalone models achieved higher scores than the standalone models of the top-ranked team (HITSZ-HLT), the ensemble did not yield significant improvements. This may be due to the student’s decisions not being that complementary to the teacher’s, as the team notes (Nguyen et al., 2021).

TBC	RE	F1 (%)	Report
LSTM	IE	38.29	Rusert (2021)
LSTM	ATT	49.70	Pluciński and Klimczak (2021)
LSTM	ATT	50.07	Rusert (2021)
LR	LIME	58.88	Benlahbib et al. (2021)
SVM	LIME	59.21	Benlahbib et al. (2021)
BERT	SHAP	<b>59.87</b>	Pluciński and Klimczak (2021)

Table 4: F1 on the evaluation set for systems employing rationale extraction (RE) mechanisms combined with post-level toxicity binary classifiers (TBC). Rationales are obtained via Input Erasure (IE), Attention (ATT), LIME, or SHAP. The binary classifier is an LSTM, Logistic Regression (LR), SVM, or BERT.

Teams that experimented with rationale extraction mechanisms (Section 4.3) did not find this approach advantageous compared to supervised sequence labeling in terms of F1 scores. However, the reported results of the rationale-based systems show that this approach is promising, especially because it does not require any data annotated at the span-level. Hence, there is scope for future work that could explore this direction further. Table 4 shows the F1 scores of all the rationale-based systems that were reported by participants. The binary toxic post classifiers that were used were LSTM, Logistic Regression (LR), Support Vector Machines (SVM), and BERT. The attention scores of an LSTM were used with (Pluciński and Klimczak, 2021) and without an orthogonality method (Rusert, 2021), with the latter being slightly bet-

ter; these are model-specific rationale extraction methods (Section 4.3). Model-agnostic approaches (Input Erasure, LIME, SHAP) were better than the model-specific ones. The best rationale-based method employed a BERT model, fine-tuned for toxic post classification, and SHAP.

Lexicon Name	F1 (%)	Report
WIEGAND 1 †	33.07	Zhu et al. (2021)
WORD-MATCH	40.86	Ranasinghe et al. (2021)
FREQ-RATIO †	41.55	Rusert (2021)
LOOKUP ‡	41.61	Burtenshaw and Kestemont (2021)
WIEGAND 2 †	50.98	Zhu et al. (2021)
ORTHRUS	61.07	Palomino et al. (2021)
HITSZ-HLT ‡	<b>64.98</b>	Zhu et al. (2021)
+WORDNET	64.09	Zhu et al. (2021)
+GLOVE	64.19	Zhu et al. (2021)

Table 5: F1 on the evaluation set for lexicon-based systems. Systems that are followed by † and ‡ use exclusively external and internal resources respectively.

Lexicon-based approaches were only used as baselines or components in ensembles, as already noted. In principle, all lexicon-based systems are extremely efficient and interpretable. Table 5 shows they can also achieve surprisingly high scores. Recall that we used the best performing lexicon-based system, developed by Zhu et al. (2021), as BENCHMARK II. Its score is included in Table 3. Despite the fact that it is low ranked, its F1 score is less than 6 percent points lower than that of the best submission. We also note that BENCHMARK II is a high-precision classifier; it outperforms even the best system in terms of precision (Zhu et al., 2021). Attempts to expand its lexicon using WordNet and GloVe, improved recall, but eventually harmed precision and its F1 score.

## 6.4 Error analysis

A common theme across many competitor reports was the serious challenge posed by comments with no toxic spans. It is not readily evident why this is a common occurrence in the task, and certainly the way that annotation consensus is used to combine annotations can be a contributing factor. However, many systems seemed determined to tag *some* spans and many authors noted that performance on posts with no tagged span was extremely poor compared to performance on posts with tagged spans.

Many systems were also reluctant to tag function words like ‘of’ and ‘and’, which can be included in multi-word spans (e.g., ‘piece of crap’), leading to a decline in performance as measured by the chosen F1 measure. The overwhelming presence

of single word gold spans in the training set favors short spans. But the majority of the short spans comprises common cuss or clearly abusive words, which can be directly classified as toxic (Ghosh and Kumar, 2021); by contrast, the infrequent longer spans are rather context dependent and more challenging to detect. This probably also contributed to the performance of the best system (HITSZ-HLT), since one of the two components of that ensemble handled better long spans, as already discussed in Section 6.3.

Other error analysis highlighted challenges intrinsic to the task. The strong dependency of toxicity on context makes it particularly difficult to solve with systems based on vocabulary. Toxicity, when expressed with subtle language, can appear through non-local text features: some comments are toxic without showing any obvious toxic span in them. Such posts made the task more difficult for participants, because systems had learnt to label the words bearing the most negative sentiment (Bansal et al., 2021). Annotation mistakes were also reported (Table 6).

Type	Description
INCONSISTENCIES	Not all the occurrences of the same toxic span are annotated in the same post.
FALSE NEGATIVES	Toxic words missed.
FALSE POSITIVES	Non-toxic words labelled.

Table 6: The types and descriptions of the annotation mistakes that were detected by some of the participants.

Participants that were notable for their effort in error analysis include Bansal et al. (2021), Hoang and Nguyen (2021), Ding and Jurgens (2021), and Ghosh and Kumar (2021), where an additional effort was made to examine their model’s ability to correctly tag words in toxic and non-toxic contexts. Interestingly Sans and Farràs (2021) also noted in their analysis that racial and ethnic terms are labeled in biased ways that reflect patterns not only in the training toxic spans, but also in external data used to pre-train underlying Transformer models.

## 7 Conclusions

We provided 10,629 posts that were annotated for toxic spans and we defined the task of toxic span detection. The task was popular, attracting almost 500 individual participants. Eventually 91 teams were formed, out of which 36 submitted a description report. This overview described the approaches of these 36 teams and discussed their results.

Pre-trained Transformers, fine-tuned by viewing the task as a sequence labelling one, performed well and solutions that combined these models within an ensemble were highly-rated. The performance of these models increases further with the help of pre-trained word embeddings or by using multiple Transformer layers to embed words.

Long toxic spans were more likely context-dependent and less frequent in the dataset compared to single-word spans, which made their detection a challenge. The winners included in their ensemble an approach that performed better on long spans, but we note that the problem of detecting long uncommon toxic spans is far from solved.

Of particular interest were approaches that employed rationale extraction mechanisms, which do not require any training data annotated at the span level. They performed much worse than sequence labeling approaches, but this is a promising direction that was considered by only a few participants.

Future similar competitions could benefit from tracks that separate supervised from unsupervised solutions. The development of datasets created with the help of crowd annotators should focus on addressing ambiguity, bias, inconsistencies, and misannotations. This could be accomplished by adding more annotators per post. Future competitions could also require participants to both classify posts as toxic or not, and detect toxic spans only when posts are classified as toxic, instead of providing the participants only with posts already classified as toxic. Finally, future competitions could require participants to distinguish toxic posts of different kinds (e.g., insult, threat, profanity, along with supporting spans), which are sometimes easier to define compared to the more general umbrella toxicity term we (and others) have used.

## Abstract

We describe *SemEval-2021 task 6 on Detection of Persuasion Techniques in Texts and Images*: the data, the annotation guidelines, the evaluation setup, the results, and the participating systems. The task focused on memes and had three subtasks: (i) detecting the techniques in the text, (ii) detecting the text spans where the techniques are used, and (iii) detecting techniques in the entire meme, i.e., both in the text and in the image. It was a popular task, attracting 71 registrations, and 22 teams that eventually made an official submission on the test set. The evaluation results for the third subtask confirmed the importance of both modalities, the text and the image. Moreover, some teams reported benefits when not just combining the two modalities, e.g., by using early or late fusion, but rather modeling the interaction between them in a joint model.

## 1 Introduction

Internet and social media have amplified the impact of disinformation campaigns. Traditionally a monopoly of states and large organizations, now such campaigns have become within the reach of even small organisations and individuals (Da San Martino et al., 2020b).

Such propaganda campaigns are often carried out using posts spread on social media, with the aim to reach very large audience. While the rhetorical and the psychological devices that constitute the basic building blocks of persuasive messages have been thoroughly studied (Miller, 1939; Weston, 2008; Torok, 2015), only few isolated efforts have been made to devise automatic systems to detect them (Habernal et al., 2018; Habernal et al., 2018; Da San Martino et al., 2019b).

WARNING: This paper contains meme examples and wording that might be offensive to some readers.

Figure 1: A meme with a civil war threat during the President Trump’s impeachment trial. Two persuasion techniques are used: (i) *Appeal to Fear* in the image, and (ii) *Exaggeration* in the text. **Source(s):** Image ; License

Thus, in 2020, we proposed *SemEval-2020 task 11 on Detection of Persuasion Techniques in News Articles*, with the aim to help bridge this gap (Da San Martino et al., 2020a). The task focused on text only. Yet, some of the most influential posts in social media use memes, as shown in Figure 1,<sup>1</sup> where visual cues are being used, along with text, as a persuasive vehicle to spread disinformation (Shu et al., 2017). During the 2016 US Presidential campaign, malicious users in social media (bots, cyborgs, trolls) used such memes to provoke emotional responses (Guo et al., 2020).

In 2021, we introduced a new SemEval shared task, for which we prepared a multimodal corpus of memes annotated with an extended set of techniques, compared to SemEval-2020 task 11. This time, we annotated both the text of the memes, highlighting the spans in which each technique has been used, as well as the techniques appearing in the visual content of the memes.

<sup>1</sup>In order to avoid potential copyright issues, all memes we show in this paper are our own recreation of existing memes, using images with clear copyright.

Based on our annotations, we offered the following three subtasks:

**Subtask 1 (ST1)** Given the textual content of a meme, identify which techniques (out of 20 possible ones) are used in it. This is a multilabel classification problem.

**Subtask 2 (ST2)** Given the textual content of a meme, identify which techniques (out of 20 possible ones) are used in it together with the span(s) of text covered by each technique. This is a multilabel sequence tagging task.

**Subtask 3 (ST3)** Given a meme, identify which techniques (out of 22 possible ones) are used in the meme, considering both the text and the image. This is a multilabel classification problem.

A total of 71 teams registered for the task, 22 of them made an official submission on the test set and 15 of the participating teams submitted a system description paper.

## 2 Related Work

**Propaganda Detection** Previous work on propaganda detection has focused on analyzing textual content (Barrón-Cedeno et al., 2019; Da San Martino et al., 2019b; Rashkin et al., 2017). See (Martino et al., 2020) for a recent survey on computational propaganda detection. Rashkin et al. (2017) developed the TSHP-17 corpus, which had document-level annotations with four classes: *trusted*, *satire*, *hoax*, and *propaganda*. Note that TSHP-17 was labeled using distant supervision, i.e., all articles from a given news outlet were assigned the label of that news outlet. The news articles were collected from the English Gigaword corpus (which covers reliable news sources), as well as from seven unreliable news sources, including two propagandistic ones. They trained a model using word  $n$ -grams, and reported that it performed well only on articles from sources that the system was trained on, and that the performance degraded quite substantially when evaluated on articles from unseen news sources. Barrón-Cedeno et al. (2019) developed a corpus QProp with two labels (propaganda vs. non-propaganda), and experimented with two corpora: TSHP-17 and QProp. They binarized the labels of TSHP-17 as follows: propaganda vs. the other three categories.

They performed massive experiments, investigated writing style and readability level, and trained models using logistic regression and SVMs. Their findings confirmed that using distant supervision, in conjunction with rich representations, might encourage the model to predict the source of the article, rather than to discriminate propaganda from non-propaganda. The study by Habernal et al. (2017, 2018) also proposed a corpus with 1.3k arguments annotated with five fallacies, including *ad hominem*, *red herring*, and *irrelevant authority*, which directly relate to propaganda techniques.

A more fine-grained propaganda analysis was done by Da San Martino et al. (2019b), who developed a corpus of news articles annotated with the spans of use of 18 propaganda techniques, from an inventory they put together. They targeted two tasks: (i) binary classification —given a sentence, predict whether any of the techniques was used in it; and (ii) multi-label multi-class classification and span detection task —given a raw text, identify both the specific text fragments where a propaganda technique is being used as well as the type of technique. They further proposed a multi-granular gated deep neural network that captures signals from the sentence-level task to improve the performance of the fragment-level classifier and vice versa. Subsequently, an automatic system, Prta, was developed and made publicly available (Da San Martino et al., 2020c), which performs fine-grained propaganda analysis of text using these 18 fine-grained propaganda techniques.

**Multimodal Content** Another line of related research is on analyzing multimodal content, e.g., for predicting misleading information (Volkova et al., 2019), for detecting deception (Glenski et al., 2019), emotions and propaganda (Abd Kadir et al., 2016), hateful memes (Kiela et al., 2020), and propaganda in images (Seo, 2014). Volkova et al. (2019) developed a corpus of 500K Twitter posts consisting of images and labeled with six classes: disinformation, propaganda, hoaxes, conspiracies, clickbait, and satire. Glenski et al. (2019) explored multilingual multimodal content for deception detection. Multimodal hateful memes were the target of the *Hateful Memes Challenge*, which was addressed by fine-tuning state-of-art methods such as ViLBERT (Lu et al., 2019), Multimodal BERT (Kiela et al., 2019), and VisualBERT (Li et al., 2019) to classify hateful vs. not-hateful memes (Kiela et al., 2020).

**Related Shared Tasks** The present shared task is closely related to *SemEval-2020 task 11 on Detection of Persuasion Techniques in News Articles* (Da San Martino et al., 2020a), which focused on news articles, and asked (i) to detect the spans where propaganda techniques are used, as well as (ii) to predict which propaganda technique (from an inventory of 14 techniques) is used in a given text span. Another closely related shared task is the *NLP4IF-2019 task on Fine-Grained Propaganda Detection*, which asked to detect the spans of use in news articles of each of 18 propaganda techniques (Da San Martino et al., 2019a). While these tasks focused on the text of news articles, here we target memes and multimodality, and we further use an extended inventory of 22 propaganda techniques.

Other related shared tasks include the FEVER 2018 and 2019 tasks on *Fact Extraction and Verification* (Thorne et al., 2018), the SemEval 2017 and 2019 tasks on predicting the veracity of rumors in Twitter (Derczynski et al., 2017; Gorrell et al., 2019), the SemEval-2019 task on *Fact-Checking in Community Question Answering Forums* (Mihaylova et al., 2019), the NLP4IF-2021 shared task on *Fighting the COVID-19 Infodemic* (Shaar et al., 2021). We should also mention the CLEF 2018–2021 *CheckThat!* lab (Nakov et al., 2018; Elsayed et al., 2019a,b; Barrón-Cedeño et al., 2020; Barrón-Cedeño et al., 2020), which featured tasks on automatic identification (Atanasova et al., 2018, 2019) and verification (Barrón-Cedeño et al., 2018; Hasanain et al., 2019, 2020; Shaar et al., 2020; Nakov et al., 2021) of claims in political debates and social media. While these tasks focused on factuality, check-worthiness, and stance detection, here we target propaganda; moreover, we focus on memes and on multimodality rather than on analyzing the text of tweets, political debates, or community question answering forums.

### 3 Persuasion Techniques

Scholars have proposed a number of inventories of persuasion techniques of various sizes (Miller, 1939; Torok, 2015; Abd Kadir and Sauffiyan, 2014). Here, we use an inventory of 22 techniques, borrowing from the lists of techniques described in (Da San Martino et al., 2019b), (Shah, 2005) and (Abd Kadir and Sauffiyan, 2014). Among these 22 techniques, the first 20 are applicable to both text and images, while the last two, *Appeal to (Strong) Emotions* and *Transfer*, are reserved for images.

Below, we provide a definition for each of these 22 techniques; more detailed instructions of the annotation process and examples are provided in Appendix A.

1. **Loaded Language:** Using specific words and phrases with strong emotional implications (either positive or negative) to influence an audience.
2. **Name Calling or Labeling:** Labeling the object of the propaganda campaign as either something the target audience fears, hates, finds undesirable, or loves, praises.
3. **Doubt:** Questioning the credibility of someone or something.
4. **Exaggeration or Minimisation:** Either representing something in an excessive manner, e.g., making things larger, better, worse (“*the best of the best*”, “*quality guaranteed*”), or making something seem less important or smaller than it really is, e.g., saying that an insult was just a joke.
5. **Appeal to Fear or Prejudices:** Seeking to build support for an idea by instilling anxiety and/or panic in the population towards an alternative. In some cases, the support is built based on preconceived judgments.
6. **Slogans:** A brief and striking phrase that may include labeling and stereotyping. Slogans tend to act as emotional appeals.
7. **Whataboutism:** A technique that attempts to discredit an opponent’s position by charging them with hypocrisy without directly disproving their argument.
8. **Flag-Waving:** Playing on strong national feeling (or positive feelings toward any group, e.g., based on race, gender, political preference) to justify or promote an action or idea.
9. **Misrepresentation of Someone’s Position (Straw Man):** When an opponent’s proposition is substituted with a similar one, which is then refuted in place of the original proposition.
10. **Causal Oversimplification:** Assuming a single cause or reason, when there are actually multiple causes for an issue. It includes transferring blame to one person or group of people without investigating the actual complexities of the issue.

11. **Appeal to Authority:** Stating that a claim is true because a valid authority or expert on the issue said so, without any other supporting evidence offered. We consider the special case in which the reference is not an authority or an expert as part of this technique, although it is referred to as *Testimonial* in the literature.
12. **Thought-Terminating Cliché:** Words or phrases that discourage critical thought and meaningful discussion about a given topic. They are typically short, generic sentences that offer seemingly simple answers to complex questions or that distract the attention away from other lines of thought.
13. **Black-and-White Fallacy or Dictatorship:** Presenting two alternative options as the only possibilities, when in fact more possibilities exist. As an extreme case, tell the audience exactly what actions to take, eliminating any other possible choices (*Dictatorship*).
14. **Reductio ad Hitlerum:** Persuading an audience to disapprove of an action or an idea by suggesting that the idea is popular with groups that are hated or in contempt by the target audience. It can refer to any person or concept with a negative connotation.
15. **Repetition:** Repeating the same message over and over again, so that the audience will eventually accept it.
16. **Obfuscation, Intentional Vagueness, Confusion:** Using words that are deliberately not clear, so that the audience can have their own interpretations.
17. **Presenting Irrelevant Data (Red Herring):** Introducing irrelevant material to the issue being discussed, so that everyone’s attention is diverted away from the points made.
18. **Bandwagon** Attempting to persuade the target audience to join in and take the course of action because “everyone else is taking the same action.”
19. **Smears:** A smear is an effort to damage or call into question someone’s reputation, by propounding negative propaganda. It can be applied to individuals or groups.
20. **Glittering Generalities (Virtue):** These are words or symbols in the value system of the target audience that produce a positive image when attached to a person or an issue.
21. **Appeal to (Strong) Emotions:** Using images with strong positive/negative emotional implications to influence an audience.
22. **Transfer:** Also known as *Association*, this is a technique that evokes an emotional response by projecting positive or negative qualities (praise or blame) of a person, entity, object, or value onto another one in order to make the latter more acceptable or to discredit it.

## 4 Dataset

The annotation process is explained in detail in Appendix A, and in this section, we give a just brief summary.

We collected English memes from our personal Facebook accounts over several months in 2020 by following 26 public Facebook groups, which focus on politics, vaccines, COVID-19, and gender equality. We considered a meme to be a “*photograph style image with a short text on top of it*”, and we removed examples that did not fit this definition, e.g., cartoon-style memes, memes whose textual content was strongly dominant or non-existent, memes with a single-color background image, etc. Then, we annotated the memes using our 22 persuasion techniques. For each meme, we first annotated its textual content, and then the entire meme. We performed each of these two annotations in two phases: in the first phase, the annotators independently annotated the memes; afterwards, all annotators met together with a consolidator to discuss and to select the final gold label(s).

The final annotated dataset consists of 950 memes: 687 memes for training, 63 for development, and 200 for testing. While the maximum number of sentences in a meme is 13, the average number of sentences per meme is just 1.68, as most memes contain very little text.

Table 1 shows the number of instances of each technique for each of the tasks. Note that *Transfer* and *Appeal to (Strong) Emotions* are not applicable to text, i.e., to Subtasks 1 and 2. For Subtasks 1 and 3, each technique can be present at most once per example, while in Subtask 2, a technique could appear multiple times in the same example. This explains the sizeable differences in the number of instances for some persuasion techniques between Subtasks 1 and 2: some techniques are over-used in memes, with the aim of making the message more persuasive, and thus they contribute higher counts to Subtask 2.

Persuasion Techniques	Subtask 1	Subtask 2	Subtask 3	
	#	Len.	#	#
Loaded Language	489	2.41	761	492
Name Calling/Labeling	300	2.62	408	347
Smears	263	17.11	266	602
Doubt	84	13.71	86	111
Exaggeration/Minimisation	78	6.69	85	100
Slogans	66	4.70	72	70
Appeal to Fear/Prejudice	57	10.12	60	91
Whataboutism	54	22.83	54	67
Glittering Generalities (Virtue)	44	14.07	45	112
Flag-Waving	38	5.18	44	55
Repetition	12	1.95	42	14
Causal Oversimplification	31	14.48	33	36
Thought-Terminating Cliché	27	4.07	28	27
Black-and-White	25	11.92	25	26
Fallacy/Dictatorship	24	15.96	24	40
Appeal to Authority	22	20.05	22	35
Reductio ad Hitlerum	13	12.69	13	23
Obfuscation, Intentional Vagueness, Confusion	5	9.8	5	7
Presenting Irrelevant Data	5	15.4	5	7
Bandwagon	5	8.4	5	5
Transfer	—	—	—	95
Appeal to (Strong) Emotions	—	—	—	90
<b>Total</b>	<b>1,642</b>	<b>2,119</b>	<b>2,488</b>	

Table 1: Statistics about the persuasion techniques. For each technique, we show the average length of its spans (in number of words) and the number of its instances as annotated in the text only vs. in the entire meme.

Note that the number of instances for Subtasks 1 and 3 differs, and in some cases by quite a bit, e.g., for *Smears*, *Doubt*, and *Appeal to Fear/Prejudice*. This shows that many techniques cannot be found in the text, and require the visual content, which motivates the need for multimodal approaches for Subtask 3. Note also that different techniques have different span lengths, e.g., *Loaded Language* and *Name Calling* are about 2–3 words long, e.g., *violence*, *mass shooter*, and *coward*. However, for techniques such as *Whataboutism*, the average span length is 22 words.

Figure 2 shows statistics about the distribution of the number of persuasion techniques per meme. Note the difference for memes without persuasion techniques between Figures 2a and 2c: we can see that the number of memes without any persuasion technique drastically drops for Subtask 3. This is because the visual modality introduces additional context that was not available during the text-only annotation, which further supports the need for multimodal analysis. The visual modality also has an impact on memes that already had persuasion techniques in the text-only phase.

We observe that the number of memes with only one persuasion technique in Subtask 3 is considerably lower compared to Subtask 1, while the number of memes with three or more persuasion techniques has greatly increased for Subtask 3.

(a) Subtask 1

(b) Subtask 2

(c) Subtask 3

Figure 2: Distribution of the number of persuasion techniques per meme. Subfigure (b) reports the **number of instances** of persuasion techniques for a meme. Note that a meme could have multiple instances of the same technique for this subtask. Subfigures (a) and (c) show the number of **distinct** persuasion techniques in a meme.

## 5 Evaluation Framework

### 5.1 Evaluation Measures

**Subtasks 1 and 3** To measure the performance of the systems, for Subtasks 1 and 3, we use Micro and Macro  $F_1$ , as these are multi-class multi-label tasks, where the labels are imbalanced. The official measure for the task is Micro  $F_1$ .

**Subtask 2** For Subtask 2, the evaluation requires matching the text spans. Hence, we use an evaluation function that gives credit to partial matches between gold and predicted spans.

Let document  $d$  be represented as a sequence of characters. The  $i$ -th propagandistic text fragment is then represented as a sequence of contiguous characters  $t \subseteq d$ . A document includes a set of (possibly overlapping) fragments  $T$ . Similarly, a learning algorithm produces a set  $S$  with fragments  $s \subseteq d$ , predicted on  $d$ . A labeling function  $l(x) \in \{1, \dots, 20\}$  associates  $t \in T$ ,  $s \in S$  with one of the techniques. An example of (gold) annotation is shown in Figure 3, where an annotation  $t_1$  marks the span *stupid and petty* with the technique *Loaded Language*.

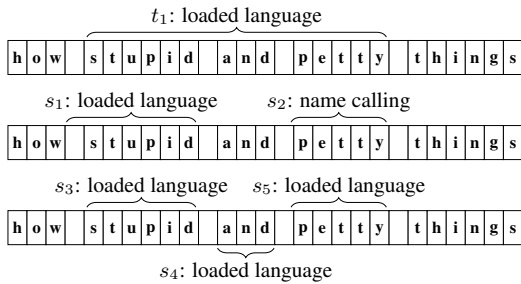

Figure 3: Example of gold annotation (top) and the predictions of a supervised model (bottom) in a document represented as a sequence of characters.

We define the following function to handle partial overlaps of fragments with the same labels:

$$C(s, t, h) = \frac{|(s \cap t)|}{h} \delta(l(s), l(t)), \quad (1)$$

where  $h$  is a normalizing factor and  $\delta(a, b) = 1$  if  $a = b$ , and 0, otherwise. For example, still with reference to Figure 3,  $C(t_1, s_1, |t_1|) = \frac{6}{16}$  and  $C(t_1, s_2, |t_1|) = 0$ .

Given Eq. (1), we now define variants of precision and recall that can account for the imbalance in the corpus:

$$P(S, T) = \frac{1}{|S|} \sum_{\substack{s \in S, \\ t \in T}} C(s, t, |s|), \quad (2)$$

$$R(S, T) = \frac{1}{|T|} \sum_{\substack{s \in S, \\ t \in T}} C(s, t, |t|), \quad (3)$$

We define (2) to be zero if  $|S| = 0$ , and Eq. (3) to be zero if  $|T| = 0$ . Following Potthast et al. (2010), in (2) and (3) we penalize systems predicting too many or too few instances by dividing by  $|S|$  and  $|T|$ , respectively. Finally, we combine Eqs. (2) and (3) into an  $F_1$ -measure, the harmonic mean of precision and recall.

### 5.2 Task Organization

We ran the shared task in two phases:

**Development Phase** In the first phase, only training and development data were made available, and no gold labels were provided for the latter. The participants competed against each other to achieve the best performance on the development set. A live leaderboard was made available to keep track of all submissions.

**Test Phase** In the second phase, the test set was released and the participants were given just a few days to submit their final predictions.

In the *Development Phase*, the participants could make an unlimited number of submissions, and see the outcome in their private space. The best score for each team, regardless of the submission time, was also shown in a public leaderboard. As a result, not only could the participants observe the impact of various modifications in their systems, but they could also compare against the results by other participating teams. In the *Test Phase*, the participants could again submit multiple runs, but they would not get any feedback on their performance. Only the latest submission of each team was considered as official and was used for the final team ranking. The final leaderboard on the test set was made public after the end of the shared task.

In the *Development Phase*, a total of 15, 10 and 13 teams made at least one submission for ST1, ST2 and ST3, respectively. In the *Test Phase* the number of teams who made official submissions was 16, 8, and 15 for ST1, ST2, ST3, respectively.

After the competition was over, we left the submission system open for the development set, and we plan to reopen it on the test set as well. The up-to-date leaderboards can be found on the website of the competition.<sup>2</sup>

## 6 Participants and Results

Below, we give a general description of the systems that participated in the three subtasks and their results, with focus on those ranked among the top-3. Appendix C gives a description of every system.

### 6.1 Subtask 1 (Unimodal: Text)

Table 2 gives an overview of the systems that took part in Subtask 1. We can see that transformers were quite popular, and among them, most commonly used was RoBERTa, followed by BERT. Some participants used learning models such as LSTM, CNN, and CRF in their final systems, while internally, Naïve Bayes and Random Forest were also tried. In terms of representation, embeddings clearly dominated. Moreover, techniques such as ensembles, data augmentation, and post-processing were also used in some systems.

The evaluation results are shown in Table 3, which also includes two baselines: (i) random, and (ii) majority class. The latter always predicts *Loaded Language*, as it is the most frequent technique for Subtask 1 (see Table 1).

The best system **MinD** (Tian et al., 2021) used five transformers: BERT, RoBERTa, XLNet, DeBERTa, and ALBERT. It was fine-tuned on the PTC corpus (Da San Martino et al., 2020a) and then on the training data for Subtask 1.

Rank	Team	F1-Micro	F1-Macro
1	MinD	.593	.290 <sub>2</sub>
2	Alpha	.572	.262 <sub>5</sub>
3	Volta	.570	.266 <sub>3</sub>
4	mmm	.548	.303 <sub>1</sub>
5	AIMH	.539	.245 <sub>6</sub>
6	LeCun	.512	.227 <sub>8</sub>
7	WVOQ	.511	.227 <sub>8</sub>
8	TeamUNCC	.510	.236 <sub>7</sub>
9	NLyticsFKIE	.498	.140 <sub>13</sub>
10	TeiAS	.497	.214 <sub>10</sub>
11	DAJUST	.497	.187 <sub>11</sub>
12	YNUHPCC	.493	.263 <sub>4</sub>
13	CSECUDSG	.489	.185 <sub>12</sub>
14	TeamFPAI	.406	.115 <sub>15</sub>
15	NLPITR	.379	.126 <sub>14</sub>
	<i>Majority baseline</i>	.374	.033
16	TriHeadAttention	.184	.024 <sub>18</sub>
	<i>Random baseline</i>	.064	.044

Table 3: Results for Subtask 1. The systems are ordered by the official score: *F1-micro*.

The final prediction for MinD averages the probabilities for these models, and further uses post-processing rules, e.g., each bigram appearing more than three times is flagged as a *Repetition*.

Team **Alpha** (Feng et al., 2021) was ranked second. However, they used features from images, which was not allowed (images were only allowed for Subtask 3).

Team **Volta** (Gupta et al., 2021) was third. They used a combination of transformers with the [CLS] token as an input to a two-layer feed-forward network. They further used example weighting to address class imbalance.

We should also mention team **LeCun**, which used additional corpora such as the PTC corpus (Da San Martino et al., 2020a), and augmented the training data using synonyms, random insertion/deletion, random swapping, and back-translation.

## 6.2 Subtask 2 (Unimodal: Text)

The approaches for this task varied from modeling it as a question answering (QA) task to performing multi-task learning. Table 4 presents a high-level summary. We can see that BERT dominated, while RoBERTa was much less popular. We further see a couple of systems using data augmentation. Unfortunately, there are too few systems with system description papers for this subtask, and thus it is hard to do a very deep analysis.

8	TriHeadAttention	.080	.170 <sub>7</sub>	.052 <sub>8</sub>
	<i>Random Baseline</i>	<i>.010</i>	<i>.034</i>	<i>.006</i>

Table 5: Results for Subtask 2. The systems are ordered by the official score: *F1-micro*.

The best model by team **Volta** (Gupta et al., 2021) used various transformer models, such as BERT and RoBERTa, to predict token classes by considering the output of each token embedding. Then, they assigned classes for a given word as the union of the classes predicted for the subwords that make that word (to account for BPEs).

Team **HOMADOS** (Kaczyński and Przybyła, 2021) was second, and they used a multi-task learning (MTL) and additional datasets such as the PTC corpus from SemEval-2020 task 11 (Da San Martino et al., 2020a), and a fake news corpus (Przybyła, 2020). They used BERT, followed by several output layers that perform auxiliary tasks of propaganda detection and credibility assessment in two distinct scenarios: sequential and parallel MTL. Their final submission used the latter.

Team **TeamFPAI** (Xiaolong et al., 2021) formulated the task as a question answering problem using machine reading comprehension, thus improving over the ensemble-based approach of Liu et al. (2018). They further explored data augmentation and loss design techniques, in order to alleviate the problem of data sparseness and data imbalance.

## 6.3 Subtask 3 (Multimodal: Memes)

Table 6 presents an overview of the approaches used by the systems that participated in Subtask 3. This is a very rich and very interesting table. We can see that transformers were quite popular for text representation, with BERT dominating, but RoBERTa being quite popular as well. For the visual modality, the most common representations were variants of ResNet, but VGG16 and CNNs were also used. We further see a variety of representations and fusion methods, which is to be expected given the multi-modal nature of this subtask.

Rank. Team	Transformers	Models	Representations	Fusion	Misc

Table 6: **ST3**: Overview of the approaches used by the participating systems. =part of the official submission; =considered in internal experiments. References to system description papers are shown below the table.

Table 7 shows the performance on the test set for the participating systems for Subtask 3. The two baselines shown in the table are similar to those for Subtask 1, namely a random baseline and a majority class baseline. However, this time the most frequent class baseline always predicts *Smears* (for Subtask 1, it was *Loaded Language*), as this is the most frequent technique for Subtask 3 (as can be seen in Table 1).

Team **Alpha** (Feng et al., 2021) pre-trained a transformer using text with visual features. They extracted grid features using ResNet50, and salient region features using BUTD. They further used these grid features to capture the high-level semantic information in the images. Moreover, they used salient region features to describe objects and to caption the event present in the memes. Finally, they built an ensemble of fine-tuned DeBERTa+ResNet, DeBERTa+BUTD, and ERNIE-VIL systems.

Team **MinD** (Tian et al., 2021) combined a system for Subtask 1 with (i) ResNet-34, a face recognition system, (ii) OCR-based positional embeddings for text boxes, and (iii) Faster R-CNN to extract region-based image features. They used late fusion to combine the textual and the visual representations. Other multimodal fusion strategies they tried were concatenation of the representation and mapping using a multi-layer perceptron.

Team **1213Li** (Peiguang et al., 2021) used RoBERTa and ResNet-50 as feature extractors for texts and images, respectively, and adopted a label embedding layer with a multi-modal attention mechanism to measure the similarity between labels with multi-modal information, and fused features for label prediction.

## 7 Conclusion and Future Work

We presented *SemEval-2021 Task 6 on Detection of Persuasion Techniques in Texts and Images*. It was a successful task: a total of 71 teams registered to participate, 22 teams eventually made an official submission on the test set, and 15 teams also submitted a task description paper.

In future work, we plan to increase the data size and to add more propaganda techniques. We further plan to cover several different languages.

### Acknowledgments

This research part of the Tanbih mega-project,<sup>3</sup> which is developed at the Qatar Computing Research Institute, HBKU, and aims to limit the impact of “fake news,” propaganda, and media bias by making users aware of what they are reading.

### Ethics and Broader Impact

**User Privacy** Our dataset only includes memes and it contains no user information.

**Biases** Any biases in the dataset are unintentional, and we do not intend to do harm to any group or individual. Note that annotating propaganda techniques can be subjective, and thus it is inevitable that there would be biases in our gold-labeled data or in the label distribution. We address these concerns by collecting examples from a variety of users and groups, and also by following a well-defined schema, which has clear definitions and on which we achieved high inter-annotator agreement.

Moreover, we had a diverse annotation team, which included six members, both female and male, all fluent in English, with qualifications ranging from undergrad to MSc and PhD degrees, including experienced NLP researchers, and covering multiple nationalities. This helped to ensure the quality. No incentives were provided to the annotators.

**Misuse Potential** We ask researchers to be aware that our dataset can be maliciously used to unfairly moderate memes based on biases that may or may not be related to demographics and other information within the text. Intervention with human moderation would be required in order to ensure this does not occur.

## Appendix

### A Data Collection and Annotation

#### A.1 Data Collection

To collect the data for the dataset, we used Facebook, as it has many public groups with a large number of users, who intentionally or unintentionally share a large number of memes. We used our own private Facebook accounts to crawl the public posts from users and groups. To make sure the resulting feed had a sufficient number of memes, we initially selected some public groups focusing on topics such as politics, vaccines, COVID-19, and gender equality. Then, using the links between groups, we expanded our initial group pool to a total of 26 public groups. We went through each group, and we collected memes from old posts, dating up to three months before the newest post in the group. Out of the 26 groups, 23 were about politics, US and Canadian: left, right, centered, anti-government, and gun control. The other 3 groups were on general topics such as health, COVID-19, pro-vaccines, anti-vaccines, and gender equality. Even though the number of political groups was larger (i.e., 23), the other 3 general groups had a higher number of users and a substantial amount of memes.

#### A.2 Annotation Process

We annotated the memes using the 22 persuasion techniques from Section 3 in a multi-label setup. Our annotation focused (i) on the text only, using 20 techniques, and (ii) on the entire meme (text + image), using all 22 techniques.

We could not annotate the visual modality as an independent task because memes have the text as part of the image. Moreover, in many cases, the message in the meme requires both modalities. For example, in Figure 28, the image by itself does not contain any persuasion technique, but together with the text, we can see *Smears* and *Reductio at Hitlerum*.

The annotation team included six members, both female and male, all fluent in English, with qualifications ranging from undergrad to MSc and PhD degrees, including experienced NLP researchers, and covering multiple nationalities. This helped to ensure the quality of the annotation, and our focus was really on having very high-quality annotation. No incentives were given to the annotators.

We used PyBossa<sup>4</sup> as an annotation platform, as it provides the functionality to create a custom annotation interface that we found to be a good fit for our needs in each phase of the annotation process. Figure 4 shows examples of the annotation interface for the five different phases of annotation, which we describe in detail below.

**Phase 1: Filtering and Text Editing** The first phase of the annotation process is about selecting the memes for our task, followed by extracting and editing the textual contents of each meme. After we collected the memes, we observed that we needed to remove some of them as they did not fit our definition: “*photograph style image with a short text on top of it.*” Thus, we asked the annotators to exclude images with the characteristics listed below. During this phase, we filtered out a total of 111 memes.

- Images with diagrams/graphs/tables (see Figure 5a).
- Cartoons. (see Figure 5b)
- Memes for which no multi-modal analysis is possible: e.g., only text, only image, etc. (see Figure 5c)

Next, we used the Google Vision API<sup>5</sup> to extract the text from the memes. As the resulting text sometimes contains errors, manual checking was needed to correct it. Thus, we defined several text editing rules, and we asked the annotators to apply them on the memes that passed the filtering rules above.

1. When the meme is a screenshot of a social network account, e.g., WhatsApp, the user name and login can be removed as well as all “Like”, “Comment”, “Share”.
2. Remove the text related to logos that are not part of the main text.
3. Remove all text related to figures and tables.
4. Remove all text that is partially hidden by an image, so that the sentence is almost impossible to read.
5. Remove all text that is not from the meme, but on banners carried on by demonstrators, street advertisements, etc.

Figure 4: Examples of the annotation interface for different phases.

- Remove the author of the meme if it is signed.
- If the text is in columns, first put all text from the first column, then all text from the next column, etc.
- Rearrange the text, so that there is one sentence per line, whenever possible.
- If there are separate blocks of text in different locations of the image, separate them by a blank line. However, if it is evident that the text blocks are part of a single sentence, keep them together.

**Phase 2: Text Annotation** The annotations for phase 2 are targeted at Subtasks 1 and 2. Given the list of propaganda techniques for text only annotation, as discussed in Section A.4 (i.e., techniques 1-20), and the textual content of the target meme, the annotators were asked to identify which techniques appear in the text, and also to annotate the span of each instance of a technique use. In this phase, there were three annotators per example.

**Phase 3: Text Consolidation** Phase 3 is the consolidation step for the annotations from phase 2. The three annotators met with the rest of the team, who acted as consolidators, and discussed each annotation, so that a consensus could be reached.

**As some #European countries refuse full lockdown the deaths per week are skyrocketing.**

(b) Example of a **cartoon** meme; *Source(s):* Image ; License

(c) Example of a meme with **only text** modality; License .

Figure 5: Examples of memes we filtered out.

We made sure to consider different interpretations and to anotate techniques corresponding to the most likely one. While this phase was devoted to checking the annotations from phase 2, when a novel instance of a technique was found, it could be added; conversely, an instance of a technique with perfect agreement from phase 2 could also be dropped. Phase 3 was essential for ensuring quality, and it served as an additional training opportunity for the entire team, which was very useful.

**Phase 4: Multimodal Annotation** In this phase, the goal is to identify which of the 22 techniques, discussed in Section A.4, appear in the meme: in the text and in the visual content. Note that some of the techniques occurring in the text might be identified only in this phase because the image provides the necessary context. Thus, we presented the meme with the consolidated propaganda labels from phase 3. We intentionally provided the consolidated text labels to the annotators in order to ensure that they focus their attention on identifying propaganda techniques that require both modalities rather than repeating what was already labeled in the earlier phases. In this phase, there were three annotators per example.

**Phase 5: Multimodal Consolidation.** In phase 5, we consolidated the annotations from phase 4 in a discussion of the entire team of six annotators (just as we did for phase 3).

### A.3 Annotation Agreement

We assessed the quality for the individual annotators from phases 2 and 4 (i.e., when combining the annotations for the meme’s text and for the entire meme) to the final consolidated labels at phase 5. Since our annotation is multi-label, we computed Krippendorff’s  $\alpha$  (Artstein and Poesio, 2008). The results are shown in Table 8, and the numbers indicate moderate to substantial agreement (Landis and Koch, 1977).

Agreement Pair	Krippendorff’s $\alpha$
Annotator 1 vs. Consolidated	0.83
Annotator 2 vs. Consolidated	0.91
Annotator 3 vs. Consolidated	0.56
<b>Average</b>	<b>0.77</b>

Table 8: Inter-annotator agreement in terms of Krippendorff’s  $\alpha$  between each of the annotators and the consolidated annotation.

### A.4 Propaganda Techniques: Definitions

Below, we present the definitions of our 22 propaganda techniques, together with examples: both textual, and memes. Note that, for copyright reasons, we show our own recreated versions of actual memes from our dataset, where, for each meme, we indicate the image(s) we used and the corresponding license terms (as hyperlinks in the image caption).

**1. Loaded Language:** Using specific words and phrases with strong emotional implications (i.e., either positive or negative) to influence an audience.

An example meme is shown in Figure 6, which contains four instances of this persuasion technique in its text: *killed thousands of innocents*, *retaliate*, *kill*, and *warmonger*.

Figure 6: Example for **Loaded Language**; *Source(s)*: Image 1, Image 2; License 1, License 2

**2. Name Calling or Labeling:** Labeling the object of the propaganda as either something the target audience fears, hates, finds undesirable, or loves, praises.

Figure 7 shows three instances of this technique: *the two biggest threats to America*, *the worst senate leader ever*, and *the most corrupt President ever*. Figure 6 also contains an instance: *warmonger*.

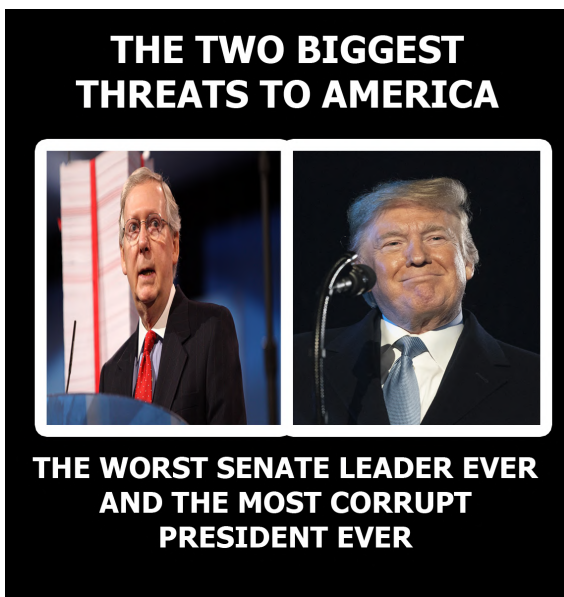

Figure 7: Example for **Name Calling**; *Source(s)*: Image 1, Image 2; License 1, License 2

**3. Doubt:** Questioning the credibility of someone or something.

An example is shown in Figure 8, where the entire text in the meme represents a span for this technique, while the image is just for illustration.

Reminder: This building in Oklahoma City was blown up and destroyed just 4 days before Hilary Clinton was to be indicted in the Whitewater scandal. All documents lost!

Figure 8: Example for **Doubt**; *Source(s)*: Image ; License

**4. Exaggeration or Minimisation:** Representing something in an excessive manner, making it larger, better, worse (e.g., *the best of the best*); or making it seem less important or smaller than it really is (e.g., saying that an insult was just a joke).

An example is shown in Figure 9, where the entire meme conveys an exaggeration. Moreover, all three *Name Calling* instances in Figure 7 are also examples of *Exaggeration*.

Figure 9: Example for **Exaggeration**; *Source(s)*: Image ; License

**5. Appeal to Fear/Prejudice:** Seeking to build support for an idea by instilling anxiety and/or panic in the population towards an alternative. In some cases, the support is built based on preconceived judgments.

An example is shown in Figure 10, where both the text and the image instill fear.

Figure 10: Example for **Appeal to Fear**; *Source(s):* Image ; License

**6. Slogans:** A brief and striking phrase that may include labeling and stereotyping. Slogans tend to act as emotional appeals.

An example is shown in Figure 11, which contains a slogan in its textual content: “*Vaccines. It isn’t always about you.*”

Figure 11: Example for **Slogan**; *Source(s):* Image ; License

**7. Whataboutism:** A technique that attempts to discredit an opponent's position by charging them with hypocrisy without directly disproving their argument.

An example meme is shown in Figure 12, where the entire text represents a span for this technique, while the image is just for illustration.

Figure 12: Example for Whataboutism; *Source(s):* Image ; License

**8. Flag-Waving:** Playing on strong national feeling (or to any group such as race, gender, political preference) to justify or promote an action or idea.

An example is shown in Figure 13, with the technique expressed in the text and the image.

Figure 13: Example for Flag-Waving; *Source(s):* Image ; License

**9. Misrepresentation of Someone’s Position (Straw Man):** An opponent’s proposition is substituted with a similar one, which is then refuted in place of the original proposition.

An example meme is shown in Figure 14, which contains an instance of this technique in its text: here, the entire text in the meme represents a span for this technique, while the image is irrelevant for that technique (however, it is relevant for other techniques such as *Smears*).

Figure 14: Example for Misrepresentation of Someone’s Position (Straw Man); Source(s): Image ; License

**10. Causal Oversimplification:** Assuming a single cause or reason when there are actually multiple causes for an issue. It includes transferring blame to one person or group of people without investigating the complexities of the issue.

An example meme is shown in Figure 15, which contains an instance of this technique in its text: “*You can’t get rich in politics unless you are a crook.*” This statement says that if somebody got rich in politics, the only reason for this happening should be that this person is a crook, while in reality there are typically multiple causes. The image is irrelevant for that technique (however, it is relevant for other techniques such as *Smears*).

Figure 15: Example for Causal Oversimplification; Source(s): Image 1, Image 2; License 1, License 2

**11. Appeal to Authority:** Stating that a claim is true simply because a valid authority or expert on the issue said it was true, without any other supporting evidence offered. We consider the special case in which the reference is not an authority or an expert in this technique, although it is referred to as *Testimonial* in literature.

An example meme is shown in Figure 16, which contains a quote by the 3rd President of the United States.

Figure 16: Example for **Appeal to Authority**; *Source(s)*: Image ; License

**12. Thought-Terminating Cliché:** Words or phrases that discourage critical thought and meaningful discussion about a given topic. They are typically short, generic sentences that offer seemingly simple answers to complex questions or that distract attention away from other lines of thought.

Figure 17 shows a meme with an instance of this technique in its text: “*PERIOD.*”

Figure 17: Example for **Thought-Terminating Cliché**; *Source(s)*: Image 1, Image 2; License 1, License 2

**13. Black-and-White Fallacy:** Presenting two alternative options as the only possibilities, when in fact more possibilities exist. We also include dictatorship, where one tells the audience exactly what actions to take, eliminating any other choices.

An example of this technique is shown in Figure 18, which offers only two choices.

Figure 18: Example for **Black-and-White Fallacy**; *Source(s)*: Image 1, Image 2; License 1, License 2

**14. Reductio ad Hitlerum:** Persuading an audience to disapprove an action or idea by suggesting that the idea is popular with groups hated or in contempt by the target audience. It can refer to any person or concept with a negative connotation.

Figure 19 shows a meme trying to discredit the idea of being anti-union by saying that so is Donald Trump, who in turn is shown in bad light.

Figure 19: Example for **Reduction ad Hitlerum**; *Source(s): Image , License*

**15. Repetition:** Repeating the same message, so that the audience eventually accepts it.

An example is shown in Figure 20, where the repetition has a clear rhetorical function.

Figure 20: Example for **Repetition**; *Source(s): Image 1, Image 2, Image 3, Image 4; License 1, License 2, License 3, License 4*

**16. Obfuscation, Intentional Vagueness, Confusion:** Using words that are deliberately unclear, so that the audience may have their own interpretations.

Figure 21, shows an example, where the entire quote by Joe Biden is a span of this technique, as it is unclear what exactly is meant here.

Figure 21: Example for **Obfuscation, Intentional vagueness, Confusion**; *Source(s): Image ; License*

**17. Presenting Irrelevant Data (Red Herring):** Introducing irrelevant material to the issue being discussed, so that everyone’s attention is diverted away from the points made.

An example meme is shown in Figure 22, which contains an instance of this technique in its text. We can see that there is no real connection between the two sentences. Here, the entire text represents a span for this technique, while the image is for reinforcement.

Figure 22: Example for **Presenting Irrelevant Data (Red Herring)**; *Source(s):* Image ; License

**18. Bandwagon:** Attempting to persuade the target audience to join in and take the course of action because “everyone else is taking the same action.”

Figure 23 shows an example that covers the entire text; the image less relevant.

Figure 23: Example for **Bandwagon**; *Source(s):* Image ; License

**19. Smears:** A smear is an effort to damage or to call into question someone’s reputation, by propounding negative propaganda. It can be applied to individuals or groups.

An example meme is shown in Figure 24, where the combination of the image and the text conveys the idea that Biden is unpopular.

Figure 24: Example for **Smears**; *Source(s):* Image ; License

**20. Glittering Generalities:** These are words or symbols in the value system of the target audience that produce a positive image when attached to a person or issue. Peace, hope, happiness, security, wise leadership, freedom, “The Truth”, etc. are virtue words. Virtue can be also expressed in images, where a person or an object is depicted positively.

Figure 25 shows an example of the use of this technique, in the right half of the meme. The technique covers the entire text span starting from “2 & 1/2 years . . .” until “GDP up 3.2% . . .” It is also expressed in the image, which depicts Donald Trump in a positive way. The text–image combination further strengthens the technique.

Figure 25: Example for **Glittering Generalities**; *Source(s):* Image 1, Image 2; License 1, License 2

**21. Appeal to (Strong) Emotions:** Using images with strong positive/negative emotional implications to influence an audience. We reserve this technique to the images content only.

An example is shown in Figure 26, which invokes strong emotions in the audience.

Figure 26: Example for **Appeal to (Strong) Emotions**; *Source(s):* Image ; License

**22. Transfer:** Also known as *Association*, this is a technique of projecting positive or negative qualities (praise or blame) of a person, entity, object, or value onto another one to make the second one more acceptable or to discredit it. It evokes an emotional response, which stimulates the target to identify with recognized authorities. Often highly visual, this technique often utilizes symbols (for example, the swastikas used in Nazi Germany, originally a symbol for health and prosperity) superimposed over other visual images.

Figure 27 shows an example, where the *Transfer* technique makes use of a communist symbol (namely, hammer and sickle) on top of the pictures of two targeted politicians, with the aim of depicting them in a negative way. The technique is further reinforced by the use of the red color (which is also a symbol of Communism), and by the two instances of *Name Calling* (“*Moscow Mitch*” and “*Moscow’s bitch*”), which make a connection to Moscow (which in turn was the capital of the former Communist block).

Figure 27: Example for **Transfer**; *Source(s)*: Image 1, Image 2; License 1, License 2

## B Subtasks: Definition, Data Format, and Data Examples

Below, we describe the three subtasks and the general data format for each of them. We further show an example of an annotated example for each subtask.

### B.1 Subtask 1

This is a multi-label classification problem, defined as follows:

**Subtask 1 (ST1)** Given only the “textual content” of a meme, identify which of the 20 techniques are used in it.

The data for ST1 comes as a JSON object in the following format:

```
{
  id -> example identifier,
  labels -> list of persuasion
           techniques,
  text -> text of the meme
}
```

Here is an example:

```
{
  "id": "125",
  "labels": [
    "Loaded Language",
    "Name calling/Labeling"
  ],
  "text": "I HATE TRUMP\n\n
          MOST TERRORIST DO"
}
```

### B.2 Subtask 2

ST2 is a more complex version of ST1, as it asks not only for the techniques but also for the exact spans of use each technique. This subtask is a combination of the two subtasks in *SemEval-2020 task 11*. It is a multi-label sequence tagging problem, defined as follows:

**Subtask 2 (ST2)** Given only the “textual content” of a meme, identify which of the 20 techniques are used in it together with the span(s) of text covered by each technique.

The data for ST2 comes as a JSON object with the following format:

```
{
  id -> example identifier,
  text -> text of the meme
  labels : [ -> list of objects
    {
      start -> start index,
      end -> end index,
      technique -> technique,
      text_fragment -> text
    }
  ]
}
```

Here is an example:

```
{
  "id": "125",
  "text": "I HATE TRUMP\n\n
          MOST TERRORIST DO"
  "labels": [
    {
      "start": 2,
      "end": 6,
      "technique": "Loaded Language",
      "text_fragment": "HATE"
    },
    {
      "start": 19,
      "end": 28,
      "technique": "Name calling/
Labeling",
      "text_fragment": "TERRORIST"
    }
  ]
}
```

Note that the labels to be predicted for ST2 are the same ones as for ST1, but this time the spans are to be predicted as well.

### B.3 Subtask 3

ST3 is a multi-modal version of ST1, where the image is also provided. It is a multi-label classification problem, defined as follows:

**Subtask 3 (ST3)** Given a meme, identify which of the 22 techniques are used both in the textual and in the visual content of the meme.

The data for ST3 comes as a JSON object with the following format:

```
{
  id -> example identifier,
  labels -> list of persuasion
           techniques,
  image -> name of the image file,
  text -> text of the meme
}
```

Here is an example:

```
{
  "id": "125",
  "labels": [
    "Loaded Language",
    "Name calling/Labeling",
    "Reductio ad hitlerum",
    "Smears",
  ],
  "image": "125_image.png"
}
```

Here, the image, which is shown in Figure 28), gives rise to two additional persuasion techniques compared to ST1: *Reductio ad Hitlerum* and *Smears*. These techniques are not clearly present in the text alone. Indeed, the image is needed for us to see that there is *Smears*, as this can be only seen when we understand that this is a dialog with a negative propaganda targeting one of the participants (Ilhan Omar). Similarly, we need the image for *Reductio ad Hitlerum*: the image shows us that Ilhan Omar is depicted as a bad person (she is targeted by the *Name Calling* “terrorist”, and she is also the target of the *Smears*), and thus the message being conveyed is that any choice that such a bad person does has to be a bad choice, i.e., hating Trump is a bad thing to do as this is something terrorists do.

Figure 28: The meme with id=125; *Source(s)*: Image 1, Image 2; License 1, License 2

## C Participating Systems

Below, we give a brief description of the participating systems, listed in alphabetical order, with reference to the corresponding task description paper. The numbers in square brackets refer to the official ranking of the target system on the individual subtasks.

**1213Li (Peiguang et al., 2021)[ST3: 3rd]** used RoBERTa and ResNet-50 as feature extractors for texts and images. They used a label embedding layer with a multi-modal attention mechanism to measure the similarity between labels with the multi-modal information and fused features for label prediction.

**AIMH (Messina et al., 2021) [ST1: 5th, ST3: 4th]** used transformer-based models and proposed visual-textual transformers to mainly address subtask 3 (ST3). For the visual part, they used ResNet50, and for the textual part, they used BERT. The same network used the multi-label classification on text (ST1) by using only the textual part of the network.

**Alpha (Feng et al., 2021) [ST1:2nd, ST3:1st]** team pre-trained a transformer using text with visual features. They extract grid features, using ResNet50, and salient region features, using BUTD. They used grid features to capture the high-level semantic information found in the images. Additionally, they used salient region features to describe objects and to caption the event present in the memes. For ST1, they combined the text and the text representation of the visual features, and trained DeBERTa. For ST3, they built an ensemble of fine-tuned DeBERTa+ResNet, DeBERTa+BUTD, and ERNIE-VIL.

**HOMADOS (Kaczyński and Przybyła, 2021) [ST2: 2nd]** used a multi-task learning (MTL) approach with additional datasets such as the PTC corpus from SemEval-2020 (Da San Martino et al., 2020a), and a fake news corpus (Przybyła, 2020). The model was trained using BERT followed by several output layers, which solve auxiliary tasks of propaganda detection and credibility assessment in two distinct scenarios: sequential and parallel MTL, effectively accelerating the training process. The final submission used a parallel MTL approach on the propaganda detection of SemEval-2020, which ranked second.

**TeamFPAI (Xiaolong et al., 2021) (ST2: 3rd)** formulated the task as a question answering one in a machine reading comprehension (MRC) framework, which achieved better results compared to an ensemble-based approach (Liu et al., 2018). Moreover, data augmentation and loss design techniques were also explored to alleviate the problem of data sparseness and imbalance. Their system was ranked 3rd in the final evaluation phase.

**CSECUDSG (Hossain et al., 2021) (ST1: 13th, ST2: 6th, ST3: 6th)** participated in all three subtasks. For ST1, they used a majority vote late fusion on top of logistic regression, decision tree, and fine-tuned DistilBERT models. For ST2, they reformulated the task as one of multi-label classification, where a pre-trained BERT model was used to design binary classifiers for each technique in a multi-label classification setting. For ST3, they used a majority voting late fusion on top of fine-tuned DistilBERT, ResNet50, and a predicted label from an early fusion model. The early fusion model consisted of features from (i) multi-kernel CNN on top of the LSTM model with word embeddings including (ii) word2vec (Mikolov et al., 2013), (iii) word embeddings fine-tuned FastBERT (Liu et al., 2020), (iv) RoBERTa, (v) sentence embeddings from FastBERT, (vi) image features from YouTube-8M (Abu-El-Hajja et al., 2016), and (vii) multimodal features from VisualBERT (Li et al., 2019).

**LeCun (Dia et al., 2021) [ST1: 6th]** trained five models and combined them in an ensemble. Initially, they pre-processed text using stemming. Later, they trained DeBERTa and RoBERTa models with augmented data using synonym replacement, random insertion, random swap, random deletion and back-translation. They first trained the five models separately, and then they fine-tuned the ensemble on the official non-augmented data.

**LIIR (Ghadery et al., 2021)[ST3: 8th]** used data augmentation through back-translation and CLIP to obtain image and text representations, which were then fed to a chained classifier that uses the correlations between the output techniques.

**LT3-UGent (Singh and Lefever, 2021) [ST3: 14th]** participated in subtask 3 only. They used Multimodal Compact Bilinear Pooling to combine representations from ResNet-51 and BERT. They further fine-tuned on the PTC corpus (Da San Martino et al., 2020a).

**MinD (Tian et al., 2021) [ST1: 1st, ST3: 2nd]** used five pre-trained models for ST1: BERT, RoBERTa, XLNet, DeBERTa, and ALBERT. They first fine-tuned them on the PTC corpus (Da San Martino et al., 2020a), and then on the training data. For the final prediction, they averaged the probabilities of the models. They also used a post-processing rule: a bigram that appeared more than three times was flagged as a *Repetition*. The system for ST1 was also used for ST3, combined with (i) ResNet-34, a face recognition system, (ii) OCR-based positional embeddings for text boxes in the image, and (iii) Faster R-CNN to extract region-based image features. They combined the textual and the visual representations by averaging their probabilities. Other multimodal fusion strategies included concatenation of the representation and mapping them to the space using a multilayer perceptron.

**NLP-IITR (Gupta and Sharma, 2021) [ST1: 15th]** used an ensemble that included included fine-tuned RoBERTa, BERT, and three additional models. They further used pre-processing. To tackle data scarceness for some rare labels, they used data augmentation using back-translation.

**NLyticsFKIE (Pritzkau, 2021) [ST1: 9th, ST3: 13th]** used RoBERTa as a text encoder in ST1 and ST3. For ST1, they used RoBERTa’s output to build a classifier to predict each label separately. For ST3, they still used RoBERTa to encode the text and a VGG-16 layer to encode the image. They used multiple copies of a cross-modality encoder that outputs an encoding of the image features with respect to the text features, and vice versa. The concatenation of the two cross-encoders’ outputs was then passed through a residual layer followed by layer normalization.

**Volta (Gupta et al., 2021) [ST1: 3rd, ST2: 1st, ST3: 5th]** used a combination of transformers for all subtasks. For ST1, they used RoBERTa’s [CLS] token, which they fed to a feed-forward neural network, and example weighting to take care of class imbalance. For ST2, they predicted token classes by considering the output of each token embedding as obtained by RoBERTa. To account for subwords’ class, they merged each subword belonging to the same token and assigned the union of the subwords’ labels. For ST3, they separately encoded the textual features (extracted using RoBERTa) and the multi-modal features (extracted using UNITER,

VisualBERT, and LXMERT). This layer’s input was a sequence of textual subwords and visual tokens extracted by keeping the top 36 regions of interest as returned by Faster R-CNN. A concatenation of the two different [CLS] tokens was then fed into an MLP, and weighted labels were used with a cross-entropy loss.

**WVOQ (Roele, 2021) [ST2: 5th]** used a novel approach to ST2 consisting of adopting an encoder–decoder strategy. The encoder encodes the passage, while the decoder generates a marked version of the input, where the markup outlines the various spans along with the classes they belong to. In this way, the system performed simultaneous span detection and classification. The encoder–decoder used a specialization of BART.

**YNU-HPCC (Zhu et al., 2021) [ST1: 12th, ST2: 7th, ST3: 11th]** For ST1, they used a CNN on top of ALBERT and fine-tuned the model for multi-label classification. For ST2, each propaganda technique was considered as an independent task, and features were extracted from the pre-trained BERT model. Subsequently, the problem was addressed as a multi-task sequence labeling one, and the results for each task were combined. For ST3, a multi-modal network was used, where embeddings from textual and visual networks were concatenated, which was followed by a fully connected layer. For the text, the same approach was used for ST1, and for the image, ResNet and VGGNet were used for image feature extraction.

## Abstract

This paper describes our system participated in Task 6 of SemEval-2021: this task focuses on multimodal propaganda technique classification and it aims to classify given image and text into 22 classes. In this paper, we propose to use transformer-based (Vaswani et al., 2017) architecture to fuse the clues from both image and text. We explore two branches of techniques including fine-tuning the text pre-trained transformer with extended visual features and fine-tuning the multimodal pre-trained transformers. For the visual features, we experiment with both grid features extracted from ResNet(He et al., 2016) network and salient region features from a pre-trained object detector. Among the pre-trained multimodal transformers, we choose ERNIE-ViL (Yu et al., 2020), a two-stream cross-attended transformers model pre-trained on large-scale image-caption aligned data. Fine-tuning ERNIE-ViL for our task produces a better performance due to general joint multimodal representation for text and image learned by ERNIE-ViL. Besides, as the distribution of the classification labels is extremely unbalanced, we also make a further attempt on the loss function and the experiment results show that focal loss would perform better than cross-entropy loss. Lastly, we ranked first place at sub-task C in the final competition.

## 1 Introduction

Propaganda is usually adopted to influence the audience by selectively displaying the facts to encourage specific synthesis or perception, or using the loaded language to produce emotion rather than emotion itself. It was often associated with materials prepared by governments in the past century. In the internet era, activist groups, companies, religious organizations, the media, and individuals also

produce propaganda, and sometimes it can reach very large audiences (Da San Martino et al., 2020). With the recent research interest in detecting “fake news”, the detection of persuasion techniques in the texts and images has emerged as an active research area. Most previous work like (Patil et al., 2020) and (Chauhan and Diddee, 2020) have performed the analysis at the language content level only. However, in our daily life, memes consist of images superimposed with texts. The aim of the image in a meme is either to reinforce a technique in the text or to convey one or more persuasion techniques.

SemEval-2021 Task6-c offers a different perspective, multimodal multi-label classification (Dimitrov et al., 2021), identify which of the 22 techniques are used both in the textual and visual content of memes. Since memes are combinations of texts and images, for this propaganda classification task, we proposed to use transformer-based architecture to fuse the clues from both linguistic and visual modalities. Two branches of fine-tuning techniques are explored in this paper. First, a text pre-trained transformer is applied with extended visual features. Specifically, we initialize the transformer with pre-trained text transformers and fine-tune the model with extended visual features including grid features(e.g., ResNet(He et al., 2016)) and region features(e.g., BUTD (Anderson et al., 2018)) from an image feature extraction network and an object detector respectively. Second, pre-trained multimodal transformers from ERNIE-ViL(Yu et al., 2020) are used due to its better multimodal joint representations characterizing cross-modal alignments of detailed semantics.

Our contributions are three-folds:

- We propose to use transformer architecture for fusing the visual and linguistic clues to tackle the propaganda classification task.

\*indicates equal contribution.

- We find that the multimodal pre-trained transformers work better than using text pre-trained transformers with visual features. And the experiment results have shown that fine-tuning the ERNIE-ViL model could achieve state-of-the-art performance for this task.
- Our ensemble result of several models obtains the best score and ranks first in Semeval-2021 Task 6-c multimodal classification task.

## 2 Related work

### 2.1 Text Transformers

Transformer network (Vaswani et al., 2017) is first introduced in neural machine translation in which encoder and decoder are composed of multi-layer transformers. After then, pre-trained language models, such as BERT (Devlin et al., 2018) and GPT (Radford et al., 2018), adopting transformer encoder as the backbone network, have significantly improved the performance on many NLP tasks. One of the main keys to their success is the usage of transformer to capture the contextual information for each token in the text via self-attention. Later text pre-training works, such as ERNIE2.0 (Sun et al., 2020), RoBERTa (Liu et al., 2019) and XLNET (Yang et al., 2019) are all shared the same multi-layer transformer encoder and mainly put their effort on modification of pre-training task.

### 2.2 Visual Feature Extraction

Visual feature extractors are mainly composed of plenty of convolutional neural networks (CNN) since CNN has a strong ability to extract complex features that express the image with much more details and learn the task-specific features much more efficiently. Existing works can be divided into the following two types which are based on two different image inputs: image grids and object regions. Some of those methods, such as VGG (Simonyan and Zisserman, 2014), ResNet (He et al., 2016) operate attention on CNN features corresponding to a uniform grid of equally-sized image regions. While the other works like Faster R-CNN (Ren et al., 2015) operate a two-stage framework, which firstly identifies the image regions containing the specific objects, and then encodes them with multi-layer CNNs.

### 2.3 Multimodal Transformers

Inspired by text pre-training models (Devlin et al., 2018), many cross-modal pre-training models for

vision-language have been proposed. To integrate visual features and text features, recent multimodal pre-training works are mainly based on two variables of transformers. Some of them, like UNITER (Chen et al., 2019) and VILLA (Gan et al., 2020) use a uniform cross-modal transformer modelling both image and text representations. As fine-tuning on multimodal classification tasks, such as the Visual-question-answering (VQA) (Antol et al., 2015) task (a multi-label classification task), unified transformers take textual and visual features as the model input, treat the final hidden state of  $h_{[CLS]}$  as the vision-language feature. While the others like Vilbert (Lu et al., 2019), LXMERT (Tan and Bansal, 2019), ERNIE-ViL (Yu et al., 2020) are based on two-stream cross-modal transformers, which bring more specific representations for image and text. These two transformers are applied to images and texts to model visual and textual features independently and then fused by a third transformer in a later stage. The fusion of the final hidden state of  $h_{[CLS]}$  and  $h_{[IMG]}$  are used to do the classification.

## 3 Approach

We propose to use a transformer encoder to fuse the clues from both linguistic and visual modalities and our approach is summarized in two branches, the first one is fine-tuning a text pre-trained transformer with extended visual features, and the other one is fine-tuning a multimodal pre-trained model. For the first one, we try two different sets of visual features, grid features based on equally-split patches of the image and salient region features based on an object detector. For the second one, a SoTA multimodal model, ERNIE-ViL (Yu et al., 2020) is applied with a multi-label classification loss. A unified framework for the two branches is shown in Figure 1. We will introduce more details in this section.

### 3.1 Text Pre-trained Transformer with Visual Features

Our model consists of three parts: a) input feature extractor, b) feature fusion encoder, c) classification encoder.

For the first part, the text is tokenized into subwords to lookup the embedding while the image is processed by a feature extractor, such as a grid feature processor or a salient region feature processor to convert into vision embeddings. The input em-

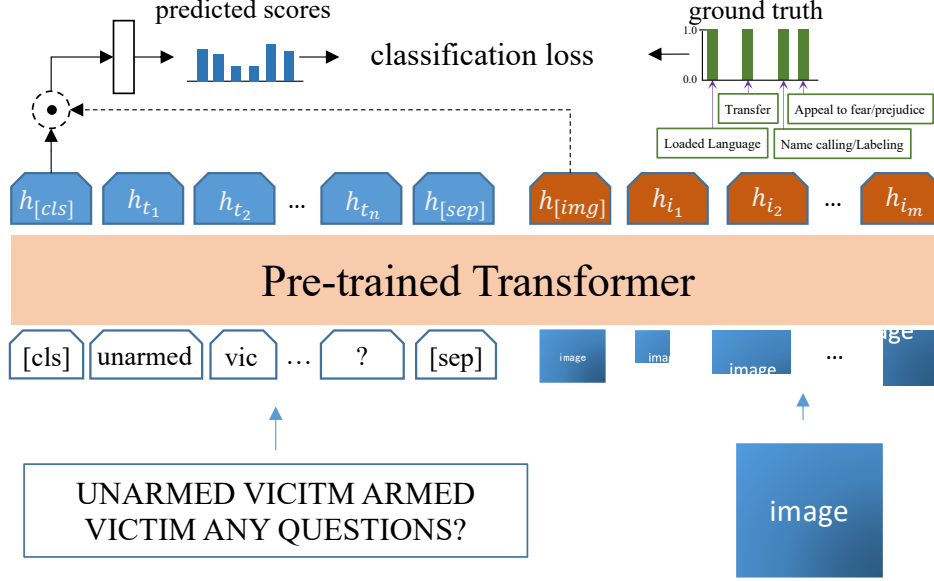

Figure 1: A unified framework used for the multimodal classification task.

beddings are combinations of image embeddings and text embeddings and represented as

$$h_{[CLS]}, h_{t_1}, \dots, h_{t_n}, h_{[SEP]}, h_{i_1}, \dots, h_{i_m}, h_{[SEP]}$$

where the  $h_{[CLS]}$ ,  $h_{[SEP]}$  are the vector representations of special tokens  $[CLS]$  and  $[SEP]$  respectively. The  $[CLS]$  token is inserted in the beginning of the sequence, which act as an indicator of the whole text, specifically, it is used to perform complete text classification. The  $[SEP]$  is a token to separate a sequence from the subsequent one and indicate the end of a text.  $h_{t_1}, \dots, h_{t_n}$  are the text embeddings, and  $h_{i_1}, \dots, h_{i_m}$  are the vision embeddings. For the vision embeddings part, grid features and salient region features are used.

**Grid Features** Convolutional neural networks have potent capabilities in image feature extraction. The feature map obtained after the image goes through multiple stacked convolution layers contains high-level semantic information. Given an image, we can use a pre-trained CNN encoder, such as ResNet, to transform it to a high-dimensional feature map and flatten each pixel on this feature map to form the final image representation.

**Salient Region Features** Object detection models are widely used to extract salient image regions from the visual scene. Given an image, we use a pre-trained object detector to detect the image regions. The pooling features before the multi-class

classification layer are utilized as the region features. The location information for each region is encoded via a 5-dimension vector representing the fraction of image area covered and the normalized coordinates of the region and then is projected and summed with the region features.

For the second part, the transformer encoder fuses the input text and image embedding, and finally a cross-modal representation of size  $D$  is achieved for this sequence.

The last part of our model is the classification encoder and loss function. After obtaining the encoding representation of the image and the text from the transformer encoder, we send the representation of  $[CLS]$  through the classification head, which is consisted of a fully connected layer and a *Sigmoid* activation for predicting the score of each category and loss with the ground truth.

### 3.2 Multimodal Pre-trained Transformer

Different from a single-modal pre-trained text transformer described above, a multimodal pre-trained transformer for vision-language can learn more efficient presentations. In this part, a SoTA model, ERNIE-ViL, is applied.

For the generation of input embedding of text and image, it is mostly the same as the procedure described in the previous section. Differences are two-folds. First, for the vision feature, a faster R-CNN encoder (Anderson et al., 2018) is used to detect the salient regions while the position infor-

mation is taken into consideration. Second, The text and the visual input embedding is represented as

$$h_{[CLS]}, h_{t_1}, \dots, h_{[SEP]}, h_{[IMG]}, h_{i_1}, \dots, h_{i_m}$$

where there is a new token  $h_{[IMG]}$  represents the feature for the entire image.

For the feature fusion part, ERNIE-ViL utilized a two steam cross-modal transformer to fuse the multimodal information. For more details, you may refer to (Yu et al., 2020).

### 3.3 Criterion

In this task, there are 22 classes and the distribution of positive and negative samples is extremely unbalanced. To solve this problem, we use the focal loss to improve the imbalance of positive and negative samples. For  $i$ -th class

$$L_{class_i} = \begin{cases} \alpha(1-p)^\gamma \log(p) & \text{if } y=1 \\ (1-\alpha)p^\gamma \log(1-p) & \text{otherwise} \end{cases}$$

where  $y$  is the ground truth;  $p$  is model prediction, which is the confidence score of category  $i$ ;  $\alpha$  and  $\gamma$  are hyper-parameters,  $\alpha$  is used to control the loss weight of positive and negative samples, and  $\gamma$  is used to scale the loss of difficult and easy samples.

## 4 Experiment

### 4.1 Implementation Details

In this task, we choose DeBERTa-large+ResNet50, DeBERTa-large+BUTD and ERNIE-ViL as the final models. We performed all our experiments on a Nvidia Tesla V100 GPU with 32 GB of memory. The models are trained for 20 epochs and we pick the model which has the best performance on validation set.

For the DeBERTa transformer, the Adam optimizer with a learning rate of 3e-5 is used. Also, we have applied the linear warm strategy for the learning rate. We set  $\alpha = 0.9$  and  $\gamma = 2.0$  for the focal loss. To ensure robustness under a small dataset, we set the threshold to 0.5 instead of performing a threshold search strategy on the validation set. For the pre-trained object detector, we choose Faster R-CNN (Anderson et al., 2018) and name the region features as BUTD in the experimental results.

For the ERNIE-ViL transformers, we use the same input preprocessing methods as (Yu et al.,

	Positive(%)	Negative(%)
train	1745(11.55%)	13369(88.45%)
dev	183(13.20%)	1203(86.80%)
test	523(13.49%)	3877(86.51%)

Table 1: Statistics of the positive and negative distribution of the dataset.

Loss Function	Precision	Recall	F1
cross-entropy	76.12	55.74	64.35
focal loss	71.18	66.12	68.56

Table 2: Results of different loss functions.

2020) and choose the large scale model<sup>1</sup> pre-trained on all the four datasets. We finetune on our multimodal classification dataset with a batch of 4 and a learning rate of 3e-5 for 20 epochs.

### 4.2 Experimental Analysis

#### 4.2.1 DeBERTa with Visual Features

**Unbalanced Distribution** There are 687/63/200 examples includes 22 categories in the train/validation/test datasets respectively. As shown in Table 1, the distribution of the classes is extremely unbalanced. If the cross-entropy loss is adopted directly during model training(the visual features are from ResNet50), the model output may have a greater chance of predicting the majority class(negative class in this task), which results in a lower recall. To solve this problem, the focal loss is applied. From Table 2, it can be seen that the result with focal loss performs much better than with cross-entropy loss respective to the F1 score.

**Visual Features** We evaluate the improvement brought by extended visual features and explore different types of visual feature extractors, e.g., from pre-trained image classification networks or pre-trained object detectors. The results are illustrated in Table 3. Firstly, it can be seen that the final score is significantly improved with mixing image features compared with using only text features (Row “w/o vision feature”), which indicates that the visual information is significantly beneficial for recognizing cross-modal propaganda techniques. Then, for features extracted from ResNet, we find that the depth of the network affects the results, especially on the validation dataset, with the best result from ResNet50. The reason may be

<sup>1</sup>the pre-trained model is downloaded from <https://github.com/PaddlePaddle/ERNIE/tree/repro/ernie-vil>

	<b>dev-F1</b>	<b>test-F1</b>
w/o vision feature	65.73	55.10
ResNet18	65.92	55.59
ResNet50	68.56	55.96
ResNet152	65.91	55.63
BUTD	66.29	56.21

Table 3: The results of using features extracted different networks.

<b>region numbers</b>	<b>Dev F1</b>	<b>Test F1</b>
5	64.91	54.00
10	66.67	54.60
36	67.40	57.14
100	67.45	56.07

Table 4: Results comparisons with different object region number inputs.

that the shallower network has insufficient feature extraction capabilities, and the deeper network is very difficult to train. Finally, the region features from the pre-trained object detector (Row “BUTD”) work best with an improvement of 0.25 on the test dataset compared to ResNet50 features.

#### 4.2.2 ERNIE-ViL

We compare the performance between ERNIE-ViL with different object region inputs, which are number dynamic ranges between 0 and 36 with a fixed confidence threshold of 0.2 and constantly fixed 5, 10, or 100 boxes. The results are illustrated in Table 4.

Results show that a larger box number can always achieve better performance within a certain range. Utilizing 0-36 boxes leads to huge performance improvement with a 3.14 and 2.54 on Test-F1 compared with using constant 5 boxes and constant 10 boxes respectively. It can be concluded that more object regions in a certain range can provide more useful information. However, the performance with 100 boxes is worse than that with 0-36 boxes. The reason may lie in that there are not enough objects in the task sample. The ex-

<b>Models</b>	<b>Dev-F1</b>	<b>Test-F1</b>
DeBERTa + ResNet50	68.56	55.96
DeBERTa + BUTD	66.29	56.21
ERNIE-ViL	67.40	57.14
Ensemble	69.12	58.11

Table 5: Final ensemble result.

tracted low-confidence object regions may mislead the multimodal model, therefore fuse useless or harmful visual features with text features. As a result of that, brings a performance decrease on the final score.

#### 4.3 Ensemble Results

The performance comparison between our two branches of approach is shown in Table 5. It can be concluded that fine-tuning the multimodal pre-trained transformer (Row “ERNIE-ViL”) works better than fine-tuning text pre-trained transformers with visual features (Row “DeBERTa + BUTD”). Overall, fine-tuning ERNIE-ViL has achieved state-of-the-art performance for this multimodal classification task.

Since the training dataset is small, we train multiple models under various model structures and different parameter configurations to take full advantage of the training dataset and increase the diversity of models. We choose three models of all model structures and all parameter configuration that performs best on the validation set and then ensemble them together. After performing ensemble strategy on those three models, both validation and test scores increases. As a result of that, we achieved a 58.11 score at F1 in the test set and ranked first place in the task competition.

### 5 Conclusion

We explore two branches to fine-tune pre-trained transformers to jointly modelling texts and images for the propaganda classification task. The first branch, fine-tuning pre-trained text transformer with visual feature, obtain significant performance improvement compared to text classification which validate the importance of visual clues for this task. Visual features from object detector yield slightly better results than grid features from ResNet. Importantly, fine-tuning pre-trained multimodal transformers obtain the best single model performance. And this improvement further validates the claim made by previous work that vision-language pre-training learned general joint representation needed for multimodal tasks. Besides, since the distribution of the classification labels is extremely unbalanced, we also make a further attempt on the loss function. Training models with focal loss can lead to a huge performance improvements than training with cross entropy loss.

## Abstract

SemEval 2021 Task 7, HaHackathon, was the first shared task to combine the previously separate domains of humor detection and offense detection. We collected 10,000 texts from Twitter and the Kaggle Short Jokes dataset, and had each annotated for humor and offense by 20 annotators aged 18-70. Our subtasks were binary humor detection, prediction of humor and offense ratings, and a novel controversy task: to predict if the variance in the humor ratings was higher than a specific threshold. The subtasks attracted 36-58 submissions, with most of the participants choosing to use pre-trained language models. Many of the highest performing teams also implemented additional optimization techniques, including task-adaptive training and adversarial training. The results suggest that the participating systems are well suited to humor detection, but that humor controversy is a more challenging task. We discuss which models excel in this task, which auxiliary techniques boost their performance, and analyze the errors which were not captured by the best systems.

## 1 Introduction

Humor is a key component of many forms of communication, and so it is commanding an increasing amount of attention in the natural language processing (NLP) community (Attardo, 2008; Taylor and Attardo, 2017; Amin and Burghardt, 2020). However, like much of figurative language processing, humor detection requires a different perspective on several traditional NLP tasks. For example, the problem of reducing lexical or syntactic ambiguity differs when ambiguity is key to some humor mechanisms. Tackling these challenges has the potential to improve many downstream applications, such as content moderation and human-computer interaction (Rayz, 2017).

However, humor is a subjective phenomenon, which evokes varying degrees of funniness in its audience, while also provoking other reactions such as offense, in certain listeners. The perception of humor is known to vary along the lines of age, gender, personality and other factors (Ruch, 2010; Kuipers, 2015; Hofmann et al., 2020). That humor can also evoke offense may be partly due to differences in acceptability judgements across demographic groups, and may also be in part due the use of humor to mask hateful or offensive content (Sue and Golash-Boza, 2013). Lockyer and Pickering (2005) expand on this by highlighting that it is common for societies to explore the link between humor and offense, free speech and respect.

HaHackathon is the first shared task to combine humor and offense detection, based on ratings from a wide variety of demographic groups. Task participants were asked to detect if a text was humorous and to predict its average ratings for both humor and offense. We also introduce a novel humor controversy detection task, which represents the extent to which annotators agreed/disagreed with each other over the humor rating of a joke. A humorous text was labelled as controversial if the variance in the humor ratings was higher than the median humor rating variance in the training set.

## 2 Related Work

Computational humor detection is a relatively established area of research. Taylor and Mazlack (2004) were one of the first to explore recognising wordplay with ngrams. Mihalcea and Strapparava (2005; 2006) experimented with 16,000 one-liners and 16,000 non-humorous texts, using a feature-driven approach. More recently, Zhang and Liu (2014) turned to online domains, by detecting humor on Twitter with a view to improving downstream tasks such as sentiment analysis and opinion

mining.

Workshops on humor detection have become more prominent with each shared task, and have attracted many new researchers to the field. SemEval 2017 (Potash et al., 2017) featured Hashtag Wars, a humor task with a unique data annotation procedure. This task featured tweets that had been submitted in response to a number of comedic hashtags released by a Comedy Central program. The top-10 response tweets were selected by the show’s producers and the winning tweet was selected by the show’s audience. Based on these labels, (top-10, winning tweet, and other) the sub-tasks required competitors to predict the labels, and to predict which text was funnier, given a pair tweets. The winning systems were split between feature-driven support vector machines (SVMs) and recurrent neural networks (RNNs).

The first Spanish-language humor detection challenges were the HAHA tasks in 2018 (Castro et al., 2018) and 2019 (Chiruzzo et al., 2019). These collected data from more than fifty different humorous Twitter accounts, representing a wide variety of humor genres. The sub-tasks asked competitors to predict if a text was humorous, and to predict the average funniness score given to the humorous texts. In the first year, the top teams used evolutionary algorithms to optimize linear models like Naive Bayes, as well as bi-directional RNNs. In the second year, the top teams started to use pre-trained language models (PLMs) like BERT (Devlin et al., 2018) and ULMFit (Howard and Ruder, 2018).

Most recently, Hossain et al. (2020) generated data for their task by collecting news headlines, and asking annotators to make a micro-edit to the headline to render it funny. These edited headlines were rated for funniness by other annotators. The sub-tasks were to rank the funnier of two edits, and to predict the average funniness score given by the annotators. The winning teams used ensembles of various PLMs, and RNNs.

### 3 Data

#### 3.1 Data Collection

In order to examine naturally-occurring humorous and offensive content in English, we sourced 80% of our data from Twitter. The remaining 20% of texts, we selected from the Kaggle Short Jokes dataset<sup>1</sup> for the following reasons:

<sup>1</sup><https://www.kaggle.com/abhinavmoudgil195/short-jokes>

Target	Keywords
Sexism	She, woman, mother, girl, b*tch, he, man, blond, p*ssy, hooker, slut, wh*re
Body	Fat, thin, skinny, tall, short, bald, amputee, redneck
Origin	Mexico, Mexican, Ireland, Irish, Indian, Pakistan, China, Chinese, Polish, German, France, Welsh, Vietnam, Asian, American, Russia, Arab, Jamaican, homeless
Sexual Orientation	Gay, lesbian, d*ke, f*ggot, homo, aids, LGBT, trans, tr*nny
Racism	Black, Africa, African, wop, n***** white people,
Ideology	Feminism, leftie/lefty
Religion	Muslim, Islam, Jew, Jewish, Catholic, Protestant, Hindu, Buddhist, ISIS, Jesus, Mohammed
Health	Wheelchair, blind, deaf, r*tard, Steven Hawking, Stevie Wonder, Helen Keller, dyslexic

Table 1: Targets and Sample Keywords

- **Humor Quota:** To ensure that a sample of texts in the dataset were intended to be humorous. Our annotation procedure asks raters if the intention of the text is to be humorous (as evidenced by the the setup/punchline structure, or absurd content). As the texts were sourced from the /r/jokes and /r/cleanjokes subreddits, we were confident that the intention of the text was to be humorous.
- **Traditional Humor Quota:** We wanted to represent jokes which have a traditional setup and punchline structure. Twitter humor is known to use a number of unique features (Zhang and Liu, 2014), which may not be equally recognisable to all annotators and so we wanted to have a selection of conventionally recognisable texts in order to gauge what the audience response was, and to use as a quality check for annotators (see below).
- **Offense Quota:** To ensure that a proportion of texts were likely to be considered offensive by the annotators, half of the texts selected according to the procedure below.

To select potentially offensive texts, we used some of the keywords associated with Silva et al.’s (2016) sub-categories of hate speech in social media, and queried the Kaggle dataset for these.

Text	Keyword = Target
A <b>fat</b> woman just served me at McDonalds and said "Sorry about the wait". I replied and said, "Don't worry, you'll lose it eventually".	Yes
Don't worry if a <b>fat</b> guy comes to kidnap you... I told Santa all I want for Christmas is you.	No

Table 2: Sample of potentially offensive and non-offensive texts

From these texts, we identified the target, or butt, of the joke and made the assumption that a text could be potentially offensive to our annotators if the hate speech keyword was the target of the joke. We selected 1,000 texts this way. We also assumed that the text would likely be considered not offensive if the keyword was mentioned, but was not the target and selected a further 1,000 texts like this. This was to reduce the probability that a humor/offense detection system would learn to classify texts simply based on the presence of a hate speech keyword.

### 3.1.1 Selection of Twitter texts

In order to avoid introducing annotation confounds such as a lack of cultural or linguistic knowledge (Meaney, 2020), we selected the texts and the annotators from the same region – the US. When sourcing the humorous Twitter data, we selected accounts according to whether they were based in the US and posted almost exclusively humorous content (e.g. @humorous1liners, @conanobrien). For the non-humorous Twitter accounts, we elected not to use news sources, e.g. CNN due to stylistic differences between news and humor (Mihalcea and Strapparava, 2006) making them easy to differentiate. The non-humorous accounts we selected centred on US celebrities (e.g. @thatonequeen, @Oprah), organisations that represent the targets of hate speech groups (e.g. @BlkMentalHealth, in order to increase the occurrences of the keywords in a non-humorous and non-offensive context), trivia accounts (e.g. @UberFacts, as the question and answer structure is similar to some types of setup and punchline) and tv/movie quotation accounts (e.g. @MovieQuotesPage, in order to resemble the dialogue-type jokes that are common on Twitter). Please see the appendix for a comprehensive list of accounts.

Using the Twitter API, we crawled up to 2,000 tweets from each account, and removed retweets and texts containing links. We also removed tweets that contained references to US Politics, the pandemic, or TV show characters as topical humor can

be difficult to understand once the event it is tied to has passed (Highfield, 2015). From an initial 76,542 texts, we were left with 8,000 tweets. From these, we removed hashtags that labelled the texts as humorous, e.g. #joke, and using Ekphrasis (Baziotis et al., 2017) we split up any remaining hashtags into their constituent words so as to make them less easy to differentiate from the Kaggle texts.

### 3.2 Annotation

We recruited annotators from the Prolific<sup>2</sup> platform. Participants were recruited based on their self-reported native English-speaker status, US citizenship, and membership of one of the following age groups: 18-25, 26-40, 41-55, 56-70. Each text was annotated by 5 members of each age group, giving a total of 20 annotations per text. Batches comprised 100 texts, and annotators answered the following questions:

1. Is the intention of this text to be humorous?
2. Is this text generally offensive?
3. Is this text personally offensive?

In the case that a user answered ‘yes’ to any of these questions, they were asked to rate the humor or offense from 1-5 (see figure 1). For the humor rating, the user was also given the option to select ‘I don’t get it’, meaning that they recognised by the structure or content that the text was intended to be humorous, but that they were unsure of why the text was funny. This is distinct from a rating of 1, which is a recognition of humor, with little appreciation for it.

The annotator instructions outlined that the first annotation question was intended to determine the *genre* of the text, and should be distinguished from *funniness*. Annotators were instructed to look at the structure of the joke, e.g. setup and punchline, or the content of the joke, e.g. absurdity, in order to determine if the intention was to be humorous.

<sup>2</sup><https://www.prolific.co/>

In terms of offense, we posed two annotation questions in order to avoid ambiguity about which type of offense was meant. We instructed annotators to consider as generally offensive, a text which targets a person or group of people, simply for belonging to a certain group. Alternatively, they could select yes for generally offensive if they thought that a large number of people were likely to be offended by the joke. The last question asked annotators if they felt personally offended by the text, or if they felt offended on another person’s behalf. We used only the generally offensive ratings in this task.

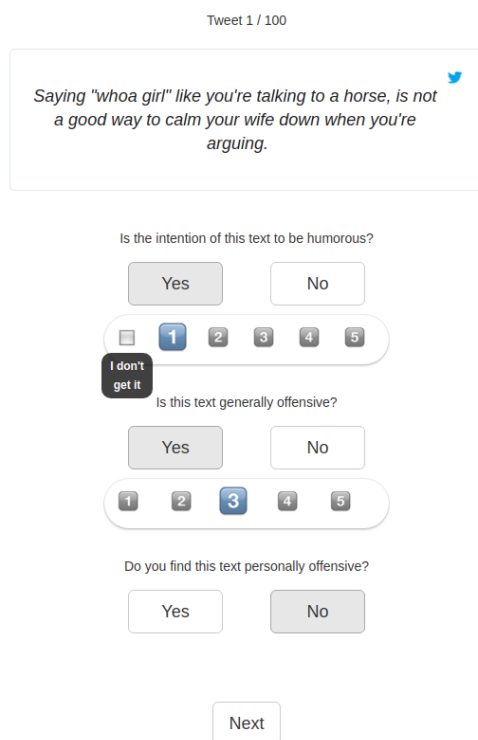

Figure 1: Screenshot from the tool used to annotate the texts.

### 3.3 Quality Control and Data Discarded

Each batch of 100 texts comprised approximately 20% of texts from Kaggle. As the majority of these have a setup and punchline structure, or other recognisable humor traits, we used these as a quality control. If an annotator did not label at least 60% of these as humor, it was clear that they they did not follow the instructions for the first question, and annotated based on perceived humor, as opposed to observation of humorous characteristics. We therefore discarded these submissions and replaced the annotators. Of 2,364 annotation sessions (e.g.

batches of 100), 301 submissions were discarded and replaced, and the ratings of the remaining 2,062 annotation sessions make up the dataset. Of these, 1,569 annotators rated one batch of texts with an additional 492 doing a second batch.

### 3.4 Data Statistics

Post-annotation, we classed a text as humorous if the majority of its twenty votes labelled it as such. In a small number of cases where votes were tied, we assigned the label humorous. For the texts labelled humorous, we calculated the average humor score, which was the average of the numerical votes. “No” ratings did not count towards this value, and votes of “I don’t know” were counted as 0, because this was deemed to be a recognizable humor structure, but one in which the humor was not successful.

Label	Affirmative	Negative	Average Rating
Humorous	6179	3821	2.24
Controversial	3052	3017	N/A
Offensive	5754	4246	1.02

Table 3: Data Statistics

The humor controversy label was based on whether the variance between the humor ratings was higher or lower than the median variance in the training set (median  $s^2 = 1.79$ ). The offense rating was the average of all ratings given, including ‘no’ as 0. Table 3 summarises the labels in the dataset, and in the case of offense, affirmative indicates that the rating is higher than 0.

Ratings	Krippendorff’s $\alpha$
Class label	0.736
Humor rating	0.124
Offense rating	0.518

Table 4: Inter-annotator agreement (Krippendorff’s  $\alpha$ ) for ratings used in subtask 1a, 1b and 2

The dataset was split 80:10:10 for training, development and test sets. The texts and annotations will continue to be available on the Codalab website, and the tweet ids, and usernames will be retained for non-commercial research use, in line with the Twitter Academic Developer Policy.

## 4 Task Description and Evaluation

We divided our tasks into four subtasks.

### Task 1a: Humor Detection

This was a binary classification task to detect, given a text, if the majority label assigned to it was humorous or not. This was evaluated using F-score for the humorous class and overall accuracy

$$Accuracy = \frac{C}{N}$$

$$F_1 = 2 * \frac{Precision \times Recall}{Precision + Recall}$$

### Task 1b: Humor Rating Prediction

This was a humor rating regression task. Participants predicted the average rating given to texts from 0-5. Texts which had not been labelled as humorous by our annotators did not have a humor rating, and predictions for these texts were not counted towards the final score by our scoring system. The metric for this task was root mean squared error (RMSE).

$$RMSE = \sqrt{\sum_{i=1}^n \left(\frac{y_i - \hat{y}_i}{N}\right)^2}$$

### Task 1c: Humor Controversy Detection

This task was also a binary classification task to predict whether the humor ratings given to the text showed it to be controversial or not. This was based on the variance in the ratings being higher or lower than the median variance in the training set humor ratings. This was also evaluated using F-score and accuracy.

### Task 2: Offense Detection

This was an offense rating regression task. Unlike the humorous task, this rating was not dependent on the text having been labelled as humorous. All annotator ratings were considered, and each text had a rating from 0-5. The metric was RMSE.

## 5 Benchmark Systems

We created simple, linear benchmarks using sklearn (Pedregosa et al., 2011) for the classification tasks which consists of a Naive Bayes classifier with bag of words features. For the regression tasks, we used a support vector regressor with term-frequency inverse document frequency features.

We also built a BERT-base classification/regression model which was run for one epoch, with a batch size of 16 and a learning rate of 5e-5, for all sub-tasks. As this system out-performed the linear benchmarks on all sub-tasks, we refer to this as the baseline in the rest of the paper.

## 6 Participant Systems

### 6.1 Overview

In total 63 teams submitted systems for the different tasks: 58 for task 1a, 50 for task 1b, 36 for task 1c and 48 for task 2. Tables 5, 6, 7 and 8 show the highest results for each task, with performance broken down by subsets of texts from the Kaggle jokes dataset and from Twitter. -\*/

### 6.2 Highest Ranking Systems

The top-ranking teams were selected based on F-score, in the case of a tie in accuracy score. The top-10 made extensive use of pre-trained language models such as BERT, ERNIE 2.0 (Sun et al., 2020), ALBERT (Lan et al., 2019), DeBERTa (He et al., 2020) or RoBERTa (Liu et al., 2019). Ensembling these models by majority voting or averaging scores proved to be a popular and useful approach.

Similarly, many teams experimented with single and multi-task learning setups, and multi-task models tended to be more successful across sub-tasks. Further improvements were achieved with domain adaptation strategies and adversarial training.

### 6.2.1 DeepBlueAI (Song et al., 2021)

DeepBlueAI achieved high performance in sub-tasks 1a and 2. This team used stacked transformer models, which used the majority vote (in the case of classification) or the average prediction (for regression) from a RoBERTa and an ALBERT model. They optimized the performance of these PLMs with a number of techniques. First, they employed task-adaptive fine-tuning (Gururangan et al., 2020) by continuing pre-training on the text of the Ha-

Table 8: Results of the top performing systems for participants of task 2 (offense rating), showing RMSE for whole test set, for kaggle texts only and tweets only.

Hackathon data. They then augmented the dataset by using pseudo-labelling to generate labels for the test set, and added these to the training data. Then, after encoding the input, they used adversarial training (Miyato et al., 2016), e.g. the addition of perturbations to the embedding layer, to improve generalization. The predictions were produced after Multi Sample Dropout was applied. This approach achieved third place in task 1a and first place in task 2.

### 6.2.2 abcbpc (Pang et al., 2021)

This team deployed ERNIE 2.0 in a multi-task setup with task-specific gradients and loss for each sub-task. Using a cross-validation approach, they fine-tuned their model on each fold of data and took the average, or majority decision of their best-performing models as their predictions. Experiments demonstrated that their multi-task setup performed better than single-task learning with ERNIE 2.0, and they achieved the best score in task 1b.

### 6.2.3 Humor@IITK (Gupta et al., 2021)

This team also experimented with single-task and multi-task learning on pre-trained language models. They implemented two ensembling methods: in the single-task setup, they concatenated the embeddings produced by BERT, RoBERTa, ERNIE 2.0, DeBERTa and XLNET. In the multi-task setup, they used vote-based classification, or a weighted aggregate of outputs for the regression tasks. They also implemented an ensemble comprising a weighted average of best single-task and multi-task models, which achieved third place on task 1b. Interestingly, this team’s experiments on data augmentation, e.g. generating slightly different variations of the input sentences, disimproved performance. The team hypothesize that the impact of both humor and offense often hinges on the choice of specific words, and replacing these words with synonyms may undermine the humorous or offensive effect.

### 6.2.4 SarcasmDet (Faraj and Abdullah, 2021)

For tasks 1a, 1b and 2, this team used either BERT or RoBERTa models with different hyperparameters, and used an ensemble of these models to make predictions with hard (e.g. majority or average) voting. Interestingly, for task 1c, in which they placed third, they used a rule, that if the humor rating predicted for a text was greater or equal to 3, they labelled the text as controversial.

### 6.2.5 HumorHunter (Xie et al., 2021)

This team used DeBERTa with an embedding table which took into account the relative position of each token in the sentence. In an error analysis, they noted that texts with a question and answer were more often misclassified as humorous, possibly because this mimics the structure of a setup and punchline.

### 6.2.6 Others

PALI and stce, the top-ranking teams in task 1a, both used an ensemble of RoBERTa large, and ERNIE 2.0, but declined to submit a paper outlining further details. Similarly, the team named mmmm, which placed 2nd in both task 1b and 1c, did not furnish details of their approach.

## 6.3 Trends

### 6.3.1 Domain Adaptation

Given that the majority of the data was sourced from Twitter, several teams implemented domain adaptation strategies at different stages of their pipeline. YoungSheldon (Sharma et al., 2021) used the Ekphrasis (Baziotis et al., 2017) toolkit, which is designed for Twitter-specific preprocessing. DLJUST (Al-Omari et al., 2021) also used it in their preprocessing pipeline, and found that this achieved better results, when used in combination with some further manual spelling correction.

Domain-specific models also showed some performance improvements. UPB (Smădu et al., 2021) used BERTweet (Nguyen et al., 2020), a transformer-based language model trained on tweets for their embedding layer, and DLJUST found that this model gave slightly better performance than RoBERTa on subtask 1a, but not on the regression tasks.

Amherst685 (Gugnani et al., 2021) used intermediate fine-tuning to adapt a series of pre-trained models to the style of language used in humorous and offensive texts. They used two large humor datasets, and two offense datasets, to adapt a variety of transformer models to the task, however, they did not see performance gains from this. Similarly to DeepBlueAI, RoMa (Labadie et al., 2021) and IITH (Raha et al., 2021) used task-adaptive pre-training, and the latter team saw performance improvements of 1-5%.

### 6.3.2 Data Augmentation/Perturbation

Similarly to DeepBlueAI, MagicPai (Ma et al., 2021) experimented with pseudo-labelling in order

to increase the amount of data available. MagicPai also tried adversarial training by adding perturbations to the embedding layer, and along with Grenzlinie (Liu and Zhou, 2021) and UPB, found this to improve their transfer learning models' performance. Amherst685 tried backtranslation in order to generate more sample texts, however they found that this was not successful.

### 6.3.3 Contrasting Models and Task Setup

The majority of teams who contrasted RNNs with PLMs found that the latter was more suited to this task. ES-JUST (Bashabsheh and Alasal, 2021) found that RoBERTa performed better than RNNs and BERT. This finding replicates the ablation study by Morishita et al. (2020) in the 2020 SemEval task, which also demonstrated that RoBERTa performed better than other PLMs. However Tsia (Guan, 2021) found that RoBERTa was better suited to the regression task, and combining BERT+CNN gave better performance on the classification task. This contrasts with YoungSheldon, who achieved their best results with BERT-Base. Across all cases, we did not observe a single dominant architecture, indicating that the choice of hyperparameters and task setup played a large role in the results achieved by each team. However, teams like CS-UM6P (Essefar et al., 2021), who contrasted single and multi-task learning setups, found that the latter improved performance.

## 6.4 Other notable approaches

DUTH (Karasakalidis et al., 2021) produced a rigorous examination of different preprocessing approaches applied to data given to linear and neural models. They achieved an impressive 12th place on task 1b, with a combination of Light Gradient Boosting Machine (LGBM), XGBoost and Bayesian Ridge. They also achieved 12th place in task 1c using a combination of features such as POS-tagging, numerical features, a bigram term frequency inverse document frequency (TF-IDF) vectorizer as input to an LGBM model.

The utility of TF-IDF features was also seen in the transfer learning approaches as team hub also found that adding TF-IDF features improved the performance of their ALBERT/BERT+CNN models.

IITH found that including lexical features such as letter and punctuation counts, named entities marking, identifying personal pronouns, wh-words and question marks, as well as a lexicon of hurtful

words (Hurtlex, Bassignana et al., 2018) improved the performance of their task-adaptively pre-trained RoBERTa model for detecting humor and predicting the rating, but that only the Hurtlex features improved offense detection, and neither of these improved controversy prediction.

## 7 Analysis and Discussion

### 7.1 Correlations between Tasks

As Table 9 indicates, humor rating is moderately correlated with humor controversy across the dataset. There are no discernible trends in offense rating and humor controversy. Interestingly, there is a moderate negative correlation between humor and offense rating overall, but this is not significant for the Twitter data, and becomes a much stronger negative correlation when we look at just the Kaggle data. This may have been a factor in the finding that multi-task setups tended to achieve better results than single-task systems. It may also suggest that in naturally occurring data, such as the Twitter texts, the relationship between humor and offense may be more subtle, and therefore more difficult to detect.

Task 1	Task 2	Overall	Twitter	Kaggle
Humor	Humor	0.15	0.14	0.18
Rating	Controversy	$p = 0.0001$	$p = 0.003$	$p = 0.009$
Offense	Humor	0.07	0.11	-0.02
Rating	Controversy	$p = 0.06$	$p = 0.028$	$p = 0.82$
Humor	Offense	-0.156	-0.03	-0.42
Rating	Rating	$p = 0.0001$	$p = 0.51$	$p = 0.0011$

Table 9: Correlations between tasks, Pearson’s  $r$  and  $p$ -value

### 7.2 Differences between Kaggle Texts and Tweets

As seen in tables 5, 6 and 7, the systems’ performance for subtasks 1a, 1b and 1c seems to be consistently better for Kaggle texts than for tweets. One possible reason why systems are better at predicting humor from Kaggle texts, is that the Kaggle test set contains almost all humorous texts, while only about half of the tweets are considered humorous.

On the other hand, performance for task 2 is consistently better (lower RMSE) for tweets than for Kaggle texts, and the differences are sometimes very large. We noticed the distributions of offense ratings between Kaggle texts and tweets are very different, with tweets being more often classified

as not offensive: more than 60% of the tweets have 0.1 offense rating or less (in a scale from 0 to 5), while less than 10% of the Kaggle texts do. This difference in distribution might in part come from differences in sampling methods, because some Kaggle texts were specifically selected to have certain offensive categories, while the tweets were selected at random. In order to check if the difference in scores could come from the difference in offense rating distributions, we resampled a subset of tweets from the Kaggle set and another one from the Twitter set, trying to keep a uniform offense rating distribution, and calculated task 2 scores for those subsets. The difference between scores for these new subsets was much lower for all teams, and even some of the teams got better scores for the Kaggle subset, which might be an indication that the sharp differences in score were caused by the difference in distributions.

### 7.3 Error Analysis: Humans and Machines vs Irony

Several interesting issues arise when analyzing the top-ten systems’ errors. Irony continues to be a challenging problem, both at the annotation side, and the classification side. Several texts which were sourced from humorous accounts, and which had just less than a majority of annotator votes for humorous were classed as not-humorous in our dataset. In the following two examples, all of the top-10 systems classed this as humorous, and arguably, they are intended to be humorous, even though the majority of annotators technically did not class them as such.

1. What do you call a homosexual man on a wheel chair?  
A human being
2. It’s almost like I gotta keep myself busy with random things like fluffing pillows just so I don’t over eat.

The first example is an ironic subversion of a homophobic joke, using incongruity to undermine the anticipated punchline. While it is possible that the setup and punchline structure is what misled the system, similar question and answer structures were correctly classified.

The second example is arguably sarcasm, and all of the top systems classified it as humor, even though the annotators did not. However, there were several other texts which were classed as humorous

by the annotators, and which demonstrate traits of irony or sarcasm, were difficult to classify for the top teams, and produced mixed results:

1. If alcohol influences short-term memory, what does alcohol do?
2. How much should I rest between sets at the gym? I've been doing anywhere between 60 to 90 days to give my muscles a good chance to recover.

In terms of tasks 1b and 2, we analyzed the texts which proved most difficult to predict the humor and offense ratings for the top-10 systems. We calculated the mean average error (MAE) between the top 10 systems' predictions and the ground truth. We then examined the 75th percentile of MAE.

	Twitter	Kaggle
Humor	70%	30%
Offense	55.2%	44.8%

Table 10: Percentage of texts with highest MAE from the different sources

Interestingly, there was a disproportionately high number of Kaggle texts among the offensive texts whose rating was difficult to predict (44.8% while the Kaggle text make up only 20% of the data). A quick examination of these texts revealed there was a large number of ironic texts which were predicted to be highly offensive, although the ground truth did not reflect this, for example:

Why do black people eat fried chicken?  
Because it tastes good.

#### 7.4 Humor Controversy

As we were interested in the rule-based approach that team SarcasmDet took for this task, we investigated the upper-bound of success for any threshold-based heuristic which determines whether a text was controversial given the humor score alone. Figure 2 shows the hypothetical F1-score and accuracy that could be achieved by such a system. Assuming a perfect score on humor rating prediction, if teams assigned a controversial label for any text with a humor rating of over 2, they could achieve first place in this task in terms of accuracy with a score of 0.580. A threshold of 1.45 given perfect knowledge of the humor labels would result

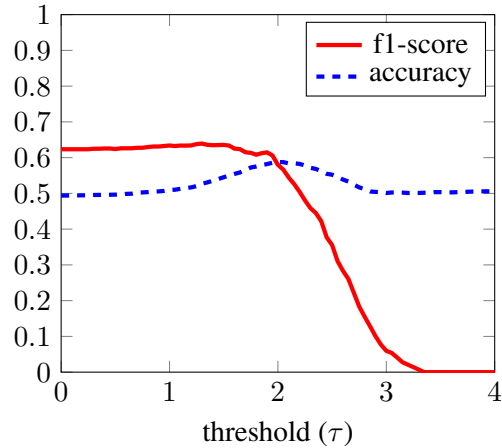

Figure 2: For varied values of a threshold,  $\tau$ , accuracy and f1-score achieved by a hypothetical model predicting the label *controversial* for all texts in the test set with ground-truth humor score  $> \tau$ . Note that participants did not have access to these ground-truth scores for the test set, making these results an upper-bound for this type of threshold-based approach.

in a leaderboard-topping F1-score of 0.635. However, the teams that took part did not obtain the perfect humor rating scores required for this simple rule to work so effectively, yet were still able to achieve similar scores on the task. This suggests that their systems were learning something, but that ultimately the task is a difficult one.

Although we aimed to increase inter-annotator agreement in this task's annotation procedure, by matching the origin of the texts and annotators, the agreement on humor ratings was low, and indeed the task which aimed to capture this controversy proved difficult.

## 8 Conclusion

We provided 10,000 texts annotated for humor and offense by a broad range of annotators. Transformer models were a dominant approach to this task, with the exception of the humor controversy task, which proved to be difficult for most teams, and in which a simple, rule-based system achieved one of the top-3 scores. As multi-task learning setups proved more effective than single-task learning demonstrates, this that there is some correlation between humor and offense detection. It was also interesting to note which model adaptations were useful and which were not. Finally, an analysis of the errors in humor analysis reveals some types of humor which may be captured inaccurately, even by the most powerful models.

## Acknowledgments

This work was supported in part by the EPSRC Centre for Doctoral Training in Data Science, funded by the UK Engineering and Physical Sciences Research Council (grant EP/L016427/1) and the University of Edinburgh. The authors also wish to thank William J. Toner who acted as a last-minute Idea Bouncer.

niladri@maths.iitd.ac.in

## Abstract

The present work aims at assigning a complexity score between 0 and 1 to a target word or phrase in a given sentence. For each Single Word Target, a Random Forest Regressor is trained on a feature set consisting of lexical, semantic, and syntactic information about the target. For each Multiword Target, a set of individual word features is taken along with single word complexities in the feature space. The system yielded the Pearson correlation of 0.7402 and 0.8244 on the test set for the Single and Multiword Targets, respectively.

## 1 Introduction

Presence of complex words can lead to poor comprehension of a text. Identification of such complex words in a given text is a core component in the task of Automatic Simplification and Evaluation (Shardlow, 2013). The Lexical Complexity Prediction Task of SemEval 2021 (Shardlow et al., 2021) aims at development of systems for prediction of complexity scores for a target word/phrase in a given sentence. In literature, binary classification of target words in a text into complex or non-complex is referred to as Complex Word Identification (CWI) (Paetzold and Specia, 2016; Zampieri et al., 2017; Gooding and Kochmar, 2018; AbuRa'ed and Saggion, 2018; Yimam et al., 2018). Unlike previous works, a continuous complexity score is assigned to the target word in the present task which is referred to as Lexical Complexity Prediction (LCP) (Shardlow et al., 2020). For the present work, regression is performed for LCP on a set of linguistic features covering semantic, syntactic and contextual aspects of the target word as described in Section 3. Additionally, various lexicon based features are used to indicate the rarity of target words. The system achieves 0.8194 Pearson correlation for Single Word Target and 0.7482 for Multiword Target on the trial set.

## 2 Task Setup

The task is divided into two subtasks, namely Single Word Target and Multiword Target based on the length of the target. The dataset and evaluation metrics are described below.

- **Dataset:** The dataset consists of an augmented version of CompLex (Shardlow et al., 2020). It comprises sentences from three corpora, viz. World English Bible Translation, English Portion of the European Parliament proceedings, and articles from CRAFT corpus belonging to biomedical domain. It is split into three subsets Train, Trial, and Test.
- **Evaluation Metrics:** The systems are evaluated using Pearson correlation coefficient (P), Spearman rank correlation coefficient (S), Mean absolute error (MAE) and Coefficient of Determination ( $R^2$ ).

## 3 Features

In this section we present the details of the feature space used in the present work.

### 3.1 Corpus Features

A feature, named Corpus, is used to indicate to which of the 3 corpora the input sentence belongs.

### 3.2 Shallow Features

Word level shallow features used in the present work are number of letters (Nlet), syllables (Nsyl), vowels (Nvow), percentage of upper case alphabets (PerUp), simple universal part-of-speech tag (POS), and detailed Penn part-of-speech tag (Tag) of the target word extracted using SpaCy.

### 3.3 NLTK WordNet Features

Number of hypernyms (Nhyper) and number of morphemes (Nmorph) of the target word consider-

ing its POS tag in the given sentence are also used as features.

### 3.4 Exquisite Corpus (EC) Features

Exquisite Corpus<sup>1</sup> compiles texts from seven different domains namely Wikipedia, Subtitles, News, Books, Web, Twitter and Reddit. We have used the frequency (WordFreq) in EC and the Zipf frequency (ZipfFreq) of the target word as features (van Heuven et al., 2014).

### 3.5 SUBTLEX Features

Frequency (SubtFreq) of the target word extracted from SUBTLEXus<sup>2</sup> and its Contextual Diversity (ConDiversity) i.e. percent of the films in which the word appears are used as features.

### 3.6 Language Model (LM) Features

Given an input sentence  $S = w_1 w_2 \dots w_N$  and a target word  $w_t$  where  $t \in 1, 2, \dots, N$ , the following features are extracted from a trigram language model trained on the Gigaword corpus<sup>3</sup>.

- Perplexity of the input sentence (Perplexity) computed as:  

$$Perplexity(S) = \sqrt[N]{1/P(w_1 w_2 \dots w_N)}$$
- The phrase score (PhrScore) of  $w_j \dots w_t \dots w_k$  defined as  $\log_{10} P(w_j \dots w_t \dots w_k)$  where  $j = \max(1, t - 2)$  and  $k = \min(N, t + 2)$
- Average of conditional probabilities involving the target word (AvgCP)

$$Avg \left( \begin{array}{l} P(w_t | w_{t-1}, w_{t-2}), \\ P(w_{t+1} | w_t, w_{t-1}), \\ P(w_{t+2} | w_{t+1}, w_t) \end{array} \right)$$

### 3.7 Character Language Model (CharLM) Feature

The probability of the target word (Prob3c) calculated using trigram character language model is considered as a feature. The trigram<sup>4</sup> probabilities are calculated using letter counts from Google Web Trillion Word Corpus. Suppose a word  $W$  consist of  $N$  letters,  $W = w_1 \dots w_N$  then, the corresponding feature value will be computed as:  

$$Prob3c(W) = \frac{1}{N-2} \sum_{i=1}^{N-2} \log_{10} P(w_i w_{i+1} w_{i+2})$$

<sup>1</sup><https://pypi.org/project/wordfreq/>

<sup>3</sup>lm\_giga\_64k\_nvp\_3gram.zip

<sup>4</sup>[http://norvig.com/ngrams/count\\_3l.txt](http://norvig.com/ngrams/count_3l.txt)

### 3.8 Psycholinguistic Features

The following features are extracted using MRC psycholinguistic database (Wilson, 1988): Age of acquisition (AOA), Concreteness (CONC), Imageability (IMAG) and Meaningfulness ratings (MeanC, MeanP) of the target word.

### 3.9 Kucera and Francis (KF) Features

The features derived by Kučera and Francis (1967), namely target word's written frequency of occurrence (KFFreq) and the number of categories of text in which the target word was found (KFNcats) are used.

### 3.10 Ogden Feature

A binary feature is used to indicate presence of the target word in the list of 1000 words included in Ogden's Basic English<sup>5</sup> (IsOgden).

### 3.11 Inquirer Tag Features

The General Inquirer classifies about 7500 words using 182 General Inquirer categories developed for social science content analysis (Stone et al., 1966). A binary feature is created for each category to indicate its occurrence for the target word. The POS tag of the target is matched with the 'OthTags' category to filter out incompatible categories as given in Table 1

POS of the Target	Compatible OthTags
NOUN   PRON   PROPN	NOUN   PRON
VERB   AUX   ADV	VERB   SUPV

Table 1: Inquirer Tags Filtering

## 4 Single Word Target

In the Single Word Target task, complexity scores between 0 to 1 needs to be assigned for a target word of the input sentence. Various regression models are trained using the optimal set of features using scikit-learn<sup>6</sup>. The results are presented in Table 2. For both Decision Tree and Extra Tree Regressors the maximum depth (maxdepth) is tuned between 1 to 20, and the optimal maxdepth is found to be 6 and 8, respectively. Random Forest Regressors with the default setting produced the best results for the trial dataset. Using the above, our submission to the shared task achieved 0.7402 Pearson correlation on the test set.

<sup>5</sup><http://ogden.basic-english.org/>

<sup>6</sup><https://scikit-learn.org/stable/>

Regressor	P	S	MAE	R <sup>2</sup>
Decision Tree	0.761	0.699	0.069	0.58
Extra Tree	0.757	0.650	0.071	0.57
Gradient Boosting	0.794	0.731	0.065	0.63
Random Forest	<b>0.819</b>	<b>0.748</b>	<b>0.062</b>	<b>0.69</b>
+Bagging	0.805	0.738	0.064	0.64
+Adaptive Boosting	0.798	0.734	0.065	0.63

Table 2: Results on the Trial Set

#### 4.1 Feature Importance

The Gini importance of the top 5 features are reported in Table 3. Gini importance of a feature is computed as the (normalized) total reduction of the mean squared error brought by that feature. The importance of the features is also analyzed by removing a set of features at a time and training a Random Forest Regressor for the reduced feature space. Each of the features from the optimal feature space has a positive effect on the performance of the system as indicated in Table 4. The experiments indicate that exclusion of Exquisite Corpus features led to the maximum decline in the results. Hence, this may be considered as the most important feature subset.

Feature	Gini importance
ConDiversity	0.443
Prob3c	0.072
ZipfFreq	0.068
Perplexity	0.067
AvgCP	0.060

Table 3: Gini Importance of Features

##### 4.1.1 Inquirer Tags Importance

The effect of inclusion of Inquirer Tags in the feature space has a positive effect however the magnitude is low. This may be due to the low coverage of these features as reported in Table 5. The coverage is defined as the percentage of target words having at least one Inquirer Tag.

#### 4.2 Additional Features

The following set of features when included in the feature space led to a decrease in performance for the present task on the trial set.

- Etymological Feature: The ISO code of the target word’s origin language

Features	P	S	MAE	R <sup>2</sup>
All	<b>0.819</b>	<b>0.748</b>	<b>0.062</b>	<b>0.67</b>
w/o Ogden	0.816	0.744	0.063	0.66
w/o Inquirer	0.815	0.744	0.063	0.66
w/o KF	0.815	0.746	0.063	0.66
w/o WordNet	0.814	0.747	0.063	0.66
w/o Psych	0.813	0.740	0.063	0.66
w/o LM	0.810	0.744	0.063	0.65
w/o CharLM	0.806	0.747	0.064	0.65
w/o Corpus	0.798	0.740	0.065	0.63
w/o SUBTLEX	0.795	0.725	0.066	0.63
w/o Shallow	0.786	0.728	0.067	0.61
w/o EC	0.782	0.713	0.067	0.61

Table 4: Feature Set Elimination Results for the Trial Set

Data	All	Bible	Biomed	Europarl
Train	21.14	20.23	21.48	21.77
Trial	22.09	23.78	19.26	23.08
Test	23.77	19.79	27.34	24.06

Table 5: Inquirer Tags Coverage

- Named Entity Feature: The named entity tag<sup>7</sup> of the target word.

Post task evaluation on the test set indicates their inclusion improves the performance of the system. (See Table 6)

#### 4.3 BERT Features

BERT was introduced in (Devlin et al., 2019), and its usage has resulted in state-of-the-art performance for various downstream NLP tasks, such as Question Answering, Textual Entailment and Paraphrase detection. In the present work, BERT embedding for the target word is extracted from the pre-trained BERT-base-uncased model<sup>8</sup>. Additionally, in an effort to enhance the contextualized BERT embeddings (Agarwal et al., 2020), the embedding vector is supplemented with the feature vector corresponding to linguistic features described in Section 3. Finally, a Neural Network is trained to minimize the Mean Absolute Error using Adam optimizer (Kingma and Ba, 2015). Hyper parameter tuning is performed using hyperas<sup>9</sup> and TPE algorithm. The number of intermediate dense layers are tuned between {2, 3}. The encoding dimensions are tuned between {50, 100,

<sup>7</sup>extracted using <https://spacy.io/api/entityrecognizer>

Yes	Yes	0.8175	0.7466	0.0627	0.6654	0.7418	0.6974	0.0659	0.5475

Table 6: Results for Additional Features

200, 300, 500, 700, 1000} and dropouts between {0.1, ..., 0.9}. Batch size is set to 16. The results are presented in Table 7. It can be observed that BERT embeddings do not improve the performance. Moreover, Neural Networks when applied on just linguistic features have a lower performance than Random Forest Regressors.

#### 4.4 Error Analysis

Error analysis indicates that absolute error for 87% test samples were less than 0.10. Samples belonging to Biomedical corpus had highest errors. Some predictions of the proposed model are presented in Table 8. The correlation between the actual and predicted complexity for similar targets in dissimilar contexts is high. However, it is revealed that difference in complexity of proper noun targets in distinct contexts could not be captured effectively through the present set of linguistic features.

### 5 Multiword Target

In the present task the Multiword Targets are pairs of two adjacent words. We have experimented with two approaches for predicting complexity scores for Multiword Targets, as described in Section 5.1 and Section 5.2

#### 5.1 Single Word Combination

In this approach, each word of a Multiword target is considered as individual single word targets, and the complexity scores are predicted using the Single Word Target<sup>10</sup> model. The individual word scores are combined using Average, Maximum, and Minimum. Additionally, Algebraic Sum ( $a + b - ab$ ) and Product ( $ab$ ) of the individual scores are also considered. These are taken from Fuzzy s-norm and t-norm (Klir and Yuan, 1995). The results are indicated in Table 9. For both trial and test set, maximum of the complexity score of each word of the multiword target gives the least MAE and the highest  $R^2$  value. But, the highest P

for trial set is obtained when algebraic sum of the individual complexity scores are taken and highest S is obtained when product of the individual complexity scores are taken. For the test set, algebraic sum gives highest P and S.

#### 5.2 Feature Combination

In this approach features corresponding to the individual words are concatenated, and then a regression model is trained with the increased feature space for complexity prediction. The individual target word complexity value predicted by the Single Word Target model is also considered as a feature. The results are presented in Table 10. Bagging and Adaptive Boosting are applied on Random Forest. The results indicate that inclusion of individual complexity scores enhances the performance of the system, and the best results are obtained for Bagging ensemble. Our submission to the shared task was derived using Bagging on the Random Forest Regressor. The feature set contains individual word features along with complexity scores. It achieved Pearson correlation of 0.8244 on the test set.

### 6 Conclusion

Identification of difficult words is an important task for Automatic Text Simplification. LCP aims at assigning scores to words of a given sentence to indicate its complexity. In this work we utilize word level features to capture its lexical, semantic and syntactic information. LM based features are used for indicating the semantics of the target word in a given context. Frequency and occurrence based features are used to indicate the overall rarity of the target words. For Single Word Target, Random Forest Regressors trained on the linguistic feature set achieved the highest results. Error analysis revealed that the model can be further improved to capture the context of the target word.

For Multiword Target, two approaches were explored. In the first approach complexity scores of individual target words predicted by the Sin-

<sup>10</sup>Random Forest Regressor w/o additional features

## Abstract

This article describes a system to predict the complexity of words for the Lexical Complexity Prediction (LCP) shared task hosted at SemEval 2021 (Task 1) with a new annotated English dataset with a Likert scale. Located in the Lexical Semantics track, the task consisted of predicting the complexity value of the words in context. A machine learning approach was carried out based on the frequency of the words and several characteristics added at word level. Over these features, a supervised random forest regression algorithm was trained. Several runs were performed with different values to observe the performance of the algorithm. For the evaluation, our best results reported a M.A.E of 0.07347, M.S.E. of 0.00938, and R.M.S.E. of 0.096871. Our experiments showed that, with a greater number of characteristics, the precision of the classification increases.

## 1 Introduction

The identification of complex words (CWI) is the task of detecting in the content of documents the words that are difficult or complex to understand by the people of a certain group (Rico-Sulayes, 2020). The CWI and the substitution of words identified as complex may significantly improve readability and understandability of a given text (Zotova et al., 2020).

CWI has become an area of great interest in recent years for the computational linguistics community in making proposals that allow researchers to develop computational semantic analysis systems, as demonstrated by the shared tasks of CWI in SemEval 2016 (Paetzold and Specia, 2016), y NAACL-HTL 2018 (Yimam et al., 2018), and the CWI task of the ALexS 2020 competition, hosted at IberLEF 2020 (Ortiz-Zambrano and Montejo-Ráez, 2020).

This article introduces a system that has participated in the Lexical Complexity Prediction (LCP) shared task hosted at SemEval 2021 (Task 1) (Shardlow et al., 2021a). The task releases a new annotated English dataset with a Likert scale. Located in the Lexical Semantics track, the task consisted of predicting the complexity value of the words in context.

We have explored different features for representing words and multi-words and their context. Some preprocessing steps have been evaluated along with the effect of feature selection.

## 2 Related Work

(DuBay, 2004) defines readability as allowing one text to be easier to read than another. For many people, the understanding of a text can be affected by the presence of lexically and semantically complex words and phrases, for example for children (Petersen and Ostendorf, 2009), non-native speakers (Petersen and Ostendorf, 2009), and people with various cognitive or reading disabilities (Saggion et al., 2015).

Predicting which words a given target population has difficulty to understand is a critical step for many NLP applications, such as in text simplification, which has traditionally focused its attention on second language learners, native speakers with low levels of literacy, and people with language disabilities reading (Saggion et al., 2015). This task is also known as complex word identification (CWI). The prediction of the lexical complexity carried out with precision can allow to adapt texts according to the needs of the readers (Shardlow et al., 2020). Actually, in an early study in the 1920s, a very simple way to predict the level of difficulty of a text was discovered by educators, who used vocabulary difficulty and sentence length as main indicators (DuBay, 2004).

corpus	bible	europarl	biomedic	total
single	2574	2576	2512	7662
multi	505 1	498	514	1517

Table 1: Total number of sentences in each training corpus.

### 3 Dataset

The training data set provided to the participants consisted of an augmented version of CompLex (Shardlow et al., 2021b). It uses data from three different sources: the Bible, Europarl, and biomedic texts (see Table 1). It is a set of multidomain English data made up of sentences, the targeted token, and its respective level of complexity as described in (Shardlow et al., 2020).

### 4 The system

This section describes the details of the system applied to the task, as our approach to complex word identification. A machine learning approach was followed based on the frequency of the words and further characteristics added at word level. Over these features, a supervised random forest regression algorithm was trained. In this section, first, the features considered in the supervised learning approach are introduced. Then, the method to determine whether a candidate word is complex or not is detailed.

#### 4.1 Features

We computed a total of 15 features, taking into consideration the linguistic measures of the work carried out by (Mc Laughlin, 1969) and the experiments of the shared tasks of the CWI BEA 2018 respectively by (Paetzold and Specia, 2016; Gooding and Kochmar, 2018). These are the features obtained on the target word (token).

- *Absolute frequency (abs-frequency)*: the absolute frequency. This frequency is computed based on the unannotated corpora compiled by José Cañete<sup>1</sup> from different sources. It contains about 3 billion words.
- *Relative frequency (rel-frequency)*: the relative frequency of the target word.
- *Word length (length)*: the number of characters of the token.

<sup>1</sup>Available at <https://github.com/josecannete/spanish-corpora>

- *Number of syllables (number-syllables)*: the number of syllables.
- *Target word position (token-position)*: the position of the target word in the sentence.
- *Number of words in the sentence (n-words-sentences)*: number of words in sentence.
- *Part Of Speech (POS)*: the Part Of Speech category.
- *Relative frequency of the previous the token (freq-rel-word-before)*: the relative frequency of the word before the token.
- *Relative frequency of the word after the token (freq-rel-word-after)*: the relative frequency of the word after the token.
- *Length of previous word (len-word-before)*: the number of characters in the word before the token.
- *Length of the after word (len-word-after)*: the number of characters in the word after the token.
- *Measure of Textual Lexical Diversity (MTLD-diversity)*: the lexical diversity of the target word in the sentence using the metric proposed by (McCarthy and Jarvis, 2010)<sup>2</sup>.

Additionally, the following WordNet (Fellbaum, 2010) features were also considered for each target word:

- *Number of synonyms (number-synonyms)*.
- *Number of hyponyms (number-hyponyms)*.
- *Number of hyperonyms (number-hyperonyms)*.

In the case of multiple words, the following characteristics were applied: absolute frequency, relative frequency, token length, number of syllables, total number of words in the sentence, MTDL diversity.

<sup>2</sup>Computed using this Python library: <https://pypi.org/project/lexical-diversity/>

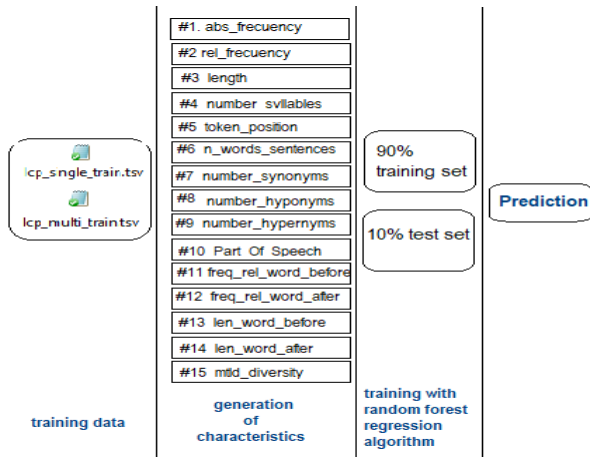

Figure 1: Training process applying the Random Forest Regression algorithm. A different model is trained for each training subset of data.

## 4.2 Method

The numeric input variables were scaled to a standard range, as many machine learning algorithms have been found to perform better when the data set is normalized. A polynomial transformation on the features characteristics was then applied with a degree value of 2, so new features were created.

A forest of trees was built with the training set  $(X, y)$ , where we assigned to the independent variable  $(X)$  an array that contains all the word-level characteristics that were obtained from the token, the same ones that were described in the section 4.1; and the value of the dependent variable  $(y)$  corresponds to the level of complexity’s word.

To build the Random Forest Regression Model, we split the dataset into the training set and test set, that is, 10% of the data set was used as test set, and the remaining 90% was used as the training set. Figure 1 shows the training process applying the random forest regression algorithm.

## 5 Experimental Results

### 5.1 Results on Trial and Simulated Data

To calculate the prediction value of the word complexity on the data of the evaluation corpus, the  $(X, y)$ , where we assigned to the independent variable  $(X)$  which we called  $X_{Test}$ , was built, was an array that contained all the word-level characteristics that were obtained from the token. Finally, we train the algorithm with the evaluation data and predict the results of the test set with the model trained on the testing set values using the regressor predict

#Trees	K	MAE	MSE	RMSE
150	7	0.07347	0.00938	0.09687
130	7	0.07354	0.00940	0.09700
150	8	0.07356	0.00942	0.09710

Table 2: Results obtained with Random Forest with selecting K-best features on single words subset.

#	Team Name	MAE	MSE	$R^2$
1	JUST_Blue	0.0609	0.0062	0.6172
2	DeepBlueAI	0.0610	0.0061	0.6210
3	Alejandro M.	0.0619	0.0064	0.6062
50	SINAI	0.0875	0.0131	0.1930

Table 3: Final results of the Lexical Complexity Prediction task on the single words dataset

function.

Several runs were made with different values to observe the performance of the algorithm and fine-tune the hyperparameters of the model.

Our best configuration was with 150 nodes and 7 features, selected by their F ANOVA between label / feature. The selected characteristics were: abs\_frequency, rel\_frequency, length, number\_syllables, token\_position, number\_synonyms, Part\_of\_speech. Finally, the prediction value of the words for the test data set was obtained, obtaining the best result: MAE of 0.07347, MSE of 0.00938, and RMSE of 0.096871 (see Table 2).

### 5.2 Results on test Data

In this section we present the results obtained from our system, and we carry out a discussion regarding the results presented by the organizers of the workshop.

The final results were sent to the SemEval 2021 organizers after the execution of our system. The final published results are those shown in Table 3, where the winners of the first three positions are presented. The results that we obtained in the contest for the case of the evaluation corpus of simple words were, MAE of 0.0875, MSE of 0.0131 and R-squared of 0.1930. Taking into account the number of competitors (quite large) and the result obtained by the first place winner (MAE of 0.0609), we see that there is a small difference, which allows us to be confident with our simple approach.

## 6 Conclusion

In this article, the results of our participation in Task 1: Lexical Complexity Prediction in the Lexical semantics track hosted at the SemEval 2021 international workshop have been presented. Both the training corpus and the evaluation corpus were provided by the sponsoring organization of this competition. We applied machine learning and built the model using the random forest regression algorithm, relying on well-known word based and contextual features.

As future work, we plan to perform error analysis on the predictions, to identify the weaknesses of the proposed approach based on a characterization of the instances where the system performs poorly. Also, a better analysis of multi-word scenario is foreseen.

## Acknowledgments

## Abstract

In this paper, we present our systems submitted to *SemEval-2021 Task 1* on *lexical complexity prediction* (Shardlow et al., 2021a). The aim of this shared task was to create systems able to predict the *lexical complexity* of word tokens and bigram multiword expressions within a given sentence context, a continuous value indicating the difficulty in understanding a respective utterance. Our approach relies on gradient boosted regression tree ensembles fitted using a heterogeneous feature set combining linguistic features, static and contextualized word embeddings, psycholinguistic norm lexica, *WordNet*, word- and character bigram frequencies and inclusion in word lists to create a model able to assign a word or multiword expression a context-dependent complexity score. We can show that especially contextualised string embeddings (Akbik et al., 2018) can help with predicting lexical complexity.

## 1 Introduction

In this paper, we present our contribution to *SemEval-2021 Shared Task 1* (Shardlow et al., 2021a), a shared task focused on the topic of lexical complexity prediction. The term *lexical complexity prediction* describes the task of assigning a word or multiword expression a continuous or discrete score signifying its likeliness of being understood well within a given context, especially by a non-native speaker. Solving this task could benefit second-language learners and non-native speakers in various ways. One could imagine using such scores to extract vocabulary lists appropriate for a learner level from corpora and literature (Alfter and Volodina, 2018), to judge if a given piece of literature fits a learner’s skill or to assist authors of textbooks in finding a level of textual difficulty appropriate for a target audience.

Predicting these scores can be formulated as a regression problem. Our approach to solve this

problem relies on *gradient-boosted regression tree ensembles* which we fit on a heterogeneous feature set including different word embedding models, linguistic features, *WordNet* features, psycholinguistic lexica, corpus-based word frequencies and word lists. We assumed that lexical complexity could be correlated with a wide range of features, neural ones as much as distributional or psycholinguistic ones, which is why we chose to use an ensemble-based method in the form of gradient boosting (Mason et al., 1999) for our system as it usually performs best for tasks where such a feature set is needed compared to solely neural models which need dense, homogeneous input data to perform well.

Out of all participants, our systems were ranked 15/54 in the single word- and 19/37 in the multiword category during the official shared task evaluations according to *Pearson’s correlation coefficient*. Our key discovery is that while features from nearly all categories provided by us were used by our systems, *contextual string embeddings* (Akbik et al., 2018) were the by far most important category of features to determine lexical complexity for both systems. The code and our full results can be found at <https://github.com/SGombert/tudacclsemeval>.

## 2 Background

### 2.1 Task Setup

For the shared task, *CompLex* corpus (Shardlow et al., 2020, 2021b) was used as data set. This English corpus consists of sentences extracted from the *World English Bible* of the multilingual corpus consisting of bible translations published by Christodoulopoulos and Steedman (2015), the English version of *Europarl* (Koehn, 2005), a corpus containing various texts concerned with European policy, and *CRAFT* (Bada et al., 2012), a corpus

consisting of biomedical articles.

*CompLex* is divided into two sub-corpora, one dealing with the complexity of single words and the other one with the complexity of bigram multiword expressions. Accordingly, the shared task was divided into two sub-tasks, one dedicated to each sub-corpus. Within both *CompLex* sub-corpora, the sentences are organised into quadruples consisting of a given sentence, a reference to its original corpus, a selected word, respectively a multiword expression from this sentence, and a continuous complexity score denoting the difficulty of this selected word or bigram which is to be predicted by systems submitted to the shared task. For the task, both subcorpora were partitioned into training, test and trial sets.

The scores given for simple words, respectively multiword expressions, were derived from letting annotators subjectively judge the difficulty of understanding words respectively word bigrams on a Likert scale ranging from 1 to 5 with 1 indicating a very simple and 5 a very complex word. The assigned scores were then projected onto values between 0 and 1 and averaged between all annotators to calculate the final scores.

## 2.2 Related Work

The first approaches to the systematic prediction of lexical complexity were made during *SemEval-2016 Task 11* (Paetzold and Specia, 2016). Here, the problem of determining the complexity of a word was formulated as a classification task designed to determine whether a word could be considered as being complex or not. The data set used for this task was created by presenting 20 non-native speakers with sentences and letting them judge whether the words contained within these sentences were rated as complex or not. From these judgements, two different data sets were derived. In the first one, a word was considered complex if at least one of the annotators had judged it as such, and in the second one, each word was given 20 different labels, one per annotator. The most important findings for this shared task were that ensemble methods performed best in predicting lexical complexity with word frequency being the best indicator.

In 2018, a second shared task was conducted on the same topic as described in Yimam et al. (2018). This shared task focused on predicting lexical complexity for English, German, Spanish and a multi-

lingual data set with a French test set. The data for this was acquired by presenting annotators on *Amazon Mechanical Turk* with paragraphs of text and letting them mark words which according to their perception could hinder the same paragraph from being understood by a less proficient reader. The findings of this shared task confirmed the finding of the previous one that using ensemble methods yield best results for complex word identification with a system submitted by Gooding and Kochmar (2018) relying on decision tree ensembles.

## 3 System Overview

Our systems rely on *gradient-boosted regression tree ensembles* (Mason et al., 1999) for predicting lexical complexity scores. We trained one model to predict single word lexical complexity scores and another one to predict bigram multiword expression complexity scores. Our models are based on the implementation of gradient boosting provided by *CatBoost*<sup>1</sup> (Dorogush et al., 2018; Prokhorenkova et al., 2018). We set the growing policy to *loss-guide*, the *L2 leaf regularisation* to 15, the *learning rate* to 0.01, *tree depth* to 6 and the *maximum number of leaves* to 15. Additionally, we set the *number of maximum iterations* to 5000 and then used the trial set to perform *early stopping* during training in order to determine the exact number of required iterations.

The motivation behind using this algorithm was its general ability to perform well on heterogeneous and sparse feature sets which allowed us to mix regular linguistic features, *WordNet* features, word embeddings, psycho-linguistic norm lexica, corpus-based word frequencies and selected word lists as all of these were features we assumed to possibly correlate with lexical complexity. Moreover, the reportings of Paetzold and Specia (2016) and Yimam et al. (2018) that ensemble-based learners perform best for *complex word identification* contributed to this decision, as well. While the problem presented in their paper is formulated as a binary classification task using different data sets, we wanted to test if their findings would still translate to a regression task on *CompLex*.

### 3.1 Feature Engineering

The following paragraphs describe the features we used to create the feature vectors used to represent words. In case of our system dealing with bigram

<sup>1</sup><https://catboost.ai/>

multiword expressions, we calculated such a vector for each of both words and then concatenated them to acquire the final input vectors. Thus, the exact number of input features was 7424 for our system dealing with single words and 14848 for our system dealing with multiword expressions.

**Syntactic features:** This category of features includes *XPOS*-, *UPOS*-, *dependency*- and *named entity tags* as well as *universal features*<sup>2</sup> inferred using the English *Stanza*<sup>3</sup> (Qi et al., 2020) model fit to the version of the *English Web Treebank* following the *Universal Dependencies* formalism (Silveira et al., 2014). In addition to the tags assigned to the word(s) whose score was to be predicted, we included the *XPOS*- and *UPOS* tags of the two neighbouring words to the left and to the right as well as the dependency tags of the siblings, direct children and the parent of the word(s) within the dependency structure of a given sentence. All of these features are encoded as *one*-, respectively *n-hot vectors* using the *LabelBinarizer* and *MultiLabelBinarizer* classes provided by *Scikit-learn* (Pedregosa et al., 2011).

**WordNet features:** Here, we included the numbers of *hypernyms*, *root hypernyms*, *hyponyms*, *member holonyms*, *part meronyms* and *member meronyms* of the respective word(s) as well as the number of given examples and the *length of the shortest hypernym path* from *WordNet* (Miller, 1995). In cases where multiple *synsets* were given for a word, we calculated the respective means and in cases where a given word was not included in the resource, we set all respective feature values to 0. We accessed *WordNet* using *NLTK* (Bird et al., 2009). The main intuition behind using this resource was that the *length of the shortest hypernym path* and the count for the different lexico-semantic relations could be a good indicator for lexical complexity.

**Word embeddings:** We used multiple static and contextual word embedding models for our feature set. This includes the *transformer-based* (Devlin et al., 2019) *BiomedNLP-PubMedBERT-base-uncased-abstract* (Gu et al., 2020), *distilgpt2*<sup>4</sup> (Radford et al., 2018) and *distilbert-base-uncased* (Sanh et al., 2019), the *contextual string embed-*

*ding* models *mix-forward* and *mix-backward*<sup>5</sup> (Akbik et al., 2018), and the static *GloVe*<sup>6</sup> (Pennington et al., 2014) and English *fastText*<sup>7</sup> (Bojanowski et al., 2017) embeddings.

This collection of embeddings was derived from previous experiments on the *CompLex* corpus where we tried to fine-tune a purely neural model using the approach of stacking different embedding models in combination with an attached prediction head central to *flairNLP*<sup>8</sup> (Akbik et al., 2019). More precisely, in the setup we chose, the outputs of all language models were fed to a feed-forward layer responsible for calculating the final complexity scores. This network was then trained for 5 epochs with a *learning rate* of 0.000001, *mean squared error* as loss function and *Adam* (Kingma and Ba, 2015) as optimizer on the training set part of *CompLex*. During this training, fine-tuning was active for all transformer-based language models so that their weights were adjusted during the process and *scalar mixing* (Liu et al., 2019) was used for the transformer-based language models as it was not foreseeable which layers of the transformer models would influence results the most.

This model achieved a *Pearson's correlation coefficient* score of 0.7103 when evaluated on the trial set. While we deemed this an okay result, we decided to stick with gradient boosting for our final systems as early experiments with this algorithm yielded results superior to the purely neural approach when evaluated on the same set. As we switched to using gradient boosting for our final systems, we decided to use the fine-tuned variants of the transformer embedding models as using them led to small improvements when testing our models on the shared task trial sets compared to using the non-fine-tuned variants.

**Psycholinguistic norm lexica:** Our feature set includes two psycholinguistic norm lexica. The first one is described in Warriner et al. (2013) and scores words with empirical ratings for *pleasantness*, *arousal* and *dominance* using the *SAM score* (Bradley and Lang, 1994). These ratings were acquired from annotators on the *Amazon Mechanical Turk* platform. The second lexicon is described in

<sup>2</sup><https://universaldependencies.org/u/feat/all.html>

<sup>3</sup><https://stanfordnlp.github.io/stanza/>

<sup>4</sup><https://huggingface.co/distilgpt2>

<sup>5</sup>[https://github.com/flairNLP/flair/blob/master/resources/docs/embeddings/FLAIR\\_EMBEDDINGS.md](https://github.com/flairNLP/flair/blob/master/resources/docs/embeddings/FLAIR_EMBEDDINGS.md)

<sup>6</sup><https://nlp.stanford.edu/projects/glove/>

<sup>7</sup><https://fasttext.cc/>

<sup>8</sup><https://github.com/flairNLP/flair>

Malandrakis and Narayanan (2015) and includes ratings for *arousal, dominance, valence, pleasantness, concreteness, imagability, age of acquisition, familiarity, pronouncability, context availability* and *gender ladenness*. The ratings within this lexicon were derived algorithmically from smaller lexicons using linear combinations and semantic similarity scores to approximate the ratings for words not included in the source lexica. In both cases, the inclusion of these features was mainly motivated by our general intuition that the perceived complexity of words could be linked to different psycholinguistic variables.

**Word frequencies:** We utilised three resources containing corpus-based word respectively character bigram frequencies. The first of these data sets was the frequency list extracted from the *SUBTLEXus* corpus (Brysbaert and New, 2009) consisting of various movie subtitles from which we used the *log-normalised* term frequency and the *log-normalised* document frequency as features. Besides *SUBTLEXus*, we utilised the character bigram frequencies from Norvig (2013) which were extracted from the *Google Books Corpus*. Here, to represent a word, we calculated the mean of all frequencies of the bigrams constituting the same and used this as feature. In the case of both sets, our intuition was that lower frequency would likely function as a proxy for complexity. The third set we used was *EFLLex* (Dürlich and François, 2018) which lists the frequencies of words within several pieces of English literature appropriate for different *CEFR*<sup>9</sup> levels. We included this set as we deemed that *CEFR* as a framework for rating language competence could also function as an according proxy.

**Word Lists:** We used two different word lists as features. The first one is *Ogden’s Basic English Vocabulary*<sup>10</sup>, a list of simple words used for writing *simple English* as described in Ogden (1932). Here, our idea was that this could help to identify simple words within *CompLex*. The other one was the *Academic Word List* as described in Coxhead (2011), a structured lexicon of terms used primarily in academic discourse which we believed to contain more complex words. In both cases, we encoded the inclusion of a word within a respective word list binarily.

## 4 Results

Throughout the shared task, the systems were evaluated with regard to *Pearson’s correlation coefficient*, *Spearman’s rank correlation coefficient*, *mean average error*, *mean squared error* and *R2* with *Pearson’s correlation coefficient* determining the main ranking. According to this, our systems achieved the 15th and 19th rank respectively. Table 1 shows the results achieved by our system dealing with single words and Table 2 the results achieved by our system dealing with multiword expressions. The results show that our systems, while only achieving upper mid-table results on average, come close to the best systems performance-wise which speaks for our approach. Further hyperparameter tuning and the addition of more features could likely close this gap. The full results for all submitted systems are presented in Shardlow et al. (2021a).

### 4.1 Most Important Features

To determine which features were used by our models to predict lexical complexity, we rely on the functionality provided by *CatBoost* which scores each feature for its influence on a given final prediction. This is achieved by changing a respective feature values and observing the resulting change

Rank	Feature	Importance
1	flair-mix-b.	25.10
2	flair-mix-b.	11.79
3	flair-mix-b.	7.03
4	flair-mix-f.	4.09
5	flair-mix-f.	2.98
6	flair-mix-b.	1.33
7	flair-mix-f.	1.20
8	distilbert-b.-u.	1.19
9	BiomedNLP	1.12
10	GloVe	1.03

Table 3: The 10 most important features observed for our system dealing with single word complexity and their categories. Each entry refers to a single dimension of the feature vector.

in the model prediction (see <sup>11</sup> for further information on the exact method). The outputs of this method are normalised so that the sum of the importance values of all features equals 100. *Feature importance* was calculated using the evaluation set of *CompLex*.

Inspecting the results of these calculations, we noticed that our systems did not use the character bigram frequencies derived from the *Google Books Corpus*, nor the frequencies from *EFLLex* or the word list inclusion features. While features from all other categories were utilised, the most dominant features by far are contained in the word embedding category. Within this category, the most dominant features for both models came from the *flair-mix-backward* and *flair-mix-forward* models (see Tables 3 and 4). A few single dimension from the embeddings provided by *flair-mix-backward* seem to play the major role here.

In the case of our model dealing with multiword expressions, the ten most important features all stem from the *flair-mix-backward* embedding of the second word. This could be explained by the fact that most multiword expressions within the *CompLex* corpus follow the structure of a semantic head in combination with a modifier as most of them are either multi token compounds or single token nouns modified by adjectives. It is intuitive from a linguistic point of view that in such cases, the semantic head, which comes as second element, should play the dominant semantic role resulting in it being more influential in the overall results.

<sup>11</sup><https://catboost.ai/docs/concepts/fstr.html>

Rank	Feature	Importance
1	flair-mix-b. (2nd w.)	9.28
2	flair-mix-b. (2nd w.)	7.24
3	flair-mix-b. (2nd w.)	6.09
4	flair-mix-b. (2nd w.)	3.80
5	flair-mix-b. (2nd w.)	3.60
6	flair-mix-b. (2nd w.)	3.17
7	flair-mix-b. (2nd w.)	2.44
8	flair-mix-b. (2nd w.)	1.88
9	flair-mix-b. (2nd w.)	1.34
10	flair-mix-b. (2nd w.)	1.08

Table 4: The 10 most important features observed for our system dealing with multiword expression complexity and their categories. Each entry refers to a single dimension of the feature vector.

While the exact reason for the strong influence of the *contextualised string embeddings* is hard to determine due to the fact that embeddings lack the property of being easily interpretable, we assume that the dominant role they play for the results could be determined by them being calculated on the character level (Akbik et al., 2018) instead of the level of fixed words or subword units such as morphemes. As a consequence, such models use fewer input dimensions and each of the dimensions present is in turn involved in the encoding of more different words. This links each input dimension also to a larger variety of latently encoded distributional knowledge which could then contain certain regularities strongly correlated with lexical complexity. However, without further research, this currently remains pure speculation.

## 4.2 Predictions vs. Ground Truth

In order to compare the predicted values of our models to the ground truth data, we scatterplotted the relationship between ground truth labels and the scores predicted by our systems (see Figures 1 and 2) using the *CompLex* evaluation set. It can be observed that both systems, especially the one dealing with single word complexity, show the tendency to assign slightly higher scores than given in the ground truth for simple words and slightly lower scores for complex words. The system dealing with multiword expressions does not assign any value below 0.2 at all and the one dealing with single word complexity rarely does so. This indicates that our feature set does not contain features which could help our models to identify very simple words.

Figure 1: Scatterplot visualising the relationship between the ground truth and the predictions of our model for single word complexity. **X**: ground truth **Y**: prediction

Figure 2: Scatterplot visualising the relationship between the ground truth and the predictions of our model for multiword expression complexity. **X**: ground truth **Y**: prediction

## 5 Conclusion

We presented both our systems submitted to *SemEval-2021 Task 1* combining a heterogeneous feature set with gradient boosting as regression algorithm. Our systems were ranked 15/54 and 19/37 during shared task evaluations according to *Pearson's correlation coefficient*. However, the results achieved by our systems were still close to the best results, especially in the case of the system dealing with single word complexity. The type of feature playing the most important role for our models are *contextual string embeddings* as they influenced the outcome the most. We attribute this to a relationship between lexical complexity and the distribution of characters throughout words and sentences, but this needs further clarification which could be the objective of future work. Moreover, our systems rarely assign scores below 0.2. It must be explored further if there are features which could improve our systems in this respect. In summary, we can report that ensemble methods turned out to be fruitful when applied to *CompLex*.

## Abstract

In this paper, we present our contribution in SemEval-2021 Task 1: Lexical Complexity Prediction, where we integrate linguistic, statistical, and semantic properties of the target word and its context as features within a Machine Learning (ML) framework for predicting lexical complexity. In particular, we use BERT contextualized word embeddings to represent the semantic meaning of the target word and its context. We participated in the sub-task of predicting the complexity score of single words.

## 1 Introduction

Over the last decade, automated methods for detecting complex words have been developed. At the beginning, most of these methods assumed that lexical complexity is binary, words are either "difficult" or "not difficult". Thus, the first Complex Word Identification (CWI) shared task referred to binary identification of complex words (Zampieri et al., 2017). The main limitation of this assumption is that a word close to the decision boundary is considered to be as complex as one farther apart. Therefore, three years ago, the CWI included an additional probabilistic classification task where the participants were asked to give a probability of the given target word in particular context being complex (Štajner et al., 2018).

Recently, CompLex, a new English corpus for lexical complexity prediction was introduced (Shardlow et al., 2020). The corpus is annotated using a 5-point Likert scale (1-5) (corresponding to very easy, easy, neutral, difficult, and very difficult), and covers 3 genres: Bible translation, European Parliament proceedings, and biomedical articles. SemEval-2021 (Task 1) shared task on Lexical Complexity Prediction (LCP) (Shardlow et al., 2021a,b) provided the participants with CompLex and defined two sub-tasks: predicting the com-

plexity score of single words, and predicting the complexity score of multi-word expressions.

We present our system for the first sub-task of predicting the complexity score of single words. Our system incorporates linguistic, statistical, and semantic properties of the target word and its context as features within a Machine Learning (ML) framework for predicting lexical complexity.

This paper is organized as follows: First, in Section 2, we describe features from previous works that we have adopted. Then, in Section 3, we describe our feature sets, the feature selection process, and the results on the trial data. Finally, Our system results on the test data are detailed in Section 4, followed by conclusions in Section 5.

## 2 Related work

In this section, we shortly describe linguistic, statistical, and semantic features which were encoded as features in previous complexity prediction tasks and were integrated in our system.

Linguistics features, such as Part-Of-Speech (POS) tag, dependency parsing relations, and syllable counts, as well as statistical features, such as word length and word frequency, have been widely used for predicting lexical complexity (Mukherjee et al., 2016; Ronzano et al., 2016; Alfter and Pilán, 2018; Gooding and Kochmar, 2018; Hartmann and Dos Santos, 2018; Kajiwara and Komachi, 2018; Wani et al., 2018). Some of these works found WordNet (Miller, 1998) as a valuable source of lexical features. The main extracted feature is the number of synsets, but also information on hypernyms, hyponyms, holonym, and meronym is useful (Gooding and Kochmar, 2018; Hartmann and Dos Santos, 2018; Wani et al., 2018).

Semantic features were commonly encoded using word embedding representation of the meaning of words (Kuru, 2016; AbuRa'ed and Sag-

gion, 2018). These word embeddings were generated using Word2Vec context-independent models (Mikolov et al., 2013). Word2Vec models combine different senses of the word into one single vector. However, recently, there is a growing interest in contextualized word representations, such as BERT (Devlin et al., 2018). BERT model generates context-dependent embeddings that allow a word to have several vector representations depending on the context in which it is used. In contrast to previous works that only use context-independent embeddings, our system uses the BERT-based context-dependent embeddings.

### 3 System Description

We adopt a supervised Machine Learning (ML) approach for lexical complexity prediction. The first step in a classifier training is to determine which text characteristics are relevant and how those features are coded.

#### 3.1 Feature Sets

We next detail how the semantic properties of the sentence, as well as the linguistic and statistical properties found useful in prior work, are encoded as features. Then, in Section 3.2, we describe our feature analysis procedure and the supervised ML model. The features in our model are divided into 3 sets: linguistic, statistical and semantic.

##### 3.1.1 Linguistic features

Our dataset contains three corpora: Bible, Europarl, and Biomedical, to add variation. Since each corpus has its own unique linguistic features, we first encode the text source by three binary features.

Most of our linguistic features are based on information extracted from a POS tagger. Our linguistic properties include two families of properties: morphological and syntactical.

First, we encode the target word POS. The POS is extracted by the Spacy’s statistical POS tagger<sup>1</sup>. Each possible POS tag is represented as a binary feature. We use the following 12 tags from the Universal POS tags<sup>2</sup>: ADJ, ADP, ADV, CONJ, DET, NOUN, NUM, PRT, PRON, VERB and X (other). As an additional feature, the number of syllables in the target word is encoded<sup>3</sup>. Then,

<sup>1</sup><https://spacy.io/>

<sup>2</sup><https://universaldependencies.org/u/pos/index.html>

<sup>3</sup><https://eayd.in/?p=232>

we calculate the number of punctuation marks and stopwords in the sentence (two features).

Next, we represent syntactic forms by POS patterns. The POS pattern refers to seven words, the target word and three words before and after it. Each of the words is encoded by 12 binary features, resulting with 84 features.

We also measure the polysemy degree of the target word using the number of senses in WordNet. We obtain two lexical features: number of synsets for the target word and number of synsets for the target word given its POS.

##### 3.1.2 Statistical features

We define some statistical features based on frequency. First, we calculate target word length and sentence length. Then, we extract the target word frequency using Google N-gram<sup>4</sup> word frequencies. We encode the logarithm of this frequency as a feature to speed the ML algorithm’s convergence (three features).

##### 3.1.3 Semantic features

We represent the meaning of the surrounding context of the target word by vectors in the same semantic space. We use the BERT semantic space. BERT is a bidirectional transformer pre-trained on a large corpus containing the Toronto Book Corpus and Wikipedia using a combination of masked language modeling objective and next sentence prediction. BERT contextualizing vectors are used to represent the semantic meaning of the sentence by averaging the BERT vectors of seven words, the target word and three words before and after it. Thus, our semantic representation add 768 features (the size of BERT output layer).

To extract additional features, we use two machine learning algorithm: K-Means and k-Nearest Neighbors (KNN) algorithm. K-Means is an unsupervised learning algorithm used for clustering. It takes the unlabeled dataset and tries to group them into  $k$  number of clusters. We encode the K-Mean results by four binary features, a feature per cluster ( $k=4$ ). The results of the KNN algorithm are encoded similarly. However, KNN is a supervised learning algorithm used for classification. It takes the labeled dataset and uses it to learn how to label other sentences. KNN classifies an unseen sentence using its  $k$  nearest neighbors voting. We use four complexity classes: 0-0.25, 0.26-0.5, 0.51-0.75, 0.76-1.

<sup>4</sup><https://books.google.com/ngrams>

### 3.2 Feature Selection

For each of the above feature sets, we tried to filter out non-relevant features using several approaches.

First, we discharged features that decrease the system performance on the training set, namely, the POS pattern features, the WordNet features, and the K-Means and KNN features. We were left with 794 features. These features were selected using the Linear Regression algorithm, which was also selected as a baseline algorithm by the task organizers. To further improve the performance of our systems, we used additional ML algorithms, such as SVM and XGBoost (see more details in Section 3.3).

Next, since correlated features do not carry unique information and may interfere the learning, we tried to discharge highly correlated features. We implemented this approach using the following iterative process. The input is the desired final number of features. First, we define an initial correlation threshold (0.9). Then, we calculate the features' pairwise correlation and features with correlation above the threshold are removed. Next, if we still have more features than desired, we will lower the correlation threshold (by 10%) and repeat the process. This approach improved the performance of the SVM and Linear Regression models (selecting 97 features), but did not increase the performance of the XGBOOST method.

We note that we also tried to filter out feature using the principal component analysis (PCA) feature selection method (Song et al., 2010). PCA aims to pick a subset of features that retains as much information present in the full data as possible. PCA was performed both on the full feature list and on specific features, such as BERT features, but it was not successful.

Some of the classification models had low performance using such amount of features (794 features). Therefore, we further filleted features by calculating their correlation with the complexity score and discarding features with low correlation (less than 0.072). We resulted with the following list of 101 features:

- Biomedical corpus indicator
- Europal corpus indicator
- NOUN POS tag
- PRON POS tag

- number of syllables in the target word
- target word length
- target word frequency (Google N-gram)
- 94 features from BERT vector

It is interesting to note that even though, there are 12 POS tags, only 2 are informative for the complexity prediction task. Considering the source text indicators, the third Bible indicator is not useful. Out of the BERT 768 features, only 94 remained (12.2% of the vector).

The BERT representation of the sentence is generated by pre-trained language representation model. These models can be trained on different datasets of various domains. Since one of our corpora is from the Biomedical domain, we examined the system performance using the domain specific BioBERT (Lee et al., 2020). Figure 1 shows a comparison between the error rate of our system using the classic BERT and BioBERT (BERT on the left and BioBERT on the right). The columns show the error rate for different text sources. The red line is the average error rate. Columns from left to right: Bible, Biomedical, and Europarl. Surprisingly, the error rate of the BioBERT on the Biomedical domain is higher than that of the classic BERT. However, the average error for both is the same ( $\sim 0.69$ ).

### 3.3 Application of five Machine Learning methods

We combined the features in a supervised classification framework using five ML methods: Linear Regression, Supported Vector Machine (SVM), XGBoost (XGB), KNN, and Stacking (Stack). We trained the ML methods on the train set and evaluated their performances on the trial set.

We ran these ML methods by the scikit-learn open-source machine-learning package in python<sup>5</sup> (Pedregosa et al., 2011) using the default parameters. Table 1 shows the performances of the different ML methods on the feature set of 101 features, as described above. The MAE is omitted from the table because it is similar for all the ML algorithms (0.01). The performance differences between the algorithms were not so substantial. Therefore, we next report the performances of all these methods on the test set.

<sup>5</sup><https://scikit-learn.org/stable/>

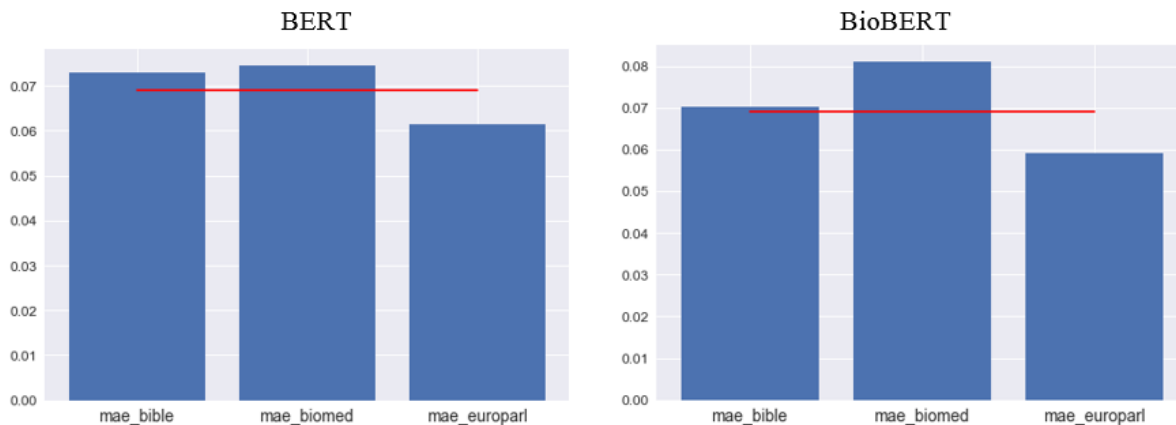

Figure 1: A comparison between the error rate of our system using the classic BERT and BioBERT

Alg.	Pearson	Spearman	MSE	R2
LR	0.672	0.656	0.077	0.45
SVM	0.693	0.67	0.075	0.476
XGB	0.671	0.655	0.076	0.449
KNN	0.682	0.64	0.077	0.464
Stack	0.689	0.66	0.077	0.436

Table 1: The performances of the different ML algorithms on the trial set

## 4 Results

To increase the size of our train set for the test phase of the task, we used both the train and trial sets to train the final model. Table 2 presents our results on the test set. The predictions of the XGBoost were submitted to the shared task competition. The results of the different algorithms are close to each other and consistent with the results on the trial set. The results of the KNN method are a bit lower. Even though, stacking allows to use the strength of each individual classifier by using their output as input of a final classifier, it did not obtain better result. This may imply that the different classifiers exploit the same information and do not reveal supplementary information.

Alg.	Pear.	Spea.	MAE	MSE	R2
LR	0.629	0.622	0.079	0.01	0.384
SVM	0.669	0.645	0.074	0.009	0.439
XGB	0.666	0.646	0.074	0.009	0.44
KNN	0.618	0.598	0.074	0.01	0.358
Stack	0.658	0.633	0.079	0.009	0.433

Table 2: The performances of the different ML algorithms on the test set

To analyze our results, we converted the complexity scores to labels following [Shardlow et al. \(2020\)](#) descriptors. In Figure 2, we present the classification confusion matrix of the XGBoost algorithm. Each column of the matrix represents the instances in a predicted class while each row represents the instances in an actual class. Most of the classification errors (18.54%) were due to incorrect classification of very easy words as easy. There were also errors in the opposite direction (4.36%). Most of the rest of the classifications were between neutral and easy in both directions (7.42% + 6.43% = 13.85%). We note that the 5<sup>th</sup> class, very difficult, does not appear in the confusion matrix since there are not any very difficult words in the test set and the system did not classified any of the words as very difficult.

True	Predicted			
	very easy	easy	neutral	difficult
very easy	35 3.82%	170 18.54%	8 0.87%	0 0.00%
easy	40 4.36%	441 48.09%	68 7.42%	0 0.00%
neutral	1 0.11%	59 6.43%	72 7.85%	2 0.22%
difficult	0 0.00%	6 0.65%	14 1.53%	1 0.11%

Figure 2: A confusion matrix for the XGBoost complexity predictions

## 5 Conclusions and Future Work

We have implemented a system that incorporates linguistic, statistical, and semantic features to predict lexical complexity of target word in context. BERT semantic space was used to represent the word and its context. We investigated several feature selection approaches and used various supervised algorithms.

Even though our system was not highly ranked, we believe that some of the presented ideas can be useful for future research on lexical complexity prediction. In particular, we think that BERT is a powerful model that should be explored. Perhaps, fine-tuning BERT for the complexity prediction task would increase the system performance.

## Abstract

This paper describes our submission to SemEval-2021 Task 1: predicting the complexity score for single words. Our model leverages standard morphosyntactic and frequency-based features that proved helpful for Complex Word Identification (a related task), and combines them with predictions made by Transformer-based pre-trained models that were fine-tuned on the Shared Task data. Our submission system stacks all previous models with a LightGBM at the top. One novelty of our approach is the use of multi-task learning for fine-tuning a pre-trained model for both Lexical Complexity Prediction and Word Sense Disambiguation. Our analysis shows that all independent models achieve a good performance in the task, but that stacking them obtains a Pearson correlation of 0.7704, merely 0.018 points behind the winning submission.

## 1 Introduction

Complex Word Identification (CWI) consists of determining which words or multi-word expressions (MWE) in a text could be difficult to understand by certain readers. This is one of the first steps in the typical Lexical Simplification pipeline (Shardlow, 2014). CWI has traditionally been treated as either a binary (Paetzold and Specia, 2016) or regression (Štajner et al., 2018) task. For the latter, the complexity of a word/MWE was computed as a percentage of binary complexity ratings. Recently, Shardlow et al. (2020) proposed to move away from the binary definition of CWI, and instead collected complexity ratings using Likert scales. This allows re-defining the task as Lexical Complexity Prediction (LCP). Leveraging this new collected data, the First LCP Shared Task was organised in SemEval-2021 (Shardlow et al., 2021).

Our team participated in Sub-task 1: predicting the complexity score of single words. Basically, given a sentence and a target word in it, the

goal is to predict the complexity score of the target. One particular challenge is that the same target can have different complexity scores depending on the sentence it appears in. Therefore, our proposed approach takes the context of the target into consideration in two ways. First, we use contextualised word representations from pre-trained Transformer-based models, such as RoBERTa (Liu et al., 2019) and XLNet (Yang et al., 2019). In particular, we use the LCP data to fine-tune two RoBERTa models and one XLNet model that receive as input the target and a context window of 1, and a RoBERTa model whose inputs are the target and a context window of 2. Second, we hypothesise that different contexts could evoke different senses of the target word. As such, we exploit data for Word Sense Disambiguation (WSD) through multi-task learning. In particular, we fine-tune a BERT (Devlin et al., 2019) model with two tasks: LCP and WSD, using the Unified Evaluation Framework (Raganato et al., 2017) for the latter. The predictions from all these models are combined with several morphosyntactic and corpus-based features, and used to train a Gradient Boosting Decision Tree with LightGBM (Ke et al., 2017).

On the test set of the Shared Task, our model achieved a Pearson correlation of 0.7704 and ranked 10th, only 0.018 points behind the winner. An ablation study shows that all independent models contributed to the stacked model’s performance, with the predictions from the BERT model fine-tuned in a multi-task fashion having the greatest impact in predicting lexical complexity. The code to reproduce our results is available in: [https://github.com/kdrivas/lexical\\_complexity](https://github.com/kdrivas/lexical_complexity).

## 2 Background

The LCP Shared Task on SemEval-2021 asks participants to develop models that predict the com-

Sentence with Target	Complexity
<i>His left hand is under my <b>head</b>.</i>	0.125
<i>Do therefore according to your wisdom, and don't let his gray <b>head</b> go down to Sheol in peace.</i>	0.383

Table 1: Annotated sentences in the dataset of the LCP Shared Task. The target word is boldfaced.

plexity of a target word/MWE in a sentence in English (Shardlow et al., 2021). This Shared Task builds on previous editions that focused on Complex Word Identification (Paetzold and Specia, 2016; Štajner et al., 2018), with a key difference: complexity ratings are continuous scores instead of binary. Furthermore, the same target word/MWE can appear in more than one sentence but with different complexity scores. Table 1 presents an example from the data.

The data for the Shared Task is an extension of CompLex (Shardlow et al., 2020), a dataset with complexity ratings for target words/MWE in sentences in English in three domains: Bible, Europarl and Biomed. The dataset is split into two subtasks: LCP for single words and LCP for MWEs.

### 3 System Description

This section details our stacking approach to the LCP Shared Task Sub-task 1. An overview of our system can be seen in Figure 1.

#### 3.1 Features

After joining all the data from both subtasks (single word and MWE), we extracted some features presented in (Yimam et al., 2018; Finnimore et al., 2019) and other custom ones, such as (1) the complexity of the target words in the lexicon proposed in (Maddela and Xu, 2018), (2) the predictions from four fine-tuned Transformer based models, and (3) the number of senses and dependencies of the target word/MWE.

##### 3.1.1 Morphosyntactic and Lexical Features

First, we computed the number of characters and the number of words surrounding the target word/MWE. In addition, we obtained the part-of-speech of the first token and the syntactic dependencies of the whole target using the spaCy library.<sup>1</sup> We also counted the number of possible part-of-speech tags for the token using the Brown dictio-

<sup>1</sup><https://spacy.io/>

nary in NLTK.<sup>2</sup> Then, we counted the number of propositions, verbs, nouns, adverbs and got the ratio between the number of nouns and verbs using the whole sentence. Finally, we calculated the total number of syllables and morphemes.

##### 3.1.2 N-gram Features

We formed n-grams considering one and two tokens surrounding the target word/MWE. Then, we computed their frequency in the Children’s Book Test (Hill et al., 2015) and Simple Wikipedia (Kauchak, 2013). In addition, using the previous corpora, the Lang-8 corpus (Mizumoto et al., 2011) and the Tatoeba corpus,<sup>3</sup> we computed the frequency of the target tokens.

##### 3.1.3 Word Complexity Lexicon

The lexicon created in (Maddela and Xu, 2018) contains complexity scores for more than 15,000 words. After lower-casing the words in the lexicon and the datasets from the Shared Task, we assigned the complexity from the lexicon to the words in the LCP data. If the word does not appear in the lexicon we assigned a null value.

##### 3.1.4 Transformer-based Model Predictions

The last set of features is composed of the predictions of four pre-trained language models fine-tuned on the training data of both subtasks. The first three were a RoBERTa (Liu et al., 2019) and an XLNet (Yang et al., 2019) models that received as input the target word/MWE and a context window of 1, and a RoBERTa model with the target and a context window of 2. The last model was a BERT fine-tuned in a multi-task fashion with two tasks: LCP and Word Sense Disambiguation (WSD). For the former task, we only used the data generated with a window size of 1 and, for the latter, the Unified Evaluation Framework (Raganato et al., 2017).

**Multi-Task Model.** Given a sentence  $S$  of the dataset of the Shared Task and a complex word  $w$  in position  $a$  whose part of speech is  $p$ , we obtain a subsequence of size 1,  $sub = \langle w_{a-1}, w_a, w_{a+1} \rangle$ ; then:

$$CLS = BERT(sub) \quad (1)$$

where  $CLS$  is the  $CLS$  token of BERT, which

<sup>2</sup><https://www.nltk.org/>

<sup>3</sup>Available in <https://tatoeba.org/> under a CC-BY 2.0 FR licence.

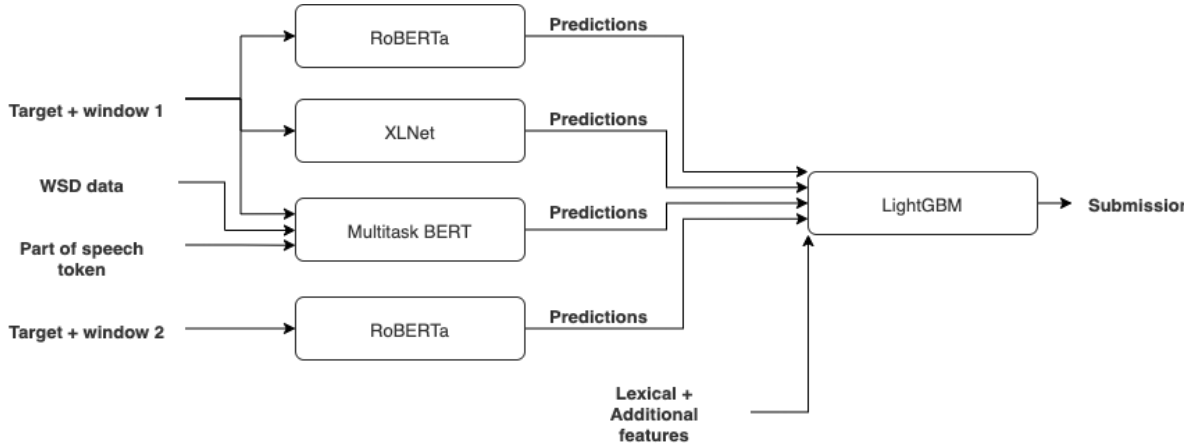

Figure 1: We used a LightGBM on the top of our architecture. It received the additional features and, the predictions from a XLNet and a BERT models using a window size of 1 and two RoBERTa models using a window size of 1 and 2.

represents the sentence. This representation is concatenated with the embedding token of  $p$ :

$$c = \text{concat}(CLS, \text{embed}(p)) \quad (2)$$

The concatenated vector is then used as input to a dropout layer and a linear layer:

$$\text{out}_1 = \text{Linear}(\text{Dropout}(c)) \quad (3)$$

Using  $\text{out}_1$ , we computed loss  $L_1$  using mean squared error. After getting the first task loss, we computed the loss for the second one. Given an ambiguous sentence  $S$  and a sequence output of senses id  $A$ , we used the BertForTokenClassification implementation in HuggingFace<sup>4</sup> to obtain the output  $\text{out}_2$ , and then used cross entropy to compute loss  $L_2$ . Finally, we multiply a weight per each task loss to get the final overall loss:

$$L = W_1 * L_1 + W_2 * L_2 \quad (4)$$

Finally, we perform other experiments

### 3.2 Architecture

Our model architecture is shown in Figure 1. First, we got the predictions from the four language models. Then, we concatenated those predictions with the additional features, and stacked a LightGBM model that received them as input features.

<sup>4</sup>[https://huggingface.co/transformers/model\\_doc/bert.html#bertfortokenclassification](https://huggingface.co/transformers/model_doc/bert.html#bertfortokenclassification)

## 4 Experimental Setup

As previously described, we used four different models: RoBERTa, XLNet, BERT and LightGBM. In addition, for training/fine-tuning each model we chose the Mean Absolute Error (MAE) as our validation metric.

### 4.1 RoBERTa and XLNet

We fine-tuned the models for 4 epochs with a batch size of 24. In addition, we used a learning rate of  $2e-5$  and Adam optimizer. We used the models for sequence classification provided by HuggingFace.<sup>5</sup>

### 4.2 Multitask BERT

We fine-tuned a BERT model using two tasks: LCP and WSD. We trained the WSD task using the Unified Evaluation Framework (Raganato et al., 2017), but filtered sentences with a size greater 22 tokens. For fine-tuning, we used a learning rate of  $2e-5$  and Adam optimizer. We fine-tuned the models for 5 epochs with a batch size of 32. We calculated the loss accumulating the gradients from both tasks. Also, we experimented with assigning different weights to each task, and found that the best configuration was 0.8 for LCP and 0.2 for WSD.

### 4.3 LightGBM

At the top of our architecture, we used a LightGBM model. Using Hyperopt, a bayesian optimization framework, we set up a max depth of 5, num-leaves

<sup>5</sup>[https://huggingface.co/transformers/model\\_doc/roberta.html#robertaforsequenceclassification](https://huggingface.co/transformers/model_doc/roberta.html#robertaforsequenceclassification)

of 8, min-sum-hessian-in-leaf of 0.9, a bagging-fraction of 0.9, a bagging-freq of 100, a learning-rate of 0.08, and a min-data-per-group of 100. We trained using 500 iterations with an early stopping of 90. Also, we declared the type of corpus and the part of speech as categorical features.

## 5 Results

The test set contains more than 1,000 sentences with 573 different target words. Table 2 shows the official evaluation metrics for each domain-corpora in the LCP dataset. Overall, we achieved a Pearson correlation of 0.7704, and finished in 10th place in the Shared Task Sub-task 1, only 0.018 points behind the winning submission.

Corpus	Pearson	Spearman	MAE	MSE
Bible	0.7536	0.7300	0.064	0.0074
Europarl	0.7492	0.7028	0.052	0.0045
Biomed	0.7898	0.7608	0.070	0.0083
Overall	0.7704	0.7361	0.618	0.0066

Table 2: Results in test set grouped by corpus domain.

The scores in the validation set (Table 3) follow a similar behaviour as those in the test set. For both, the corpus where our model achieves the best Pearson correlation is Biomed. However, looking at other metrics such as MAE, this corpus has the greatest error, with Europarl having the lowest. The differences may be because, even though the model may well capture the trend of the outputs, it could be more difficult to predict values in a corpus with higher variance of complexity scores, as is the case for Biomed (Figure 2).

Corpus	Pearson	Spearman	MAE	MSE
Bible	0.7353	0.6441	0.068	0.0072
Europarl	0.7946	0.7640	0.050	0.0039
Biomed	0.8571	0.8367	0.066	0.0075
Overall	0.8228	0.7643	0.062	0.0062

Table 3: Results in validation set grouped by corpus domain.

## 6 Ablation Study

Table 4 shows the contribution of each set of features (including predictions of fine-tuned models) to the final score. Although the predictions of

Figure 2: Distribution of the word complexity in validation set.

the fine-tuned Transformers-based models perform very well independently, the combination of all the predictions and the additional traditional features achieves the best performance in the validation set.

Another way of visualising the importance of each feature is using SHAP values (Lundberg and Lee, 2017). Figure 3 reports the 10 most important features for the LightGBM model, i.e. the impact of each feature in predicting the target complexity score. The X-axis shows the increase or decrease of target complexity, while the red and blue colours refer to the feature value’s size. For example, in the case of feature `size_of_sentence`, if the number of characters is larger there will be a positive impact, i.e. the complexity will increase. On the other hand, if the sentence length is smaller, there will be a negative impact, i.e. the complexity will decrease. We can observe that the most important feature is the predictions given by the BERT Multitask model since they have the greatest impact. This signals that WSD data could benefit predicting lexical complexity. It is also noted that the predictions of the Transformers-based models are in the top 5 of importance. Other features, such as the size of the sentence or the number of word senses, also have good contributions to the impact.

## 7 Conclusion

In this paper, we presented our system for the single word complexity prediction sub-task in the LCP Shared Task. Our approach consisted of combining lexical features and predictions from fine-tuned pre-trained Transformer-based models. We found that each set of features achieved a good performance on their own, and that combining all of them achieved our best result. In particular, we found that fine-tuning a pre-trained Transformer-

Approach	Pearson	Spearman	MAE	MSE
(a) BERT multitask with a window of 1	0.7972	0.7457	0.0642	0.00691
(b) BERT with a window of 1	0.7936	0.7507	0.0650	0.00703
(c) RoBERTa with a window of 1	0.7760	0.6946	0.0691	0.00776
(d) RoBERTa with a window of 2	0.7902	0.7179	0.0659	0.00729
(e) XLNet with a window of 1	0.7761	0.7253	0.0704	0.00795
(f) LightGBM with additional features	0.7859	0.7326	0.0663	0.0073
(a), (c), (d), (e) and (f)	0.8228	0.7643	0.0616	0.00618

Table 4: Results of each approach on validation data

Figure 3: Shap analysis for the top 10 most important features

based model using multi-task learning with data from word sense disambiguation helped the most with learning to predict lexical complexity.

Considering that there were unseen tokens in validation and test sets, the task resembles a zero shot classification problem. Therefore, as future work, semi-supervised learning approaches or data augmentation algorithms could be explored, and training in a multitask fashion another transformer-based models like RoBERTa.

# Uppsala NLP at SemEval-2021 Task 2: Multilingual Language Models for Fine-tuning and Feature Extraction in Word-in-Context Disambiguation

Huiling You, Xingran Zhu, and Sara Stymne

Uppsala University

Uppsala, Sweden

{Huiling.You.7480, Xingran.Zhu.2781}@student.uu.se

sara.stymne@lingfil.uu.se

## Abstract

We describe the Uppsala NLP submission to SemEval-2021 Task 2 on multilingual and cross-lingual word-in-context disambiguation. We explore the usefulness of three pre-trained multilingual language models, XLM-RoBERTa (XLMR), Multilingual BERT (mBERT) and multilingual distilled BERT (mDistilBERT). We compare these three models in two setups, fine-tuning and as feature extractors. In the second case we also experiment with using dependency-based information. We find that fine-tuning is better than feature extraction. XLMR performs better than mBERT in the cross-lingual setting both with fine-tuning and feature extraction, whereas these two models give a similar performance in the multilingual setting. mDistilBERT performs poorly with fine-tuning but gives similar results to the other models when used as a feature extractor. We submitted our two best systems, fine-tuned with XLMR and mBERT.

## 1 Introduction

SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation (MCL-WiC) (Martelli et al., 2021) is an extension from WiC (Pilehvar and Camacho-Collados, 2019), a shared task at the IJCAI-19 SemDeep workshop (SemDeep-5). WiC was proposed as a benchmark to evaluate context-sensitive word representations. The WiC dataset<sup>1</sup> consists of a list of English sentence-pairs. Each sentence-pair has a target word, and the task is to determine whether the target word is used in the same meaning or different meanings in the two sentences, thus as a binary classification task. MCL-WiC extends WiC to multilingual and cross-lingual datasets,<sup>2</sup> and covers 5

<sup>1</sup><https://pilehvar.github.io/wic/>.

<sup>2</sup><https://github.com/SapienzaNLP/mcl-wic>

Example	Label
The cat chases after the <i>mouse</i> . Click the right <i>mouse</i> button.	F
The cat chases after the <i>mouse</i> . La <i>souris</i> mange le fromage. (‘The <i>mouse</i> eats the cheese’)	T

Table 1: Examples for multilingual (top) and cross-lingual (bottom) word-in-context disambiguation.

languages: Arabic, Chinese, English, French, and Russian. The MCL-WiC task is also framed as a binary classification task: given a sentence-pair with a target word, either in the same language or in different languages, the goal is to determine whether the target word is used in the same meaning or in different meanings. Table 1 shows two example sentence pairs where the target word (*mouse*) has either an ‘animal’ or a ‘computer’ sense. In the **multilingual** setting, the two sentences are from the same language. In the **cross-lingual** setting, the two sentences are from different languages, English and one of the other four languages. Training data is only available for English–English, effectively leading to a zero-shot setting for the other languages.

Our main interest is to investigate the usefulness of pre-trained multilingual language models (LMs) in this MCL-WiC task, without resorting to sense inventories, dictionaries, or other resources. As our main method, we **fine-tune** the language models with a *span classification head*. We also experiment with using the multilingual language models as **feature extractors**, extracting contextual embeddings for the target word. In this setting, we also add information about syntactical dependency (i.e. head words and dependent words), with the intuition that it can contain relevant contextual information for disambiguation, as in Figure 1,

where the head words *chases* and *button* could help in disambiguating *mouse*. We compare three different LMs: XLM-RoBERTa (XLMR), multilingual BERT (mBERT) and multilingual distilled BERT (mDistilBERT).

We show that the fine-tuned models are stronger than any of the models based on feature extraction, by a large margin. XLMR is stronger than mBERT in the cross-lingual setting both with fine-tuning and feature extraction. mDistilBERT gives poor results with fine-tuning, but is competitive to the other LMs when used for feature extraction. Adding dependency syntax to our feature extraction method led to mixed results. We submitted our two strongest systems to the shared task, those fine-tuned with XLMR and mBERT.

## 2 Related Work

In WiC at SemDeep-5, many participating systems capitalized on contextualized word representations. The LMMS (Language Modelling Makes Sense) system by [Loureiro and Jorge \(2019\)](#) used word embeddings from BERT, together with sense embeddings from WordNet 3.0 ([Marciniak, 2020](#)). [Ansell et al. \(2019\)](#) used the contextualized representations from ELMo ([Peters et al., 2018](#)) and trained a separate classification model. [Soler et al. \(2019\)](#) experimented with several contextualized representations and used cosine similarity to measure word similarities. [Wang et al. \(2019\)](#) included WiC as one of the tasks in the proposed SuperGLUE benchmark, with the approach of fine-tuning BERT. At the end of the WiC evaluation period, the best result was achieved by [Wang et al. \(2019\)](#) with an accuracy of 68.36%, while human-level performance is 80%, as provided by the dataset curators.

[Scarlini et al. \(2020\)](#) recently proposed SensEmBERT<sup>3</sup>, a knowledge-based approach to sense embeddings for multiple languages. An important source for building SenseEmBERT is the contextualized representations from a pretrained language model. They experimented with SensEmBERT on both English and multilingual word sense disambiguation (WSD) tasks, and showed that SensEmBERT is able to achieve state-of-the-art result on both English and multilingual WSD datasets.

<sup>3</sup><http://sensembert.org/>

## 3 Multilingual Language Models

### 3.1 XLMR

XLMR (XLM-RoBERTa) is a scaled cross-lingual sentence encoder ([Conneau et al., 2020](#)), which is trained on 2.5T of data obtained from Common Crawl that covers more than 100 languages. XLMR has achieved state-of-the-art results on various cross-lingual NLP tasks.

### 3.2 mBERT

mBERT (multilingual BERT) is pre-trained on the largest Wikipedias ([Libovický et al., 2019](#)). It is a multilingual extension of BERT ([Devlin et al., 2019](#)) that provides word and sentence representations for 104 languages, which has been shown to be capable of clustering polysemic words into distinct sense regions in the embedding space ([Wiedemann et al., 2019](#)).

### 3.3 mDistilBERT

mDistilBERT (multilingual distilled BERT) is a light Transformer trained by distilling mBERT ([Sanh et al., 2019](#)), which reduces the number of parameters in mBERT by 40%, increases the speed by 60%, and retains over 97% of mBERT’s performance.

### 3.4 Sub-word models

XLMR, mBERT, and mDistilBERT all use sub-word models ([Wu et al., 2016](#); [Kudo and Richardson, 2018](#)), so the target word is usually represented by several sub-tokens. For example, given “qualify” as target word, it will be represented by “quali” and “fy” in XLMR. mBERT and mDistilBERT use a WordPiece model with a vocabulary size of 119,447 and XLMR use a SentencePiece model with a vocabulary size of 250,002. In our work, when the target word is represented by multiple sub-words, we use the averaged embedding as feature vector for the target word.<sup>4</sup>

## 4 System Description

We use the pre-trained language models in two different ways: for fine-tuning (Section 4.1) and as feature extractors (Section 4.2 - 4.3). Depending on whether feature transformation is involved, the features extracted can be further categorized into target

<sup>4</sup>We also explored summing sub-words, which gave similar results to averaging.

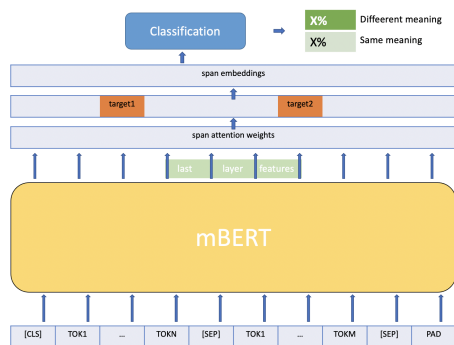

Figure 1: Model Structure of Fine-tuning mBERT

word embeddings (Section 4.2) and dependency-based syntax-incorporated word embeddings (Section 4.3). In the following sub-sections, we describe the three systems respectively. Due to time constraints we did not use XLMR in the systems with feature extraction.

#### 4.1 Fine-Tuning

The fine-tuning setup follows the architecture designed by Wang et al. (2019),<sup>5</sup> but extends to datasets in multiple languages. A *span classification head* is stacked on top of pre-trained language models, and attends only to the target words. The *span classification head* consists of a *span attention extractor* and a classifier. The *span attention extractor* is responsible for extracting the span embeddings, namely the target words embeddings. First, the unnormalized attention score of each token of the input document is computed. Span attention scores are the normalized scores of all tokens inside the span. Given the attention distributions over spans, each span gets a weighted representation of the last-layer hidden states of either mBERT, mDistilBERT or XLMR.

In this task, only the two target word spans will be returned, by masking out the rest of input. The attended span embeddings are then passed to the classifier, a linear transformation layer, to produce the output logits, which have a dimension of two, since there are only two labels (True or False). Figure 1 exemplifies the model structure when fine-tuning mBERT. The same structure also applies to XLMR and mDistilBERT.

<sup>5</sup>The package for SuperGLUE tasks is available at <https://github.com/nyu-ml1/jiant>

#### 4.2 Target Words Embeddings

In this setup, the multilingual language models serve as pure feature extractors, to get target word embeddings from last-layer hidden states. The input sample of a sentence-pair will then be the concatenation of the pair of target word embeddings.

We feed the two sentences separately to the models, and concatenate the embeddings for the two target words.<sup>6</sup> The extracted feature vectors are then fed to a classifier to perform the binary classification task. We experimented with two classifiers, logistic regression (LR) and a multi-layer perceptron (MLP).

#### 4.3 Dependency-based Syntax-Incorporated Embeddings

In this setup we ran a limited number of experiments. Only four languages (English, French, Chinese, and Russian)<sup>7</sup> and two pre-trained language models (mBERT and mDistilBERT) are explored.

The reasoning behind using syntax information to improve WiC classification results is as following. Given a pair of sentences, where the first sentence is “The cat chases after the mouse”, and the second one is “Click the right mouse button”, the target word *mouse* has different head words: in the first sentence, the singular verb *chases* is the head word, whereas in the second sentence, the noun *button* is the head word. Since it is more natural for a real mouse (as a small rodent) to be *chased* by its predators than to be related to a *button*, while in contrast, it is more common for a computer mouse (as a hand-held pointing device) to have a *button* than to be *chased*, the head words therefore reveal information on different contexts of the target word. The same reasoning applies to dependent words as well.

First, each sentence is parsed using the spaCy dependency parser,<sup>8</sup> from which we extract the target word, its head word, and its dependent word(s). Next, the sentence is passed to mBERT or mDistilBERT, and the corresponding target word embedding, head word embedding, and dependent

<sup>6</sup>We also experimented with concatenating the two sentences before feeding it to the LM, which gave slightly better results in some experiments. For consistency among all experiments we do not report these results.

<sup>7</sup>The latest version of spaCy (3.0.0), which is the dependency parsing library used in this work, does not support dependency parsing for Arabic, thus we do not run experiments on Arabic in this setup.

<sup>8</sup><https://spacy.io/usage/linguistic-features#dependency-parse>

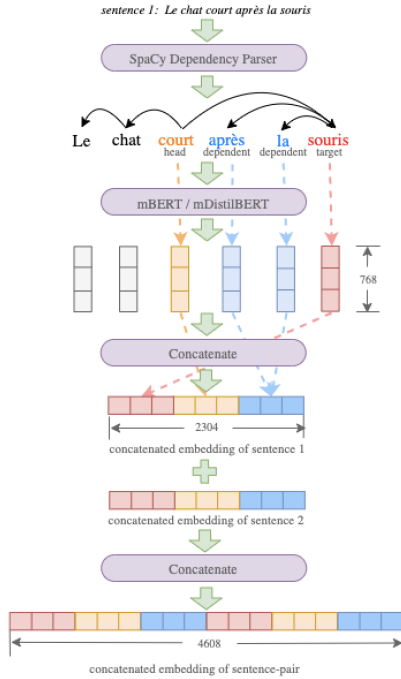

Figure 2: Construct a dependency-based syntax-incorporated embedding for a sentence-pair

word embedding(s) are retrieved, and concatenated. Note that if the target word has no head or dependent word, the *null* token embedding<sup>9</sup> is used instead; if the target word has more than one dependent word, all dependent word embeddings are summed element-wise.<sup>10</sup> Finally, the concatenated embeddings of two constituent sentences are further concatenated to form the sample feature vector of the sentence-pair, which is then fed to an MLP.

Figure 2 illustrates the process of constructing one such dependency-based syntax-incorporated embedding for a sentence-pair, of which the first sentence is *Le chat court après la souris*. The default embedding size of mBERT/mDistilBERT is 768. The sizes of different concatenated embeddings are shown in Figure 2. Again, we experimented with two classifiers, logistic regression and a multi-layer perceptron.

## 5 Experimental Setup

**Dataset** Only the datasets provided by SemEval-2021 Task 2 are used, see Table 2. All systems are trained on the English set, the multilingual development sets are used during development, and the

<sup>9</sup>That is, simply feeding the word *null* into mBERT/mDistilBERT and using the generated embedding directly.

<sup>10</sup>We also explored averaging the dependent word embeddings, which gave equivalent results to summing.

	Train	Dev	Test
en-en	8000	500	1000
ar-ar	–	500	1000

en-ar	–	–	1000
en-fr	–	–	1000
en-ru	–	–	1000
en-zh	–	–	1000

Table 2: SemEval-2021 Task 2 Datasets. At development time, we only use half of the provided size (1000) of each dev set.

systems are tested on the multilingual and cross-lingual test sets.

**Fine-tuning** The three multilingual language models (mBERT, mDistilBERT, XLMR) are fine-tuned for three iterations, with batch size of 32, learning rate of 1e-5, and parameters optimized with AdamW (Loshchilov and Hutter, 2018), provided by Huggingface’s Transformers library<sup>11</sup>.

**Logistic Regression** All logistic regression (referred to as “LR” in the following sections) models are trained for 150 iterations, with batch size of 32, learning rate of 0.0025 and parameters optimized with standard stochastic gradient descent (SGD).

**MLP** All MLP models are 2-layer and follow the architecture suggested by Du et al. (2019), outputting classification label based on the probability:

$$\mathbf{p} = \text{softmax}(L_2(\text{ReLU}(L_1(\mathbf{e})))) \quad (1)$$

where  $\mathbf{e}$  is in the input embedding,  $L_i(\mathbf{x}) = \mathbf{W}_i\mathbf{x} + \mathbf{b}_i$  are fully-connected layers,  $\mathbf{W}_1 \in \mathbb{R}^{H \times H}$  and  $\mathbf{W}_2 \in \mathbb{R}^{2 \times H}$  are layer parameter matrices, and  $H$  is the input embedding size. All MLP models are trained for maximum 200 iterations, with learning rate of 0.001 and parameters optimized with Adam ( $\beta_1 = 0.9, \beta_2 = 0.999$ ) (Kingma and Ba, 2015).

**Language Model** We use the base version of all multilingual language models, with 12 layers, 12 attention heads, and hidden dimension of 768. Due to time constraints we did not use XLMR in the systems with feature extraction and an MLP.

Table 3: System results on test sets. At task evaluation time, two fine-tuned systems were submitted, mBERT and XLMR; other systems were tested at post-evaluation time.

## 6 Results and Analysis

The evaluation results on the test sets are shown in Table 3. We can see that the fine-tuning approach is preferable to the feature extraction approach. All feature extraction variants fall behind the fine-tuned systems by a large margin. In many cases the systems based on feature extraction is just over chance performance (50%), and in a few cases it is even below it.

Among the fine-tuned systems, XLMR and mBERT give the best results, whereas mDistilBERT falls behind by quite a large margin in most cases, in several cases by more than 10 percentage points. The performance of mDistilBERT is especially weak in the cross-lingual setting. XLMR gives the best results for all cross-lingual language pairs, with an improvement over mBERT of 4.1–10.5 percentage points. The improvement is largest for English–Russian. For the multilingual setting, the difference between mBERT and XLMR is smaller with at most 3.6 percentage points. XLMR gives the best score in two cases and mBERT in three cases.

Among the systems with feature extraction, the relative performance of the three sets of contextual embeddings differ from the fine-tuning. Here, mDistilBERT are competitive to the other two embeddings. We only use XLMR with LR, and again, we see that it gives the best performance in the cross-lingual setting among all systems with LR, just as with fine-tuning. In the multilingual setting, XLMR is also strong, having the best result for three out of five languages. Compared to fine-tuning, mDistilBERT performs surprisingly well here. It is on par or better than mBERT in most cases across all settings.

Comparing the different architectures used with the feature extraction strategy, we see that using an MLP is preferable to LR, leading to large improvements in most cases. An exception is

English–Chinese, where the MLP without syntax performs worse than LR. For English–French on the other hand, the MLP outperforms LR by around 10 percentage points, whereas we see small improvements for English–Russian. Finally, the addition of syntax leads to mixed results. For the English–Chinese system, we see large improvements, whereas we see the opposite for English–French. For English–Russian as well as for all multilingual systems, the differences are overall smaller.

We also note that the performance is stronger for English–English than for the other languages in most settings. This is expected, since we only have English–English training data. A notable exception is for LR, where English–English performs considerably worse than in all other settings and is on par with the other languages in the same setting. With fine-tuning we overall see stronger results in the multilingual setting, than in the cross-lingual setting, where we mix language pairs. We do not see this difference for our feature extraction systems, however.

## 7 Conclusion and Future Work

We have investigated the use of three large language models for multilingual and cross-lingual word-in-context disambiguation. We found that fine-tuning the language models is preferable to using them as feature extractors either for an MLP or for logistic regression. Trying to add dependency-based syntax information in the MLP gave mixed results. We also found that XLMR performed better than mBERT in the cross-lingual setting, both with fine-tuning and feature extraction, whereas the two models had a more similar performance in the multilingual setting. mDistilBERT did not perform well with fine-tuning, but was competitive to the other models in the feature extraction setting. We submitted our two best systems, fine-tuning with

XLMR and mBERT to the shared task.

The fact that XLMR performs better than mBERT in the cross-lingual setting seems to indicate that it has a better representation of words across languages than mBERT and mDistilBERT. We think it would be worth investigating this hypothesis in more detail. XLMR and mBERT also use different sub-word models and another research direction is to explore the impact of this difference. We would also like to investigate the effect of using representations from different layers of the pre-trained multilingual language models.

## Abstract

In this paper, we present a system for the solution of the cross-lingual and multilingual word-in-context disambiguation task. Task organizers provided monolingual data in several languages, but no cross-lingual training data were available. To address the lack of the officially provided cross-lingual training data, we decided to generate such data ourselves. We describe a simple yet effective approach based on machine translation and back translation of the lexical units to the original language used in the context of this shared task. In our experiments, we used a neural system based on the XLM-R (Conneau et al., 2020), a pre-trained transformer-based masked language model, as a baseline. We show the effectiveness of the proposed approach as it allows to substantially improve the performance of this strong neural baseline model. In addition, in this study, we present multiple types of the XLM-R based classifier, experimenting with various ways of mixing information from the first and second occurrences of the target word in two samples.

## 1 Introduction

The goal of the second task of SemEval-2021 (Martelli et al., 2021) is to perform multilingual and cross-lingual word-in-context disambiguation. More specifically, participants are asked to distinguish whether the meanings of a target word in two provided contexts are the same or not. Organizers provided a training set of 8 000 English language (en-en) context pairs and validation sets of 1 000 context pairs for English-English (en-en), French-French (fr-fr), Russian-Russian (ru-ru), Arabic-Arabic (ar-ar), and Chinese-Chinese (zh-zh) languages. Since no cross-lingual training data were provided, except for a very small trial set barely usable for training, we decided to venture into generating such data automatically.

Essentially, the given task is a binary classification problem. The first question was which supervised model to use for the classification of context pairs. Recently, pre-trained masked language models such as BERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) have been used to reach promising results in a variety of similar NLU classification tasks. Thus, we decided to make use of contextualized embeddings from XLM-R, which provides multilingual-lingual embeddings for more than 100 languages, covering all language pairs of interest in the shared task. In all our experiments, this model is used as the backbone.

A straightforward way of solving tasks where two contexts are to be compared, as the word-in-context tasks, is to use deep contextualized embeddings and train a classifier over these embeddings as has been explored in the original monolingual word-in-context task (Pilehvar and Camacho-Collados, 2019). Note that commonly embeddings of two contexts are simply concatenated (Ma et al., 2019) and this operation is asymmetric. In our work, we explored various symmetric ways of aggregating embeddings from two contexts.

The contributions of our work are two-fold. First, we present a simple yet effective method for the generation of cross-lingual training data, showing that it can substantially improve the performance compared to the model trained using monolingual data. Second, we test various ways of encoding two input target word occurrences contexts using the XLM-R model.

## 2 Baseline Supervised WiC System

Massively multilingual transformers pretrained with language modeling objectives XLM-R were shown to be useful for zero-shot cross-lingual transfer in NLP (Lauscher et al., 2020). As a baseline, we rely on a supervised system that takes as an

Figure 1: Principal scheme of the supervised model used in our experiments. Context pairs are sent to XLM-R base and then contextualized embeddings of target words are merged and sent to MLP which outputs the prediction probability of them having the same meaning. XLM-R is frozen.

input two sentences and spans corresponding to occurrences of the target word. Pre-trained multilingual encoders are used to represent sentences in different languages in the same space.

## 2.1 Multilingual Sentence Encoder

We use XLM-R masked language model (Conneau et al., 2020) as the basis in our experiments as it supports all required languages by the shared task. This is a multilingual transformer-based masked language model pre-trained on a large corpus consisting of texts from the Web in 100 languages. This model is a strong baseline on various NLU tasks. Besides, our preliminary experiments have shown that it is capable of encoding sentences written in different languages in the same vector space. This property, therefore, is crucial as it allows similar methods, which were used to successfully solve the monolingual word-in-context task in the past (Pilehvar and Camacho-Collados, 2019).

Figure 1 presents the overall schema of the model used in our experiments. The XLM-R model is used for obtaining contextualized embeddings of the target words, while a multi-layered perceptron is used to perform the classification. We thoroughly tested various meta-parameters of this architecture. Different aggregation methods are presented in the following section.

## 2.2 Symmetric Aggregation of Deep Contextualized Embeddings

Each training example consists of two contexts with marked target words and a label representing these words being in the same or different meanings. In our approach, both contexts are sent to XLM-R, and then contextualized embeddings for target words (averaged activations from two last layers) are extracted and merged into one embed-

ding with the following symmetric procedure: concatenate element-wise product of two embeddings and the absolute value of the element-wise difference of two embeddings. This helps to obtain a vector containing deep contextualized representation of a target word in both contexts. Then this merged embedding is sent to a 3-layer MLP which outputs the probability of two words been in the same senses (Figure 1).

More specifically, we test different ways of aggregating embeddings from two contexts. We conducted several experiments, including two asymmetric aggregation approaches and four symmetric. Let  $\vec{a} = \{a_1, \dots, a_n\}$  be the contextualized embedding of a target word from the first context and  $\vec{b} = \{b_1, \dots, b_n\}$  – from the second.

The tested two following commonly used asymmetric approaches of merging two embeddings:

1. Concatenating of embeddings:

$$\vec{c} = \{a_1, \dots, a_n, b_1, \dots, b_n\}$$

2. Difference of embeddings:

$$\vec{c} = \{a_1 - b_1, \dots, a_n - b_n\}$$

Besides, we tested four symmetric approaches to embedding aggregation listed below:

1. Sum of embeddings:

$$\vec{c} = \{a_1 + b_1, \dots, a_n + b_n\}$$

2. Elementwise product of embeddings:

$$\vec{c} = \{a_1 \cdot b_1, \dots, a_n \cdot b_n\}$$

3. Absolute value of difference of embeddings:

$$\vec{c} = \{|a_1 - b_1|, \dots, |a_n - b_n|\}$$

4. Concatenation of variants 2 and 3:

$$\vec{c} = \{a_1 \cdot b_1, \dots, a_n \cdot b_n, |a_1 - b_1|, \dots, |a_n - b_n|\}$$

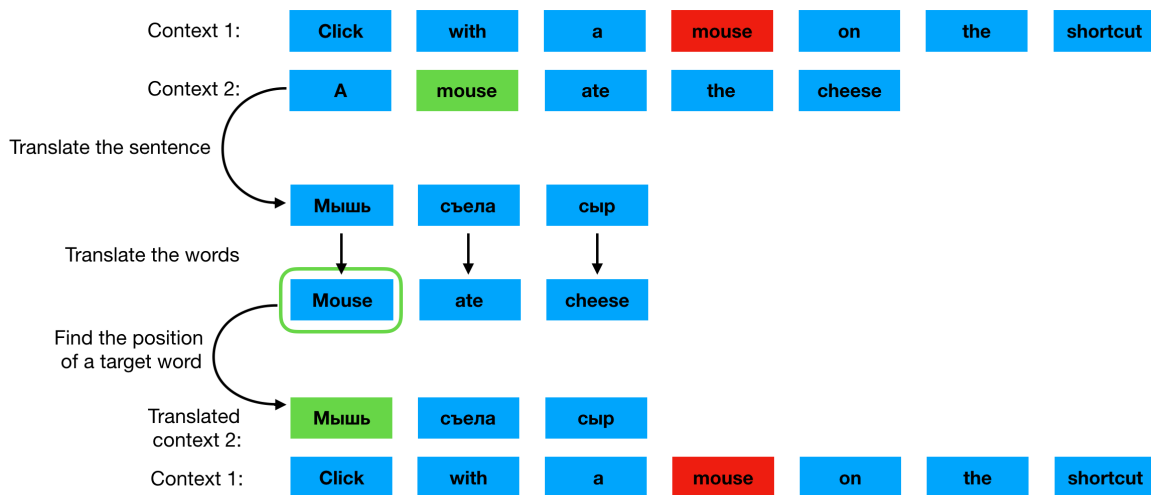

Figure 2: An illustration of the cross-lingual data generation. Given two sentences, we pick one and translate it to a target language. Then in order to find the position of a target word, every lexical unit is back-translated and compared with a target lemma. If the target word is found, the translated sentence is used in addition to the second sentence from the initial pair as a new cross-lingual training example.

### 3 Generation of Cross-lingual Training Data using Machine Translation

In this section, we describe a machine-translation-based method for the generation of synthetic training data for the cross-lingual word-in-context task to address the lack of cross-lingual training data usable for the supervised model described above.

#### 3.1 Method

We suggest the forward-backward translation approach, which helps not just to translate a sentence but to identify the position of a target word which is essential for the word-in-context task.

We decided to use the provided 8 000 English-English pairs of texts and translate them to the desired languages. But there is a difficulty: after translation the position of target word in the context is unknown, or even target word is replaced by several words like in the following example of Russian-English translation (the target words are underlined):

- ru: “налей кипяток в стакан”
- en: “pour boiling water into a glass”

In our experiments, we filter similar examples which do not have a uniword translation of a target word.

Overall, our algorithm amounts to the following procedure:

Figure 3: Amount of the English training/development data and amount of synthetic cross-lingual data generated from it.

1. Translate a sentence from the source language to a target with a neural machine translation.<sup>1</sup>
2. Back translate every word independently without a context. For the translation of single words, we use the word2word<sup>2</sup> library
3. If there is a target lemma in the list of back-translated words, then the lemma index in the back-translated words list is the index of the target word in the translated sentence.
4. If there is no target lemma in the list of back-translated words, then we do not use this sentence.

Table 1: Symmetric (S) vs asymmetric (A) ways of merging XLMR-large contextualized embeddings. Concatenation of symmetric: concatenation of elementwise multiplication and absolute difference.

A schematic illustration of our algorithm is presented in Figure 2.

### 3.2 Generation Result

The synthetic examples for English-Russian are presented in Figure 4. The first two sentence pairs (with the False, F label) represent negative training examples, i.e., pairs of sentences in which target words are used in different senses (across languages). The last two sentence pairs (with the True, T label) represent contexts where words are used in the same sense. As one may observe, the generated examples are semantically coherent, and the position of the target word was identified correctly using our back-translation heuristic.

The overall amount of generated training cross-lingual examples for each language compared to the amount of initial English language data presented in Figure 3. The unequal number of samples is due to the translation errors and the fact that back translation does not always point to the original word. That is why we also present results for the fixed sizes of synthetic datasets for each language in the Table 2.

## 4 Experiments and Results

Below we report the results of the two setups of this shared task: multi- and cross-lingual settings. We train the model six times; reporting mean and standard deviation of accuracy on the test dataset.

### 4.1 Results on Various Embedding Aggregation Methods

All embedding aggregation methods were tested on the French language development set, been trained on the English training set. The experimental results are presented in Table 1. Experimental results demonstrate that the suggested symmetric aggregation of embeddings is a better choice for such symmetric problems like two context comparisons than a common asymmetric aggregation. We suppose that this experimental fact is caused by the symmetric nature of a comparison problem and hence all similar tasks should exploit symmetrically merged embeddings.

### 4.2 Results on Multilingual Datasets

In a multilingual setting, context pairs are provided in four languages, but pairs are written in the same language. As XLM-R provides contextualized text representations in the same space for different languages, we supposed that our XLM-R based model should work in a zero-shot setting: being trained on only one language shows decent results on other languages. To verify our hypothesis, we conducted the following experiments:

1. Training only on 8 000 MCL-WiC English context pairs (zero-short setting).
2. Training on 8 000 MCL-WiC English context pairs (from the training set) + 5 000 multi-language pairs (from development set).

The results are presented in Table 2: substantially higher results than the random baseline (50

Training set	en-en	fr-fr	ru-ru	ar-ar	zh-zh
English train data	87.5 ± 0.9	82.1 ± 1.4	78.9 ± 1.7	69.2 ± 1.9	65.2 ± 1.5
English train and multilingual dev	<b>89.9 ± 0.8</b>	<b>84.1 ± 1.5</b>	<b>86.5 ± 1.1</b>	<b>72.4 ± 1.3</b>	<b>70.2 ± 1.0</b>

Table 2: Results on test data in multi-lingual setting.

Training set	en-fr	en-ru	en-ar	en-zh
English train data	64.1 ± 2.7	61.4 ± 2.1	59.1 ± 2.1	52.9 ± 1.3
English train and multilingual dev	66.5 ± 1.2	62.0 ± 1.0	58.9 ± 1.8	52.1 ± 0.7
Synthetic for each language (fixed)	70.1 ± 2.1	69.7 ± 1.9	<b>63.1 ± 2.1</b>	<b>60.1 ± 1.4</b>
Synthetic for each language (full)	72.6 ± 2.0	71.4 ± 1.4	62.7 ± 2.1	<b>60.1 ± 1.4</b>
All data	<b>73.5 ± 1.9</b>	<b>72.8 ± 1.5</b>	58.8 ± 1.7	52.1 ± 0.6

Table 3: Results on test data in cross-lingual setting.

percent) are obtained. Note that in this case, the dataset is balanced, so the most frequent class classifier is equivalent to the random one. This confirms the fact that a zero-shot transfer using XLM-R is possible.

### 4.3 Results on Cross-lingual Datasets

In a cross-lingual setting, context pairs are provided in four languages, and pairs are written in different languages. The main challenge of the task is cross-lingual Word-in-Context disambiguation. We approach this task from two sides: zero-shot learning capabilities of multilingual XLM-R based systems and generation with a machine translation of cross-lingual synthetic training data. To verify that zero-shot learning works in a cross-lingual setting and synthetically generated data improves the results in cross-lingual tests, we performed the following experiments:

1. Training only on 8 000 MCL-WiC English context pairs (zero-shot setting).
2. Training on 8 000 MCL-WiC English context pairs + 10 000 multi-language pairs.
3. Training on synthetic cross-lingual examples. Training and testing each language separately.
4. Training on all data including MCL-WiC train, development sets, and synthetic cross-lingual data for all languages simultaneously.

Results are presented in the Table 3. The best results for Russian and French are obtained using all the available data, including the generated synthetic dataset. For Arabic and Chinese, the best results

are obtained using synthetic data only. Overall, performance in all settings for Chinese and Arabic is substantially lower. This may be due to the more complex morphological structure of these languages and the way how the XLM-R pre-trained model handles it (while the European languages like French and Russian have similar alphabet structures). Overall, the experiments suggest the usefulness of the generated synthetic data for the solution of the cross-lingual word-in-context task.

## 5 Conclusion

In this paper, we presented a solution to the cross-lingual word-in-context task. The main challenge of this task, as formulated by the organizers, is the lack of explicit training data. To address it, we developed a way of generating synthetic cross-lingual data for the word-in-context disambiguating task; we demonstrate the positive influence of such synthetic data on the performance of a model on test datasets.

As the baseline model in our experiments, a supervised model based on XLM-R pre-trained language model (Conneau et al., 2020) was used. We performed tests of various settings based on this model and demonstrated that symmetric aggregation of embeddings for context comparison tasks outperforms asymmetric ways on zero-shot and supervised settings.

The code and the produced data, enabling reproducing our experiment, are available online.<sup>3</sup>

## Abstract

This paper presents our contribution to SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation (MCL-WiC). Our experiments cover English (EN-EN) sub-track from the multilingual setting of the task. We experiment with several pre-trained language models and investigate an impact of different top-layers on fine-tuning. We find the combination of Cosine Similarity and ReLU activation leading to the most effective fine-tuning procedure. Our best model results in accuracy 92.7%, which is the fourth-best score in EN-EN sub-track.

## 1 Introduction

The increasing progress in Natural Language Processing is closely related with development of word representations. The context-independent word embeddings, such as word2vec (Mikolov et al., 2013) and fastText (Bojanowski et al., 2017) brought the idea of measuring the relatedness of the meanings as the distance between the vectors encoding them. The introduction of the methods of pre-training context dependent embeddings, such as ELMo (Peters et al., 2018), ULMFit (Howard and Ruder, 2018), and BERT (Devlin et al., 2018) made the next crucial breakthrough overcoming the shortcomings of previous methods to encode the meaning. Despite the fact that the primal objective of word embeddings is to encode the meaning of words, it is not obvious how to evaluate them directly. While common manner to examine the superiority of particular type of embeddings is to look at their performance on some downstream tasks, the more direct way to evaluate their ability to represent semantic is challenging.

SemEval-2021 Task 2: Multilingual and Cross-lingual Word-in-Context Disambiguation (MCL-WiC) (Martelli et al., 2021) presents a new framework to evaluate embeddings. In this paper we

present our contribution for the task. We explore the potential of different pre-trained context-dependent embeddings based on pre-trained language models. We find that the Cosine Similarity can produce fruitful results when used for fine-tuning the weights of the pre-trained models, while adding linear layers to learn the similarity from the limited data leads to instant overfitting.

## 2 Background

The traditional approach to evaluate the ability of embeddings to catch the meaning of words is Word Sense Disambiguation (WSD) task (Navigli, 2009). WSD is defined as classification problem, when a given word is classified between its predefined senses. WSD by design comes with an important limitation, being connected directly with predefined sense inventories such as WordNet<sup>1</sup> (Fellbaum, 2005).

The Word in Context (WiC) benchmark (Pilehvar and Camacho-Collados, 2019) addresses these limitations. The task proposes a binary classification setting for English, when, given two sentences  $s_i$  and  $s_k$  and two words  $w_i$  and  $w_k$  in them, the system needs to decide whether the word  $w_i$  in  $s_i$  and  $w_k$  in  $s_k$  have same or different meanings. The main advantage of WiC task is a possibility to expand its consideration to the languages that lack such sense inventories.

MCL-WiC extends the WiC approach to new senses and new languages, covering data in five languages: Arabic, Chinese, English, French and Russian. The task provides data of two types: in the multilingual setting one needs to predict the label to the pair of sentences in one language (AR-AR, ZH-ZH, EN-EN, FR-FR, RU-RU sub-tracks), in the cross-lingual setting the first sentence is in English and the second one is in one of the four

<sup>1</sup><https://wordnet.princeton.edu>

other considered languages (EN-AR, EN-ZH, EN-FR, EN-RU sub-tracks).

After preliminary experiments we decided to focus our efforts on the only sub-track with training data, namely the English sub-track from the multilingual setting. Our solution<sup>2</sup> is fourth placed in the EN-EN leaderboard with 92.7% accuracy and is 0.6% behind the winner.

### 3 System overview

Approaching the task we conduct multiple experiments with a variety of architectures, however all of them are deeply based on contextual embeddings fine-tuning. For our experiments we use pre-trained embeddings from BERT and XLM-RoBERTa (Conneau et al., 2020) models and fine-tune them for our task.

#### 3.1 Target word embeddings

Design of BERT and XLM-RoBERTa models assumes that text is first split to tokens and embeddings for these tokens are evaluated. Therefore we define our technique to obtain the embeddings, representing target words in the sentences.

For a single sentence we take embeddings of all sub-tokens corresponding to the target word in it and max pool them into one embedding. Repeating this procedure for both sentences in each pair we obtain two embeddings as the result: first — corresponding to target word in the first sentence and second — corresponding to target word in the second sentence.

#### 3.2 Multilayer Perceptron Architecture

In our initial setup we build a system based on Multilayer Perceptron neural network. The purpose of this approach is to train the system to predict that target words have the same meaning in both sentences.

This model calculates embeddings of the target word in both sentences of the pair and concatenates them together, taking the result as an input layer. The model contains one hidden layer with 100 neurons, ReLU activation before it and an output layer, activated by sigmoid.

Interpreting the model output as the probability that target words have the same meaning in both of the sentences, we predict True if the output turns

---

<sup>2</sup>Source code, experiments, requirements and results can be found at <https://github.com/zhestyatsky/MCL-wiC>

out to be greater than 0.5 or we predict False otherwise.

To enrich the knowledge of the model about the task we also experiment with a slightly different input, making use of [CLS] tokens. Each [CLS] token represents the whole sentence. Taking [CLS] tokens embeddings for each sentence in a pair we concatenate them together and afterwards concatenate the result with an input layer (consisting of target word embeddings concatenation) defined above. We use the resulting embedding as an input layer for our model and do not change other parameters in the setup.

#### 3.3 Cosine Similarity Architecture

As an alternative to Multilayer Perceptron approach we define a Cosine Similarity approach, illustrated on Figure 1. which proves to be our best system for the task. The purpose of this approach is to train the system to predict the probability that the target word has the same meaning in both sentences.

During training our system takes embeddings of the target word in each sentence in a pair and calculates Cosine Similarity between them. It activates the similarity through ReLU layer. The result value is considered the output of the model.

After the training is finished we have to make predictions, which is achieved by defining the probability threshold as a hyperparameter. In this way we predict True if the output of the model is greater than the threshold or False otherwise.

To maximize the accuracy of the model we calculate the probability threshold by building the Receiver Operating Characteristic (ROC) curve and choosing the value corresponding to the maximum difference between true positive and false positive rates.

We note that in this approach no new weights are introduced in contradistinction to Multilayer Perceptron approach. Therefore only pre-trained weights of BERT and XLM-RoBERTa models are fine-tuned.

To provide a comparison option for Cosine Similarity approach we also try applying sigmoid as an activation instead of ReLU.

#### 3.4 Datasets

Speaking about the datasets for training and validation we fully utilize train and development English data provided by the competition organisers for the EN-EN sub-track. However, to achieve the

Figure 1: The scheme presents Cosine Similarity Architecture, which was used in the model achieving the best performance in our experiments.

best possible results we extend our train and development datasets with WiC dataset (Pilehvar and Camacho-Collados, 2019)<sup>3</sup>, included to SuperGLUE (Wang et al., 2019) benchmark, for English sentence pairs.

We also conduct an experiment with our best model, using only default datasets provided by competition organisers. This experiment will be described at the end of Results section.

#### 4 Experimental setup

In our setup we mix train and development data and split it randomly by unique lemmas in proportion 97.5% to 2.5%. Having 14680 samples in the first chunk and 386 samples in the second chunk we use the first chunk for training and the second for validation.

During training, the data is processed by batches of size 8. Each sentence is split into 118 tokens maximum. In this way it is guaranteed that the longest sentence in the dataset is not going to be truncated.

Experiments with four different types of embeddings are conducted<sup>4</sup>:

- *bert-base-cased*: 12-layer, 768-hidden, 12-heads, 109M parameters;
- *bert-large-cased*: 24-layer, 1024-hidden, 16-heads, 335M parameters;
- *xlm-roberta-base*: ~270M parameters with 12-layers, 768-hidden-state, 3072 feed-forward hidden-state, 8-heads;
- *xlm-roberta-large*: ~550M parameters with 24-layers, 1024-hidden-state, 4096 feed-forward hidden-state, 16-heads.

We train our models for a maximum of 8 epochs and define an early stopping criteria. Every half of epoch (after training on the half of all the batches) we check if the loss on validation dataset is decreasing. If the loss does not decrease for 2 checks in a row, we stop training.

In all our experiments we use Binary Cross Entropy Loss as the loss function and AdamW optimizer with a learning rate set to 1e-5.

To conduct experiments we use version 1.7.1 of PyTorch (Paszke et al., 2019) together with version 0.8.2 of torchvision<sup>5</sup> and version 0.8.1 of torchtext<sup>6</sup>,

<sup>3</sup><https://pilehvar.github.io/wic/>

<sup>4</sup><https://huggingface.co/transformers>

<sup>5</sup><https://github.com/pytorch/vision>

<sup>6</sup><https://github.com/pytorch/text>

version 1.1.6 of PyTorch Lightning<sup>7</sup> framework and version 4.2.2 of HuggingFace’s Transformers (Wolf et al., 2020). From the latter we obtain BERT and XLM-RoBERTa model implementations.

As we define a probability threshold as a hyperparameter in Cosine Similarity approach, we provide its values for all experimental configurations in the Table 1.

embeddings	activation	threshold
<i>xlm-roberta-large</i>	<b>sigmoid</b>	0.680
<i>xlm-roberta-base</i>		0.632
<i>bert-large-cased</i>		0.609
<i>bert-base-cased</i>		0.678
<i>xlm-roberta-large</i>	<b>ReLU</b>	0.638
<i>xlm-roberta-base</i>		0.642
<i>bert-large-cased</i>		0.519
<i>bert-base-cased</i>		0.509

Table 1: Probability thresholds for Cosine Similarity Architecture. Abbreviations used: **activation** stands for *activation function* used, **threshold** stands for *probability threshold* of the model.

## 5 Results

In the Table 2 the results of the fine-tuning of language models with Multilayer Perceptron on top are presented. During the experiments we found out that for this dataset not only additional linear layers can not learn to measure the distance effectively, but they lead to overfitting in a few epochs. It is seen by the number of the passed epochs before the early stopping.

As [CLS] token is designed to accumulate sentence meaning we expected it to make the representations for each instance in a pair more complete. The results in the Table 2 show that the usage of [CLS] tokens give a moderate improvement to all models except for one with *xlm-roberta-large* embeddings.

Pre-trained language models, like BERT and XLM-RoBERTa, have the property of associating close vectors with similar words. Therefore to provide a baseline for the model described in Cosine Similarity approach we measure the accuracy of it without additional fine-tuning. Due to the technique used to evaluate the probability thresholds, the accuracies for configurations with different activations are identical in this case. Accuracies for dif-

<b>BERT-b</b>		2.5	<b>0.601</b>	<b>0.592</b>

Table 2: Accuracy of models with Multilayer Perceptron Architecture. Abbreviations used: **embed** stands for *embeddings*, **add cls** defines if [CLS] token embedding was used, **val** stands for *accuracy on validation dataset*, **test** stands for *accuracy on test dataset*. We refer to *xlm-roberta-large* as **XLMR-l**, to *xlm-roberta-base* as **XLMR-b**, to *bert-large-cased* as **BERT-l** and to *bert-base-cased* as **BERT-b**.

ferent embeddings and thresholds for sigmoid and ReLU activations can be found in Table 3. Viewing the results on validation dataset we can estimate the quality of the approach and the results on test dataset confirm its relevance. Best accuracy on validation dataset is provided by *bert-large-cased* embeddings. In addition, the thresholds in Table 3 show how differently the vector spaces are arranged for BERT and XLM-RoBERTa models: for the second, a threshold of about 0.99 distinguishes vectors of words with different meanings from words with the same meanings.

embed	sigm thld	ReLU thld	val	test
<b>XLMR-l</b>	0.73	0.995	0.645	0.659
<b>XLMR-b</b>	0.72	0.994	0.666	0.719
<b>BERT-l</b>	0.66	0.64	<b>0.710</b>	<b>0.780</b>
<b>BERT-b</b>	0.69	0.77	0.690	0.780

Table 3: Accuracy of models with Cosine Similarity Architecture without fine-tuning. Abbreviations used: **embed** stands for *embeddings*, **sigm thld** stands for *probability threshold of model using sigmoid activation*, **ReLU thld** stands for *probability threshold of model using ReLU activation*, **val** stands for *accuracy on validation dataset*, **test** stands for *accuracy on test dataset*. As models are not fine-tuned, accuracies on validation and test datasets are independent of the activation function. We refer to *xlm-roberta-large* as **XLMR-l**, to *xlm-roberta-base* as **XLMR-b**, to *bert-large-cased* as **BERT-l** and to *bert-base-cased* as **BERT-b**.

Finally, Table 4 presents results of the experimental setup when the language models are fine-tuned using Cosine Similarity measure. It is worth mentioning that in such a setup there are no additional weights and only the layers of the language model are changing. It can be seen that such an architecture allows the model not to overfit for longer epochs.

embed	activ	epochs	val	test
<b>XLMR-l</b>	<b>sigm</b>	6	0.661	0.748
<b>XLMR-b</b>		3	0.679	0.746

<b>XLMR-l</b>	<b>ReLU</b>	5.5	0.785	0.876
<b>XLMR-b</b>		2	0.730	0.769
<b>BERT-l</b>		<b>4.5</b>	<b>0.808</b>	<b>0.927</b>
<b>BERT-b</b>		4	0.790	0.889

Table 4: Accuracy of models with Cosine Similarity Architecture. Abbreviations used: **embed** stands for *embeddings*, **activ** stands for the *activation function* used, **sigm** stands for *sigmoid activation function*, **val** stands for *accuracy on validation dataset*, **test** stands for *accuracy on test dataset*. We refer to *xlm-roberta-large* as **XLMR-l**, to *xlm-roberta-base* as **XLMR-b**, to *bert-large-cased* as **BERT-l** and to *bert-base-cased* as **BERT-b**.

While conducting the experiments, we judged the models by their performance on the validation dataset, not being able to check how representative it is. According to the obtained scores, the validation dataset is representative enough and is more challenging for the models than the test dataset.

To provide a convenient report we conduct an experiment with our best model (using *bert-large-cased* embeddings together with Cosine Similarity Architecture, using ReLU activation), which only uses data provided by organisers. We perform no further processing with the data and use it as is: train dataset is used for training and development dataset for validation. Being trained for 4 epochs the model in the experiment demonstrates 0.886 accuracy on validation dataset and **0.913** accuracy on test dataset. This result shows that using additional data leads to better performance.

## 6 Error analysis

Our best model leads to accuracy 92.7%. It means that our model has erroneously labeled 73 sentences in the 1000-sentence testset. The error analysis revealed that our model is not biased towards

one or another class, it produced 37 false negative predictions and 36 false positive predictions. The next observation is related to the construction feature of the dataset. The dataset is organized in the following manner: for each combination of lemma and POS-tag there are two instances in the dataset. All three possible combinations of labels are presented, with prevalent case when one pair is labeled False and second True. The peculiarity of the dataset is that both instances have the same first sentence. We found that 20 out of 73 errors have these repeating first sentence. In other words, if the model produces incorrect prediction for one instance for lemma it tends to make a mistake for the second instance in the dataset. Due to the described peculiarity of the data, we can not speculate that certain lemma is a stumbling block for the model or it is just a context of the first sentence, that for example differs by genre or thematically from second sentence and complicates the prediction. The manual analysis of the errors has not revealed instances that could be considered hard and unclear for human assessment.

In order to reveal objectively hard instances among the errors of the best model, we have intersected the mislabeled pairs for all the models fine-tuned with Cosine Similarity. The intersection indicated that all but two instances were predicted correctly by at least one of the models. We can conclude that no objectively hard instances were presented in the erroneously labeled pairs by the best model. Additionally, the possible conclusion could be that an ensemble of our models could result in even more powerful solution for the task.

## 7 Conclusion

We have provided an overview of different approaches to fine-tune pre-trained language models for the task that is naturally suitable for them – detecting the distance between representations of the words.

We have showed that, for the data of given amount and type, learning distance between words in context with Multilayer Perceptron neural network is not applicable and generally leads to overfitting.

Using Cosine Similarity to predict probability during pre-trained embeddings fine-tuning leads to much more promising results, when activated with ReLU layer.

## Abstract

In this paper, we introduce our system that we participated with at the multilingual and cross-lingual word-in-context disambiguation SemEval 2021 shared task. In our experiments, we investigated the possibility of using an all-words fine-grained word sense disambiguation system trained purely on sense-annotated data in English and draw predictions on the semantic equivalence of words in context based on the similarity of the ranked lists of the (English) WordNet synsets returned for the target words decisions had to be made for. We overcame the multi,-and cross-lingual aspects of the shared task by applying a multilingual transformer for encoding the texts written in either Arabic, English, French, Russian and Chinese. While our results lag behind top scoring submissions, it has the benefit that it not only provides a binary prediction whether two words in their context have the same meaning, but also provides a more tangible output in the form of a ranked list of (English) WordNet synsets irrespective of the language of the input texts. As our framework is designed to be as generic as possible, it can be applied as a baseline for basically any language (supported by the multilingual transformed architecture employed) even in the absence of any additional form of language specific training data.

## 1 Introduction

A major obstacle in solving word sense disambiguation (WSD) problems in a supervised manner is the scarcity of annotated training corpora. As the construction of high quality sense-annotated training data can be extremely labor-intensive and difficult (Gale et al., 1992), the Word-in-Context (WiC) disambiguation task was recently proposed by Pilehvar and Camacho-Collados (2019) as a surrogate for the traditional WSD problem. While in the traditional fine-grained WSD setting, the aim is to

assign a precise and often nuanced meaning to a word in its context according to some sense inventory, WiC is framed as a binary classification problem, where the task is to decide whether two target words originating from a pair of input sentences have the same meaning. This kind of binary decision can also be made in the absence of a nuanced sense inventory, making the annotation process less demanding and also more suitable across languages (Raganato et al., 2020).

In this paper, we analyze the utilization of multilingual transformer-based language models for performing both multi-lingual and cross-lingual WiC in the zero-shot setting, by employing nothing but English sense annotated training data and utilizing the model predictions in a transductive model that is capable of performing zero-shot WSD and WiC disambiguation for any language that is supported by the multilingual transformer encoder model that gets employed.

Loureiro and Jorge (2019) showed that a simple, nearest neighbor approach relying on contextual word embeddings can achieve impressive WSD results in English. In our follow-up work (Berend, 2020), we demonstrated, how sparse contextualized word representations can be exploited for obtaining significant improvements over the LMMS approach introduced by Loureiro and Jorge (2019). Our shared task participation was focused on comparing the two techniques in a zero-shot multilingual and cross-lingual WiC evaluation setting.

## 2 System overview

At the core of our multi,-and cross-lingual WiC systems, we employed fine-grained WSD systems, originally intended to solely handle English texts. The two models that we employed were the LMMS (Loureiro and Jorge, 2019) and the S-LMMS (Berend, 2020) approaches. We dub the

latter solution as S-LMMS, highlighting its resemblance to the LMMS approach and the fact that it operates with *sparse* contextualized word representations. Both LMMS and S-LMMS requires sense-labeled training data for constructing their respective fine-grained WSD models.

We provide a brief overview of the two approaches and encourage readers interested in more details to read the original papers (Loureiro and Jorge, 2019; Berend, 2020) introducing them. LMMS and S-LMMS both has in common, that they encode the inputs with a transformer model (BERT-large). LMMS constructs a prototype vector for each English synset based on the BERT-encoded vectors of the sense-annotated training data and the actual contents of the English WordNet glosses. For a given token in its context, LMMS takes its BERT-encoded contextualized vector and finds the nearest synset prototype for determining its sense.

The way S-LMMS differs from LMMS is that it additionally incorporates a sparsity inducing dictionary learning step, which turns the contextualized word representations into a sparse format, i.e., to such vectors that contain a high fraction ( $> 90\%$ ) of zero coefficients. Additionally, the methodology for creating the synset prototype vectors has substantial differences between the two approaches, as LMMS uses the actual contextualized embeddings pertaining to a certain synset as prototypes, whereas S-LMMS distills a vectorial representation to each synset based on an information theoretic measure.

The important technical change that we performed over the previously described fine-grained WSD models, so that they can be employed in the cross-lingual setting, is that we replaced the BERT-large encoders that the LMMS and S-LMMS models use by default to the XLM-RoBERTa-large (Conneau et al., 2020) architecture. We shall refer to the variants of LMMS and S-LMMS that were obtained by relying on XLM-RoBERTa as an encoder as opposed to BERT-large as mLMMS and mS-LMMS, owing to the multilingual nature of XLM-RoBERTa. We used the transformers library (Wolf et al., 2020) for obtaining the contextualized multilingual embeddings for our experiments.

When performing fine-grained WSD in English, one can simply restrict the scope of predicting the most likely synset for some word to those that are deemed viable for a given word in WordNet. Addi-

tionally, one can also filter the synsets over which the prediction is performed, based on the part-of-speech category of a word in question. With these heuristics, it is possible to reduce the number of synsets that a word can belong to a few dozens of synsets even for the most ambiguous cases.

In order to test a solution that is as generic as possible, we did not integrate any of these heuristics into our framework, meaning that our models returned a ranked list over *all* the 117,659 English WordNet synsets to any word from some sentence. This way, our solution can also work basically any language (supported by the multilingual transformer employed), even in the absence of a multilingual sense-inventory resource such as BabelNet (Navigli and Ponzetto, 2010) and also when we have no access to the part-of-speech information, nor to a part-of-speech tagger for some language. These design choices ensures that we are able to handle a much wider range of languages as if we decided otherwise. To this end, we regard our approach a particularly good fit being used as a baseline for WSD related evaluations involving low-resource languages.

As mentioned previously, our  $\ast$ LMMS models assigned a ranked list of 117,659 English synsets to every target word irrespective of the language of the sentence it was written in. Since the ranking of the synsets for a given word was performed over all the synsets of WordNet, it would be too restrictive to expect that words with identical meaning should be assigned the exact same most likely English synset. To this end, we measured the similarity for a pair of ranked lists that a model returned for a pair of words in their contexts and decided about the semantic equivalence of the two words based on that similarity score. As the similarity scores calculated for the ranked lists of synsets that fit those pairs of words that have the same meaning are expected to be higher on average, we decided to determine a threshold for the similarity scores of the ranked lists above which we predicted the two words to have the same meaning, and to have a different meaning otherwise.

We experimented with three strategies for measuring the similarity of two ranked synset lists for a pair of words. Let  $S_1$  and  $S_2$  refer to the ranked lists of WordNet synsets assigned to two words. As the bottom of the ranking is arguably not as meaningful as its top-ranked elements, we decided to formulate  $S_1^{(100)}$  and  $S_2^{(100)}$ . These ranked lists

differed from  $S_1$  and  $S_2$  in that they contained their top 100-ranked elements, respectively.<sup>1</sup>

Since we only focus on the highest ranked synsets from  $S_1$  and  $S_2$ , it is almost sure that certain element from  $S_1^{(100)}$  are not included in  $S_2^{(100)}$ , and vice versa. As such, the usage of standard rank correlation scores would be inconvenient for measuring the similarity between ranked lists  $S_1^{(100)}$  and  $S_2^{(100)}$ . One motivation behind the introduction of ranking-biased overlap (RBO) (Webber et al., 2010) was particularly this, i.e. to provide such a distance metric that is capable of operating between non-conjoint rankings. RBO is an overlap-based metric, that can operate over such rankings when the ranked elements themselves are not totally identical. To this end one of our metric for measuring the similarity between  $S_1^{(100)}$  and  $S_2^{(100)}$  was based on the RBO metric.

Our other approach for measuring the similarity of ranked lists  $S_1^{(100)}$  and  $S_2^{(100)}$  was to simply take their Jaccard similarity, i.e. the fraction of the size of their intersection and the elements in their union. As a third approach, we calculated the harmonic mean of the mean reciprocal rank (MRR) of the highest ranked synset from  $S_1^{(100)}$  in the ranked list  $S_2^{(100)}$  and similarly, that of the highest ranked synset from  $S_2^{(100)}$  in  $S_1^{(100)}$ . We then based our predictions with the similarity scores calculated by either of the above manner.

Instead of using some supervised approach, we determined a threshold for the similarity score for a pair of ranked synset lists  $S_1^{(100)}$  and  $S_2^{(100)}$ , above which we predicted that the words they got assigned to had identical meaning. We determined this threshold in a transductive manner, without using any of the labeled training or development set sentence pairs at all. For the cross-lingual evaluation it would have been impossible at the first place, as no annotated pairs of sentences were released during the shared task.

We used expectation maximization for determining the similarity threshold above which we predicted a pair of words to have the same meaning. That is, we took all the similarity scores that we calculated for a certain test set based on the  $S_1^{(100)}$  and  $S_2^{(100)}$  ranked synset lists, and fitted a Gaussian Mixture Model over the similarity scores. That way, we managed to fit a Gaussian distribution for

<sup>1</sup>Experiments with different thresholds (10, 25, 50, 250 and 500) also provided similar results that we omit for brevity.

the similarity scores of pairs of words with identical and different meanings. We identified the fitted Gaussian distribution with the higher expected value to be the one that corresponds to the distribution of similarity scores for those words that have identical meaning. As expectation maximization algorithms are prone to find local optima, we initialized each model 100 times and chose the one which resulted in the best log-likelihood score. Our decisions for a particular test sample was then based on the density functions on the similarity scores of the two classes determined by the best fitting model.

### 3 Experiments

We tested our approach on both the multilingual and the cross-lingual subtasks of the shared task (Martelli et al., 2021). The multilingual test sets consisted of sentence pairs that were written in the same language (either Arabic, English, French, Russian or Chinese), whereas, an input was comprised of an English and a non-English (either Arabic, French, Russian or Chinese) sentence for the cross-lingual scenario.

The fine-grained WSD model that we built our system on was trained over English sense-annotated training data. We used two sources of training signal, the SemCor dataset as well as the Princeton WordNet Gloss Corpus (WNGC), which has been shown to improve fine-grained WSD results (Vial et al., 2019; Berend, 2020). Unless stated otherwise, we used these three sources of sense-annotated training data for obtaining our \*LMMS models.<sup>2</sup>

#### 3.1 Monolingual all-words WSD experiments

We first evaluated LMMS and S-LMMS models on standard fine-grained all-words disambiguation data included in the unified evaluation framework from (Raganato et al., 2017). What we were interested here is the change in the standard WSD performance of these systems when replacing the English specific BERT-large model that LMMS and S-LMMS originally employ to XLM-RoBERTa-large. At this point we evaluated our fine-grained WSD performance in terms of F-score over the concatenation of the five standard evaluation benchmarks from SensEval2 (Edmonds and Cotton, 2001), SensEval3 (Mihalcea et al., 2004), SemEval 2007 Task 17 (Pradhan et al., 2007), SemEval 2013 Task 12

<sup>2</sup>Our source code can be found at [https://github.com/begab/sparsity\\_makes\\_sense](https://github.com/begab/sparsity_makes_sense)

(a) BERT-large

(b) Using XLM-RoBERTa-large

Table 1: Comparison of the model performances towards fine-grained WSD using the standard benchmark from (Raganato et al., 2017) (consisting of the concatenated test sets of the SensEval2-3 and the SemEval 2007, 2013 and 2015 shared tasks on fine-grained WSD), when using different layers from different transformer models and model variants \*LMMS.

(Navigli et al., 2013), SemEval 2015 Task 13 (Moro and Navigli, 2015). This test set consisted of 7,253 English test cases in total.

Table 1 includes our results using the four different models that were using different layers from the transformer model that was employed for encoding the input texts. As expected, replacing the English specific transformer model to a multilingual encoder resulted in a decreased performance, however, the overall decrease was not very severe. Comparison of the results in Table 1a and Table 1b reveals that the performance of S-LMMS is less affected by the integration of the multilingual RoBERTa model in place of the English-only BERT model for encoding. Additionally, using the encodings from the 21th layer of the transformer models seem to provide a slight edge over the utilization of the concatenation of the last four layers irrespective of the encoder and the specific WSD model used. To this end, we participated in the shared task-related with such \*LMMS models that were using the contextualized word representations from the 21th layer alone, as opposed to the average of the last four layers.

### 3.2 Evaluation on the shared task data

In Table 2, we list those test scores that we obtained by differently configured versions of our architecture. Our results span the different strategies for performing all-words fine-grained WSD (mLMMS/mS-LMMS) and different strategies for calculating the similarity between two ranked list of most likely synsets assigned to the test words (Jaccard/MRR/RBO) as described earlier in Section 2.

We can see from Table 2 the same phenomenon as for our monolingual fine-grained WSD evalua-

tions in Table 1, i.e., the mS-LMMS approach had a clear advantage over LMMS for both the multilingual and the cross-lingual evaluation settings.

Regarding the effects of choosing different ways to calculate the similarity scores between a pair of ranked lists of synsets, the application of the Jaccard similarity and the RBO metric-based similarity seems to perform very similarly, with the mean reciprocal rank based similarity scoring slightly underperforming the other two alternatives. Overall, the results seem to be balanced over the languages, with the choice of the fine-grained WSD system being more influential to the final results as the choice of the similarity calculation between the ranked lists of synsets returned by them to a pair of test words.

For training our \*LMMS models, we decided to experiment with the integration of a recent source of sense tagged training dataset, UWA (Loureiro and Camacho-Collados, 2020), which is a sense-annotated corpus containing unambiguous words from Wikipedia and OpenWebTex. We relied on the recommended version of the UWA corpus which contains 10 example sentences for each unambiguous word. By expanding the number of sense annotated training text, it becomes possible to increase the coverage of the fine-grained WSD systems. We investigated the downstream effects for our WiC system of extending the amount of sense annotated training data used by our fine-grained WSD systems.

Our evaluation results over the same set of models as in Table 2, with the only difference that we additionally used the UWA10 sense-annotated corpus for creating our all-words WSD models are included in Table 3. This additional training corpus was not always helpful, however, increased our

average accuracy by a slight ( $\approx 1\%$ ) margin.

## 4 Conclusions

In this paper, we introduced our cross,-and multilingual WiC framework that we approached from an all-words fine-grained word sense disambiguation perspective. As such, our model not only provides a yes or no answer for a pair of words in their contexts, but also provides a more tangible explanation for it in the form of the similarity between the ranked lists of English WordNet synsets assigned to the target words.

During the design of our approach, we made such choices that would make our framework conveniently applicable to new languages without the need for any training data. Although the results of our framework lags behind the top performing systems, due to of its convenient applicability to new languages and the fact that practically no additional training data is required for applying it to new and possibly low-resourced languages, we think it can provide an easy to use baseline in further WiC-related research efforts.

amittal@iitk.ac.in

ashutoshm@cse.iitk.ac.in

## Abstract

This paper describes our system for Task 4 of SemEval-2021: Reading Comprehension of Abstract Meaning (ReCAM). We participated in all subtasks where the main goal was to predict an abstract word missing from a statement. We fine-tuned the pre-trained masked language models namely BERT and ALBERT and used an ensemble of these as our submitted system on Subtask 1 (ReCAM-Imperceptibility) and Subtask 2 (ReCAM-Nonspecificity). For Subtask 3 (ReCAM-Intersection), we submitted the ALBERT model as it gives the best results. We tried multiple approaches and found that Masked Language Modeling (MLM) based approach works the best.

## 1 Introduction

Computers' ability to understand, represent, and express text with abstract meaning is a fundamental problem towards achieving true natural language understanding. In past decades, significant advancement has been achieved in representation learning. SemEval-2021 Task 4 : Reading Comprehension of Abstract Meaning (ReCAM) (Zheng et al., 2021) explores the ability of machines to understand abstract concepts and proposes to predict abstract words just as humans do while writing article summaries. In the shared task, text passages are provided to read and understand abstract meaning. It consists of three subtasks where the first two subtasks are based on two different definitions of abstractness 1) Imperceptibility (Spreen and Schulz, 1966) and 2) Non-specificity (Changizi et al., 2008) and the third subtask discusses their intersection.

Many cloze-style reading comprehension datasets like CNN/Daily Mail (Hermann et al., 2015) and Children's Book Test (CBTest) dataset (Hill et al., 2016) and models (Dhingra et al., 2016;

Munkhdalai and Yu, 2017) similar to this task exist, where a missing word has to be inferred. However, these previous datasets and models have mostly focused on inferring concrete words or concepts like named entities, but this task moves the focus from concreteness to abstractness of words in reading comprehension. This can prove to be quite useful for current ongoing research in the field of abstractive summarization.

We participated in all the three subtasks. We mainly used an ensemble of BERT and ALBERT as our final model for submission on subtasks 1 and 2. We were ranked 13th on Subtask 1 and 11th on Subtask 2. We submitted the ALBERT model on Subtask 3. All of our code is made publicly available on Github<sup>1</sup>. We approached this task in two ways. One is a Multiple Choice Question answering (MCQ) based approach and other a Masked Language Modeling (MLM) approach. Through experiments, we concluded that such tasks are best addressed using a masked language model.

The rest of the paper is organised as follows. Section 2 describes the problem statement formally and also gives a brief description of the dataset provided by the task organizers. Section 3 introduces the related work. Section 4 describes our proposed approach and Section 5 gives the experimental details. We enlist our results in Section 6 with a brief error analysis. Finally, we give concluding remarks in Section 7.

## 2 Background

### 2.1 Problem Description

A passage  $P$ , a followup question  $Q$  with a **@placeholder** and a list of candidate answer words  $W = \{W_1, W_2, W_3, W_4, W_5\}$  are given as an input to the model. The task is to output the correct answer

$W_i$  from  $W$  ( $W_i \in W$ ) by learning the function  $F$  such that  $W_i = F(P, Q, W)$

The first two subtasks focus on the two different definitions of abstractness and the third subtask captures the relationship between the two views of abstractness. The evaluation metric for all three subtasks is the accuracy of the predictions made by the model. The subtasks are enlisted below :

1. **ReCAM-Imperceptibility** - Abstract words refer to ideas and concepts that are not immediately perceivable by our senses like culture, objective, etc.
2. **ReCAM-Nonspecificity** - According to this definition, abstract words refer to holistic terms, e.g., animal, body, etc.
3. **ReCAM-Intersection** - In the third subtask, the system needs to be trained on one definition of abstractness (Imperceptibility) and evaluated on the other (Nonspecificity) and vice-versa.

Table 1: Number of examples in dataset

## 2.2 Data Description

The task organizers have provided training and validation dataset for Subtask 1 and Subtask 2. Each training and validation set example is in the form of a dictionary containing an article, a question and 5 options. One word in the question is missing and is represented by “@placeholder”, and we have to predict the word out of the given 5 options.

The data set has English news articles and questions are constructed from the summaries of these articles. The data statistics are provided in table 1. The dataset poses two major challenges. Firstly, the passages are quite long. Their distribution is shown in figure 2 and 3. The long article length leads to a loss of context when we truncate the article in a transformer based model due to its max token length limits. Secondly, the dataset contains some ambiguous examples where more than one correct answer could be feasible or the question’s context is missing from the article. Some examples are shown in the Figure 1.

Figure 2: Task 1 Article statistics

## 3 Related Work

Much work has been done for the prediction of concrete words unlike ours where we need to predict abstract words in reading comprehensions. Gated Attention Reader (Dhingra et al., 2016) predicts missing concrete words in CNN/Dailymail datasets with a high accuracy. The attention mechanism plays a crucial role in recognizing which sections of the article are more important to answer the questions. Extracting context from the article is a vital

Figure 3: Task 2 Article statistics

part of the task. This task requires comprehensive natural language understanding, going beyond the meaning of individual words and sentences. We explored some of the pre-trained transformer models (Vaswani et al., 2017) as these capture the context better due to the self-attention mechanism. Moreover, pre-trained models are readily available.

The task is somewhat similar to a multiple choice question answering task. We experimented with the MCQ based approach as mentioned by Radford (2018) where a linear layer is built over the transformer and the correct answer is predicted by applying softmax over the probabilities of each option.

One approach to get context from the article is to extract the most relevant sentences to the question with sentence similarity techniques (Reimers and Gurevych, 2019). We experimented with this approach and extracted “Top-k” sentences that were most semantically similar to the given question from the article.

One of the major challenge in this task is to handle the long length of the article. Pappagari et al. (2019) discuss the approach of using hierarchical transformers for text classification problem to tackle long passages. BERT is applied to text segments and an LSTM layer or transformer is applied to get document embedding.

Another approach is to model the shared task as a masked language modeling task. The transformer based models like BERT (Devlin et al., 2018) and ALBERT (Lan et al., 2020) have been trained via the masked language modeling objective. BERT has also been trained on the Next Sentence Prediction task, and ALBERT has been trained on the Sentence Ordering task. In Lan et al. (2020), it is mentioned that Sentence Ordering task is a better

way to understand the similarity and extracting context from two sentences and thus, ALBERT works better than the BERT model.

## 4 System Overview

We explored multiple models and methodologies. We first experimented using an encoder with an attention based approach. From their results, we observed that an MLM based approach would work better than an MCQ based approach.

Consequently, we tried BERT and ALBERT models and their ensemble with the MLM based approach. However, for comparison purposes, we also worked with the MCQ method and its system is described below along with our other approaches.

### 4.1 Encoders with Attention

#### 4.1.1 Binary Classification with Attention

We tried a binary classification based approach where we give each option a score of being a correct answer. Our model consisted of two encoders, followed by a binary classifier. One encoder is for encoding the question and one for encoding the article. First, we feed the question into the question encoder which gives us the context vector of the question. Then, we feed the article along with the hidden weights from the question encoder into the article encoder and apply attention weights over them to find the context of question within the article. Finally, we input an option word, the hidden weights obtained from the article encoder and the context vector from question encoder into the binary classifier layer which gives us the score for the given option. The option word with highest score is predicted as our answer.

#### 4.1.2 Cosine Similarity of predicted word with options

In this approach, we use the article and question encoders as described in the first approach to encode the article and question. However, instead of using a binary classifier, we used a decoder layer to predict the missing word. We used the “@placeholder” token’s hidden embedding as an input to the decoder layer along with the context vector from question encoder and hidden weights from article encoder. This layer predicts a word from vocabulary which would fit in the place of “placeholder”. We then compute this word’s cosine-similarity with the given 5 options. The most similar option word is predicted as the answer. This method is similar

Figure 4: Masked Language Model (Image Src : (Devlin et al., 2018))

to an MLM based approach, and the first approach used above is somewhat similar to an MCQ based approach. This method gave slightly better results than the first approach, and thus, it gave us an idea that an MLM model should work better for our subtasks as compared to an MCQ based model.

## 4.2 Transformer based Models

### 4.2.1 Multiple choice Question Answering

The architecture of this approach is similar to that proposed by Radford (2018). We have a linear layer over a transformer model like BERT which takes the embedding of [CLS] token and calculates the cosine similarity of this token with given 5 options. Since, the [CLS] token represents the aggregate sequence representation (Devlin et al., 2018), it encodes the context of article and question together. The input sequence to the model is the concatenation of article and question (where the “@placeholder” is replaced by an option) delimited with the [SEP] token. On top of this, we have a softmax layer which calculates the score for each given option.

### 4.2.2 Masked Language Modeling

We used the transformer models like BERT and ALBERT for masked language modeling since they have been trained via the MLM objective. In this approach, the input sequence to our model is the concatenation of question and article tokens delimited with the [SEP] token where the “@placeholder” word in the question has been masked. We truncate the article from the end to fit into the maximum token sequence length. Since our task requires context reading from the article, we used different sentence embedding of the transformer models for question and article. An example of input sequence is given in Figure 4. The model’s output is a probability vector with probability scores of replacing

the masked token with any word in the vocabulary. We used the scores computed for the given 5 options and predicted option with the highest score as the correct answer.

We did an ensemble of BERT and ALBERT model predictions by taking the average score for each option predicted by these models. If the scores of BERT model predictions of the 5 options in a given example are  $B = \{B_1, B_2, B_3, B_4, B_5\}$  and the scores of ALBERT model predictions are  $A = \{A_1, A_2, A_3, A_4, A_5\}$ , then our Ensemble model gives the scores

$$S = \{S_i : S_i = \frac{A_i + B_i}{2} \forall i \in \{1, 2, 3, 4, 5\}\}$$

We later also did an ensemble of two ALBERT models where one is fine-tuned on the given subtask, and the other one is not. This gave us the best results on Subtask 1 and Subtask 2. However, we tried this approach in the post-evaluation phase and thus, we did not submit this system on the leaderboard.

Model	Task 1	Task 2
GAREader (baseline)	0.251	0.243
Binary Classification with Attention	0.201	0.212
Cosine Similarity approach	0.256	0.249

Table 2: Results of Encoder Based Approaches on Dev sets (Metric : Accuracy)

## 5 Experimental Setup

Our implementation uses the PyTorch library (Paszke et al., 2019) for deep learning models and the Transformers library by HuggingFace (Wolf et al., 2020) for the pre-trained transformer models and corresponding tokenizers.

	Model	Task 1	Task 2	Task 3 (Train 1, Val 2)	Task 3 (Train 2, Val 1)
1	BERT (MCQ approach)	0.195	0.202	0.201	0.198
2	BERT	0.6654	0.6523	0.475	0.449

8	Ensemble (4 + 6)	0.8375	0.8401	0.7826	0.7729
9	Ensemble (6 + 7)*	<b>0.8685</b>	<b>0.8554</b>	0.8143	0.8064

Table 3: Transformer models’ results on Dev sets of each task (Metric : Accuracy)

\* Modified System after submission and not submitted in the task

We first experimented with the baseline model, Gated-Attention reader (Dhingra et al., 2016) provided by the task organizers. This model did not give good results, as shown in Table 2.

Then, we experimented with our Encoder based approaches as described in Section 4. We experimented with various loss functions like NLL loss, MSE and CrossEntropy loss. But, the results were poor for these methods too (Table 2). However, the Cosine similarity based approach (Section 4.1.2) performed slightly better than the Binary classification with Attention approach (Section 4.1.1) indicating that an MLM approach should work better than an MCQ approach.

To verify our claim, we experimented with the BERT Base model with the MCQ approach, which gave quite less accuracy, no better than a random prediction. However, the BERT model with the MLM approach performed way better on all the subtasks. We experimented with both large and small variants of BERT and ALBERT models where the large variants performed better as expected. We fine-tuned both the models without freezing any layers with Adam optimizer (Kingma and Ba, 2017). We fine-tuned the BERT model for 3 epochs and ALBERT model for 1 epoch. We used the learning rate of  $5e-5$  and a max-sequence length of 256 for both BERT and ALBERT. We also used pre-trained ALBERT model without any fine-tuning in some of our experiments.

We also experimented with the input sequence to understand and compare the degree of context-reading done in ALBERT and BERT models. We changed the input sequence to contain only ques-

tion tokens and then passed this sequence to our models. We then compared these results with the results obtained after passing the complete input sequence containing both article and question tokens. BERT gave an improvement of around 5-6% after passing the complete input sequence. However, ALBERT shows much more improvement of around 11-12% with the complete sequence. It shows that ALBERT’s training on a Sentence Ordering task is more effective for MLM tasks like ours than the BERT’s training on Next Sentence Prediction task.

We then experimented with the ensemble of BERT Large and ALBERT xxlarge-v2 model predictions. We experimented by assigning different weights to BERT and ALBERT models and found out that equal weights to both works better. We later did an ensemble of the fine-tuned ALBERT model with a non fine-tuned ALBERT model. It gave much improved results on Subtask 1 and Subtask 2.

## 6 Results and Analysis

The results of all the transformer based approaches are given in Table 3. The recurrence based models did not work and predicted answers with a random probability. We used GloVe (Pennington et al., 2014) vector embeddings that are not contextualized, unlike BERT embeddings. Moreover, the task requires some world knowledge since we need to predict an abstract word whose meaning can possibly be encoded if it is trained on large English corpus. Transformer based models are trained on large corpora and implicitly learn concepts grounded in

Type	Example	
WC	<b>Article</b>	... "Tennis chose me. It's something I never fell in love with," Tomic told Australia's Channel Seven. "Throughout my career I've given 100%. I've given also 30%. But if you balance it out, I think all my career's been around 50%." ....
	<b>Question</b>	Bernard Tomic says he has never "really tried" throughout his tennis career, adding that he has probably been @placeholder at "around 50%".

	<b>Question</b>	Blue Peter 's Lindsey Russell has ended her attempt to cross the @placeholder between Northern Ireland and Scotland in a giant inflatable barrel for Sport Relief .
	<b>Options</b>	(A) gap (B) boundary (C) sea (D) title (E) difference
	<b>Scores</b>	(A) 24.295 (B) 26.728 (C) 26.874 (D) 4.482 (E) 18.486

Table 4: Some examples where our model makes mistakes or give correct results on Subtask 2 dev dataset. The options highlighted in blue are the correct answers and options highlighted in red are predicted by our model.

- \* WC - Wrong Confident - 27 such examples
- \* WN - Wrong Confused - 109 such examples
- \* CC - Correct Confident - 446 such examples
- \* CN - Correct Confused - 269 such examples

the world. Hence, transformer based approaches work better in our case.

The BERT model with the MCQ approach uses the embeddings of the '[CLS]' token to predict the correct option. But, it doesn't exploit the position of "@placeholder" token and hence it becomes difficult for the model to predict the correct result.

We observe that our Ensemble models work better on Subtask 1 and Subtask 2 as compared to the BERT and ALBERT models. However, on Subtask 3, the ALBERT model, which is not fine-tuned gives the best results. It owes to the fact that subtasks 1 and 2 differ a lot. If we fine-tune our model on one of the subtask, then it performs worse on the other.

For our final submission, we submitted our Ensemble model (8) (Table 3) for Subtask 1 and Subtask 2. We also submitted the fine-tuned ALBERT model on these subtasks. In Subtask 1, we are ranked 13th with our Ensemble model (8) with

an accuracy of 0.8212 on test set. In Subtask 2, we are ranked 11th with the fine-tuned ALBERT model with an accuracy of 0.8761 on test set. Surprisingly, in Subtask 2, fine-tuned ALBERT model performed better than our Ensemble model on the test set. This is possibly because our ensemble system performed only marginally better than fine-tuned ALBERT model on dev set. In Subtask 3, we submitted the non fine-tuned ALBERT model.

For understanding the mistakes made by our submitted Ensemble system, we analysed the confidence scores of our model's predictions. We performed the analysis of the system on the dev set of Subtask 2. We set a threshold factor (TF) of "1.4" for deciding between confident and confused predictions. If the confidence score of the model's predicted option is  $P$  and the score for the correct option word is  $T$ , then the model is confident in its

predicted answer if the following condition holds :

$$P \geq TF * T$$

It turns out that the model makes 50% confident predictions out of all the predictions in the dev set. Also, the model makes 20% wrong predictions confidently, while in 80% of the wrong predictions, model is confused between two options. In many cases, it is unable to understand the context properly and in a few cases, the model lacks the necessary world knowledge (Table 4). In first example in Table 4, the model predicts ‘aiming’ as the answer quite confidently. However, ‘operating’ is a more appropriate option due to the context given in the article. This example shows that our system fails to read the context properly in some cases. Also, consider the second example in Table 4. Here, the model is confused between two options : ‘chances’ and ‘standards’. Although, it is mentioned in the article clearly that Derby is performing poor in a past few matches, the model is not confident in predicting ‘standards’ which is the most suitable option here. It implies that our model is generally confused between all the option words that are semantically applicable in the question statement. Consider example 4 from Table 4. Here, the model is confused between option words ‘sea’ and ‘boundary’ because both of them fit well into the question. In order to make model more confident on such examples, we need to incorporate world knowledge into our system.

We also performed a similar post-competition analysis on our Ensemble System (9) (Table 3) and found out that it continues to make similar mistakes. But, in cases like example 1 in Table 4, it gives correct results. This is because, we used an ALBERT fine-tuned model instead of BERT fine-tuned model in this system which is better in context-reading as compared to BERT. Thus, this system gave slightly improved results.

## 7 Conclusion

The task of predicting abstract words with context from a question and article is quite novel in itself. We showed that this task can be modelled better as a masked language modeling task rather than multiple choice question answering task. The transformer based approaches worked best, where we used BERT and ALBERT models and their ensembles. These models are pretrained models and hence they perform better on our small dataset

after fine-tuning. We were able to improve the results of ALBERT model with our Ensemble model on subtasks 1 and 2, but on Subtask 3, the ALBERT model performs better. In future, we shall try to improve our results on Subtask 3. In our current approaches, we haven’t used options while training the model. We can try using a pairwise ranking loss function to rank the options according to their scores with a linear layer built on top of transformer models. This will help the model to predict answers more confidently and hence might also improve results. Moreover, we have used the same approach for Subtask 1 and 2. In future, we aim to incorporate common sense knowledge, for example, prototypical knowledge about activities in the form of scripts (Modi and Titov, 2014; Modi, 2016, 2017; Ostermann et al., 2018), or in the form of semantic networks like ConceptNet (Speer et al., 2018) for tackling two different definitions of abstractness and incorporating some knowledge in the two subtasks.

## Abstract

This paper describes our system ECNU\_ICA\_1 for SemEval-2021 Task 4: Reading Comprehension of Abstract Meaning. For this task, we utilize knowledge-enhanced Graph Attention Networks with a novel semantic space transformation strategy. It leverages heterogeneous knowledge to learn adequate evidences, and seeks for an effective semantic space of abstract concepts to better improve the ability of a machine in understanding abstract meanings of natural language. Experimental results show that our system achieves strong performance on this task in terms of both imperceptibility and nonspecificity.

## 1 Introduction

Recent years have witnessed the remarkable success of pre-trained language models in machine reading comprehension (MRC). Nevertheless, new research points out that these dominant approaches rely heavily on superficial text pattern-matching heuristics to achieve shallow comprehension on natural language (Zhang et al., 2020). For humans, the basic ability to represent abstract concepts guarantees an in-depth understanding of natural language. Consequently, teaching machines to better comprehend abstract meaning is a significant and urgent step to push the frontier technique of MRC forward.

If computers can understand passages as human do, we expect them to accurately predict abstract words that people can use in summaries of the given passages. Thus, researchers have recently proposed a reading comprehension of abstract meaning (ReCAM) task in SemEval 2021. Unlike some previous datasets such as CNN/Daily Mail (Hermann et al., 2015) that request computers to predict concrete concepts, e.g., named entities, ReCAM requires machines to fill out abstract words removed

from human written summaries. In ReCAM, subtask 1 and subtask 2 respectively evaluate the performance of machines towards imperceptibility and nonspecificity, two formal definitions of abstractness in natural language understanding (Spreeen and Schulz, 1966; Changizi, 2008). Specifically, concrete words refer to things, events, and properties that we can perceive directly with our senses (Spreeen and Schulz, 1966; Coltheart, 1981; Turney et al., 2011), e.g., donut, trees, and red. In contrast, abstract words refer to the ideas and concepts that are distant from immediate perception. Examples for abstract words include objective, culture, and economy. Subtask 1 requires machines to perform reading comprehension of abstract meaning for imperceptible concepts, while subtask 2 concentrates on hypernyms, which is more abstract and different from the concrete concepts (Changizi, 2008).

To better understand the abstract meaning, we utilize the Knowledge-Enhanced Graph Attention Network (KEGAT) architecture with a novel semantic space transformation strategy for ReCAM. It well incorporates structured knowledge base such as ConceptNet (Speer et al., 2017) and exploits a novel representation transformation strategy to improve the ability of machines in natural language understanding. The main contributions of our system are as follows:

- We utilize the KEGAT architecture to accomplish two subtasks in Reading Comprehension of Abstract Meaning, leveraging heterogeneous knowledge resources to provide adequate evidences and relying on Graph Attention Networks for the better reasoning.
- The proposed semantic space transformation strategy seeks for an effective representation mapping from concrete objects to abstract concepts, enabling machines to better understand the abstract meanings of natural language.

\*Equal corresponding authors.

- Extensive experiments show that our system achieves strong performance on this task in terms of both imperceptibility and nonspecificity.

## 2 Methodology

In this section, we describe the framework of our system and propose some strategies to enhance the reasoning ability of the model. An overview of the architecture is depicted in Figure 1.

### 2.1 Input Module

We cast the ReCAM task as a classification problem. For each instance, we assume that  $P$  is the passage,  $Q$  is the question,  $A$  is the number of candidate options, and  $O_i$  stands for the options, where  $i \in \{1, 2, \dots, A\}$ . For a specific training instance, we first replace the “@placeholder” in  $Q$  with  $O_i$ , and thus the resulting question-answer pair can be denoted as  $QO_i$ . Then we concatenate the passage and question-answer pairs as [CLS]  $P$  [SEP]  $QO_i$  [SEP], and denote this converted input as  $U_i$  for convenience. Although various approaches can be exploited to encode this  $U_i$ , we primarily adopt the basic way, in which tokens are represented with the one-hot vectors and the positional encoding is added, providing the model with a new embedding as  $E_{U_i}$  for every  $U_i$ .

### 2.2 Reasoning Module

Since pre-trained language models have achieved state-of-the-art performance in various NLP tasks (Devlin et al., 2019; Yang et al., 2019; Lan et al., 2020), we adopt the pre-trained architecture to process the embedding  $E_{U_i}$  that is obtained from the previous step to get the high-level representation as  $\hat{E}_{U_i}^{base}$ . Specifically, we use Electra (Clark et al., 2020), a word-sensitive pre-trained language model which is composed of  $N$ -layer transformer encoders (Vaswani et al., 2017) depicted in the middle of Figure 1. Then, we utilize a Knowledge-Enhanced Graph Attention Network (KEGAT) component to accomplish the reasoning process based on all relevant entities and the high-level representation of the entire question-answer pair from the pre-trained model. The working principle of our KEGAT model is introduced later.

As shown in Figure 1, our KEGAT model mainly consists of a Graph Attention Network, a self-attention submodule and a multi-layer perceptron (MLP). It enables a multi-level reasoning process

from entities to sentences. For the entity level, we utilize some structured knowledge from ConceptNet with a different integration approach to achieve the goal of conducting inferences over new constructed subgraphs. Here, we adopt the N-gram method to extract all entities from the converted input  $U_i$ , and use edge weight as the probability to select a maximum of  $k$  adjacent nodes from ConceptNet for subgraph construction. Suppose the number of entities is  $n$ , we construct  $n$  subgraphs in total, and the subgraphs may be connected with edges. Next, we utilize the conceptnet-numberbatch\* to obtain the  $i$ -th entity embedding as the initial representation  $h_i^{(0)}$ , which is subsequently refined by the  $L$ -layer Graph Attention Network (GAT). In the refinement process, the GAT module automatically learns an optimal edge weight between two entities in these subgraphs based on the ReCAM task, indicating the relevance of adjacent entities to every central entity. In other word, for a central entity, the GAT tries to only assign higher weight values to those edges connected with several most reasonable adjacent entities from the constructed subgraph, and discards some irrelevant edges. Thus, the abstract semantic inference ability of our model is highly improved with the knowledge incorporated by the refined subgraphs. The working principle of our GAT is in Eq. 1–3.

$$h_i^{(l+1)} = \sigma \left( \frac{1}{M} \sum_{m=1}^M \sum_{j \in \mathcal{N}_i} \alpha_{ij_m}^{(l)} \mathbf{W}_m^{(l)} h_j^{(l)} \right) \quad (1)$$

$$\alpha_{ij}^{(l)} = \text{softmax}_j \left( f([\mathbf{W}^{(l)} h_i^{(l)}; \mathbf{W}^{(l)} h_j^{(l)}]) \right) \quad (2)$$

We update each entity node based on Eq. 1, where  $\sigma(\cdot)$  represents a ELU function (Clevert et al., 2016),  $\mathbf{W}$  is the network parameter,  $h_i^{(l)}$  is the representation from the  $l$ -th layer of GAT, and  $\mathcal{N}_i$  stands for all adjacent nodes to the  $i$ -th entity.  $M$  is the number of independent attention mechanisms in Eq. 2, and  $\alpha_{ij}^{(l)}$  is the relevance degree of the  $j$ -th adjacent entity with respect to the  $i$ -th entity. Besides,  $f(\cdot)$  represents a projection function converting the vector to a real number, and  $[\cdot]$  stands for the concatenation operation. Finally, we define

$$\hat{E}_{U_i}^{gnn} = \frac{1}{n} \sum_{i=1}^n h_i^{(L)} \quad (3)$$

to be the final representation for entity subgraphs that are obtained from the GAT.

\*ConceptNet-Numberbatch:  
<https://github.com/commonsense/conceptnet-numberbatch>

Figure 1: The overview of our system for ReCAM.

From the sentence level, we adopt a self-attention submodule and several MLPs to promote the model to reason over both entities and input sentences. We first utilize a MLP to fuse the symbolic and semantic representations and then take a self-attention operation for refinement. Thus, the entity-level representation can be further refined by taking the question-answer pair as a reference. To sum up, some valuable dimensions can be highlighted to retain the most reasonable information from the fused representations  $\hat{E}_{U_i}^{all}$  to improve the reasoning ability. We formulate these steps as Eq. 4 and Eq. 5.

$$\hat{E}_{U_i}^{all} = \text{MLP}([\hat{E}_{U_i}^{base}; \hat{E}_{U_i}^{gnn}]) \quad (4)$$

$$G_{U_i} = \sigma(\text{SelfAttn}(\hat{E}_{U_i}^{all})) \quad (5)$$

where  $G_{U_i}$  is the refined representation,  $\text{SelfAttn}(\cdot)$  represents a self-attention operation, and  $\sigma(\cdot)$  is the activation function. Finally, we concatenate  $G_{U_i}$  and  $\hat{E}_{U_i}^{base}$  to obtain the entire reasoning representation as

$$\hat{E}_{U_i} = [G_{U_i}; \hat{E}_{U_i}^{base}] \quad (6)$$

### 2.3 Prediction Module

With the previous multi-level reasoning process, we obtain the representation of converted inputs as  $\{\hat{E}_{U_i}\}_{i=1}^A$  for each instance. In the prediction module, we use a multi-layer perceptron to solve

the downstream tasks of ReCAM based on Eq. 7–9.

$$P_i = \text{MLP}(\hat{E}_{U_i}), \quad P' = \text{softmax}(P) \quad (7)$$

$$y = \arg \max(P') \quad (8)$$

$$\mathcal{L} = - \sum_{i=1}^A y_i^* \log P'_i \quad (9)$$

where  $y$  represents the prediction result, and  $P'_i$  stands for the probability of selecting the  $i$ -th option label.  $P$  is the output of the MLP, where  $P \in \mathbb{R}^{A \times 1}$ .  $\mathcal{L}$  is the training objective to minimize negative log-likelihood and  $y^*$  here stands for one-hot vector of the optimal label.

### 2.4 Adaptive Strategies

**Noise Reduction Strategy** Previous methods of knowledge integration often lead to inevitable noise (Zhong et al., 2019; Wang et al., 2019), and it is still an open research problem to balance the impact between noise and the amount of incorporated knowledge. (Weissenborn et al., 2018; Khashabi et al., 2017). Our KEGAT can alleviate the noise that is caused by incorporated structured knowledge to a certain extent. This module accomplishes the goal of identifying the most reasonable external entities and discarding the irreverent ones. For

example, we rely on both entity-level and sentence-level inference thoroughly that is discussed in the previous Reasoning Module part to achieve this goal. Furthermore, we remove several unimportant types of edges to avoid unnecessary noises, such as `"/r/DistinctFrom"`, `"/r/ExternalURL"`, etc.

**Semantic Space Transformation Strategy** Unlike some previous MRC tasks that request computers to predict concrete concepts, ReCAM task here asks models to fill out abstract words removed from human written summaries. Thus, we utilize a semantic space transformation strategy to convert ordinary semantic representation into abstract representation for classification. Specifically, for the final answer prediction, this approach deals with the hidden vector representation  $V$  which is obtained ahead of the prediction module. One method is to extend the dimension (ED) of  $V$ . For instance, we use a MLP to expand  $V$  by 500 dimensions and then perform the downstream classification prediction. The second attempt is to transform  $V$  directly with a nonlinear activation function, such as RELU. And another method is to transform  $V$  through a simple deep neural network (DNN), which is depicted in the right of Figure 1.

### 3 Experiments

#### 3.1 Datasets and Metric

In the ReCAM task, it requires the model to fill out abstract words removed from human written summaries. The total number of abstract words that can be selected is five. We utilize Accuracy as a metric to evaluate model performance.

#### 3.2 Experimental Settings

In our experiment, we set the maximum sentence length as 210 and the batch size as 16. During training, we freeze all layers and learn 2 epochs with a learning rate of 0.001 except for the last classification layer. In the fine-tuning phase, we unfreeze all layers and learn 10 epochs with a learning rate of 0.000005. Like the training phase, it is beneficial to use the weights of the pre-trained language model to correct the randomly initialized classification layer. All layers of the entire model in the fine-tuning phase are suitable for classifying downstream tasks with the low learning rate. For each phase, we save model parameters when it reaches the highest accuracy on the dev set, and load it at the beginning of the next phase. In addition, we

adopt the Adam optimizer (Kingma and Ba, 2015) and set epsilon to be 0.000001 for the gradient descent. We train our model with Titan XP GPUs.

#### 3.3 Results

Table 1 shows the results of the top five teams from the leaderboard for ReCAM task (by February 10). Our system achieves the 3rd place in Subtask 1 in terms of Accuracy. And it can be concluded from Table 2 that our system has the ability to solve the ReCAM task.

Besides, we test the performance of our system with the strategies mentioned in Section 2.4. Here, `+KEGAT` represents our proposed model with Knowledge-Enhanced Graph Attention Networks, `+ED`, `+RELU`, `+DNN` refer to our system with different semantic space transformation strategies. In addition, Dev Acc. and Test Acc. stand for the accuracy on the dev set and test set respectively. Table 2 shows the experimental results of our system on the ReCAM task. In this table, the baseline model GA Reader provided by the competition organizer is not ideal, and its performance is slightly higher than 20% with our actual testing. We conclude that on the dev set, our system respectively achieves the relative improvement of 6.69% and 4.24% on subtask 1 and subtask 2 when adding KEGAT submodule compared with the fine-tuned Roberta large. Moreover, we test the performance of three ensemble models shown in the bottom of 2, and the `Electra-large ED + Electra-large KEGAT-RELU` ensemble obtains the best performance on the dev set, which respectively outperforms the fine-tuned Roberta large model with the relative improvement of 7.41% and 5.29% on subtask 1 and subtask 2. Here, this ensemble framework refers to the combination of two models. Therefore, it can be concluded that the ensemble models with the semantic space transformation strategy greatly improve the reasoning ability of our system, and the single system with multiple strategies performs well in most cases.

#### 3.4 Further Discussion

To further investigate this task, we have additionally assessed the impact of data bias on the model performance. By statistics, the average length of passages in the dev sets of subtask 1 and subtask 2 are 268.8 and 434.6, respectively. In general, longer passages often consist of more noise that greatly influences answer reasoning process of the model. We only select a portion of contents from

Table 2: Experimental results of ReCAM task.

	Subtask1	Subtask2
<b>AVG length</b>	268.8	434.6
<b>Position</b>	<b>Dev Acc.(%)</b>	<b>Dev Acc.(%)</b>
0-210	90.80	91.07
211-420	89.31	89.65

Table 3: Performance on different contents of passage.

the given passage for this assessment instead of the whole passage. Specially, in the given dataset, we take a fixed length of 210 as the content interval by intercepting it at two different positions, namely token ID 0 ~ 210 and token ID 211 ~ 420. Then we fine-tune the Electra-large model for each subtask using their own training set and compare the performance of the fine-tuned Electra model on two different passage intervals. It means that we have conducted experiments with different passage contents twice. Table 3 reports the results of our system on these different passage intervals. In this

table, compared to the experiment that adopts the passage content with position from 0 to 210, intercepting the one with position from 211 to 420 leads the performance to drop by about 1 ~ 2% on these two subtasks. Thus, we conclude that the positional bias indeed affects model performance to some extent.

## 4 Conclusion

We utilize a knowledge-Enhanced Graph Attention Network architecture with semantic transformation strategies for machines to better comprehend the abstract meanings of natural language. It well incorporates heterogeneous knowledge and relies on Graph Attention Networks to learn adequate evidences. The subsequent semantic transformation enables an effective representation mapping from concrete objects to abstract concepts. Our system achieves strong performance on this comprehension task in terms of both imperceptibility and non-specificity. We hope this work can shed some lights on the study of in-depth reading comprehension.

## Abstract

In this article, we present our methodologies for SemEval-2021 Task-4: Reading Comprehension of Abstract Meaning. Given a fill-in-the-blank-type question and a corresponding context, the task is to predict the most suitable word from a list of 5 options. There are three sub-tasks within this task: Imperceptibility (subtask-I), Non-Specificity (subtask-II), and Intersection (subtask-III). We use encoders of transformers-based models pre-trained on the masked language modelling (MLM) task to build our Fill-in-the-blank (FitB) models. Moreover, to model imperceptibility, we define certain linguistic features, and to model non-specificity, we leverage information from hypernyms and hyponyms provided by a lexical database. Specifically, for non-specificity, we try out augmentation techniques, and other statistical techniques. We also propose variants, namely *Chunk Voting* and *Max Context*, to take care of input length restrictions for BERT, etc. Additionally, we perform a thorough ablation study, and use Integrated Gradients to explain our predictions on a few samples. Our best submissions achieve accuracies of 75.31% and 77.84%, on the test sets for subtask-I and subtask-II, respectively. For subtask-III, we achieve accuracies of 65.64% and 62.27%. The code is available [here](#).

## 1 Introduction

A very common assessment in schools is question-answering based on a given “comprehension passage”. Students are given a comprehension passage, from which they are supposed to glean necessary information, and answer short questions (such as fill-in-the-blanks-type question) based on what they have garnered from the given passage. While trying to find the most appropriate word for the blank, the children look at the words surrounding the blank

(“context”). The word should be such that when the word fills the blank, the sentence makes sense and it is grammatically correct. Inspired by this, and perhaps, after the enormous success of Transformers (Vaswani et al., 2017), researchers at Google came up with a large number of “pretraining tasks” and built knowledge-heavy language models which could be fine-tuned on various natural language processing (NLP) downstream tasks. One of the earlier pretraining tasks was “Masked Language Modelling (MLM)”, one of the two pretraining tasks of the breakthrough model, BERT (Devlin et al., 2019). The approach here was similar to how kids are taught language at school: some tokens in the text were randomly “masked” and the model was trained to predict these masked tokens.

SemEval-2021 Task-4 (Zheng et al., 2021) focuses on a similar idea. Every sample has an article, and a corresponding question. The question has a blank which the model is supposed to predict from a set of 5 options. The novelty in the task lies in its 3 subtasks: Imperceptibility (subtask-I), Non-Specificity (subtask-II), and Intersection (subtask-III). A description of these subtasks is given in Section 3. In this work, we propose using BERT and its derivative models such as DistilBERT (Sanh et al., 2019), ALBERT (Lan et al., 2019) and RoBERTa (Liu et al., 2019). Further, we propose 2 BERT variants: (1) *BERT Voting*; (2) *BERT Max. Context*. Most importantly, we also model the concepts of imperceptibility and non-specificity. For imperceptibility, we create statistical embeddings using features that have a high correlation with concreteness. For non-specificity, we propose two approaches: (1) we augment the dataset by replacing some nouns in the article by their hypernyms; and (2) we use the options’ hyponyms to decide the most appropriate option. We also experiment with GA-Reader (Dhingra et al., 2017b) and GSAMN-based approaches (Lai et al., 2019) by trying out

\* Equal contribution. Author ordering determined by coin flip.

their various combinations with BERT.

In Section 2, we perform a succinct literature survey. Section 3 elucidates our approach, including the modelling aspect, the various variants of the base model, and the different ways we model imperceptibility and non-specificity. In Section 4, we perform an extensive ablation and comparative study.

## 2 Background

The advent of large-scale question answering systems began with straightforward tasks, like the one introduced by the SimpleQuestions Dataset (Bordes et al., 2015), which consisted of knowledge-base fact triples which were later used to answer questions. However, this dataset would only judge a model based on the ability to relate the facts to the question at hand. The purpose of NLP research is to be able to create a generalised model that may answer questions based on any context, thus datasets like the CNN Daily Mail (Hermann et al., 2015) and SQuAD (Rajpurkar et al., 2016) were created. In a typical question-answering dataset, an original and anonymised context is provided before each question. Before transformers, methods consisting of LSTM/GRUs were used to achieve good results on the aforementioned tasks. These datasets however, always had answers in the passage.

The CLOTH (Xie et al., 2018) dataset focuses on passages from middle-school and high-school text, with multiple fill-in-the-blanks in the passage. The ReCAM (Zheng et al., 2021) dataset puts a twist to archetypal fill-in-the-blank datasets by providing answer choices that are abstract in some form and which are not available in the passage itself. The models created for the QA task have to take into account semantic relations between the options and the context. GA-Reader (Dhingra et al., 2017b), is one such model, which utilises a multi-hop architecture with a novel attention mechanism, that serves as a baseline to this task.

## 3 Methodology

### 3.1 MLM-Based Transformers for Cloze-Style QA

The first model we employ follows a cloze-style question answering approach, in which we use various pretrained transformer models as encoders, followed by a decoder layer, which helps us to select the correct answer.

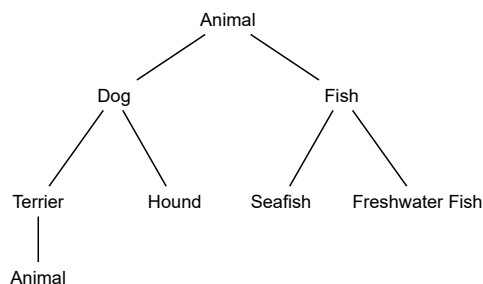

Figure 1: An example of a Hypernymy Tree

Specifically, we leverage BERT along with some of its popular and successful variants such as: DistilBERT, ALBERT, and RoBERTa. In the MLM task, tokens in the text are randomly masked, and the model is trained in a self-supervised way to predict these masked tokens. Conceptually, these transformers-based models are expected to take care of bidirectional context while predicting the masked token.

In our method, firstly, the transformer model learn the contextual embeddings of the article and the question. For the next block, the embedding of the masked token (i.e., the blank) is passed through a fully-connected layer, of which, the number of outputs corresponds to the size of the vocabulary space for the pretrained model. Each candidate option is first tokenised using WordPiece tokeniser (Wu et al., 2016), and mapped to the vector in the output vocabulary space. If the candidate option generates multiple tokens, we average the mapped scores. The model chooses the option with the highest logit value. An overview of the model is given in Figure 2.

### 3.2 Improvement Approaches

#### 3.2.1 Imperceptibility:

Nouns can be clearly demarcated into two broad categories: Concrete Nouns, and Abstract Nouns. Concrete Nouns are words that represent tangible concepts, i.e., any noun referring to a name, place, object, material, etc. is considered a concrete word. Concrete words refer to concepts that can be felt by 5 human senses: Sight, Sound, Smell, Taste, and Touch. In contrast, any noun alluding to an abstract concept that cannot be experienced by our senses is an abstract word (Spreeen and Schulz, 1966). In subtask-I, the model has to predict the most accurate and the most imperceptible word from the given options. To model the imperceptibility of

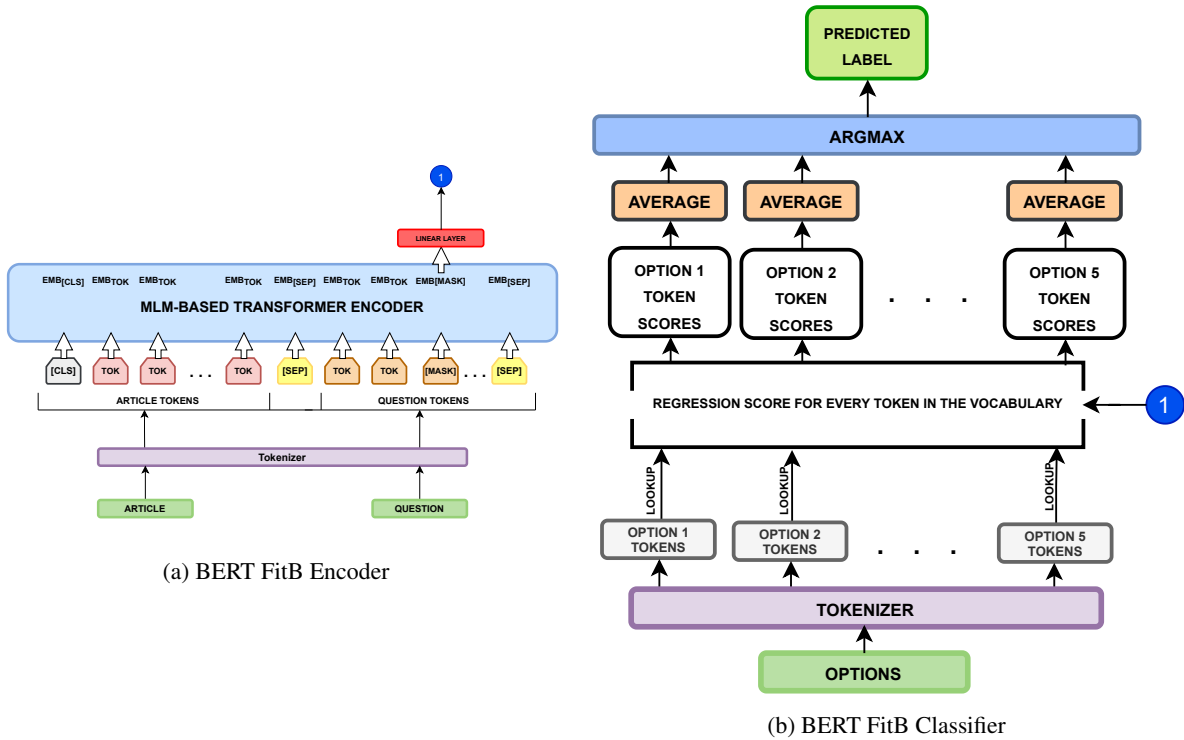

Figure 2: Architecture of Transformer-based FitB Model

every word, we incorporate certain linguistic features which are highly correlated with the notion of “imperceptibility”. These linguistic features are listed below:

**Length and Frequency of the Word** In existing literature, authors have claimed that there exists strong evidence that concrete words are, in general, shorter than abstract words (Tanaka et al., 2013). A reasonable justification provided is that more frequently used words tend to be short (Feng et al., 2011) and since humans have a penchant for describing objects, places, or things near them, these frequently used words are generally concrete nouns. It is rather intuitive that humans would prefer ease in the pronunciation of oft-used words. Moreover, many abstract words in the English language are formed by adding suffixes to the root word, such as “coarse” becomes “coarseness”, “forget” becomes “forgetfulness” and so on (Tanaka et al., 2013).

**Number of Senses of the Word** In Linguistics, polysemy refers to the capacity for a word to have multiple meanings or senses. Abstract nouns are observed to be more “polysemous” than concrete nouns (Tanaka et al., 2013). For example, in WordNet (Fellbaum, 1998), the word “dog” has 8 senses, while the word “love” has 10 senses.

**Number of Hyponyms** Tanaka et al. 2013 find a direct correlation between the abstractness of a noun and the number of hyponyms the word has. We consider the number of hyponyms of the most commonly occurring sense of the word, and the average number of hyponyms of all the senses of the word.

**Score-based Features** Abstract nouns evoke emotions in humans. SentiWordNet (Baccianella et al., 2010), another lexical database like WordNet, gives scores based on the how positive, negative or objective they are. Abstract words have a higher positive/negative score, while concrete words have a higher objective score. Again, here, we consider these scores for the most commonly occurring sense, and the average scores of all the senses of the word.

**Depth in Hypernymy Tree** This feature is more suited for non-specificity. However, we include this as a feature of imperceptibility since the concepts of imperceptibility and non-specificity are related. For example, consider the words “money” and “property”. The latter is more imperceptible and non-specific than the former. Moreover, this is particularly useful for Subtask-III. Therefore, the depth of a word in the hypernymy tree is directly proportional to the concreteness of the word.

From the features above, we have a 13-dimensional vector for every word in the lexicon. The embedding is created so that every dimension is directly proportional to the concreteness of the word. For example, the length of a word is in general, indirectly proportional to the concreteness of the word, so we take the length dimension of the vector as *large value – length of word*, where we take 10,000 as the *large value*. The large value chosen was the same for all features which are indirectly proportional to concreteness.

Towards improving the trained model, we use a method which we term as the *Difference Method*. If the difference of the top-2 probabilities predicted by the model is greater than a certain threshold, this implies that the model is sure of the prediction it has made. However, if the difference is less than the tunable threshold, the model is ambivalent about whether the option with the highest probability or the option with the second highest probability is correct. In this case, we compute for how many dimensions the value of the linguistic embedding of the second word is less than the value of the linguistic embedding of the first word. If the majority of the values (i.e., 7) are less, we change the prediction of the model to the second-most probable option. The threshold is tuned on the dev set. Furthermore, we use a *Threshold Method* towards improving the model performance. If the highest probability is less than a tunable threshold, the model is unsure of its predictions and we consider the improvement approaches on the option with the second-highest probability.

### 3.2.2 Non-Specificity

According to [Spreen and Schulz, 1966](#), a highly specific word refers to a very particular instance, while a non-specific word refers to a generic concept, i.e., it encompasses many classes/instances. For example, consider the words “animal”, “bird” and “eagle”. The words are listed in increasing order of specificity.

We find parallels between the definition of specificity/non-specificity and the linguistic phenomenon of hypernymy. [Schreuder and Baayen, 1995](#) define a hypernym as “a word with a general meaning that has basically the same meaning of a more specific word”. The more specific word is the corresponding hyponym. In simpler terms, each word is related to some super-types and sub-types, called as hypernyms and hyponyms, respectively. In linguistics, hyponymy is a semantic relation be-

tween a hyponym denoting a subtype and a hypernym denoting a supertype.

For example, in figure 1, as we traverse up the hypernymy tree, assuming we consider the word “dog”, we find that its hypernym is “animal”, which is much broader than “dog”. On the other hand, as we go down the hypernymy tree, we find more specific terms for the word “dog” such as “terrier”. Essentially, hyponyms represent “IS-A” relationships. For example, “terrier” is a “dog”. We leverage the hypernymy property of words to help the model in deciding the most non-specific option. The two methods which we implement are:

**Hypernym Augmentation Method** In order to infuse a sense of non-specificity (other than training on the given dataset for non-specificity), we augment the dataset for subtask-I. We randomly select  $n$  nouns from the article by using a basic POS Tagging pipeline. For each noun, we use the Lesk algorithm ([Lesk, 1986](#)) to find the most appropriate sense of the word based on its context. For this sense of the word, we find its hypernyms, pick a hypernym uniformly at random from this list of hypernyms and replace the noun in the article with the hypernym. We do this for all  $2^n$  combinations, i.e., corresponding to every sample, we have  $2^n$  augmented samples. Furthermore, we randomly mask tokens in this dataset and train BERT on the MLM task, on this dataset. This serves a dual purpose. Firstly, it serves as a sort of domain adaptation, and secondly, it infuses a sense of non-specificity in the model.

While finetuning BERT MLM on the augmented dataset, we freeze two layers, due to time and computational constraints. We replace the normal BERT Encoder in our BERT FitB model with the BERT Encoder fine-tuned on the augmented dataset.

**Hyponyms Options Method** Here, we use the *Difference Method/Threshold Method*. If the model is sure of its prediction, we keep the prediction of the model. Otherwise, we generate hyponyms for each option using WordNet. After the hyponyms are tokenised, we use the trained model’s output and map each hyponym token to the output vocabulary space and get the corresponding scores. We then take the maximum score amongst all of the hyponyms as the predicted probability for that option. The reason for incorporating this approach pertains to how the transformer models were pre-

trained. Consider the following sentence: “He had a [MASK] and it was bitter”. Now, suppose that we have two options: “beer” and “drink”. Generally, our transformer-based model would look at the word “bitter” and predict “beer”. However, “drink” is more non-specific than “beer”.

### 3.2.3 BERT Fill-in-the-blanks Variants

To address the limitations of the vanilla transformer-based models, we attempt multiple modifications to the proposed baseline transformer models, specifically for BERT. The major limitation of the pretrained BERT model that we’ve used, is the restriction on the length of the tokenised inputs. Only 512 tokens from a sample can be processed by BERT in one parse and hence, some articles end up getting truncated and context is lost. The following are some of the modifications we’ve made to improve the performance of our models:

**Voting** We tokenise the question and the article. We split the article into chunks and pair each chunk with the question such that the length of the tokenised  $(chunk, question)$  pair is 512. While splitting the article into chunks, we keep a max-overlap stride of 128 so that the context of the previous chunk is not lost. We train the model on these newly formed  $(chunk, question)$  pairs. During inference, we take the weighted sum of the logits. For *BERT FitB Voting (Similarity)*, the weights are calculated as:

$$weight_{ij} = \frac{u_i \cdot v_j}{\|u_i\| \|v_j\|} \quad (1)$$

where  $u_i$  is the embedding of the question in the  $i^{th}$  sample, and  $v_j$  is the embedding of the  $j^{th}$  chunk of the sample’s article. To find the embeddings, we extract the [CLS] embedding from a pretrained BERT encoder.

We also try out an alternate way of defining the weights:

$$weight_{ij} = \frac{|\{q_i \text{ toks.}\} \cap \{chunk_j \text{ toks.}\}|}{|\{chunk_j \text{ toks.}\}|} \quad (2)$$

where  $\{q_i \text{ toks.}\}$  is the set of tokens in the  $i^{th}$  sample’s question, and  $\{chunk_j \text{ toks.}\}$  is the set of tokens in the  $j^{th}$  chunk of the sample.  $|\cdot|$  represents the cardinality of a set. We call the method *BERT FitB Voting (Exact Matching)*.

We normalise the computed weights:

$$norm\_weight_{ij} = \frac{weight_{ij}}{\sum_{j=1}^{n_i} weight_{ij}} \quad (3)$$

where  $n_i$  is the number of chunks in the  $i^{th}$  sample.

The idea behind this is that higher the similarity between the question and the article’s chunk, higher is the weight assigned to the logits returned by the trained model with the question-chunk pair as input. In Equation 2, we find the fraction of tokens common between the question and chunk.

**Max Context** This method is a slight modification of the Voting Method. Instead of training the model on all  $(chunk, question)$  pairs for a particular sample, we train the model on the pair with the highest weight. The weights are calculated as described in Equation 2.

### 3.2.4 GA-Reader-based Approaches

We propose a few modifications to the baseline, namely GA-Reader (Dhingra et al., 2017a) provided by the organisers.

**GA-Reader BERT** We use GA-Reader on top of BERT embeddings. This could lead to potential improvement in performance for subtask-I as BERT embeddings are more feature-rich than GloVe embeddings.

**GA-BERT** Based on the Gated-Attention Reader, we came up with an approach that uses Gated-Attention across two-BERT streams. The first stream takes in the question input, and works like the regular BERT model. The second stream takes the article input. Assume the layer outputs for layer  $L$  are  $Q_L$  and  $A_L$ , respectively, for question and article streams. Then, to the layer  $L + 1$  for question stream,  $Q_L$  is passed as input, while to layer  $L + 1$  for article stream,  $GA(Q_L, A_L)$  is passed, where  $GA$  is the Gated-Attention function. This is done for all 12 layers of BERT-BASE. Finally, on this model, two types of heads are attached - Selection and Pooling (similar to BERT FitB), and Attention Classification (similar to GA-Reader). The logits for each head are concatenated and a fully-connected layer is added on top. Since this is a major change in the architecture of BERT, this model needs a significant amount of pretraining.

**Answer-Attention** Since GA-Reader also attends to the candidate answer embeddings, we also attempt an approach where we pass the options to the BERT model. On the option embeddings and the [MASK] token embeddings, we apply multiplicative attention (dot product) to get attention

Model Information		Imperceptibility		Non-Specificity	
Model	Variant	Val Acc.	Test Acc.	Val Acc.	Test Acc.
BERT Fill-in-the-Blank	base	67.03%	66.77%	64.39%	65.74%
BERT Fill-in-the-Blank	large	<b>74.79%</b>	<b>75.30%</b>	<b>72.73%</b>	<b>75.16%</b>
DistilBERT Fill-in-the-Blank	base	67.03%	66.02%	63.69%	62.67%
RoBERTa Fill-in-the-Blank	base	52.45%	51.11%	33.73%	35.99%
RoBERTa Fill-in-the-Blank	large	51.02%	52.44%	33.14%	34.95%
ALBERT Fill-in-the-Blank	base-v2	31.42%	30.46%	31.84%	31.14%
ALBERT Fill-in-the-Blank	large-v2	31.06%	30.76%	30.08%	33.27%
GA-Reader (baseline)	-	21.23%	21.51%	21.50%	21.86%

Table 1: Results of the Vanilla Fill-in-the-Blank(FitB) Models and GA-Reader

scores. These scores are directly used as logits for the prediction.

### 3.2.5 GSAMN-based Approaches

**BERT-GSAMN-Cloze** Lai et al. (2019) propose a combination of Gated-Attention and Self-Attention - Gated Self-Attention (GSA). They show improvements on smaller datasets compared to Compare-Aggregate Approaches. We use two GSA layers on top of BERT Embeddings, and use the same decoder and selection method as BERT FitB.

## 4 Experimental Setup

In all our experiments, we use the PyTorch implementations of the transformers-based models provided by the HuggingFace (Wolf et al., 2019). The metric for all the 3 subtasks is accuracy. For subtask-I, to obtain the linguistic features mentioned in 3.2, and to obtain the hypernyms and hyponyms for subtask-II, we use the lexical database, WordNet provided by NLTK (Bird and Loper, 2004), a library in Python. For both subtasks, we train our models on train + trial dataset, and evaluate them on the dev set.

The training and the evaluation of systems was on Google Colaboratory’s free GPU (NVIDIA K80/P100). The training time varies with the models. It is around 1-2 hours for the base variants and 2-4 hours for the large models, which is well within the 12 hour limit of Colab. DistilBERT took about half an hour for training.

For finetuning the BERT FitB Hypr Aug Model on the augmented dataset on the MLM task, we use Nvidia-DGX Station with the following specifications: four 32 GB Tesla V100 GPUs, 256 GB RAM and forty Intel Xeon 2.20GHz processors since it is a computationally intensive task.

### 4.1 Hyperparameters

For all our experiments, we use Adam Optimiser (Kingma and Ba, 2017) and Cross Entropy Loss. For choosing the optimal set of hyperparameters, we run a Grid Search on our models. We zero in on a learning rate of 1e-5. Schedulers such as Linear Scheduler, Cosine Annealing Scheduler, etc. seem to have a negative impact on the results. For the FitB models, we keep all the layers unfrozen. Additionally, the maximum input length is kept as 512. We train our models for 4 epochs, keeping a batch size of 2.

### 4.2 Ablation Study/Results

Among the vanilla models, BERT FitB Large performs the best. This is understandable when it comes to DistilBERT and ALBERT, since these models are pruned and distilled for faster computation. Notably, DistilBERT gives comparable performance to BERT FitB Base. A slightly surprising observation was that there is a degradation in accuracy on using RoBERTa. This could be because even though it was pretrained more robustly than BERT on the MLM task, it was not pretrained on the Next Sentence Prediction Task, and hence, might perform worse on Textual Entailment tasks. A peculiar observation is that the large variants of ALBERT FitB and RoBERTa FitB models perform worse than their base variants. This may imply that more training data is needed to train the large variants. For subtask-I, in table 2, we also demonstrate the results of BERT Ensemble, in which we ensemble (i.e., averaging over the predictions) two checkpoints saved during the training process. When it comes to the *Difference Method* using Linguistic Features for imperceptibility, we observe an improvement on the dev set, but a slight fall is observed while evaluating it on the test set. This might be solved by careful tuning of the threshold.

The polls are already years overdue and were scheduled for Sunday . They were postponed because of an ongoing stalemate between the government and a group of opposition senators over an electoral law . Haiti is the poorest country in the region and is still struggling to recover from a 2010 earthquake . Protesters lit piles of wood in the central neighbourhood of Bel Aire before marching to a wealthy hillside neighbourhood , where riot police guarded hotels , shops and Haiti 's elections office . Some demanded President Michel Martelly 's resignation for his " inability to organise elections in the country " . Two opposition activists who had organised the protest were arrested by police for " public unrest and inciting violence " . Mid - term senate elections in Haiti had been due in May 2012 , while the municipal poll is three years behind schedule as Haiti slowly emerges from the earthquake which left much of the country devastated in 2010 . In June , President Michel Martelly decreed that the elections be held on 26 October . The date was set after lengthy talks mediated by the president of Haiti 's Bishops ' Conference , Cardinal Chibly Langlois , intended to overcome the political deadlock between the opposition and the government . But after the National Assembly failed to pass an electoral law in time , the office of Mr Martelly announced another postponement on Sunday . No new date has been set , but the statement said that " President Michel Martelly , in his constant concern to guarantee political stability , promises to pursue consultations with the different sectors of national life in order to hold the elections as soon as possible " . Opposition politicians accuse President Martelly of wanting to rule by decree - a likely scenario if no elections are held before the lower chamber 's term runs out in January . The government argues that opposition politicians are also dragging their feet in the hope of extending their time in office without elections . Thousands of Haitians marched in the capital Port - au - Prince on Sunday in protest at a delay in the country 's [MASK] and municipal elections .

Options: Local, Annual, **Legislative**, Municipal, Devastating

Figure 3: Explanation of a Correctly Classified Sample from Subtask-I (Imperceptibility). The correct option is highlighted in green.

Model	Variant	Val Acc.	Test Acc.
BERT FitB LF	large	75.75%	75.06%
DistilBERT FitB LF	base	68.10%	65.73%
BERT FitB ENS	large	75.15%	<b>77.28%</b>
BERT FitB ENS LF	large	75.87%	75.26%
BERT FitB EM	large	76.58%	76.35%
BERT FitB EM LF	large	<b>76.82%</b>	76.10%
BERT FitB VS	large	76.58%	76.54%
BERT FitB VS LF	large	<b>76.82%</b>	76.20%
BERT MC	large	74.07%	73.76%

Table 2: Results and Ablation Study of the Improvement Methods on Subtask-I<sup>0</sup>

In the future, we aspire to learn embeddings using these Linguistic Features as input to common models such as Word2Vec (Mikolov et al., 2013).

For non-specificity, with the hypernym augmentation method, BERT FitB achieves lower accuracy. A possible reason for this could be that replacing the nouns with their hypernyms in some contexts changes the meaning of the sentence (even though we use Lesk Algorithm for WSD, not all hypernyms make sense). For example, the word "drink" is replaced with "food". For the hyponyms method, we can improve our results by recursively generating hyponyms for a particular option, instead of taking the immediate hyponyms. Again, threshold tuning may help.

In Table 3, a positive sign for the *Difference Method* or the *Threshold Method* is the improvement in the results of BERT FitB Voting (Exact Matching) when we consider the hyponyms. The accuracy jumps from 72.86% to 75.79% on the dev set and from 77.83% to 78.98% on the test set. This reinforces our claim that with more careful tuning of the threshold, we might get improvements on the test set in other methods.

Model	Variant	Val Acc.	Test Acc.
BERT FitB Hypo	large	75.09%	72.83%
BERT FitB Hypr Aug	large	62.26%	60.78%
BERT FitB Hypr Aug Hypo	large	64.51%	55.52%
BERT FitB EM	large	72.86%	77.83%
BERT FitB EM Hypo	large	<b>75.79%</b>	<b>78.98%</b>
BERT FitB VS	large	73.09%	77.59%
BERT FitB VS Hypo	large	75.56%	78.63%
BERT MC	large	71.33%	71.21%

Table 3: Results and Ablation Study of the Improvement Methods on Subtask-II<sup>0</sup>

BERT FitB Voting performs better than vanilla BERT FitB on both subtasks. This is intuitive since in the latter, we truncate the article to 512 tokens without any consideration of how much context is lost. Voting, on the other hand, considers all contexts and hence, gives a superior performance.

For GA-Reader-BERT, when compared with the GA-Reader baseline, the accuracy improves from 21% to 39% on subtask-I dev set. Due to computational restrictions, we couldn't pretrain GA-BERT, and only fine-tuned it for subtask-I to get an idea about its performance, which was sub-optimal (19%). The Answer-Attention system gave us a dev score of  $\approx 61\%$  on subtask-I, which is much higher than the baseline.

BERT-GSAMN-Cloze achieves  $\approx 31\%$  accuracy on subtask-I dev set. The reasons for this could be lack of pretraining, unlike the original paper, or different way to getting the output logits. We see improvement as we reduced number of layers to 1 ( $\approx 38\%$ ) and to 0 ( $\approx 73\%$ ). Hence, we discarded this approach.

<sup>0</sup>LF=Linguistic Features, ENS=Ensemble, FitB=Fill-in-the-Blank, EM=Exact Matching, VS=Voting (similarity), MC=Max Context, Aug=Augmentation, Hypr=Hypernym, Hypo=Hyponym

The Royal College of Physicians of Edinburgh warned that being overweight may now be considered "the norm". It claimed a tax would help fund the "spiralling" healthcare costs associated with the problem. The British Soft Drinks Association (BSDA) insisted that the case is "not compelling". It cited research which suggested a 20% tax would save just four calories per day. Liverpool University chair of clinical epidemiology, Simon Capewell, is due to speak at a conference on the issue in Edinburgh later, entitled: "Obesity: A 21st Century Epidemic". Professor Capewell will cite Mexico as one example where a 10% sugary drinks tax is believed to have contributed to a 10% reduction in the consumption of such beverages while Finland, France, Hungary, Latvia and the USA have also introduced sugar taxes. He said: "The revenues raised can then be invested back into initiatives to increase children's health in these countries, as is happening in Mexico." Scotland has an excellent track record in addressing public health issues. Notable achievements include smoke-free public places and proposals for minimum unit pricing for alcohol. We need to explore how these developments could be repeated with sugary drinks. Gavin Partington, BSDA director general, said: "The efforts by soft drinks companies including product reformulation, smaller pack sizes and increased promotion of low and no-calorie drinks have led to a 7% reduction in calories from soft drinks in the last three years." It's also worth noting that politicians in Belgium and Denmark rejected the notion of a tax in 2013 and the experience in France shows that while sales of soft drinks initially fell after a tax was introduced in 2012, they have increased since. Doctors have called for the introduction of a tax on sugary drinks and drinks to tackle what they describe as an "obesity epidemic".

Options: Food, Terms, Head, Unit, Snacks

Figure 4: Explanation of a Correctly Classified Sample from Subtask-II (Non-Specificity). The correct option is highlighted in green.

Imperceptibility		Non-Specificity	
Model	Test Acc.	Model	Test Acc.
BERT FitB	65.64%	BERT FitB	61.83%
DistilBERT FitB	52.16%	BERT FitB with Hyponyms	59.95%
DistilBERT FitB + Linguistic Features	51.61%	BERT FitB with Hypernym Augmentation	45.98%
BERT FitB + Linguistic Features	65.54%	BERT FitB Voting (Exact Matching)	62.27%
BERT FitB Ensemble + Linguistic Features	64.95%	-	-

Table 4: Submitted Results of Subtask-III: Testing the performance of a system that is trained on one subtask and evaluated on the other.

### 4.3 Analysis of BERT FitB using Integrated Gradients

We use the method of Integrated Gradients (Sundararajan et al., 2017). We follow Ramnath et al. (2020) to compute the word-wise attribution scores for BERT FitB for both subtasks. We compute the Integrated Gradients of the target with respect to the embedding outputs. The Riemann Right Approximation Method with  $n_{steps} = 25$  is used. After obtaining the token-wise attribution scores, we obtain the word-wise attribution scores by using token-to-word offset mapping. We pick the top-10 word-wise attribution scores and normalise them. To implement IG, we use the Captum (Kokhlikyan et al., 2020) library. In favour of brevity, we present one example for each subtask.

In Fig. 3, the correct answer is "legislative". The attribution scores of words like *senate*, *senators*, *municipal* and *President* are high, as is demonstrated by the intensity of the colour. The word "legislative" is, in a sense, more imperceptible than any of the words mentioned above. The *senate* is the legislative branch of the government, and *senators* are its members; *municipal* refers to municipal corporations which are the grassroots governing bodies, etc. Moreover, other words such as *elections*, *political*, *country* also have high attribution scores. These words are related to "legislative"

which exhibits the fact that BERT FitB is not only able to learn the concept of imperceptibility, but is also able to predict a suitable word.

Similarly, in Fig. 4, the correct answer is "food". Note that "snacks" is also an option; however, food is more non-specific than "snacks" and hence, food is the correct option. Another interesting thing to note is the high attribution scores for words/phrases like *calories*, *beverages*, *sugar* and *sugary drinks*. This backs the fact that the model is able to learn the concept of non-specificity, i.e., the above mentioned words are essentially hyponyms of "food".

## 5 Conclusion

We tried out myriad approaches, taking care to not only focus on the architecture aspect, but also how we can quantify imperceptibility and non-specificity. Although we did not achieve favourable improvements in all approaches, we did observe gains in accuracy on the dev set. We reckon that with more careful tuning of parameters such as the threshold in the *Difference Method*, we will be able to achieve these gains on the test set.

We further interpreted the outputs of transformers-based models using Integrated Gradients, and demonstrated that transformer models are able to learn the concepts of imperceptibility and non-specificity. In the future, we intend

to solidify our proposed approaches and carry out further research in this interesting field.

## Acknowledgments

We thank Rajaswa Patil<sup>1</sup> and Somesh Singh<sup>2</sup> for their support. We would also like to express our gratitude to our colleagues at the Language Research Group (LRG)<sup>3</sup>, who have been with us at every stepping stone.

## Abstract

This paper introduces our systems for all three subtasks of SemEval-2021 Task 4: Reading Comprehension of Abstract Meaning. To help our model better represent and understand abstract concepts in natural language, we well-design many simple and effective approaches adapted to the backbone model (RoBERTa). Specifically, we formalize the subtasks into the multiple-choice question answering format and add special tokens to abstract concepts, then, the final prediction of QA is considered as the result of subtasks. Additionally, we employ many finetuning tricks to improve the performance. Experimental results show that our approach gains significant performance compared with the baseline systems. Our system<sup>¶</sup> achieves eighth rank (87.51%) and tenth rank (89.64%) on the official blind test set of subtask 1 and subtask 2 respectively.

## 1 Introduction

The computer’s ability in understanding, representing, and expressing abstract meaning is a fundamental problem towards achieving true natural language understanding. SemEval-2021 Task 4: Reading Comprehension of Abstract Meaning (ReCAM) provides a well-formed benchmark that aims to study the machine’s ability in representing and understanding abstract concepts (Zheng et al., 2021).

The Reading Comprehension of Abstract Meaning (ReCAM) task is divided into three subtasks, including Imperceptibility, Nonspecificity, and Interaction. Please refer to the task description paper (Zheng et al., 2021) for more details. To address the above challenges in ReCAM, we first formalize all subtasks as a type of multiple-choice

Question Answering (QA) task like (Xing et al., 2020). Recently, the large Pre-trained Language Models (PLMs), such as GPT-2 (Radford et al., 2019), BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), demonstrate their excellent ability in various natural language understanding tasks (Wang et al., 2018; Zellers et al., 2018, 2019). So, we employ the state-of-the-art PLM, RoBERTa, as our backbone model. Moreover, we design many simple and effective approaches to improve the performance of the backbone model, such as adding special tokens, sentence re-ranking, label smoothing and back translation.

This paper describes approaches for all subtasks developed by the IIE-NLP-Eyas Team (Natural Language Processing group of Institute of Information Engineering of the Chinese Academy of Sciences). Our contributions are summarized as the followings:

- We design many simple and effective approaches to improve the performance of the PLMs on all three subtasks, such as special tokens, sentence re-ranking, siamese encoders and back translation and label smoothing;
- Experiments demonstrate that our proposed methods achieve significant improvements compared with baselines and we obtain the 8th-place in subtask-1 and the 10th-place in subtask-2 on the final official evaluation.

## 2 Approaches

Since the format of the tasks in ReCAM is the same, we use the unified framework to address all tasks. The following is the detail of our methods.

**Task Definition** We first present the description of symbols which are used in this paper. Formally, suppose there are seven key elements in all subtasks, i.e.  $\{D, Q, A_1, A_2, A_3, A_4, A_5\}$ . We sup-

<sup>§</sup>Corresponding author.

<sup>¶</sup>Our Code is publicly available at <https://github.com/indexfziq/IIE-NLP-Eyas-SemEval2021>.

pose the  $D$  denotes the given article, the  $Q$  denotes the summary of the article with a *placeholder*, the  $A_*$  denotes the candidate abstract concepts for all subtasks to fill in the *placeholder*.

**Multi-Choice Based Model** The pre-trained language models have made a great contribution to MRC tasks. Recently, a significant milestone is the BERT (Devlin et al., 2019), which gets new state-of-the-art results on eleven natural language processing tasks. In this section, we present the description of the multi-choice based model which we use in all subtasks. Consider the BERT-style model RoBERTa’s (Liu et al., 2019) stronger performance than BERT, we utilize it as our backbone model, which introduces more data and bigger models for better performance. A multiple-choice based QA model  $\mathcal{M}$  consists of a PLM encoder and a task-specific classification layer which includes a feed-forward neural network  $f(\cdot)$  and a softmax operation. For each pair of question-answer, the calculation of  $\mathcal{M}$  is as follow:

$$score_i = \frac{\exp(f(S_i))}{\sum_{i'} \exp(f(S_{i'}))} \quad (1)$$

$$S_i = \text{PLM}([Q; A_i; D]) \quad (2)$$

where the  $[\cdot]$  is the input constructed according to the instruction of PLMs, and the  $S_*$  is the final hidden state of the first token ( $\langle s \rangle$ ). For more details, we refer to the original work of PLMs (Liu et al., 2019). The candidate answer which owns a higher *score* will be identified as the final prediction. The model  $\mathcal{M}$  is trained end-to-end with the cross-entropy objective function.

**Special Tokens** Considering the great performance of special tokens in entity and relation extraction (Zhong and Chen, 2021), as well as of the prompt template on commonsense reasoning (Xing et al., 2020), we attach special tokens to highlight the semantic representation of candidate abstract concepts in the input layer. To help the PLMs represent and understand the abstract concept (i.e. option word in ReCAM tasks) in textual description (i.e. summary of the article in ReCAM task), we use  $\langle e \rangle$  and  $\langle /e \rangle$  to add on both ends of the abstract concept, i.e.  $\langle e \rangle$  abstract concept  $\langle /e \rangle$ . It is interesting that the special tokens are useful features contributing to most of the system’s boost, and we have tried many other useful special tokens which will be discussed in section 4.

**Sentence Ranking** As the given passage is too long to be deal with the Pre-trained Language Models (PLMs), we consider refining the passage input by rearranging the order of the sentences in the passage. With this reorder process, the sentence, which is more critical to the question, can appear at the beginning of the passage. Although the passage’s sequential information is sacrificed, we keep the more question-relevant information of the passage. Supposing the passage  $D$  contains  $N$  sentences, i.e.,  $D = \{W_1, W_2, \dots, W_N\}$ , where each sentence  $W_n = \{t_1, t_2, \dots, t_M\}$  including  $M$  tokens. We denote the given cloze-style question as  $Q$ . To rank the sentences in  $D$ , we resort BERT to compute the similarity score between each sentence, i.e.  $W_n$ , and  $Q$  following the algorithm in Zhang et al. (2020). After ranking, the sentences in  $D$  are sorted in descending order of similarity scores, and we can get a rearranged passage  $\hat{D}$  as the passage input to the QA model. In the implement progress,  $\hat{D}$  will be truncated to fit into the PLM encoder with our setting max length.

**Siamese Encoders** When exploring the dataset, we find that the complete question statement, representing the result statement after replacing the *placeholder* token with the candidate option, also contains the semantic information which can help to make the judgment about options. Based on the observation, we propose a siamese encoders based architecture to inject the additional complete question statement information while not influence the input with passage. On the other hand, it can be seen as introducing an auxiliary task to assist the main task. Specifically, the training of siamese encoder based architecture is as following:

$$l_i^1 = \text{PLM}([\hat{Q}_i])[0] \quad (3)$$

$$l_i^2 = \text{PLM}([Q; A_i; D])[0] \quad (4)$$

$$P^1(A_i|\hat{Q}) = \text{softmax}(f(l_i^1)) \quad (5)$$

$$P^2(A_i|D, Q) = \text{softmax}(f(l_i^2)) \quad (6)$$

where the  $\text{PLM}(\cdot)$  stands for PLM encoder,  $\hat{Q}_i$  is the complete question statement,  $i$  indicates the  $i$ -th candidate answer,  $f(\cdot)$  is the feed forward network. To coordinate the two losses, we opt for an uncertainty loss (Kendall et al., 2018) to adjust it adaptively through  $\sigma_{\{1,2\}}$  as:  $\mathcal{L}(\theta, \sigma_1, \sigma_2) = \frac{1}{2\sigma_1^2} \mathcal{L}^1(\theta) + \frac{1}{2\sigma_2^2} \mathcal{L}^2(\theta) + \log \sigma_1^2 \sigma_2^2$ , where  $\mathcal{L}^{\{1,2\}}$  are the cross-entropy loss between the model prediction  $P^{\{1,2\}}$  and the ground truth label respectively.

**Back Translation** Generally speaking, more successful neural networks require a large number of parameters, often in the millions. In order to make the neural network implements correctly, a lot of data is needed for training, but in actual situations, there is not as much data as we thought. The role of data augmentation includes two aspects. One is to increase the amount of training data and improve the generalization ability of the model. The other is to increase the noise data and improve the robustness of the model. A large number of the works (Buslaev et al., 2018; Bloice et al., 2019; Chen et al., 2020; Cubuk et al., 2020; Sato et al., 2018; Zhu et al., 2020) consider the data augmentation to make better performances. In the field of computer vision, a lot of work (Buslaev et al., 2018; Bloice et al., 2019; Chen et al., 2020; Cubuk et al., 2020) uses existing data to perform operations, such as flipping, translation or rotation, to create more data, so that neural networks have better generalization effects. Adding Gaussian distribution to text processing (Sato et al., 2018) can also achieve the effect of data augmentation. Besides, some works (Miyato et al., 2017; Zhu et al., 2020) utilize the adversarial training methods to do the data augmentation. For convenience and simplicity, we adopt the back translation (Sennrich et al., 2016) to increase the amount of training data, which is used to construct pseudo parallel corpus in unsupervised machine translation (Lample et al., 2018). Specifically, we use the Google API<sup>†</sup> to translate the passage into French, and then translate the translation into English in turn. The pseudo parallel corpus can be obtained as:

$$\{D'\} = bkt(\{D\}) \quad (7)$$

where  $\{D'\}$  means the translated English corpus that we used as data agument,  $bkt$  is back translation.

As for the question, given the existence of the special character *placeholder*, forced translation may result in grammatical errors and semantic gaps. Therefore, the questions and options will be kept original. After getting the pseudo parallel corpus, we train our model with the training data together with the cross-entropy loss function.

**Label Smoothing** Furthermore, for improving the generalization ability of the model trained on sole task and prevent the overconfidence of model,

<sup>†</sup>The web page is available at <https://translate.google.com>

Subtask	Train	Trail	Dev	Test
Imperceptibility	3227	1000	837	2025
Nonspecificity	3318	1000	851	2017

Table 2: Hyper-parameters of our approach.

we consider training model with label smoothing (Miller et al., 1996; Pereyra et al., 2017). Label smoothing can maintain uncertainty over the label space during training. When training with label smoothing, for classification tasks, the hard one-hot label distribution is replaced with a softened label distribution through a smoothing value  $\alpha$ , which is a hyperparameter. Specifically, for hard one-hot label distribution, the target category’s probability will be assigned to 1.0 and others are 0.0. Label smoothing will soften the label distribution by modifying the probability distribution with a discount. Then, the target category’s probability will be  $1 - \alpha$ , and the probabilities of the rest categories are  $\frac{\alpha}{\mathcal{K}-1}$ , where  $\mathcal{K}$  is the number of task categories. In our experiments, we set the smoothing value  $\alpha = 0.1$ .

### 3 Experiments and Results

#### 3.1 Experimental Setup

In all subtasks, the scale of each task is shown in Table 1. We train the model on training data and the related pseudo data generated by back translation, then select hyper-parameters based on the best performing model on the dev set, and then report results on the test set.

Our system is implemented with PyTorch and we use the PyTorch version of the pre-trained language models<sup>‡</sup>. We employ RoBERTa (Liu et al., 2019) large model as our PLM encoder in Equation 2. The Adam optimizer (Kingma and Ba, 2014) is used to fine-tune the model. We introduce the detailed setup of the best model on the development dataset. For subtask-1 and subtask-2, the hyper-parameters are shown in Table 2.

<sup>‡</sup><https://github.com/huggingface/transformers>

Models	Trial Acc.	Dev Acc.
ROBERTA <sub>LARGE</sub> (Liu et al., 2019)	85.85	82.12

Our Approach	87.10	<b>89.54</b>

Table 4: The results of our system on subtask-2. Our approach is the final, stable and best model: ROBERTA<sub>LARGE</sub> with special tokens and label smoothing. We finally obtain 89.64 Acc. on the official blind test set.

### 3.2 Evaluation Results

**Imperceptibility** From Table 3, we can see the results of our system on subtask-1 of ReCAM. Compared to the backbone model RoBERTa large model, our methods achieve significant improvements. It is interesting that the special token is the most helpful part for the Imperceptibility subtask.

**Nonspecificity** Table 4 summarizes the results of our approaches on subtask-2 of ReCAM. In Nonspecificity subtask, the model with special tokens and label smoothing performs best. Compared to the backbone model ROBERTA<sub>LARGE</sub>, all our methods achieve better performance.

**Interaction** We also perform subtask-3 of ReCAM, Interaction, which aims to provide more insights into the relationship of the two views on abstractness. In this task, we test the performance of our system that is trained on one definition and evaluated on the other. The results of our system’s performance on Imperceptibility and Nonspecificity subtasks which is shown in Table 5. We can find that our model is relatively robust for different abstract concepts.

Trained on	Tested on	Test Acc.
Subtask-1	Subtask-1	87.51
Subtask-1	Subtask-2	84.13
Subtask-2	Subtask-2	89.64
Subtask-2	Subtask-1	81.09

N/A	86.23	83.12

Table 6: The results of models with different special tokens on subtask-1.

## 4 Analysis and Discussion

### 4.1 Ablation Study

In this part, we perform an ablation study of our approaches (special tokens, sentence re-ranking, label smoothing, siamese encoders and back translation).

Table 3 and 4 shows that our proposed methods help the backbone model better represent and understand the abstract concepts. Note that the special tokens bring the PLMs with the best improvements in both subtask-1 and subtask-2. It is possible that the special tokens teach the model to focus on the abstract concept in a stronger manner. Moreover, other common tricks bring with little improvements.

### 4.2 Discussion of Special Tokens

We also search for the best special tokens for ReCAM on the dev set of subtask-1. `e` stands for the word `entity`. `#` and `$` are common special tokens for NLP downstream applications.

As shown in Table 6, `<e> </e>` enhance the representations of abstract concepts best of all. `#` and `$` work well. In addition, the `<>` and `</>` could be helpful for PLMs to pay attention to the abstract concepts. Moreover, it is interesting that each special token helps PLMs choose the right abstract concepts which are submerged in long sequential tokens (including article and summary). This result strengthen the point that special tokens can enhance the representation of abstract concepts in PLM based approaches.

## 5 Conclusion

In this paper, we design many simple and effective approaches to improve the performance of the PLMs on all three subtasks. Experiments demonstrate that the proposed methods achieve significant improvement compared with the PLMs baseline and we obtain the eighth-place in subtask-1 and tenth-place in subtask-2 on the final official evaluation. Moreover, we show that special tokens are useful features contributing to most of the system’s boost, which work well in enhancing PLMs for representing and understanding abstract concepts.

## Abstract

This paper presents a technical report of our submission to the 4th task of SemEval-2021, titled: Reading Comprehension of Abstract Meaning. In this task, we want to predict the correct answer based on a question given a context. Usually, contexts are very lengthy and require a large receptive field from the model. Thus, common contextualized language models like BERT miss fine representation and performance due to the limited capacity of the input tokens. To tackle this problem, we used the longformer model to better process the sequences. Furthermore, we utilized the method proposed in the longformer benchmark on wikipop dataset which improved the accuracy on our task data from (23.01% and 22.95%) achieved by the baselines for subtask 1 and 2, respectively, to (70.30% and 64.38%).

## 1 Introduction

Reading comprehension is the ability to understand a passage either by human or machine. One of the great benchmarks to evaluate this ability is to try to answer specific questions related to the passage (Rajpurkar et al., 2016). Generally, this problem can contain single or multiple documents as context (containing relevant information needed to understand and answer the question), a question (a sentence with at least one asking parameter), and an answer (which is the parameter value of the question).

In the Task of Reading Comprehension of Abstract Meaning (ReCAM), we have one passage as a context, one question and five candidate answers (Zheng et al., 2021). The goal is to identify the correct answer based on the context and the given question. You can see a sample of the data in Table 1. For each instance of the data, there is a passage, a question with a missing word that should be filled based on the passage, and five candidate answers to the question.

<b>Passage</b>	... observers have even named it after him, “Abenomics”. It is based on three key pillars - the “three arrows” of monetary policy, fiscal stimulus and structural reforms in order to ensure long-term sustainable growth in the world’s third-largest economy. In this weekend’s upper house elections ...
<b>Question</b>	Abenomics: The <i>@Placeholder</i> and the risks
<b>Answer</b>	(A) chances (B) prospective (C) security (D) objectives (E) threats

Table 1: An instance of the data.

The task divides into two subtasks: imperceptibility and non-specificity (Zheng et al., 2021).

- imperceptibility: this level of abstract words refers to ideas and concepts that are distant from immediate perception; such as culture, economics, and politics.
- non-specificity: In contrast to concrete words, this subtask includes more abstract words which focus on a different type of definition; for example, a concrete word like ‘cow’ could be interpreted as an ‘animal’ which is considered as a more abstract word (Changizi, 2008).

The main challenges of this task are the abstract meaning concept representation as well as the machine reading comprehension. This is the main reason we have utilized contextualized language representation models to tackle abstract meaning representation problems.

In this paper, we use an end-to-end deep contextualized architecture to model this task. This model is also capable of considering more than

one passage as the context, and more than five candidate answers. Since we use the long document transformer model (Longformer (Beltagy et al., 2020)), no limitation is considered in context passage length. We have evaluated this model both on subtask-1 and subtask-2 which resulted in 70% and 64% accuracy, respectively. Therefore, we have about 40% improvement compared to the baseline, which is a Gated Attention (GA) model (Zheng et al., 2021).

The rest of the paper is as follows: Section 2 describes the related works and the background. Section 3 includes the description of the proposed method. Section 4 contains the evaluation metrics used as well as a brief discussion, which is then followed by a conclusion and future works in section 5.

## 2 Background and Related Works

Many approaches have been presented in the literature, from pipeline-based models to end-to-end ones. Each module is also well-investigated from rule-based models to deep learning ones. Despite various configurations presented in the literature to model this problem, most of the systems consist of three modules (Baradaran et al., 2020):

- Language representation: this module is responsible to encode the inputs. Context, question, and answer need to be represented as numeric values for computational algorithms to be usable on them. Dense vectorized representations are the most popular methods, which allow us to use the majority of machine learning algorithms.
- Reasoning: this module is used to find demonstrations of why the answer is assumed to be valid. It can also be used as a limiter for searchable context.
- Prediction: this module aims to generate, retrieve or select the correct answer based on the task description.

Recent studies are provided as follows with respect to these modules that the last two modules have been merged. In the end, the longformer model is presented as our mainstay in this paper.

### 2.1 Word and text representation

One of the most important problems in NLP is representation learning. The earliest models for word

representation in the time of deep learning were the models proposed in (Pennington et al., 2014) and (Mikolov et al., 2013), which utilized the weights learned for an auxiliary task (a simplified version of the task of language modeling) for word representation. Similarly, methods proposed in (Le and Mikolov, 2014) and (Liu et al., 2015) utilized a similar structure for sentence, paragraph, or document representation learning.

While these methods were quite effective, it has been shown that using neural language models as a way of word representation results in much better, and context-aware representations. In (Howard and Ruder, 2018) it has been shown that fine-tuning language models as sentence encoders result in a significant performance improvement. At the same time, (Peters et al., 2018) used language models directly as word representations, which resulted in significant improvements. In (Devlin et al., 2018) a transformer model was trained for the task of masked language models, which resulted in significant improvements, surpassing human performance in many NLP tasks. One of the shortcomings of transformers is the lack of a memory mechanism, which results in (theoretically) lower receptive field compared with LSTMs (Beltagy et al., 2020) this shortcoming was addressed by improving the self attention mechanism in transformers so that it would have a (theoretically) unbounded receptive field. More details are presented later in this section.

### 2.2 Natural language understanding

Natural language understanding (NLU) is an umbrella term, referring to any tasks that require machine comprehension. Compared to other NLP tasks, NLU requires the model to be able to understand and reason about the data (Semaan, 2012). While great progress has been made in this field by using contextual word representation (Devlin et al., 2018), it has been found that designing the model itself must not be neglected (Zhu et al., 2018). On the other hand, it has been shown that utilizing a transfer learning setting to share knowledge between different NLU tasks results in better performance with fewer data and fewer parameters (Pilault et al., 2020), which proves a significant similarity between these tasks.

### 2.3 The Longformer

Deep contextualized language models like BERT (Devlin et al., 2019) have been well investi-

gated in the literature and achieved state-of-the-art results on various tasks. However, these models suffer from performance limitations due to their self-attention layer which results in quadratic space and time complexity concerning the sequence length. In contrast, this model removes the self-attention layer from the base language models, so the limitation resolves and the complexity scales to linear. In order to increase the quality of the model compared to basic models, they have added a global attention layer to the model end which significantly outperforms state-of-the-art models on long document (passage) tasks and competitive on normal documents. Also, this configuration increases the performance on both normal and lengthy inputs which makes it a good alternative for tasks containing large inputs. This model is also evaluated on a similar task on WikiHop dataset(Welbl et al., 2018) and improved the results in terms of accuracy(Beltagy et al., 2020).

### 3 Method

As mentioned in section 1, given a passage, a question, and a set of answers to the question, the goal is to predict the correct answer among the candidates, which can be seen as a benchmark to evaluate how well the model can comprehend the abstract meaning. To do so, we considered an end-to-end deep learning architecture based on the transformer architecture.

Specifically, we used contextual word embeddings based on the transformer to better discover and encode the information contained in the passage. In our model, both subtasks use the same architecture as shown in figure 1, although we did not experiment on the possibility of multi-task learning. The word representation models are fine-tuned on the data for better performance. The fine-tuning procedure could allow us to extract additional, task-related information which could result in better accuracy in the evaluation phase.

To model this problem, let  $c = \{c_1, c_2, \dots, c_I\}$  denote the passage as the context, where  $c_i$  corresponds to the  $i^{th}$  token (word or subword, depending on the tokenization technique used) and  $I$  is the number of tokens in the passage. Similarly, the question is considered as  $q = \{q_1, q_2, \dots, q_K\}$  where  $K$  denotes the length of the question, and  $q_k$  corresponds to the  $k^{th}$  token of the question. Each answer also denotes as  $e^j$  which is only one abstract word ( $j \in \{1, 2, \dots, 5\}$ ). Then we concatenate

the question and the candidates as:

$$a = [q; e^1; e^2; \dots; e^5]. \quad (1)$$

The size of this sequence is  $A = K + 5$  as we have only 5 candidates. Generally, this can be an arbitrary length based on the dataset.

Note that we introduce special tokens to separate the context, the question, and the candidates, similar to (Beltagy et al., 2020). Specifically, we introduce the tokens  $\langle s \rangle$  and  $\langle /s \rangle$  for separating the context,  $\langle q \rangle$  and  $\langle /q \rangle$  for separating the the question, and the tokens  $\langle ent \rangle$  and  $\langle /ent \rangle$  for separating the candidates from each other. In the case of multiple passages, all passages are concatenated to form a single context. These tokens are randomly initialized and fine-tuned.

We used the Longformer model introduced in (Beltagy et al., 2020) as the pre-trained contextual embedding model in our method. Since the context could be too long, we split the context sequence to separate chunks. Each chunk length is equal to maximum sequence length the model could accept appending the sequence  $a$ ; in fact,  $model\_max\_length = len(chunk) + len(a)$ . If  $c^l$  denote each chunk, this sequence could be showed as:

$$b = [c^l; a] \quad (2)$$

where the full context is  $c = \{c^1, c^2, \dots, c^L\}$ , and  $L$  is the last chunk. The size of this sequence is  $B$  so  $B = L + A$ .

After feeding the input  $b$  to the Longformer model, we apply a global attention only on  $a$  (concatenated question and answer candidates), and the rest is the context. As the longformer model utilizes a base model (like RoBERTa without the self-attention layer, in our case), we denote this as *basemodel* function that outputs the encoded sequence of the input. If  $GAttn$  denotes the global attention function, we have:

$$d_i = basemodel(b) \quad (3)$$

$$g_i = GAttn(d_i).1(i \in A) \quad (4)$$

where  $d_i$  is the raw output vector for each input token. The global attention function is applied if it is a question or answer candidate token. Then, we extract the outputs corresponding to the question and the candidates tokens, i.e. we have:

$$h_j = GAttn(a, c^l) \quad (5)$$

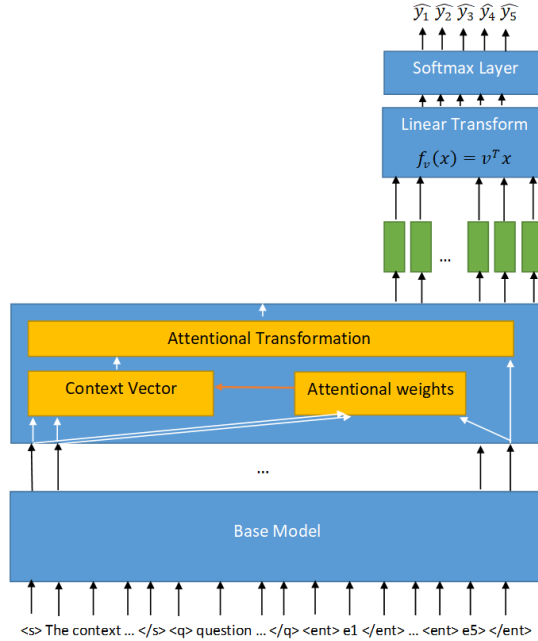

Figure 1: The model architecture. The concatenated input vector will be encoded using the base model (like RoBERTa without the self-attention layer, in our case). A global attention(Luong et al., 2015) will be applied to the question and the candidate answers representations with respect to the passage as the context. The logit (score) of each ent token will be calculated using a linear transformation function, then the prediction distribution over the answer candidates (ent tokens) will be outputted using a softmax layer.

Finally, we obtain the logit of each candidate (<ent> tokens) as  $x_j$  ( $x_j = h_j$  if  $j$  correspond to a candidate), average over different chunks, and apply a linear transformation:

$$f_j = v^T x_j \quad (6)$$

where the vector  $v$  is trainable, and  $f_j$  is the score of each candidate. And the probability distribution over the candidates will be calculated using a softmax layer on the logits. The predicted answer is the argmax of the softmax output. we fine-tuned the model using the cross-entropy loss.

## 4 Evaluation

Although we only participated in the second subtask, we will evaluate our model on both subtasks here. We will explain our configurations for utilizing the model on the task as well as other baselines which are the BERT-base as an alternative model and the Gate-Attention (GA) as our task baseline. Finally, a brief discussion will be done based on the results.

### 4.1 Metrics

Popular metrics to evaluate these models are F1, EM (Exact Match or accuracy), and MRR (Mean

Reciprocal Rank). As the precision and recall in our task are equal, so  $F1 = \text{Precision} = \text{Recall}$ . Also, F1 and EM are the same. And, the use of MRR is optional, so the metrics used to evaluate the result are the accuracy and the F1.

### 4.2 Baseline configuration

The baseline model (GA) is trained for 30 epochs, each epoch containing 101 mini-batches. The train batch size is set to 32. Dropout with the rate of 0.5 is also applied to the hidden states, and the learning rate is set to 0.001. The dimensionality of the GloVe embedding is 300, and the hidden size is set to 128. Training and evaluation take about 2 hours on a single v100 GPU.

### 4.3 BERT configuration

We use the same configuration as our method except for the global attention mechanism. In fact, we consider the output vector of each chunk as our final vector to be linearly transformed into single logit, followed by a softmax layer using the cross-entropy loss. Similarly, the logit is averaged over different chunks, before applying the linear transformation. Note that the maximum sequence length here is bounded to 512 tokens, and the model includes the  $n^2$  attention mechanism. We use the

Metrics	Baseline(GA)	BERT	Our Method
Accuracy	23.01%	63.43%	<b>70.30%</b>
Macro Avg F1	22.83%	63.38%	<b>70.23%</b>
Weighted Avg F1	22.76%	63.40%	<b>70.27%</b>

Table 2: Subtask1 evaluation metrics on the test set

Metrics	Baseline(GA)	BERT	Our Method
Accuracy	22.95%	58.76%	<b>64.38%</b>
Macro Avg F1	22.42%	58.72%	<b>64.35%</b>
Weighted Avg F1	22.45%	58.75%	<b>64.40%</b>

Table 3: Subtask-2 evaluation metrics on the test set

base version of the model and fine-tuned it on each subtask.

#### 4.4 Our method configuration

We used the same model introduced in section 3 for both subtasks. The model was initialized using the Longformer-base pre-training weights, then fine-tuned in each of the subtasks. Due to the performance issues, the model max sequence length is set to 4096 tokens which are sufficient in our case. We also used the RoBERTa-large tokenizer to tokenize the input sequence as the Longformer model has been trained on using this configuration. We used a batch size of 32 and a maximum learning rate of  $3e-5$  using the Adam optimizer with  $\beta_2=0.98$ . We then assumed the validation check interval to 250 which indicates the number of gradient updates between checking validation loss. And a weight decay of 0.01 has been considered to regularize the model and avoid overfitting.

Our proposed model is trained for 15 epochs for each task. Fine-tuning the model takes about six hours, and inference takes about nine seconds for each sample on a single V100 GPU.

#### 4.5 Evaluation od Subtask 1

Subtask1 measures imperceptibility abstract level of language understanding. This subtask includes 3227 training samples, 837 validation samples, and 2025 test samples. The size of the biggest sample in terms of context length is about 2000 tokens. We have achieved an accuracy of 70% on the validation set, which improves our baseline by about 40 percent. Table 2 showed the results of this subtask.

#### 4.6 Evaluation on Subtask 2

Subtask2 measures the non-specificity level of abstract meaning in reading comprehension. It in-

cludes 3318 training samples, 851 validation samples, and 2017 test samples. The best accuracy on the validation set is 64%. Table 3 showed the results of this subtask.

#### 4.7 Discussion

We used two baselines to find out the effect of using a pre-trained model rather than a simple RNN model. Although this task offers a higher level of representation, using the pre-train models is helpful, and there is a higher chance of modeling such abstract concepts.

The results on subtask2 are weaker than subtask1 in pre-trained models. This can be the consequence of limited semantic representation for abstract word which indicates the subtask2 includes more abstract words in terms of abstract level; for example, the word 'animal' could be matched to any animal, like 'cat' or 'dog', but the word 'entity' is hard to be represented as it could be matched to a large number of words. And the model faces a limitation in the knowledge representation. Another assumption could be the data enrichment that these model has been trained on. As most of the available texts for training consist of concrete words, it is more likely to leverage the language understanding to less abstract words to achieve a better result.

Comparing our method which is based on longformer model to usual language models like BERT indicates a new insight in terms of passage length and the attention mechanism. Popular language models like BERT and RoBERTa use a  $n^2$  attention which requires a large receptive field to represent long passages. This results in the performance limitation which bounds the input sequence up to 512 tokens. In contrast, the longformer global attention mechanism relaxes this limitation as we only need to pay attention to a small factor of context

and more focus on the local window. So the receptive field will not overflow and saves the necessary information to better represent the language.

We have analyzed the errors that mostly affect our model performance. We think that the problem is the contextual representation of the language modeling, which is not well-suited in our method i.e. concatenating the context, question, and answer. The main disadvantage of concatenating the candidate answers to each other is the missing fine contextual representation as the state-of-the-art models consume the position embedding. Additionally, incorrect candidates register additional noise to each word representation as well as the placeholder in the question.

## 5 Conclusion and Future works

We have shown how different approaches can be leveraged to machine reading comprehension of abstract meaning. We reformulated the longformer model to learn abstract meaning as a new level of semantic in machine reading comprehension. This method can also be improved by taking advantage of external knowledge and task-specific model architectures that optimize the current baseline.

# IITK@Detox at SemEval-2021 Task 5: Semi-Supervised Learning and Dice Loss for Toxic Spans Detection

Archit Bansal    Abhay Kaushik    Ashutosh Modi

Indian Institute of Technology Kanpur (IIT Kanpur)

{architb, kabhay}@iitk.ac.in

ashutoshm@cse.iitk.ac.in

## Abstract

In this work, we present our approach and findings for SemEval-2021 Task 5 - Toxic Spans Detection. The task’s main aim was to identify spans to which a given text’s toxicity could be attributed. The task is challenging mainly due to two constraints: the small training dataset and imbalanced class distribution. Our paper investigates two techniques, semi-supervised learning and learning with Self-Adjusting Dice Loss, for tackling these challenges. Our submitted system (ranked ninth on the leader board) consisted of an ensemble of various pre-trained Transformer Language Models trained using either of the above-proposed techniques.

## 1 Introduction

Content moderation has become the topic of most conversations regarding social media platforms. However, with over 4 billion active internet users, it is impossible to moderate each piece of message generated online manually. Therefore, the focus is now shifting towards tackling the issue using machine learning methods.

Various toxicity detection datasets (Wulczyn et al., 2017; Borkan et al., 2019) and models (Pavlopoulos et al., 2017; Liu et al., 2019; Seganti et al., 2019) have been successfully developed over the years to tackle the issue of moderation. However, these have mostly focused on identifying whole comments or documents as either toxic or not. In semi-automated settings, a model merely generating a toxicity score for each comment, some of which can be very lengthy, is not of much help to human moderators. To tackle this issue, the *SemEval 2021 Task 5 : Toxic Spans Detection* is introduced (Pavlopoulos et al., 2021). The task involves identifying text spans in a given toxic post that contributes towards the toxicity of that post. The task aims to promote the development of a system that

would augment human moderators by giving them more insights into what actually contributes to the text’s toxicity.

The task is challenging mainly due to the following reasons: a) small size of the dataset b) characteristics of text samples extracted from social media leading to difficulties such as out-of-vocabulary words and ungrammatical sentences c) class imbalance in the dataset d) inconsistencies in data annotations. We approached this task as a sub-token level sequence labeling task. Fine-tuned pre-trained transformer language models (Qiu et al., 2020) are the backbone of all our approaches. We investigated two main techniques to enhance the results of the fine-tuned transformer models, namely Semi-Supervised Learning (Yarowsky, 1995; Liu et al., 2011) and fine-tuning with Self-Adjusting Dice Loss (Li et al., 2020). This paper reports the results of our experiments with these different techniques and pre-trained transformer models. Our submitted system consisted of an ensemble of different pre-trained transformer models and achieved an F1 score of 0.6895 on the test set and secured 9th position on the task leaderboard. All of our code is made publicly available on Github<sup>1</sup>.

The rest of this paper is organized as follows. Section 2 discusses the previous works in the fields of offensive language detection and span identification. Section 3 describes the dataset. Section 4 explains the proposed approaches. Section 5 reports the results of various experiments with the proposed approaches, and section 6 analyzes the proposed approaches via ablation studies. We conclude with an error analysis of our model performance in section 7 and concluding remarks in section 8.

<sup>1</sup>[https://github.com/architb1703/Toxic\\_Span](https://github.com/architb1703/Toxic_Span)

## 2 Related Work

As the task involves detecting toxic spans in a text, we present the related work in two parts: (i) Offensive Language Detection and (ii) Span Identification.

**Offensive Language Detection:** Research work has been done on different abusive and offensive language identification problems, ranging from aggression (Kumar et al., 2018) to hate speech (Davidson et al., 2017), toxic comments (Saif et al., 2018), and offensive language (Laud et al., 2020; Pitsilis et al., 2018). Recent contributions to offensive language detection came from the SemEval-2019 Task 6 OffensEval (Zampieri et al., 2019). The task organizers concluded that most top-performing teams either used BERT (Liu et al., 2019) or an ensemble model to achieve SOTA results. Interestingly, the task of locating toxic spans is relatively novel, and its successful completion can be groundbreaking. A recent approach with a narrower scope is by Mathew et al. (2020), who focused on the rationality of decision in the task of hate speech detection.

**Span Identification:** Span detection/identification tasks include numerous tasks like named entity recognition (NER) (Nadeau and Sekine, 2007), chunking (Sang and Buchholz, 2000) and keyphrase detection (Augenstein et al., 2017). (Papay et al., 2020) analyzed the span identification tasks via performance prediction over various neural architectures and showed that the presence of BERT component in the model is the highest positive predictor for these tasks. Inspired by this observation, we have built our model based on the transformer architecture, further exploiting the benefits of semi-supervised learning and modified Dice Loss.

## 3 Dataset

### 3.1 Data Description

The competition dataset comprises around 10K comments extracted from the Civil Comments Dataset and annotated using crowd-raters. The organizers released the dataset in 3 phases: trial, train, and test. The trial dataset consisted of 690 texts, whereas the training dataset consisted of 7939 texts. Moreover, the test set on which our system was finally evaluated consisted of 2000 text samples.

In the initial stages of the competition, we decided to use only the training dataset to build upon

our approaches. We further split the training set into train, dev, and test sets for evaluation purposes using an 80:10:10 split (Div A). Once we tested and finalized our approaches, we combined the train and test set of Div A with the trial set as our final training set (Div B). Due to the small size of the dataset, these additions to the training set of Div A will positively impact the model performance. However, to ensure that we could compare our final models with our previous results, we transfer the dev set directly to Div B. Further details regarding the constitution of these splits is provided in the Appendix A.

### 3.2 Pre-processing

**Tokenization:** For the sake of preserving the token spans, we first tokenized our data and then performed data cleaning. For tokenizing, we used the NLTK TreebankWord Tokenizer<sup>2</sup>, which is a rule-based tokenizer that tokenizes text on spaces and punctuation, hence preserving the original form of the words.

**Data Cleaning:** We then cleaned each token using different operations such as expanding contractions and removing digits and full stops.

## 4 Proposed Approach

### 4.1 Methodology

Pre-trained transformer models built using the transformer architecture (Vaswani et al., 2017) have been able to achieve, via transfer learning techniques, SOTA performance for most NLP tasks in recent times. We fine-tuned pre-trained transformer models with linear classifier head for performing sequence labeling for this task, which meant performing subtoken-level classification (Fig. 1a). Our baseline model used the pre-trained BERT-Base-Cased model, fine-tuned with cross-entropy loss and AdamW optimizer. The different hyperparameter values used for training the baseline and all subsequent models are reported in the Appendix B to facilitate replication of results. Subsequently, we improved upon this baseline using two techniques, semi-supervised learning and Self Adjusting Dice Loss. Along with this, we fine-tuned multiple different transformer models like BERT (Devlin et al., 2019), Electra (Clark et al., 2020), DistilBERT (Sanh et al., 2020), and XLNet (Yang et al.,

<sup>2</sup>[https://www.nltk.org/\\_modules/nltk/tokenize/treebank.html](https://www.nltk.org/_modules/nltk/tokenize/treebank.html)

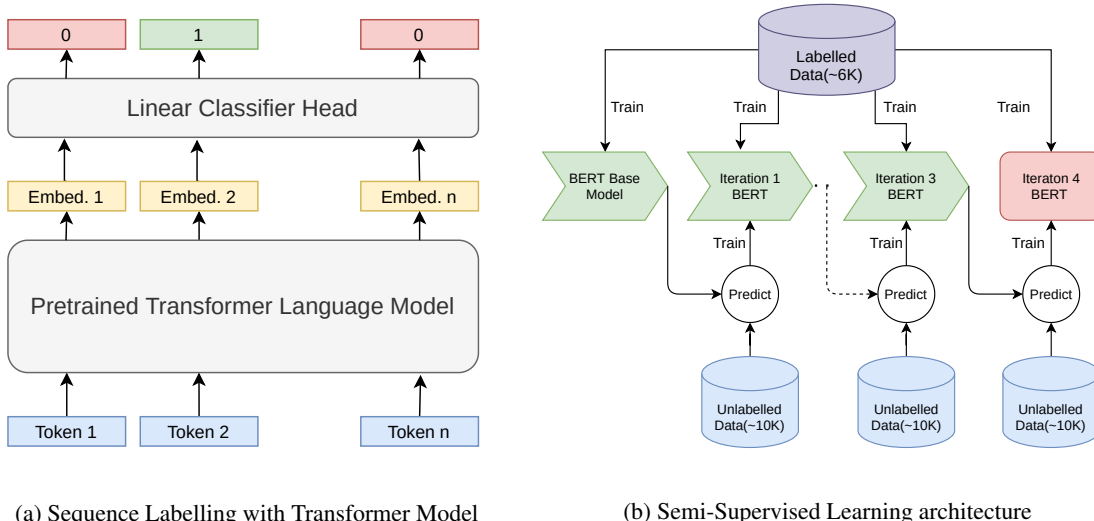

Figure 1: Model architectures

2020) for our Dice-Loss Approach and found differences in the predictions of the different transformer models to be beneficial for the final ensemble.

**Self Adjusting Dice Loss** One of the main issues with our dataset was that of class imbalance. For the sub-tokens derived from the BERT-Base-Cased tokenizer, the ratio of toxic to non-toxic sub-tokens was 1:10.16. However, we could not tackle this issue with over/under-sampling due to the nature of our problem, and training with a weighted cross-entropy loss function did not improve results. Therefore, we experimented with training with the Self-Adjusting Dice Loss (Li et al., 2020) which was proposed as an objective function for dealing with imbalanced datasets in NLP. The original dice coefficient is an F1-oriented statistic used to gauge the similarity of two sets. The paper proposed a loss function based on a modified dice coefficient, which they reported to achieve a better F1 score than models trained with cross-entropy loss.

$$DL = 1 - \frac{2(1 - p_{i1})^\alpha (p_{i1}) \cdot y_{i1} + \gamma}{(1 - p_{i1})^\alpha (p_{i1}) + y_{i1} + \gamma}$$

Here, for the  $i_{th}$  training instance,  $p_{i1}$  is the predicted probability of positive class and  $y_{i1}$  is the ground truth label. The loss function also has two hyperparameters, alpha and gamma, which we tuned for our models.

**Semi-Supervised Learning** The Civil Comments Dataset from which our training data was extracted consists of over 1 million comments; however, due to annotation constraints, the training set only had 7000 data samples. (Shams, 2014)

have shown that for text classification tasks, unlabelled data from a suitable data source could be used to train semi-supervised models that achieve better results than a model trained using supervised learning. Also, (Jurkiewicz et al., 2020) showed that the semi-supervised learning technique of self-training could improve performance on span identification tasks. Hence, we extracted 40000 toxic samples from the Civil Comments Dataset, which were labeled with a toxicity score of 0.7 or higher, and used these to perform four iterations of semi-supervised model training (Fig. 1b). We exhaustively divided the unlabelled samples into four batches of 10000 each and used each batch for exactly one iteration. As shown in Fig. 1b, for each iteration, pseudo labels were predicted for the complete batch using the model trained in the previous iteration, then these pseudo-labels along with the ground truth training labels were used to train the next model. For this approach, we only fine-tuned one transformer model, namely the pre-trained BERT-Base-Cased model.

## 4.2 Post-preprocessing

After obtaining the sub-token level labels from our model, we post-processed the results to convert them into an array of toxic character offsets. To perform this, we had mapped each sub-token to its offset span during tokenization and used that to retrieve the offsets of all the characters in the toxic sub-tokens. We also include all characters lying between two consecutive sub-tokens if both the sub-tokens are marked toxic. This was necessary

as spaces and punctuation were included in the toxic spans given by the annotators, as shown by the results in section 6.

## 5 Experiments and Results

The competition used the span level F1 score, calculated individually for each text sample from its character offsets and averaged over all the text samples, as the metric to evaluate system performance. We decided to use this metric for hyperparameter tuning and reporting the final results. However, during the training process, the models were checked for overfitting using the token level F1 score, which was also a good indicator of model performance as our training approach was that of a sequence labeling task.

The first set of experiments we performed were on the Div-A dataset. Our baseline model achieved an F1 score of 0.669 on the dev split on this set. The organizers also released a baseline model, consisting of a Spacy statistical model trained on the competition training dataset and evaluated on the competition trial dataset. The organizer’s baseline achieved an F1 score of 0.600 on the trial dataset. This score was significantly lower than that of our baseline model, and therefore we use our baseline model only to compare the performance of our subsequent models.

We then fine-tuned a BERT-Base-Cased model with the Self-Adjusting Dice Loss and AdamW optimizer and tuned the loss function’s two hyperparameters. The scores we obtained for the different hyperparameter values are reported in Table 9 in Appendix C. We got our best performing model with the hyperparameter values alpha-0.7 and gamma-0.25, achieving an F1 score of 0.6725 on the dev split.

Model	Dev F1 Score
BERT-Base-Cased	0.669
SSL Iteration-1	0.6837
SSL Iteration-2	0.6842
SSL Iteration-3	0.6882
SSI Iteration-4	<b>0.6893</b>

Table 1: Results for Semi-Supervised learning model

Next, we trained the BERT-Base-Cased model on the semi-supervised learning paradigm with cross-entropy loss and AdamW optimizer. For the first iteration, we used our baseline model to compute the pseudo labels. The model achieved

improved results with each iteration (Table 1), and our final model was scoring 0.6893 on the dev split.

To end this stage of experimentation, we computed the results on the test split of the Div-A dataset. We were able to make two inferences. Firstly the semi-supervised learning model had the best performance with an F1 score of 0.6774 on the test set but had a significantly worse score than it had on the dev set. Secondly, the dice loss trained model performed significantly better than the cross-entropy trained baseline with an F1 score of 0.662 compared to 0.648.

After this, we changed to the Div-B dataset and trained multiple different transformer models with the Self Adjusting Dice Loss. We found that the BERT-Base-Cased, Electra-Small, Electra-Base, and DistilBert-Base-Uncased models had peak performance for the hyperparameter values alpha-0.7 and gamma-0.25. However, for the XLNet-Base model, peak performance was achieved for alpha-0.4 and gamma-0.25. On further experimentation with these models, we also found that adding a full stop to the text samples during evaluation provided consistently better results on the dev set. The results obtained have been reported in Table 2.

Model	WFS	FS
BERT-Base-Cased	0.6754	0.6827
Electra-Small	0.6813	0.6861
Electra-Base	0.6776	0.6846
DistilBERT-Base-Unc.	0.6749	0.6773
XLNet-Base	0.6798	0.6852
SSI Iteration-4	0.6893	0.6932

Table 2: Effect of full stop on dev set during evaluation. Here WFS and FS represent without full stop and with full stop resp.

The final results of models trained either on modified Dice Loss or using Semi-Supervised learning, with full stop added during evaluation, are reported on the Div-B dev split and the competition test set in Table 3.

## 6 Ablation Study

After the competition, we wanted to study the effect of our different preprocessing and postprocessing techniques. We employ three main data cleaning techniques during our preprocessing, expanding contractions, removing numbers, and removing full stops. To study each particular technique’s impact, we created three new Div-B datasets, each having

	Model	Dev	Test
1	BERT-Base-Cased*	0.6827	0.668
2	Electra-Small*	0.6861	0.6771
3	Electra-Base*	0.6846	0.6720
4	DistilBERT-Base-Unc.*	0.6773	0.6822
5	XLNet-Base*	0.6852	0.6757
6	SSI Iteration-4	0.6932	0.672
	Ensemble (1,2,3,4,5,6)	0.6927	<b>0.6895</b>

Table 3: F1 Score on dev and competition test set  
\* - Models trained with modified Dice Loss

one of the preprocessing techniques missing. We then trained BERT-Base-Cased and Electra-Small models with Self Adjusting Dice Loss on each of these sets and evaluated the performance on their respective dev sets. The results are reported in Table 4 with the following acronyms:

- **TD** - All preprocessing steps used
- **WNUM** - Without removing numbers
- **WFS** - Without removing fullstops
- **WCON** - Without expanding contractions

Dataset	BERT-Base-Cased	Electra-Small
TD	0.6754	0.6813
WNUM	<b>0.6781</b>	0.6809
WFS	0.6713	0.6743
WCON	0.671	<b>0.6829</b>

Table 4: F1 Score for different preprocessing techniques on dev set

The results show that removing numbers and expanding contractions both had contrasting effects on the two models. This shows that we could have yielded better results by trying different preprocessing techniques for the different transformer models. Apart from that, we see that the most positive effect on model performance came from removing full stops from the training data in both cases.

We also wanted to see the effect of our post-processing step. For that, we compared the performance of the BERT-Base-Cased model on the Div-B dev split. As expected, the results showed minor improvement due to our postprocessing as the score increased from 0.6748 to 0.6754.

## 7 Error Analysis

The results we have obtained have brought to light some problems that need to be resolved. First of all, the data annotations have many issues, leading to a lower F1 score even though the predicted

Example Set	Val	Test
E.S Val:41 Test:394	0.0731	0.0380
N.E.S Val:753 Test:1606)	0.7265	0.8493
All Val:794 Test :2000	0.6927	0.6895

Table 5: System performance over empty span (E.S) and non-empty span(N.E.S) examples over Div-B split

toxic spans are more appropriate in many cases. We have included some examples in Appendix D. In some cases, the annotations are not uniform in what toxicity label they assign to the same word over different text samples. We have also observed that complete sentences were marked as toxic just because of the presence of a few toxic words in them. These irregularities in the annotations make it difficult for the model to generalize on the data.

Besides the incorrect annotations, we further try to analyze the type of mistakes our system is making. The dataset contains numerous examples where no toxic spans are annotated. Such a case arose when the annotators had difficulty in attributing toxicity to a particular span. Investigating our model performance shows that our model highly under-performs on such examples. Table 5 depicts the drastic difference in the performance of the system over empty span examples (E.S) and non-empty span examples (N.E.S). Upon closely following E.S examples, we discovered that annotations of such examples carry more subjectivity than the others. In such cases, our model usually labels the word with the most negative sentiment as toxic and thus performs poorly.

In addition to the empty span examples, we also discover that our model fails to capture the full context in some cases. For e.g., in the phrase “no more Chinese,” our model only predicts the word Chinese as toxic, whereas the complete phrase attributes to the toxicity of the sentence. Another problem is our model’s inconsistency in labeling the corresponding noun and adjective pairs in a sentence. However, similar types of inconsistencies were also found in the annotations and are therefore difficult to avoid [Appendix D].

## 8 Conclusion

The task of detecting toxic spans in the text is a novel one, and there is no doubt about how impor-

tant a model trained successfully for this task can turn out to be for online content moderation. However, the data gathered from online platforms tend to be noisy and corrupted. Coupled with the limitations of generating large-scale annotated datasets in real life, they pose two daunting challenges. In conclusion, our final submission shows that transfer learning through pre-trained transformer models can achieve competitive results for this task. Using modified loss functions and semi-supervised learning, even more can be extracted from limited annotated data. Moreover, considering the subjectivity involved in span detection, the task can also be expanded to report severity scores of spans and classify the type of toxicity. This will further help simplify and rationalize online content moderation.

## Appendix

### A Dataset

We worked on two different splits of the data across different stages of competition. Table 6 represent the no. of examples in train, val and test across Div-A and Div-B split.

	Div-A	Div-B
Train	6351	7835
Dev	794	794
Test	794	2000
Total	7939	10629

Table 6: Distribution of examples across Div-A and Div-B split

Div-A is basically a 80:10:10 split of the training data released by the organisers whereas Div-B split uses the train and test set of Div-A along with competition trial data as its training set. Div-B uses the official test set as its test set while keeping the dev set same as that of Div-A.

### B Model Training

In this section, we provide the hyperparameter values we used while training our final models to facilitate the replication of our results at a later time. The acronyms correspond to:

- **LR** : Learning Rate
- **ML** : Max Len
- **LC** : Data Lowercase
- **DL** : Dice Loss (Alpha, Gamma)

Hyperpara.	BERT-Base-Cased	Electra
LR	1E-5	3E-5
ML	500	500
LC	False	True
DL	0.7,0.25	0.7,0.25

Table 7: Hyperparameter Values for BERT-Base-Cased and Electra (Small and Base)

For baseline model and semi-supervised learning model, the cross-entropy loss function provided in PyTorch was used with default hyperparameters. For AdamW optimizer, we used weight decay rate of 0.01 for all model parameters apart from the bias, gamma and beta terms, for which we used 0 weight decay.

Hyperpara.	Distil-Base-Unc.	XLNet-Base
LR	1E-5	3E-5
ML	500	400
LC	True	False
DL	0.7,0.25	0.4,0.25

Table 8: Hyperparameter Values for Distil-Base-Unc. and XLNet-Base

## C Results

### C.1 Dice Loss Results

In this section, we report the results of our hyperparameter tuning for training with Self Adjusting Dice Loss. The result reported are for BERT-Base-Cased model on the Div-A dataset.

Parameter Values	Dev F1 Score
Alpha-0, Gamma-1	0.665
Alpha-0, Gamma-2	0.657
Alpha-0.5 Gamma-1	0.652
Alpha-0.7, Gamma-1	0.671
Alpha-0.8, Gamma-1	0.668
Alpha-0.7, Gamma-0.5	0.6723
Alpha-0.7, Gamma-0.25	<b>0.6725</b>

Table 9: BERT-Base-Cased trained with Self Adjusting Dice Loss on Div-A train split

## D Error Analysis

We manually crawled through a part of dataset and found several inadequate annotations as described through table 11. Apart from erroneous annotations, we also found some examples of inconsistency in the structure of annotations. Table 10 outlines a few such pairs where different strategies are used for annotating similar texts. These examples highlight the inconsistencies in labelling of corresponding noun-adjective pairs.

Text	Ground Truth
You are an idiot	['idiot']
You are truly witless	All tokens
F***ing moron ....	['F***ing']
Fucking moron needs...	['Fucking', 'moron']
Hilary is a liar...	All tokens
Trump is an idiot.	['idiot']

Table 10: Irregularity in annotation for similar text-samples.

Text	Ground Truth	Suggested
I have no doubt it was Photoshopped(by an idiot, for an idiot)	['idiot']	['idiot', 'idiot']
She's a Marxist twit.	['Marxist']	['Marxist', 'twit' ]
Move to Russia and be a fascist pig all you want.	All tokens	['fascist', 'pig']
lame. really really lame and cheap shot. pathetic actually.	['lame', 'lame', 'actually']	['lame', 'lame', 'pathetic']
So "f*** you all", "kiss my a—" and ...	['f***']	['f***', 'a-']
You are just a stick buthole!	[]	['stick', 'buthole']

## Abstract

With the ever-increasing availability of digital information, toxic content is also on the rise. Therefore, the detection of this type of language is of paramount importance. We tackle this problem utilizing a combination of a state-of-the-art pre-trained language model (CharacterBERT) and a traditional bag-of-words technique. Since the content is full of toxic words that have not been written according to their dictionary spelling, attendance to individual characters is crucial. Therefore, we use CharacterBERT to extract features based on the word characters. It consists of a Character-CNN module that learns character embeddings from the context. These are, then, fed into the well-known BERT architecture. The bag-of-words method, on the other hand, further improves upon that by making sure that some frequently used toxic words get labeled accordingly. With a  $\sim 4$  percent difference from the first team, our system ranked 36<sup>th</sup> in the competition. The code is available for further research and reproduction of the results<sup>1</sup>.

## 1 Introduction

The user generated digital content is increasing rapidly every second of the day. This can include some toxic language whose detection can be difficult due to the complexities of human languages. We address this problem by participating in SemEval Workshop 2021 Task 5 (Pavlopoulos et al., 2021).

In many cases, the data, which are considered to be toxic, contain words that have not been written in their standard forms. There might also be a lot of misspelling or letter replacements. In addition, usually the words that are considered to be the most offensive are bleeped which makes them difficult to be recognized if we use a model which learns the

content representation based on the words. Apart from word related issues, the context also plays a crucial role in the meaning that a word conveys since words in different contexts can have various meanings.

Therefore, in order to cope with these issues, we opt for a recently pre-trained language model which has been trained on character level. CharacterBERT (El Boukkouri et al., 2020) is a deep neural network model that has been pre-trained on Wikipedia and OpenWebText (Gokaslan and Cohen) corpora using the BERT architecture (Devlin et al., 2019) with an addition of a character-aware Convolutional Neural Network (CNN) (Kim et al., 2016; Peters et al., 2018). BERT-based models have now become pervasive in many different natural language processing tasks such as reading comprehension (Xu et al., 2019), named entity recognition (Liang et al., 2020), sentiment analysis (Karimi et al., 2020), and language understanding (Jiao et al., 2020) as well as similar ones to toxic language detection such as propaganda detection (Jurkiewicz et al., 2020). While the BERT model is beneficial in extracting the contextual information from the text on the word level, the character-aware CNN attends to the individual letters which helps in dealing with out-of-vocabulary, unknown and rare words.

In addition to using a deep language model for detecting toxic language, we employ a very simple Bag-of-Words model that can achieve a close performance to that of the deep model. By building a dictionary of toxic words from the training data and by taking into account their frequency and ratio of toxicity, we come up with a simple model that performs as closely as about 2 percent difference in performance to the deep model’s result. Moreover, we improve the results of CharacterBERT by combining it with the output of a version of the Bag-of-Words model.

<sup>1</sup><https://github.com/IMPLabUniPr/UniParma-at-semeval-2021-task-5>

spans	text
[8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39]	Another violent and aggressive immigrant killing a innocent and intelligent US Citizen.... Sarcasm
[0, 1, 2, 3]	Damn, a whole family. Sad indeed.
[7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17]	What a knucklehead. How can anyone not know this would be offensive??

Table 1: Three examples from the training set

## 2 System Description

Our system consists of four main stages namely, pre-processing, applying CharacterBERT, applying Bag-of-Words model, and finally combining the results of the two models. We describe each of these stages in the following subsections.

### 2.1 Pre-processing

The training dataset consists of rows of various lengths and an array of character spans indicating their toxic parts. Each row can contain several sentences. Table 1 shows three examples of the training data.

We approach the task of toxic spans detection as a sequence labelling task where each word of the input row is classified into one of the predefined classes. We define three classes of {B, I, O}, meaning that each word can be the first word (B) of a set of continuous toxic words, in between (I), or not toxic (O). Therefore, in order for both of our models to be able to process these inputs, we first need to break the rows into words and label them as one of the above-mentioned classes. This was carried out by simply splitting each input row at the *space* characters. Then, after creating a dataset that has been labeled on the word level, we can use it as the input of our models. The same is done for the Bag-of-Words model with a difference in treating the bleeped words which is described in Subsection 2.3.

### 2.2 CharacterBERT

CharacterBERT model is almost identical to the well-known BERT model with a difference in initial embedding. In the general BERT model, words are broken into pieces and the embeddings for these word pieces are computed. In CharacterBERT, however, words are divided into letters or characters. Then, using CNN modules the embeddings are computed on the character level (Figure 1). This makes the network extract features on the

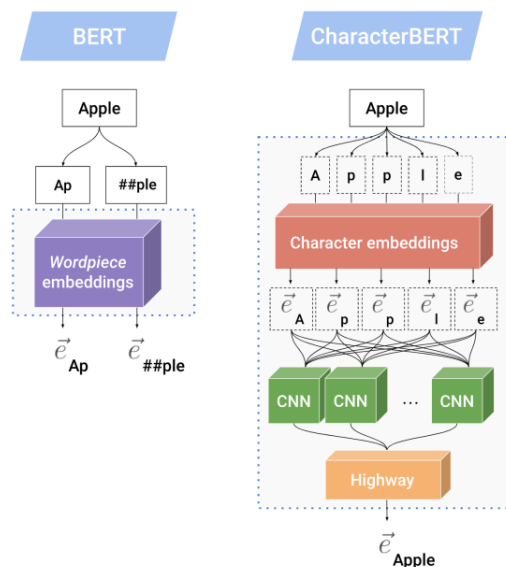

Figure 1: The difference between the BERT and CharacterBERT models is the way they compute the initial embeddings. The former uses word-piece embeddings while the latter uses character embeddings. Figure taken from El Boukkouri et al. (2020).

lowest level, making it suitable for contexts which contain many unseen vocabulary terms such as misspelled words or technical jargon. After the initial character-aware CNN layer, there is the BERT<sub>base</sub> architecture which contains 12 layers (blocks) of Transformer (Vaswani et al., 2017) with the hidden size of 768 and 12 attention heads. The final layer representations are converted into logits using a fully connected layer after which a Softmax layer is applied to extract the token’s (word’s) class.

### 2.3 Bag-of-Words Model

This model is a simple script of fewer than 80 lines of code. However, its performance on the Toxic Spans Detection task can get very close to the CharacterBERT model which has millions of parameters. In this model, by examining the training set, we first build a dictionary of toxic words with their frequency. Table 2 presents the top ten words of

Figure 2: Performance of the Bag-of-Words model on validation set. The frequencies and ratios are the minimum thresholds that specify whether or not to consider a word toxic.

Word	Frequency
stupid	973
idiot	557
idiots	353
stupidity	223
ignorant	190
dumb	157
moron	147
fool	141
pathetic	138
crap	121

Table 2: Top 10 toxic words in the training set

this dictionary in terms of frequency.

Then, we locate the words from the toxic dictionary in each sentence of the test set. If the word is found and its frequency as well as its toxicity ratio in the training set are higher than certain values, it is labeled as toxic. This ratio which we call *toxicity ratio* (defined below) along with the *term frequency* are the only parameters of the Bag-of-Words model.

$$\text{toxicity ratio} = \frac{\text{labeled as toxic frequency}}{\text{total frequency}}$$

The test dataset also contains words that are bleeped. Since these words can be considered toxic with a high certainty (otherwise they would not be bleeped), we extract them separately from the test set and label them directly as toxic.

## 2.4 Combining the Two Models

In order to get the improved version of the toxic language labeling, the union of the spans detected by

the bag-of-words model and that of CharacterBERT is taken. The results will improve if there are words labeled correctly with the Bag-of-Words model that are not in the output for CharacterBERT. This can be achieved by specifying a high toxicity ratio for a word to be labeled as toxic. Also, the wrongly labeled tokens should not be too many since it can have a negative effect on the F1 score. Therefore, the frequency with which a toxic word appears should be somewhat high. Striking a balance between these two parameters can help improve the output of CharacterBERT.

## 3 Experiments and Results

### 3.1 Performance of CharacterBERT

We ran the experiments for the general domain CharacterBERT with its default setting on a GPU (GeForce RTX 2070) which had 8GB of memory. We specified batch sizes of 4 for both training and testing and fine-tuned it on the toxic data only for one epoch which produces an F1 score of 65.13. It is worth noting that more training did not improve the performance.

### 3.2 Analysis of the Bag-of-Words model

In order to experiment with the Bag-of-Words model, we divide the original training set into a resized training set with 7000 sentences and a validation set with 939 sentences which were taken from the end of the original training set. Then, we find the best parameters on the validation set and using those parameters on the test data, we get a performance of almost 63 percent which is only 2 percent smaller than our deep model. Figure 2

Model	F1
CharacterBERT	65.13
BoW (v1)	51.75
BoW with best parameters (v2)	62.79
CharacterBERT + BoW (v2)	65.87
<b>CharacterBERT + BoW (v1)</b>	<b>66.72</b>

Table 3: Comparing results of the proposed models. The boldfaced one is the submitted version. BoW: Bag-of-Words model.

Word	Frequency	Toxicity Ratio
stupid	973	0.78
idiot	557	0.84
idiots	353	0.81
stupidity	223	0.77
moron	147	0.71
idiotic	98	0.74
hypocrite	75	0.88
shit	56	0.72
scum	52	0.70
hypocrites	44	0.76

Table 4: Words selected as the toxic words with minimum frequency of 40 and minimum toxicity ratio of 0.7 (BoW (v1))

shows this model’s performance for its two parameters on the validation set. One parameter represents the *minimum* frequency with which a toxic word appears in the resized training set and the other one is its *minimum* toxicity ratio in the resized training data.

We can see from Figure 2 that the best results are achieved when the minimum frequency is 20 and the minimum ratio is 0.3 or 0.4. Since a larger ratio can be a sign of more toxicity, we choose 0.4 as the ratio and a frequency of 20 as the thresholds with which we apply the model on the test set. This gives an F1 score of 62.79 percent (Table 3) which is not that much below the result of the deep model.

We can also see from Table 3 that although combining the output of the Bag-of-Words model with that of CharacterBERT improves the results a little bit, it is still is not as significant as the first version. In the first version of the Bag-of-Words model, which was found during our primary experiments, the minimum word frequency is 40 and the minimum toxicity ratio is 0.7. With these parameters, only 10 words are selected from the training set. The frequency and toxicity ratio of these words can be seen in Table 4.

Figure 3: Heatmap of the results (F1 scores) with different values of term frequency and toxicity ratio before combining with CharacterBERT

Figure 4: Heatmap of the results (F1 scores) with different values of term frequency and toxicity ratio after combining with CharacterBERT

Although the performance of this version is a lot lower than the second version (v2) of the BoW model, it helps to improve the performance of CharacterBERT. The reason for this behavior can be attributed to the fact that models with higher thresholds both in terms of frequency and toxicity ratio tend to output more certain results, albeit fewer words than the ones that should be labeled as toxic. Therefore, many toxic words that are less probable are not extracted and F1 score drops.

Looking at Figure 3, we can see that, indeed, the best parameters from the experiments on the validation set (ratios 0.3 and 0.4 with frequencies 10 and 20) yield some of the best results on the test set. However, when these results are combined with the output of the CharacterBERT, we see that the higher the toxicity ratio the better the results (Figure 4) until 0.7 which gives the maximum im-

provement. The 0.8 ratio makes the predictions still a little better but 0.9 does not affect them since the words that are labeled as toxic with this certainty have most probably been found also by CharacterBERT.

## 4 Conclusion

We described the system we utilized to detect toxic language. In our approach, we first fine-tune CharacterBERT, a character-level pre-trained language model, on the toxic training data. Then using a simple bag-of-words model, we further improve the results of this system. The Bag-of-Words model labels the words based on their frequency and the ratio of toxicity in the training data. We showed that this model, although extremely simple, gives a close performance to that of CharacterBERT with millions of parameters.

## Abstract

The real-world impact of polarization and toxicity in the online sphere marked the end of 2020 and the beginning of this year in a negative way. Semeval-2021, Task 5 - Toxic Spans Detection is based on a novel annotation of a subset of the Jigsaw Unintended Bias dataset and is the first language toxicity detection task dedicated to identifying the toxicity-level spans. For this task, participants had to automatically detect character spans in short comments that render the message as toxic. Our model considers applying Virtual Adversarial Training in a semi-supervised setting during the fine-tuning process of several Transformer-based models (i.e., BERT and RoBERTa), in combination with Conditional Random Fields. Our approach leads to performance improvements and more robust models, enabling us to achieve an F1-score of 65.73% in the official submission and an F1-score of 66.13% after further tuning during post-evaluation.

## 1 Introduction

Nowadays, online engagement in social activities is at its highest levels. The lockdowns during the 2020 COVID-19 pandemic increased the overall time spent online. In Germany for instance, Lemenager et al. (2021) observed that 71% of considered subjects increased their online media consumption during this period. Unfortunately, online toxicity is present in a large part of the social and news media platforms. As such, automated early detection is necessary since toxic behavior is often contagious and leads to a spillover effect (Kwon and Gruz, 2017).

Recently, a significant effort was put into the detection of toxic and offensive language (van Aken et al., 2018; Paraschiv and Cercel, 2019; Tanase et al., 2020b,a), but the challenging nature of these problems leaves several avenues unexplored. In addition, most shared tasks focus

on the distinction between toxic/non-toxic (Wulczyn et al., 2017; van Aken et al., 2018; Juuti et al., 2020) or offensive/non-offensive posts in various languages (Struß et al., 2019; Zampieri et al., 2019a,b, 2020; Mandl et al., 2020; Aragón et al., 2020). The Semeval-2021 Task 5, namely Toxic Spans Detection (Pavlopoulos et al., 2021), tackles the problem of identifying the exact portion of the document that gives it toxicity. The provided dataset is a subset of the Jigsaw Unintended Bias in Toxicity Classification dataset<sup>1</sup>, with annotated spans that represent toxicity from a document.

In this paper, we describe our participation in the aforementioned Toxic Spans Detection task using several Transformer-based models (Vaswani et al., 2017), including BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), with a Conditional Random Field (CRF) (Lafferty et al., 2001) layer on top to identify spans that include toxic language. We introduce Virtual Adversarial Training (VAT) (Miyato et al., 2015) in our training pipeline to increase the robustness of our models. Furthermore, we enhance part of our models with character embeddings based on the Jigsaw Unintended Bias dataset to improve their performance. Finally, we compare the proposed models and analyze the impact of various hyperparameters on their performance.

The rest of the paper is structured as follows. The next section introduces a review of methods related to toxic language detection, sequence labeling, and adversarial training (Kurakin et al., 2016). The third section discusses the employed models, as well as the VAT procedure. Results are presented in the fourth section, followed by discussions, conclusions, and an outline of possible future works.

## 2 Related Work

**Toxic Language Detection.** There are several research efforts to detect toxic texts based on the Jigsaw Unintended Bias dataset, out of which most focus on the Kaggle competition task - predicting the toxicity score for a document. [Morzhov \(2020\)](#) compared models based on Convolutional Neural Networks (CNNs) ([Kim, 2014](#)) and Recurrent Neural Networks ([Cho et al., 2014](#)) with a Bidirectional Encoder Representations from Transformers (BERT) architecture ([Devlin et al., 2019](#)), obtaining the best performance from an ensemble of all used models. [Gencoglu \(2020\)](#) and [Richard and Marc-André \(2020\)](#) used the same dataset to improve on the automatic detection of cyberbullying content.

**Sequence Labeling.** Predicting the type for each token from a document rather than providing a label for the whole sequence is a task often associated with named entity recognition ([Ma and Hovy, 2016](#)), but can be performed in other Natural Language Processing pipelines, including part-of-speech tagging ([Ling et al., 2015](#)) and chunking ([Hashimoto et al., 2017](#)). A common practice in sequence tagging models ([Peters et al., 2018](#); [Avram et al., 2020](#); [Ionescu et al., 2020](#)) is to use a CRF as a final decoding layer.

**Adversarial Training.** Researched first in image classification ([Szegedy et al., 2013](#)), adversarial examples are small input perturbations that are hardly distinguishable for humans, but can dramatically shift the output of a neural network. These examples can be used in adversarial training (AT) ([Goodfellow et al., 2014](#)) as a regularization method that can increase the robustness of the model. Using the worst-case outcome from a distribution of small norm perturbations around an existing training sample, a new data point is created and inserted into the training process.

Extending AT to a semi-supervised setting, VAT ([Miyato et al., 2016](#)) does not require label information for the adversarial examples. VAT aims to increase the local distributional smoothness by adding perturbations to the embedding output. Recently, several studies ([Kumar and Singh, 2020](#); [Liu et al., 2020](#); [Si et al., 2020](#)) focused on applying VAT in Transformer-based models and obtained improvements in comparison to baseline methods on several classification tasks.

## 3 Method

### 3.1 Corpus

The dataset for the competition is a subset of the Jigsaw Unintended Bias in Toxicity Classification English language corpus, with annotated spans that make the utterance toxic. From the 8,597 trial and train records, 8,101 had at least one toxic span. By cross-referencing with the original Jigsaw dataset which contains additional information, we retrieved the toxicity scores for each text and determined that the mean toxicity score for the train and test set were very close (0.8429 versus 0.8440; see [Figure 1](#) for corresponding kernel density estimates). Moreover, only 17 out of 2,000 test data rows had a toxicity score below 0.75. Nevertheless, an off-balance was noticed between the test and train set - 80.3% entries from the test set had at least one toxic span versus a considerably higher density of 94.2% in the train set.

Figure 1: Kernel density estimate using Gaussian kernels for the toxicity scores in both the training and test data.

The training dataset was split into sentences while ensuring that there are no splits inside a toxic span and there are no sentences shorter than three words. Under these settings, our training dataset consists of a total of 26,589 sentences, including 10,117 records that contained toxic spans; 15% were selected for validation. Another 2,000 entries were provided by the competition organizers for testing; the labels for this dataset were made available after the competition.

For our unsupervised training samples, we selected 20,000 random records from the Jigsaw dataset, making sure there was no overlap with the Semeval-2021 training data. Additionally, we replaced all URL-s with a special token and applied lower case on all records.

Model	F1-score validation set	F1-score competition test set
LSTM-CRF-VAT	75.82%	62.49%
LSTM-CRF-VAT+chars	76.27%	63.65%
BERT-base-CRF	79.25%	62.32%

### 3.2 Virtual Adversarial Training

The robustness of the model in Adversarial Training is improved through examples that are close to available training data, but the model would be likely to assign a different label than the training one, thus leading to loss increase. In VAT, Miyato et al. (2018) adapted the adversarial training from supervised to semi-supervised settings by adding an additional loss using the Kullback–Leibler divergence between the predictions of the original data and the same data with random perturbations. Since the output distributions are compared, the information about labels is not needed for the adversarial loss:

$$L_{adv} = KL(P(\hat{y}|e, \Theta) || P(\hat{y}|e + d, \Theta)) \quad (1)$$

where  $e$  is the embedding associated with the sample,  $d$  the perturbation, and  $\hat{y}$  is the predicted output.

True labels are required in general to compare the losses and find the worst case perturbations. However, this can be avoided by bounding the norm of the perturbation  $\delta$  to  $\eta$ ; thus, the value of the perturbation becomes:

$$d = \arg \max_{\delta; \|\delta\|_2 < \eta} KL(P(\hat{y}|e, \Theta) || P(\hat{y}|e + \delta, \Theta)) \quad (2)$$

Afterwards, we can estimate the perturbation  $d$  using also the gradient  $g$  and a hyperparameter  $\epsilon$  for the magnitude by applying the second-order Taylor approximation and a single iteration of the power method:

$$d = \frac{g}{\|g\|_2} \epsilon \quad (3)$$

where

$$g = \nabla_{\delta} KL(P(\hat{y}|e, \Theta) || P(\hat{y}|e + \delta, \Theta)) \quad (4)$$

In order to reduce the complexity and computation for the gradient, we ignore the dependency on  $\Theta$ . Also, the number of power iterations can be another hyperparameter for the model. The final loss function used by all models is a combination of the supervised and unsupervised adversarial loss:

$$L_{total} = \gamma L_{sup} + (1 - \gamma) L_{adv} \quad (5)$$

where  $\gamma$  is another tunable hyperparameter.

### 3.3 Implementation Details

In our experiments, pre-trained Transformer models are followed by a linear transformation of their last hidden state, and a final CRF layer. More precisely, we compare the effectiveness of several flavors of BERT models, alongside the VAT technique as follows: BERT base, a 768-dimensional model provided by Google (*BERT-base-CRF-VAT*), Unitary’s toxic BERT (Hanu and Unitary team, 2020) (*BERT-toxic-VAT*), BERT pre-trained on fake and hyperpartisan news (Paraschiv et al., 2020) (*BERT-news-CRF-VAT*), and *RoBERTa-large-CRF-VAT*, the equivalent of BERT-base-CRF-VAT that relies on RoBERTa instead of BERT.

In addition to these models, we experimented with enhancing the BERT-based representation with character embeddings (Kim et al., 2016). These character representations were trained on the entire Jigsaw dataset using a CNN-BiLSTM model (Ma and Hovy, 2016) with the next character prediction objective. We concatenated the

obtained character-level embeddings with the aforementioned Transformer’s last hidden state, and refer to this variant as *BERT-news-CRF-VAT+chars*.

As baseline systems, we design two methods: *LSTM-CRF-VAT* with GloVe embeddings (Pennington et al., 2014) and a *LSTM-CRF-VAT+chars* having character-level embeddings and VAT. In all BERT-based models, we used a maximum sequence length of 96 tokens and a sequence of 64 tokens for the LSTM baseline. Since the input words can consist of more than one token, we assign the toxicity label to a word if at least one component token is inferred as toxic.

The best hyperparameters for the BERT-base model were determined through grid search on the development set. The identified optimal values ( $\epsilon = 2$ ,  $\eta = 0.1$ , and two power iterations) were used in all other flavors;  $\gamma$  was set to 0.5 in the final loss function to balance both approaches. Furthermore, all BERT-based models were trained for one epoch in contrast with the LSTM-CRF-VAT and LSTM-CRF-VAT baselines that were trained for three epochs and four epochs, respectively.

## 4 Results

The evaluation metric for the Toxic Spans Detection task was an adapted version of the F1-score (Da San Martino et al., 2019) that takes into account the size of the overlap between prediction spans and golden labels.

Results for all developed models with the aforementioned hyperparameters (i.e.,  $\gamma = 0.5$ ,  $\epsilon = 2$ ,  $\eta = 0.1$ , and two power iterations) are presented in Table 1. Since the training data had a slightly different distribution of the span density, part of our models that performed worse on our dev set performed better on the competition test set. Adding the character embedding representation to BERT-based models did not prove to be of use in our pre-evaluation tests, but in post-evaluation, we noticed that slightly tweaking the  $\gamma$  hyperparameter for the loss from 0.5 to 0.6 brought the F1-score to 66.13%. Despite performance on the validation set was insensitive to the change in  $\gamma$  between 0.5 and 0.6, the results on the test set were more than 1.5% apart. This is mostly due to the unsupervised training that is strengthening the model’s confidence on edge cases which would lower its precision.

Figure 2 introduces the influence of the perturbation magnitude  $\epsilon$  on the overall performance of three models. The impact of  $\epsilon$  in the adversarial

training effectiveness is significant, but it is also highly dependant on the used model and can only be determined experimentally.

Our models performed well on the detection task, learning not only common toxic expressions like "moron", "stupid", "pathetic troll", "disgusting", "hang-em high", but also obfuscated expressions like "f\*cking nasty" and "b\*tchy". Nonetheless, the models fail to detect more obscured words like "you don't know s\*\*\*" or "Kill this F'n W\*ore on site". All models have the tendency to over-predict toxicity by adding words to the toxic expression - for example, "What a pile of shit" was automatically labeled as "What a pile of shit".

The character-level embeddings boosted the performance of the baseline LSTM-CRF-VAT model but did not improve any BERT model since it leads to detecting longer spans as toxic (see Table 2) which in return lowers precision.

Figure 2: Impact of the perturbation magnitude  $\epsilon$  on the F1-scores for the predictions on the official test set.

## 5 Discussions and Error Analysis

In this section, we analyze the BERT-toxic-CRF-VAT performance versus the golden label values from the competition test set. The precision and recall for our best model are 65.74% and 85.54%, respectively, which are indicative of a tendency to over-predict toxic spans. As we mentioned in section 3.1, even though almost all documents in the test set had a high toxicity score in the original Jigsaw dataset, many had no annotated toxic spans. Indeed, there were 295 records where our model detected a toxic span and none were labeled in the test set. Table 3 includes examples of such detected spans those labeling is subjective and other detection errors. Words like "stupid", "dumb", and "crap" were assigned as toxic throughout the test data due to their high presence in the training data spans. There were also milder errors, spans that overlap with the golden labels, but the model omits

part of the sequence of words. Samples like "You are a nut ball" detected only as "You are a nut ball" or "So like every other racist, he's a hypocrite" marked by the model as "So like every other racist, he's a hypocrite" can be perceived as likely errors even for human annotators.

## 6 Conclusions and Future Work

In this paper, several Transformer-based models (i.e., BERT and RoBERTa) were tested together with Virtual Adversarial Training to increase their robustness for identifying toxic spans from textual information. Our experiments argue that applying VAT increases performance and that domain-specific models have higher performance when compared to larger general models.

In terms of future work, we plan to experiment with self-supervised adversarial training (Chen et al., 2020) to improve the robustness of our models. As we noticed in this dataset too, online users find clever ways to hide offensive and toxic expressions. Adversarial training can be effectively employed to detect these attempts and a study of its impact on offensive and hate speech classifiers is worth pursuing as follow-up leads.

## Abstract

Toxicity detection of text has been a popular NLP task in the recent years. In SemEval-2021 Task-5 Toxic Spans Detection, the focus is on detecting toxic spans within English passages. Most state-of-the-art span detection approaches employ various techniques, each of which can be broadly classified into Token Classification or Span Prediction approaches. In our paper, we explore simple versions of both of these approaches and their performance on the task. Specifically, we use BERT-based models - BERT, RoBERTa, and SpanBERT for both approaches. We also combine these approaches and modify them to bring improvements for Toxic Spans prediction. To this end, we investigate results on four hybrid approaches - Multi-Span, Span+Token, LSTM-CRF, and a combination of predicted offsets using union/intersection. Additionally, we perform a thorough ablative analysis and analyze our observed results. Our best submission - a combination of SpanBERT Span Predictor and RoBERTa Token Classifier predictions - achieves an  $F_1$  score of 0.6753 on the test set. Our best post-eval  $F_1$  score is 0.6895 on intersection of predicted offsets from top-3 RoBERTa Token Classification checkpoints. These approaches improve the performance by 3% on average than those of the shared baseline models - RNNLS and SpaCy NER.

## 1 Introduction

Offensive language can include various categories such as threats, vilification, insults, calumny, discrimination and swearing (Pavlopoulos et al., 2019). Detection of such language is necessary for ease of moderation of content on social media. Despite their popularity, toxicity detection tasks have focused majorly on sequence classification, rather

\* Equal contribution. Author ordering determined by coin flip.

than sequence tagging. Finding which spans make a comment or document toxic in nature is crucial in explaining the reasons behind their toxicity. Additionally, such attributions would allow for more efficient semi-automated quality-based moderation of content, especially for verbose documents, in comparison to quantitative toxicity scores.

In SemEval-2021 Task-5, Pavlopoulos et al. (2021) provide a dataset of 10k English texts filtered from Civil Comments (Borkan et al., 2019) dataset. Each text is crowd-annotated with character offsets that make the text toxic. The task is to predict these character offsets given the text. The work presented in this paper aims to provide a comprehensive analysis of simple Token Classification (TC) and Span Prediction (SP) methods across multiple BERT-based models - BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and SpanBERT (Joshi et al., 2020). Additionally, we experiment with a few hybrid approaches - Multi-Span (MSP), where the model is trained on multiple spans simultaneously; Span+Token (SP-TC), where the model is trained on both kinds of tasks simultaneously; LSTM-CRF (LC), which uses a LSTM and CRF layer on top of BERT-based models; and a combination of predicted offsets for above techniques using union/intersection. In Section 2, we perform a compendious literature survey. Section 3 elucidates our approach, including the modelling aspect, the various variants of the base model, and the different Hybrid Systems. In Section 4, we describe our experimental setup and hyperparameters used for our methods. Lastly, in Section 5 we analyze our results and perform ablative analysis on our systems.

## 2 Background

Before the advent in research pertaining to toxic texts, Warner and Hirschberg (2012) modeled hate

speech as a word sense disambiguation problem where SVM was used for classification of data. Mehdad and Tetreault (2016) used RNN Language Model with character and token based methods to classify the text. Recently, however, toxic text detection has garnered a lot of attention (Nobata et al., 2016; Park and Fung, 2017; Pavlopoulos et al., 2017; Wulczyn et al., 2017). The increase in offensive language research can partly be credited to various workshops such as Abusive Language Online<sup>1</sup> (Waseem et al., 2017), as well as other fora, such as GermEval for German texts,<sup>2</sup> or TRAC (Kumar et al., 2018) and Kaggle challenges<sup>3</sup>.

Hanu and Unitary team (2020) introduced Detoxify, a comment detection library modeled using HuggingFace’s transformers (Wolf et al., 2020) to identify inappropriate or harmful text online as a result of participation in three such challenges. In a contemporary work, Pavlopoulos et al. (2020) discuss context requirement for toxicity detection.

In SemEval 2020-Task 11 (Da San Martino et al., 2020), the first sub-task - Span Identification - aims at detecting the beginning and the end offset for the propaganda spans in news articles. This sub-task is similar to SemEval 2021-Task 5. The proposed approaches for the sub-task can be broadly classified into Span Prediction or Token Classification. Most teams use multi-granular transformer-based systems for token classification/sequence tagging (Khosla et al., 2020; Morio et al., 2020; Patil et al., 2020). Inspired by Souza et al. (2019), Jurkiewicz et al. (2020) use RoBERTa-CRF based systems. Li and Xiao (2020) use a variant of SpanBERT span prediction system.

### 3 Models

#### 3.1 Token Classification Models

##### 3.1.1 Baseline Models

From the models already provided with the dataset, we use RNNSL and SpaCy NER Tagging baselines for token-wise classification.

RNNSL model is a combination of a single Bi-LSTM layer with a randomly initialized embedding layer. It uses a three-label classification task for each word in the sentence. The labels used are: *special token*, *non-toxic word*, and *toxic word*. For

<sup>1</sup><https://sites.google.com/site/abusivelanguageworkshop2017/>

<sup>2</sup><https://projects.fzai.h-da.de/iggsa/>

<sup>3</sup>Jigsaw Toxic Comment Classification Challenge

each word, the corresponding offsets are added to the predicted spans. A word with containing any toxic offset is marked as toxic during training.

SpaCy NER Tagging model is an NER classifier built on SpaCy Language Models. It is used to predict the entities which are labelled as *TOXIC* in the text using the spans provided.

#### 3.1.2 BERT-based Token Classification Models

These models comprise a BERT-based model and a classification layer over each final token embedding which predicts whether a token is toxic or not. Based on these classifications, we add the offsets for those tokens (not words) which are marked as toxic by the model. Figure 1a represents a Token Classification Model.

### 3.2 Span Prediction Models

#### 3.2.1 BERT-based Span Prediction Models

We use the BERT-based Span Prediction (Figure 1c) models based on Extractive Question Answering systems similar to work on SQuAD (Rajpurkar et al., 2016) and MRQA (Fisch et al., 2019). In these systems, the output at each token is a start logit and an end logit denoting whether that token is a start token or an end token of the span, depending on the softmax value. Since the Toxic Spans text can have multiple toxic spans, we take different contiguous spans from the given offsets, and make several ‘samples’ out of the example. Each span becomes an ‘answer’ for the particular text sample. We use the word ‘*offense*’ as a dummy question. Thus, each contiguous span leads to one ‘sample’ for every example (Table 1).

Text		Spans
...an idiot - just an embarrassingly uninformed, ignorant,...		idiot, ignorant
Question	Context	Answer
offense	...an idiot - just an embarrassingly uninformed, ignorant,...	idiot
offense	...an idiot - just an embarrassingly uninformed, ignorant,...	ignorant

Table 1: Conversion of Toxic Spans example to samples for single-span Span Prediction.

We store the start index of the text, similar to the SQuAD (Rajpurkar et al., 2016) dataset, and process the data to provide start and end token positions during training. The classifier layer on top of the encoder embeddings performs a binary classification task for start and end positions. A

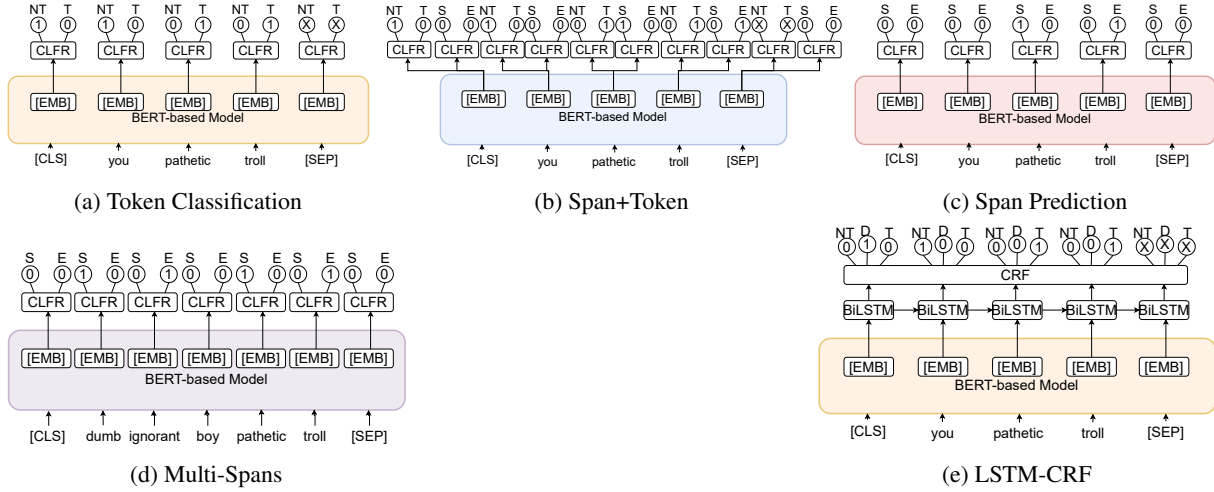

Figure 1: BERT-based Approaches\*

\* CLFR = Classifier, [EMB] = Token Embedding, NT = Non-Toxic, T = Toxic, D = Dummy, X = Don't Care, S = Start, E = End.

span is scored using the sum of predicted start and end logits. From top-K start and end logits, valid predicted answer spans<sup>4</sup> are chosen during post-processing. A union of all the corresponding offsets is taken to give the final prediction for the example. A threshold is learned on the span scores using the resulting dev set  $F_1$  score on offsets, which is then used for test set prediction. All spans with score above threshold are considered to be toxic spans.

### 3.3 Hybrid Systems

#### 3.3.1 Multi-Spans

In Section 3.2, we allow each context to have multiple single-span answers during training. This is counter-intuitive, as the model is only trained to handle a single-span at a time, and expected to predict multiple single-spans during prediction. Two toxic spans in text are equally important to predict, and thus, should not be shown at different times during training. To mitigate this issue, we try an approach which we refer to as the ‘Multi-Spans’ (MSP) approach. Here, we take all the ground start and end token positions during training, and use Binary Cross Entropy on each of the start/end logits. This essentially treats the task as a multi-label classification problem. Hence, during training, all the ground spans are used in the same iteration with the example, and only one ‘sample’ per example is generated. Figure 1d depicts a representation of the system. Note that two tokens - *dumb* and *pathetic* are marked as the start token. Similarly, both *ignorant* and *troll* are marked as the end token.

<sup>4</sup>Valid spans are those which have end index greater than start index, and length less than a maximum span length.

#### 3.3.2 LSTM-CRF

A recently popular approach in Named-Entity Recognition tasks has been to use Conditional Random Fields (CRF) with BERT-based models. Inspired by the CRF-based approaches (Souza et al., 2019; Jurkiewicz et al., 2020), we use BERT-based models with a single BiLSTM layer and a CRF layer. During training, the CRF loss is used and during prediction, Viterbi Decoding is performed. Though CRF is generally used for word-level classification, we do not mask inner and end tokens for a word as it degrades dev set performance for our systems. Hence, all the tokens of a word are considered for classification.

#### 3.3.3 Spans+Token

For this system, we use a combination of the two tasks - Token Classification and single-span Span Prediction. We use two classification layers on the token-wise embeddings - one for start and end prediction, and the other for token classification. Training is done simultaneously on both tasks, and the cross-entropy loss for each classifier is weighted. The overall loss is given as:

$$L(\hat{s}, \hat{e}, \hat{p}, s, e, p) = - \sum_t \hat{p}_t \log p_t - \frac{(\sum_t \hat{s}_t \log s_t + \sum_t \hat{e}_t \log e_t)}{2}$$

where  $s_t, e_t$ , and  $p_t$  are labels for start, end and token classifiers for token  $t$ , while  $\hat{s}_t, \hat{e}_t$  and  $\hat{p}_t$  are predictions. This is done to equally scale both SP and TC task losses. During prediction, we consider top-K start and end scores. From the valid spans,

the score is calculated as the average of start and end logit scores, as well as the mean of toxicity logits over the span under consideration. The score is given as:

$$S(i_s, i_e) = \frac{\hat{s}_{i_s} + \hat{e}_{i_e}}{2} + \frac{\sum_{k=i_s}^{i_e} \hat{t}_k}{e - s + 1}$$

where  $i_s$  and  $i_e$  are start and end indices,  $\hat{s}_{i_s}$  and  $\hat{e}_{i_e}$  are start and end logits at those indices, and  $\hat{t}_k$  is toxicity logit at index  $k$ . A threshold, similar to Section 3.2 is tuned on the dev set. The predicted offsets taken from the predicted spans are considered to be toxic.

### 3.3.4 Combination of Offset Predictions

Chen et al. (2017) proposed using the predictions from top few checkpoints and averaging the results to achieve better classification scores. Based on a similar line of thought, we also combine the predicted spans for various checkpoints of a model, as well as across different models using union or intersection.

## 4 Experimental Setup<sup>5,6</sup>

### 4.1 Hardware Requirements

The training and the evaluation of systems was performed on Google Colab’s free GPU (NVIDIA K80/P100). The training time varies with the models. For each model, it is around 4-6 hours, which is well-within the 12 hour limit of Colab.

### 4.2 Models & Hyperparameters

For RNNSL, a Keras-based BiLSTM model is provided. We use a max length of 192, batch size of 32 and a dropout of 0.1. The training is done using Adam Optimizer with early stopping (*patience\_period* = 3), which in our case halts at 5 epochs. The embedding/hidden\_state size used is 200. A threshold is used to classify a word as toxic on the predicted toxic word probability. This threshold is tuned on the trial dataset. For SpaCy, the *en\_core\_web\_sm* model is used with 30 iterations.

For all BERT-based models, we use Hugging-Face’s transformers (Wolf et al., 2020) in PyTorch. For CRF, we use the pytorch-crf (Kurniawan, 2018) library. We use a batch size of 4, train for 3 epochs,

<sup>5</sup>Our code can be found at: <https://github.com/gchhablani/toxic-spans-detection>.

<sup>6</sup>We also use Integrated Gradients to understand what the models focus on. For discussion, see Appendix B.

use a linear learning rate decay, and an AdamW optimizer with a weight decay of 0.01. The initial learning rate is  $2e-5$ . During tokenization, the maximum length allowed is 384, with the exception of RoBERTa Span+Token where it is 512. We use *LARGE* models for all - BERT, RoBERTa and SpanBERT, unless otherwise specified.

For Token Classification, we add a label for the *[CLS]* token if the percentage of toxic offsets in text is greater than 30% in order to provide a proxy text classification objective for the system. For span-based models, the K used for top-K start and top-K end logit selection is 20, and the maximum allowed answer length is 30 tokens. For LSTM-CRF systems, a dummy label is used for the *[CLS]* token, while the prediction mask for other special tokens is set to 0. A dropout of 0.2 is used. For Span Prediction systems, the overlapping stride is set to 128.

The training dataset used is *tsd\_train.csv* and the dev set used is *tsd\_trial.csv* file, unless otherwise specified. For all systems, we evaluate the  $F_1$  scores using the provided script on the checkpoints which give the lowest dev set loss.

## 5 Results and Analysis

In favor of brevity, for this section, we use the following abbreviations: BT=BERT, RBTa=RoBERTa, SBT=SpanBERT, SP=Span Prediction, TC=Token Classification, MSP=Multi-Span, LC=LSTM-CRF, B=Base, TBT=ToxicBERT, TRBTa=ToxicRoBERTa, TT=Trained on Train+Trial, (x,∩)=Intersection of offsets from x-best checkpoints, (x,∪)=Union of offsets from x-best checkpoints.

In Table 2, we mention scores for our approaches. The scores are evaluated are performed after the evaluation phase, using the hyperparameters mentioned in Section 4.2. We observe that the highest score is obtained by SBT-TC (0.6856). The baseline scores (RNNSL/SpaCy) are good ( $\approx 0.65$ ) considering that these models are not pre-trained. Notably, SP systems perform worse than their TC counterparts. A good reason could be the self-attention used in BERT-based models. Since the interaction is between tokens, and not spans, it is expected that each token is well represented and less consideration will be given to the span representation around a single token. The reason why SBT-TC performs best out of all the *LARGE* models could be the random-spans Masked Language

Model	Train $F_1$	Trial $F_1$	Test $F_1$
RNNSL	0.5904	0.5904	0.6514
SpaCy	0.6282	0.5729	0.6573
BT-TC	0.6944	0.6942	0.6781
RB-Ta-TC	0.6791	0.6769	0.6834
SBT-TC	0.6873	0.6789	<b>0.6856</b>
BT-SP	0.6639	0.6465	0.6663
RB-Ta-SP	0.6401	0.6386	0.6665
SBT-SP	0.6432	0.6212	0.6561
BT-MSP	0.5218	0.4941	0.5406
RB-Ta-MSP	0.5056	0.4886	0.5244
SBT-MSP	0.5190	0.5004	0.5084
BT-SP-TC	0.6676	0.6214	0.6186
RB-Ta-SP-TC	0.6395	0.6101	0.5901
SBT-SP-TC	0.6608	0.6491	0.5959
BT-LC	0.6887	0.6843	0.6835
RB-Ta-LC	0.7236	0.6861	0.6787
SBT-LC	0.7200	0.6982	0.6801

Table 2:  $F_1$  scores for our approaches (Post-Eval).

Modeling used in its pre-training. However, BERT and RoBERTa take over for other approaches.

LSTM-CRF approaches perform as good as Token Classification approaches, and BT-LC achieves the second highest score (0.6835). MSP performs poorly, in contrast to what is expected. Multi-Span Extraction is still an active problem in Deep NLP with only a few recent works (Segal et al., 2020; Yang et al., 2020) on it, which still incorporate sequence tagging approaches. Spans+Token approaches perform better than Multi-Span, but are worse than both TC and SP approaches across all BERT-based models.

Lastly, from combined checkpoint predictions

Combination	Test $F_1$
RB-Ta-TC(3, $\cup$ )	0.6765
RB-Ta-TC(3, $\cap$ )	<b>0.6895</b>
SBT-SP(3, $\cup$ )	0.5879
SBT-SP(3, $\cap$ )	0.6585
RB-Ta-TC(3, $\cup$ ) $\cup$ SBT-SP	0.6573
RB-Ta-TC(3, $\cup$ ) $\cap$ SBT-SP	0.6765
RB-Ta-TC $\cup$ SBT-SP(3, $\cup$ )	0.5840
RB-Ta-TC $\cap$ SBT-SP(3, $\cup$ )	0.6883

Table 3:  $F_1$  scores for combined predictions.

(Table 3), we get out best scoring system - RB-Ta-TC(3, $\cap$ ) - which achieves a score of 0.6895. However, our best official submission<sup>7</sup> was a variant of the third best combination - RB-Ta-TC(3, $\cup$ ) $\cap$ SBT-SP (0.6765). It is also observed that intersection ap-

<sup>7</sup>The most significant of our official submission scores are present in Appendix A.

proaches perform better than corresponding union and single checkpoints approaches, while union approaches perform worse than single checkpoints. This means that the individual checkpoints are predicting some extra offsets to be toxic.

## 5.1 Ablative Analysis

Model	Train $F_1$	Trial $F_1$	Test $F_1$
TBT-TC	0.6753	0.6628	0.6792
TRB-Ta-TC	0.7244	0.6954	0.6773
TBT-SP	0.6638	0.6560	0.6584
TRB-Ta-SP	0.6475	0.6358	0.6746
BT-B-TC	0.6966	0.6746	<b>0.6881</b>
RB-Ta-B-TC	0.6641	0.6482	0.6834
BT-B-SP	0.6605	0.6434	0.6611
RB-Ta-B-SP	0.6481	0.6464	0.6661
RNNSL-TT	0.6844	0.6882	0.6259
RB-Ta-TC-TT	0.7707	0.7788	0.6823
SBT-SP-TT	0.7116	0.7092	0.6669

Table 4:  $F_1$  scores for ablative approaches.<sup>8</sup>

In Table 4, we present results on TBT<sup>8</sup> and TRB-Ta<sup>9</sup> for TC and SP approaches. These are *BASE* models fine-tuned on the Civil Comments Dataset. Since the Toxic Spans dataset has similar text data, we expect these models to perform better than *BASE* models. We observe that TBT-TC and TRB-Ta-SP perform slightly better than BT-TC and RB-Ta-SP, despite being *BASE* models. Also, BT-SP and RB-Ta-TC are only slightly better than their ‘Toxic counterparts.

Yet, in comparison, *BASE* models - BT-B and RB-Ta-B, without any multi-stage pre-training perform better than their ‘Toxic’ counterparts, and are comparable, if not better than their *LARGE* counterparts. This means that there not enough data for *LARGE* models, and hence, they tend to overfit. However, the reasons behind worse performance of ‘Toxic’ systems is unclear.

We also evaluate scores for a few systems on the test set after 3 epochs of training on both train and trial data (-TT). We observe that the performance on both train and trial datasets increases significantly ( $\approx 7$ -10%), showing that these datasets have similar distribution. However, the performance on test decreases for RB-Ta-TC-TT and RNNSL-TT in comparison to the Table 2, which shows that test set distribution might be slightly different for TC task. For SBT-SP-TT, we see a slight increase, showing

<sup>8</sup><https://huggingface.co/unitary/toxic-bert>

<sup>9</sup><https://huggingface.co/unitary/unbiased-toxic-roberta>

scope of improvement for SP systems with more data.

Lastly, we evaluate the token-based predictions and span-based predictions for SBT SP-TC separately. Surprisingly, token predictions achieve a  $F_1$  score of 0.6522 on the test set, which is much better than using both token and spans (0.5959). However, for span-based predictions, we only achieve an  $F_1$  score of 0.1510. This means that the system is focusing heavily on token-based-predictions. Hence, we need to re-evaluate our architectural decisions in order to successfully incorporate both token and spans together.

## 6 Conclusion

Based on our results and analysis, we conclude that Token Classification systems have an edge over Span Prediction methods on this task. *BASE* models perform better than *LARGE* models in either of the approaches, which could imply need for more data to train *LARGE* models. Our Multi-Span approach performs poorly, but Span+Token approach shows some promise and we need to re-evaluate our architectural choices. The reason why ToxicBERT/ToxicRoBERTa perform worse than *BASE* models is also an avenue for further analysis. Finally, our individual BERT-based models tend to predict extra offsets for the task. While checkpoint ensembling using intersection is a good way to address this issue, we will explore other remedies in a future work.

## Acknowledgments

We would like to acknowledge the help and moral support provided to us by Rajaswa Patil<sup>10</sup> and Somesh Singh<sup>11</sup>. We would also like to express our gratitude to our colleagues at the Language Research Group (LRG)<sup>12</sup>, who have been with us at every stepping stone.

## A Official Submissions

During the evaluation period, we performed a ‘cleaning’ of the data by removing starting/trailing whitespace and punctuation characters in spans. Additionally, we include those partial words in spans which had more than half the number of characters in the span, and discard remaining partial words from spans. We considered this version of the *tsd\_train.csv* and *tsd\_trial.csv* to be ‘clean train’ and ‘clean trial’, respectively. During the post-eval period, we found out potential issues with the cleaning, and thus, we use original files. Additionally, since the distribution of *tsd\_test.csv* is expected to be similar to *tsd\_train.csv* and *tsd\_trial.csv*, the scores are much better for models trained on *tsd\_train.csv* file instead of *clean\_train.csv*. However, some of our official submissions were from systems trained on the ‘clean train’ data. Keeping that in mind, we report our official scores for our top-few approaches in Table 5.

Model	Trained On	Test $F_1$
RNNSL	Train+Trial	0.6446
SpaCy	Train+Trial	0.6470
RNNSL $\cup$ SpaCy	Train+Trail	0.6510
RBTa-TC	Clean Train	0.6270
RBTa-TC(3, $\cup$ )	Clean Train	0.6469
SBT-SP	Train	0.6631
RBTa-TC(3, $\cup$ ) $\cap$ SBT-SP	Clean Train, Train	<b>0.6753</b>

Table 5: Official Submission Scores

## B Integrated Gradients

We use Integrated Gradients(Sundararajan et al., 2017) from the Captum(Kokhlikyan et al., 2020) library for qualitative analysis of predictions for the SpanBERT-SP, and the RoBERTa-TC models. We calculate Integrated Gradients of the targets with respect to the embedding layer outputs. The

Riemann Right numerical approximation method is used, with  $n\_steps=50$ . Following Ramnath et al. (2020), we calculate token-wise importance distributions and word-wise distributions for a few examples. We refer the paper to the reader for more details.

For the Token Classification model, the targets are softmax outputs of toxicity logits of those tokens which the model predicts to be toxic, with a score greater than 0.5. For all such toxicity logits as targets, we calculate attributions with respect to the embedding layer outputs for all the tokens, and average them to get token-wise importance scores. For the Span Prediction model, we find start and end indices for all the predicted spans, and calculate respective attributions, add them, and then average them to get token-wise importance scores.

Table 6: The prediction output of the models for an example in the test set.

than *'pathetic troll'*. This is in contrast with Figure 2b where the Token Detection model misses out on space (because it only considers tokens) and focuses more on the words *'pathetic'*, *'troll'*. However, the word *'shrink'* seems to be important in both cases. This means that while Token Classification models perform better, there are cases which are missed by these approaches. Additionally, some words outside of the span may contribute to toxicity of a particular span. We will be analyzing such words in a future work.

## C Model Predictions

The predictions of the various systems for one example that is present in the test set, are listed in Table 6. The examples provide the following intuition about the data and the systems:

- The spaces in between the words are, predictably, ignored by the token based models. Moreover, the conjunctives like 'and' are ignored as well. This means that additional post-processing of the data will lead to improvements in performance of token classification systems.
- Sometimes, random words like 'go' and 'on' are selected to be toxic, which means that these types of prepositions and verbs can be removed by exact matching in the string, unless they form parts of larger spans.
- The best checkpoints of the span-based models tend to predict empty spans for the selected example. However, when using checkpoint ensembling, we see that union models return accurate spans.
- The ground spans are not entirely correct and are ambiguous. For example, it is not clear whether the word 'ignorant' should be considered to be toxic. The models, based on other examples, predict 'ignorant' to be toxic, but it is not present in the ground spans. This means that finding the toxic spans is not a trivial task for humans, and annotation can not be performed easily by crowd-workers.
- In some cases, one of the occurrences of the word 'ignorant' is considered to be toxic, while the other is predicted to be benign. The first instance of 'ignorant' does not seem to be as toxic as the second instance and therefore,

more analysis needs to be done to determine the 'degree' of toxicity of the spans. This can be a good direction for future research.

# UoB at SemEval-2021 Task 5: Extending Pre-Trained Language Models to Include Task and Domain-Specific Information for Toxic Span Prediction

## Abstract

Toxicity is pervasive in social media and poses a major threat to the health of online communities. The recent introduction of pre-trained language models, which have achieved state-of-the-art results in many NLP tasks, has transformed the way in which we approach natural language processing. However, the inherent nature of pre-training means that they are unlikely to capture task-specific statistical information or learn domain-specific knowledge. Additionally, most implementations of these models typically do not employ conditional random fields, a method for simultaneous token classification. We show that these modifications can improve model performance on the Toxic Spans Detection task at SemEval-2021 to achieve a score within 4 percentage points of the top performing team.

## 1 Introduction and Motivation

Moderation is crucial to promoting healthy online discussions. The anonymity afforded by computer-mediated communication enables individuals to engage in toxic behaviour which they would otherwise not consider. Although many datasets and models focusing on toxicity detection have been released, most of them classify entire sequences of text, and do not highlight the individual words that make a text toxic. The Toxic Spans Detection task at SemEval-2021 (Pavlopoulos et al., 2021) focuses on the evaluation of systems that can accurately identify toxic spans within text. Highlighting such spans can provide more information to human moderators in the form of attribution, instead of an unexplained toxicity score per post, and is thus a crucial step towards successful semi-automated moderation. In this paper we focus on the shared task, wherein systems are expected to extract a list of toxic spans, or an empty list, per text. A toxic span is defined as a sequence of words that contributes to a text’s toxicity.

Since 2018, NLP models have adopted the concept of generative pre-training on a diverse corpus of unlabelled text, followed by supervised fine-tuning on specific tasks (Radford et al., 2018). Pre-trained models are built to simulate anthropomorphic learning, wherein existing knowledge can be adapted to new tasks without the need to train on these tasks from scratch - a requirement of traditional machine learning models. This idea of transfer learning, whilst powerful, leads to models being fine-tuned on target tasks using significantly fewer epochs than was previously standard. This reduced training on the target task means that task-specific statistical information or domain-specific knowledge may not be learned by these models.

Such task-specific data may include count-based information, which has been shown to improve the performance of pre-trained models in sequence classification tasks (Lim and Madabushi, 2020; Prakash and Madabushi, 2020), or domain-specific knowledge, such as information pertaining to word toxicity, which has been shown to be one of the most predictive features of offensive commentary (Noever, 2018).

Additionally, pre-trained models tend to use a fully connected layer for classification tasks. This classification layer, however, makes an individual localised prediction for each token without accounting for predictions made on other tokens. A CRF (Lafferty et al., 2001), on the other hand, maximises the probability of the entire sequence of predictions. This makes it more effective for cases where neighbouring predictions may influence each other. NER is one such application, where the decision to assign a certain label to a token may be influenced by the labels assigned to neighbouring tokens. Souza et al. (2020) combined the transfer capabilities of BERT (Devlin et al., 2019) with the structured predictions of a CRF, with the addition of a CRF yielding performance improvements in

several token-level tasks.

Thus, this work aims to test the following hypotheses:

**Hypothesis 1** *Count-based information can aid pre-trained models in token classification tasks.*

**Hypothesis 2** *Pre-trained models are unlikely to capture domain-specific information. Such information is likely to improve their performance in token classification tasks.*

**Hypothesis 3** *Adding a CRF, which affords a sentence-level predictive scope, will improve pre-trained model performance in token classification tasks.*

To ensure reproducibility, our program code, including hyperparameters, is made available online<sup>1</sup>.

## 2 Related Work

Count-based information has been shown to improve the performance of pre-trained models in sequence classification tasks. [Lim and Madabushi \(2020\)](#) proposed an ensemble model of BERT and TF-IDF, which combined the sentence-level information captured by BERT with the corpus-level information provided by TF-IDF. The ensemble model performed 5 percentage points better than a standard BERT model on Subtask A at OffensEval-2020 ([Zampieri et al., 2020](#)), achieving a score within 2 percentage points of the top performing team. Similarly, [Prakash and Madabushi \(2020\)](#) employed an ensemble model of RoBERTa ([Liu et al., 2019b](#)) with a multilayer perceptron using TF-IDF features as input. The ensemble model improved upon the base RoBERTa model by 7 percentage points to achieve state-of-the-art results on the RumourEval-2019 dataset ([Gorrell et al., 2019](#)). We use these studies as a basis for our first hypothesis described in Section 1, and employ a similar method for incorporating TF-IDF features described in Section 3.

Domain-specific information has been shown to be an effective measure of toxicity. [Noever \(2018\)](#) evaluated the relative predictive value of 28 features of syntax, sentiment, emotion, and outlier word dictionaries for online toxicity detection. By rank-ordering features through feature selection, the most predictive feature of offensive commentary was shown to be a simple bad word list. [Peder-](#)

<sup>1</sup>[https://github.com/erikdyan/toxic\\_span\\_detection](https://github.com/erikdyan/toxic_span_detection)

[sen \(2019\)](#) compared two logistic regression classifiers against a simple word list model on Subtask A at OffensEval ([Zampieri et al., 2019](#)), with the rule-based model performing 4 percentage points better than either logistic regression model. Section 3 discusses our methodology for adding word list features, which capture key word information in the offensive language domain, to pre-trained models.

As discussed in Section 1, a CRF is a method for simultaneous token classification which is not commonly employed by pre-trained models. [Souza et al. \(2020\)](#) proposed a BERT-CRF model architecture composed of a token-level classifier on top of a BERT model followed by a linear-chain CRF. Models with a CRF improved upon or performed similarly to models without one on NER tasks in the Portuguese language. This study is, to the best of our knowledge, one of the few that directly compares the performance of a base BERT model against a BERT-CRF model. The improvements arising from adding a CRF supports our third hypothesis described in Section 1, which aims to explore whether similar improvements will arise in the context of toxic span detection.

Submissions to past toxicity detection tasks at SemEval, such as OffensEval and OffensEval-2020, highlight how effective BERT can be for toxicity detection. [Liu et al. \(2019a\)](#) used a fine-tuned BERT model to achieve state-of-the-art results on Subtask A at OffensEval, and seven of the top ten teams used BERT. Similarly, the top ten teams on Subtask A at OffensEval-2020 all used BERT, RoBERTa, or XLM-RoBERTa ([Conneau et al., 2020](#)), sometimes as part of ensemble models with CNNs and LSTMs. ([Wiedemann et al., 2020](#)) submitted the best performing model, which used an ensemble of ALBERT ([Lan et al., 2020](#)) models of different sizes. The success of these models in toxicity detection tasks led us to choose to use a BERT-based model for this work.

## 3 Methodology

Our pre-trained model of choice was DistilBERT ([Sanh et al., 2020](#)), which we used as a baseline measure of performance. We explore and present four models in addition to the baseline DistilBERT model in this paper:

1. DistilBERT+TF-IDF
2. DistilBERT+Word List
3. DistilBERT+TF-IDF+Word List
4. DistilBERT+CRF

To build a basis for comparison, all models were trained using the training data provided by the task organisers and evaluated against the validation dataset. The best performing models were then submitted for evaluation against the test dataset during the task evaluation period. The training process was performed five times, using a different random seed each time. This is because varying the random seed used in fine-tuning BERT models can yield substantially different results, even if the models are the same and identical hyperparameters are used (Dodge et al., 2020). The best performing version of each model was used for the remainder of the study.

In Section 1, we hypothesised that adding count-based information to pre-trained models would improve model performance in token classification tasks. TF-IDF is a count-based statistical measure that captures corpus-level information, accounting for global correlations and associations between words. Use of TF-IDF captures word importance, enabling the identification of key words. This word importance could contribute to the identification of a text’s toxicity, as shown by Lim and Madabushi (2020); Prakash and Madabushi (2020). Thus, we tested our first hypothesis by integrating TF-IDF with the DistilBERT model.

One of the most straightforward approaches for toxicity detection is to use a word list, whereby the toxicity of a sequence is determined by comparing the words it contains against a list of known toxic words. Such domain-specific information has been shown to be effective for toxicity detection (Noever, 2018; Pedersen, 2019). We tested our second hypothesis by adapting a word list feature for token classification and integrating it with the DistilBERT model.

We incorporated the TF-IDF and word list features by modifying the DistilBERT model. First, we removed the token classification layer on top of the baseline DistilBERT model. Then, for the TF-IDF feature, we appended each token’s TF-IDF weight to its hidden state output vector. For the word list feature, we appended a value of 0 or 1. A value of 1 was used if the token appeared in the word list, whilst a value of 0 was used if it did not. These vectors were then pushed through a fully

connected layer for classification.

We tested our third hypothesis by adding a CRF, a method for simultaneous token classification, to the DistilBERT model. We followed the more successful fine-tuning approach used by Souza et al. (2020), which uses a linear classification layer and updates all weights, including BERT’s, during training. The CRF takes the output scores from the classification layer as input and computes the log-likelihood of the given sequence of tags. The model was trained to maximise the log-likelihood of the correct tag sequence.

## 4 Results

Table 1 shows how the best performing version of each model performed when tested against the validation dataset.

Model	F1 Score
DistilBERT	0.58896
DistilBERT+TF-IDF	0.58930
DistilBERT+Word List	0.59296
DistilBERT+TF-IDF+Word List	0.58613
DistilBERT+CRF	0.58615

Table 1: Best F1 score achieved by each model, tested against the validation dataset.

We observe that the inclusion of count-based features did improve model performance, though the increase was very slight. A larger improvement resulted from the use of a word list, whilst model performance worsened when both TF-IDF and word list features were used together and when a CRF was added.

As model performance on the validation dataset was very similar, all models were submitted to the task evaluation stage. Table 2 shows the results of each model tested against the test dataset, whilst Table 3 shows how our best performing model ranked out of the 91 participating teams.

Model	F1 Score
DistilBERT	0.66937
<b>DistilBERT+TF-IDF</b>	<b>0.67609</b>
DistilBERT+Word List	0.67136
DistilBERT+TF-IDF+Word List	0.67393
DistilBERT+CRF	0.67409

Table 2: F1 score achieved by each model, tested against the test dataset.

Rank	Team	F1 Score
1	HITSZ-HLT	0.70830
2	S-NLP	0.70770
3	hitmi&t	0.69848
	...	
<b>25</b>	<b>UoB</b>	<b>0.67609</b>

Table 3: Ranking and F1 score achieved by each team’s best performing model, tested against the test dataset.

It is clear that the F1 scores achieved by all models were very similar when tested against the test dataset, with the DistilBERT+TF-IDF model improving upon the baseline DistilBERT model the most. It is worth noting, however, that whilst this difference is only 0.00672, that same difference would have increased our ranking by 6 ranks had it been added to our final F1 score. Section 5 analyses the significance of the results achieved and studies the differences between the predictions of the DistilBERT and DistilBERT+TF-IDF models in greater detail.

## 5 Discussion and Analysis

It is difficult to conclude with any certainty whether the addition of our proposed features improved model performance, as the scores achieved are very similar. Whilst the increase in performance observed may indeed be due to our additions to the model, we also propose two alternative theories.

The similarity in results may be due to the relative length of the token vectors compared to the length of the additional features. The hidden output from DistilBERT represents each token as a vector of length 768; the addition of one or two elements to each token vector may not be significant enough to discernibly impact model predictions. That being said, there are still small variations in performance between the models. Whilst this may be due to the addition of new features, it may also be due to variations in the random seed used during fine-tuning. Our most improved model performed 0.00672 F1 points better than the baseline DistilBERT model - a figure within the performance variation range observed during tests involving the random seed (the DistilBERT+TF-IDF model ranged by 0.00922 from 0.58008 to 0.58930, for example). Despite our efforts to counteract this, time and resource limitations meant we were only able to train each model five times instead of the more rigorous ten.

We conduct a more detailed analysis into the

predictions of the baseline DistilBERT model and our best performing (DistilBERT+TF-IDF) model. Tables 4 and 5 show the confusion matrix of each model, respectively. These matrices are constructed using a subset of the test dataset from which the tokens correctly predicted by both models to be non-toxic have been removed. We subset the dataset in this way to significantly reduce the size of the data and to remove less interesting tokens. Table 4 shows that the baseline DistilBERT model tends to overpredict toxic labels, resulting in 1466 false positives. Table 5 shows that the addition of the TF-IDF feature helps to mitigate this, with the DistilBERT+TF-IDF model correctly predicting over 100 of DistilBERT’s false positives as true negatives - an overall improvement of 2.5% on this subset of the test set.

		Predicted	
		Non-Toxic	Toxic
True	Non-Toxic	202	1466
	Toxic	682	1829

Table 4: Confusion matrix of the DistilBERT model on a subset of the test dataset from which the tokens correctly predicted by both the DistilBERT and DistilBERT+TF-IDF models to be non-toxic have been removed.

		Predicted	
		Non-Toxic	Toxic
True	Non-Toxic	310	1358
	Toxic	692	1819

Table 5: Confusion matrix of the DistilBERT+TF-IDF model on a subset of the test dataset from which the tokens correctly predicted by both the DistilBERT and DistilBERT+TF-IDF models to be non-toxic have been removed.

In addition to an exploration of the results and confusion matrix, we perform an error analysis by manually comparing the true labels and predictions of the DistilBERT and DistilBERT+TF-IDF models. We first observe that there are some inconsistencies in the true labels. For example, the phrase “... racist, sexist, narcissistic, pathological liar ...” is marked as non-toxic, whereas “... sexist rubbish ...” is marked as toxic. Another trend observed is that both models struggle to correctly predict phrases containing ordinarily non-toxic words which become toxic given the context. For example, consider the phrases “Trump troll”, “Bunch of

cowards”, “Total rubbish”, and “PATHETIC LIB LOSER”. Whilst the true labels classify all of these phrases as toxic, both models only predicted the words “troll”, “cowards”, “rubbish”, “pathetic”, and “loser” to be toxic.

These trends highlight some of the inherent difficulties involved in token classification tasks for both machine learning models and human annotators.

## 6 Conclusion and Future Work

This work explored the possibility of improving pre-trained model performance on the token classification task of toxic span detection. As discussed in Section 1, we hypothesised that adding 1) count-based information, 2) domain-specific knowledge, and 3) a CRF can aid pre-trained models in token classification tasks. Whilst our experimental results (Section 4) seem to suggest that all three of these features improve the performance of DistilBERT, we note that they do so only marginally (Section 5). Further analysis, however, showed that, whilst the overall F1 improvement from adding TF-IDF was small, the addition of a count-based feature helped to reduce DistilBERT’s overprediction of toxic tokens.

We believe that these improvements, whilst small, provide an interesting avenue of exploration. We intend to further explore how these and other similar features interact with pre-trained models in the task of token classification.

## Abstract

Social network platforms are generally used to share positive, constructive, and insightful content. However, in recent times, people often get exposed to objectionable content like threat, identity attacks, hate speech, insults, obscene texts, offensive remarks or bullying. Existing work on toxic speech detection focuses on binary classification or on differentiating toxic speech among a small set of categories. This paper describes the system proposed by team Cisco for SemEval-2021 Task 5: Toxic Spans Detection, the first shared task focusing on detecting the spans in the text that attribute to its toxicity, in English language. We approach this problem primarily in two ways: a sequence tagging approach and a dependency parsing approach. In our sequence tagging approach we tag each token in a sentence under a particular tagging scheme. Our best performing architecture in this approach also proved to be our best performing architecture overall with an  $F_1$  score of **0.6922**, thereby placing us 7<sup>th</sup> on the final evaluation phase leaderboard. We also explore a dependency parsing approach where we extract spans from the input sentence under the supervision of target span boundaries and rank our spans using a biaffine model. Finally, we also provide a detailed analysis of our results and model performance in our paper.

## 1 Introduction

It only takes one toxic comment to sour an online discussion. The threat of abuse and harassment online leads many people to stop expressing themselves and give up on seeking different opinions. Toxic content is ubiquitous in social media platforms like Twitter, Facebook, Reddit, the increase of which is a major cultural threat and has already lead to a crime against minorities (Williams et al., 2020). Toxic text in online social media varies depending on targeted groups (e.g. women, LGBT,

gay, African, immigrants) or the context (e.g. pro-trump discussion or the metoo movement). Toxic Text online has often been broadly classified by researchers into different categories like hate, offense, hostility, aggression, identity attacks, and cyberbullying. Though the use of various terms for equivalent tasks makes them incomparable at times (Fortuna et al., 2020), toxic speech or spans in this particular task, SemEval-2021 Task 5 (Pavlopoulos et al., 2021), has been considered as a super-set of all the above sub-types.

1. Two new contestants for America's **Dumbest Criminals**.
2. **Stealing** is what you do best.

Figure 1: Toxic spans in sentences

While a lot of models have claimed to achieve state-of-the-art results on various datasets, it has been observed that most models fail to generalize (Arango et al., 2019; Gröndahl et al., 2018). The models tend to classify comments as toxic that have a reference to certain commonly-attacked entities (e.g. gay, black, Muslim, immigrants) without the comment having any intention to be toxic (Dixon et al., 2018; Borkan et al., 2019). A large vocabulary of certain trigger terms leads to a biased prediction by the models (Sap et al., 2019; Davidson et al., 2017). Thus, it has become increasingly important in recent times to determine parts of the text that attribute to the toxic nature of the sentence, for both automated and semi-automated content moderation on social media platforms, primarily for the purpose of helping human moderators deal with lengthy comments and also provide them attributions for better explainability on the toxic nature of the post. This in turn would aid in better handling of unintended bias in toxic text classification. SemEval-2021 Task 5: Toxic Spans Detection focuses on exactly this problem of detecting toxic

spans from sentences already classified as toxic on a post-level.

In this paper, we approach the problem of multiple non-contiguous toxic span extraction from texts both as a *sequence tagging task* and as a standard *span extraction task* resembling the generic approach and architecture adopted for single-span Reading Comprehension (RC) task. For our sequence tagging approach, we predict for each token, whether it is a part of the span. For our second approach, we predict and compute a couple of scores for each token, corresponding to whether that token is the start or end of the span. In addition to this, we deploy a biaffine model to score start and end indices, thus adopting the methodology for multiple non-contiguous span extraction.

## 2 Literature

Previous work on automated toxic text detection, and its various sub-types, focuses on developing classifiers that can flag toxic content with a high degree of accuracy on datasets curated from various social media platforms in English (Carta et al., 2019; Saeed et al., 2018; Vaidya et al., 2020), other foreign languages (Zhang et al., 2018; Mishra et al., 2018; Qian et al., 2019; Davidson et al., 2017; Kamal et al., 2021; Leite et al., 2020) including code-switched text (Mathur et al., 2018a,b; Kapoor et al., 2019) and multilingual text (Zampieri et al., 2019). This topic has also evidenced a number of workshops (Kumar et al., 2018) and competitions (Zampieri et al., 2019, 2020; Basile et al., 2019; Mandl et al., 2019).

Recent work shows transformer based architectures like BERT (Devlin et al., 2019) have been performing well on the task of offensive language classification (Liu et al., 2019a; Safaya et al., 2020; Dai et al., 2020). Transformer based architectures have also produced state-of-the-art performance on sequence tagging tasks like *Named Entity Recognition (NER)* (Yamada et al., 2020; Devlin et al., 2019; Yang et al., 2019) *span extraction* (Eberts and Ulges, 2019; Joshi et al., 2020) and *QA tasks* (Devlin et al., 2019; Yang et al., 2019; Lan et al., 2020). Multiple span extraction from texts has been explored both as a *sequence tagging task* (Patil et al., 2020; Segal et al., 2019) and as span extraction as in RC tasks (Hu et al., 2019; Yu et al., 2020).

Very recently HateXplain (Mathew et al., 2020) proposed a benchmark dataset for explainable hate speech detection using the concept of rationales.

Attempts have also been made to handle identity bias in toxic text classification (Vaidya et al., 2020) and also to make robust toxic text classifiers which help adversaries not bypass toxic filters (Kurita et al., 2019).

## 3 Methodology

For our sequence tagging approach, we explore two tagging schemes. First, the well known *BIO* tagging scheme, where *B* indicates the first token of an output span, *I* indicates the subsequent tokens and *O* denotes the tokens that are not part of the output span. Additionally, we also try a simpler *IO* tagging scheme, where words which are part of a span are tagged as *I* or *O* otherwise. Formally, given an input sentence  $\mathbf{x} = (x_1, \dots, x_n)$ , of length  $n$ , and a tagging scheme with  $|S|$  tags ( $|S| = 3$  for *BIO* and  $|S| = 2$  for *IO*), for each of  $n$  tokens the probability for the tag of the  $i$ -th token is

$$\mathbf{p}_i = \text{softmax}(f(\mathbf{h}_i)) \quad (1)$$

where  $\mathbf{p} \in R^{m \times |S|}$ , and  $f$  is parameterized function with  $|S|$  outputs.

Our other approach is based on the standard single-span extraction architecture widely used for RC Tasks. With this approach, we extract toxic spans from sentences under the supervision of target span boundaries, but with an added biaffine model for scoring the multiple toxic spans instead of simply taking top  $k$  spans based on the start and end probabilities, thus giving our model a global view of the input. The main advantage of this approach is that the extractive search space can be reduced linearly with the sentence length, which is far less than the sequence tagging method. Given an input sentence  $\mathbf{x} = (x_1, \dots, x_n)$ , of length  $n$ , we predict a target list  $\mathbf{T} = (t_1, \dots, t_m)$  where the number of targets is  $m$  and each target  $t_i$  is annotated with its start position  $s_i$ , its end position  $e_i$  and the class that span belongs to (only one in our case, *toxic*).

However, to adapt to the problem of extracting multiple spans from the sentence, instead of taking the top  $k$  spans based on the start and end probabilities, we apply a biaffine model (Dozat and Manning, 2016) to score all the spans with the constraint  $s_i \leq e_i$ . Post this we rank all the spans in descending order and choose every span as long it does not clash with higher-ranked spans.

## 4 Dataset

The dataset provided to us by the organizers of the workshop consisted of a random subset of 10,000 posts from the publicly available Civil Comments Dataset, from a set of 30,000 posts originally annotated as toxic (or severely toxic) on post-level annotations, manually annotated by 3 crowd-raters per post for toxic spans. The final character offsets were obtained by retaining the offsets with a probability of more than 50%, computed as a fraction of raters who annotated the character offsets as toxic. Basic statistics about the dataset can be found in Table 1.

	Sentences	Spans
Train	7939	10298
Dev	690	903
Test	2000	1850

Table 1: Number of sentences and spans

Additionally, we provide a quick look into the length-wise distribution of spans across the train, development, and test set in Table 2. As we observe, the majority of the spans are just a single word in length and mostly comprise of the most commonly used cuss words in the *English* language. In our Results Analysis section, we show how this metric stands important for training and evaluating our systems and for the future development of toxic span extraction datasets.

	Train	Dev	Test
1	7897	687	1650
2-4	1617	153	174
$\geq 5$	784	63	26

Table 2: Length-wise segregation of the number of non-contiguous spans

## 5 Evaluation Metric

To evaluate the performance of our systems we employ  $F_I$  as used by [Da San Martino et al. \(2019\)](#). Let system  $A$  return a set  $S_A^t$  of character offsets, for parts of the post found to be toxic. Let  $S_G^t$  be the character offsets of the ground truth annotations of post  $t$ . We calculate  $F_I$  score of  $S_A^t$  w.r.t  $S_G^t$  as follows where  $|\cdot|$  denotes set cardinality.

$$P^t(A, G) = \frac{|S_A^t \cap S_G^t|}{|S_A^t|} \quad (2)$$

$$R^t(A, G) = \frac{|S_A^t \cap S_G^t|}{|S_G^t|} \quad (3)$$

$$F_1^t(A, G) = \frac{2 \cdot P^t(A, G) \cdot R^t(A, G)}{P^t(A, G) + R^t(A, G)} \quad (4)$$

If predicted span i.e  $S_A^t$  is empty for a post  $t$  then we set  $F_1^t(A, G) = 1$  if the gold truth i.e  $S_G^t$  is also empty, else if  $S_G^t$  is empty and  $S_A^t$  is not empty then we set  $F_1^t(A, G) = 0$ .

## 6 System Description

### 6.1 Sequence Tagging Approach

For our sequence tagging approach we employ the commonly used BiLSTM-CRF architecture ([Huang et al., 2015](#)) used predominately in many sequence tagging problems, but with added contextual word embeddings for each word using transformer and character-based word embeddings. We experiment with a total of 5 transformer architectures, namely BERT ([Devlin et al., 2019](#)), XLNet ([Yang et al., 2019](#)), RoBERTa ([Liu et al., 2019b](#)), ALBERT ([Lan et al., 2020](#)) and SpanBERT ([Joshi et al., 2020](#)). For all of the above mentioned transformer architectures, the *large* variant of the transformer was used except ALBERT for which we use its *xlarge-v2* variant. First, the tokenized word input is passed through the transformer architecture and the output of the last 4 encoder layers is concatenated to obtain the final contextualized word embedding  $E_T$  for each word in the sentence. Additionally, we also pass each character in a word through a character-level BiLSTM network, to obtain character-based word embeddings for the word  $E_C$  as used by [Lample et al. \(2016\)](#). Finally, both these word embeddings,  $E_T$  and  $E_C$ , for each word are concatenated and passed through a BiLSTM layer followed by a CRF layer to obtain the best probable tag for each word in the sentence.

### 6.2 Dependency Parsing Approach

For our dependency parsing approach, we employ a similar approach as proposed by [Yu et al. \(2020\)](#), using a biaffine classifier to score our spans post-extraction. This methodology fits best to our purpose of *multiple* toxic span extraction from sentences compared to span extraction systems in general RC tasks which are capable of extracting just a single span from a sentence ([Yang and Ishfaq](#)). For each word first we extract it’s BERT, FasText

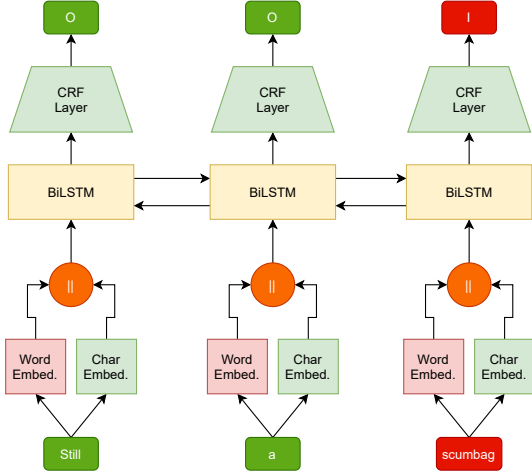

Figure 2: Sequence Tagger Model

and character-based word embeddings. We used  $BERT_{Large}$  for all our experiments and used the recipe followed by Kantor and Globerson (2019) to extract contextual embeddings for each token. After concatenating both the word embeddings and character embeddings for each word, we feed the output to a BiLSTM layer. We then apply two separate FFNNs to the output word representations  $x$  to create different representations ( $h_s / h_e$ ) for the start/end of the spans. These representations are then passed through a biaffine model for scoring all possible spans  $(s_i, e_i)$ , where  $s_i$  and  $e_i$  are start and end indices of the span, under the constraint  $s_i \leq e_i$  (the start of the span is before its end) by creating a  $l \times l \times c$  scoring tensor  $r_m$ , where  $l$  is the length of the sentence and  $c$  is the number of NER categories + 1 (for non-entity). We compute the score for a span  $i$  by:

$$h_s(i) = FFNN_s(x_{s_i}) \quad (5)$$

$$h_e(i) = FFNN_e(x_{e_i}) \quad (6)$$

$$r_m(i) = h_s(i)^T U_m h_e(i) + W_m (h_s(i) \oplus h_e(i)) + b_m \quad (7)$$

We finally assign each span a category  $y'$  based on

$$y'(i) = \arg \max r_m(i) \quad (8)$$

Post this, we rank each span that has a category other than non-entity and consider all the spans for our final prediction as long as it does not clash with higher ranked spans with an additional constraint,

whereby, an entity containing or is inside an entity ranked before it will not be selected.

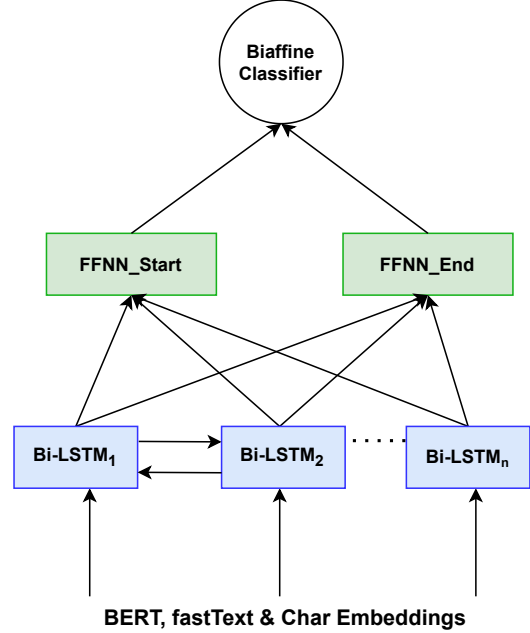

Figure 3: Biaffine Model

## 7 Experimental Setup

Data was originally provided to us in the form of sentences and the corresponding character offsets for the toxic spans of the sentence. Before converting the character offsets to our required format for our respective approaches, we apply some basic text pre-processing to all our sentences. First, we normalize all the sentences by converting all white-space characters to spaces. Second, we split all punctuation characters from both sides of a word and also break abbreviated words. These pre-processing steps help improve the  $F_1$  score of both our approaches as shown in Table 6. Post these pre-processing steps, we formulate our targets for both our approaches. For our sequence tagging approach, we tag each word in the sentence with its corresponding tag based on the tagging scheme we follow, *BIO* or *IO*. For our span extraction approach, we convert the sequence of character offsets into its corresponding word-level start and end indices for each span. In Fig. 4, we provide a pictorial representation of the above mentioned procedures we follow for data preparation for both our approaches.

We use PyTorch<sup>1</sup> Framework for building our Deep Learning models along with the Transformer

Table 4: Major hyperparameters of Dependency Parsing model

We train all our sequence tagging models with

<sup>2</sup><http://huggingface.co/>

stochastic gradient descent in batched mode with a batch size of 8. In the training phase, we keep all layers in our model, including all the transformer layers trainable. We start training our model at a learning rate of 0.01, with a minimum threshold limit of 0.0001, and half the learning rate after every 4 consecutive epochs of no improvement in the  $F_1$  score of the development set. We train our model to a maximum of 100 epochs or 4 consecutive epochs of no improvement at our minimum learning rate.

We train our our model for dependency parsing approach with Adam optimizer in batched mode with a batch size of 32 and a learning rate of 0.0001 for a maximum of 40,000 steps. With this approach too, we keep all layers trainable in the training phase except the BERT Transformer layers. Pre-trained BERT and fastText embeddings were just used to extract context-dependent and independent embeddings respectively and BERT was *not fine-tuned* in the training phase.

The training was performed on 1 NVIDIA Titan X GPU. Our code is available on Github<sup>3</sup>.

## 8 Results

In Table 5 we present  $F_1$  scores for all our systems trained for both our sequence tagging and span extraction approaches. For our sequence tagging approach, we divide our results according to the transformer architecture and tagging scheme used for that experiment.

Model	Scheme	Test	Dev
XLNet	IO	<b>0.6922</b>	0.6945
XLNet	BIO	0.6653	0.6683
spanBERT	IO	0.6777	0.6744
spanBERT	BIO	0.6887	0.6730
RoBERTa	IO	0.6647	<b>0.6967</b>
RoBERTa	BIO	0.6849	0.6789
BERT	IO	0.6830	0.6814
BERT	BIO	0.6852	0.6815
ALBERT	IO	0.6621	0.6702
ALBERT	BIO	0.6679	0.6431
Biaffine	-	0.6731	0.6627

Table 5: Test and Dev Results of different models on various tagging scheme

Our best performing architecture proved to be the sequence tagging system with XLnet trans-

<sup>3</sup><https://github.com/Sreyan88/SemEval-2021-Toxic-Spans-Detection>

former trained with *IO* tagging scheme. Additionally, in Table 6 we show how the LSTM and CRF over the transformer architecture, and our pre-processing step mentioned in Section 7 affect the performance of our best performing architecture.

	F1	$\Delta$
Our Model	0.6922	-
- LSTM	0.6912	0.0010
- CRF	0.6850	0.0072
- Pre-processing	0.6759	0.1630

Table 6: Impact of LSTM, CRF and pre-processing on learning

## 9 Results Analysis

### 9.1 Length vs Performance

We wanted to understand how the performance of the system varied with varying lengths of spans. Table 7 summarizes the performance of our best performing systems on all approaches experimented by us, on the test dataset spans, divided into 3 sets according to their length in terms of the number of words that help to make the span.

Model	Span length	F1
Seq. Tagger (IO)	1	<b>0.6546</b>
	2-4	0.1750
	$\geq 5$	0.0596
Seq. Tagger (BIO)	1	<b>0.6588</b>
	2-4	0.1524
	$\geq 5$	0.09198
Dependency Parsing	1	<b>0.6486</b>
	2-4	0.0514
	$\geq 5$	0.0

Table 7: Span Length vs. Performance

### 9.2 Learning context

Majority of single word spans in the dataset are the most commonly used cuss words or abusive words in the English language, i.e., words that can be directly classified as toxic and are not context-dependant, e.g. "stupid", "idiot" etc., with spans longer than a single word having a lesser ratio of such words. We acknowledge the fact that an AI-based system should be able to do much more, like learning the context behind which a word is used, than just detect common *English* cuss words from a sentence, which can be otherwise done by a simple

1. So you agree that **black children should be killed**. I got it. So much for innocent until proven guilty. That is a white privilege too.
2. Good luck with those emerging markets. Your state is over saturated with commercial grows and the price is plummeting. He will have to put his stuff on the **black** market and that won't work either. He's an **idiot**.

Figure 5: Toxicity classification of the word "black" in toxic and non-toxic context

dictionary search. The deteriorating performance of the model with an increase in span length makes us dig deeper into our test set results to find out if our model is being able to detect *context-based* toxic spans from sentences. We follow a two step procedure to analyze this. First, we calculate our model performance on single-word spans consisting of just the top 25 most commonly occurring context-independent cuss words<sup>4</sup>. Table 8 shows an analysis of these results. Second, we take the word "black" and analyze two sentences in our test where the word black was mentioned in a toxic and non-toxic context. Fig. 5 shows how our model indeed tags the latter black as toxic and the former one as non-toxic.

Single Word Cuss Spans	Others
0.6894	0.1736

Table 8: F<sub>1</sub> score of context independent cuss words

## 10 Conclusion

In this paper, we present our approach to SemEval-2021 Task 5: Toxic Spans Detection. Our best submission gave us an *F<sub>1</sub>* score of **0.6922**, placing us 7<sup>th</sup> on the Evaluation Phase Leaderboard. Future work includes independently incorporating both post level and sentence level context for determining the toxicity of a word, and also collating a dataset with toxic spans comprising of a healthy mixture of simple cuss words (which can always be attributed as toxic independent of the context) and words for which the toxicity of the word depends on the context in which it appears, thereby making better systems towards *contextual* toxic span detection.

<sup>4</sup>List of cuss words used for analysis can be found in our GitHub repository

## Abstract

This paper describes the system submitted to SemEval 2021 Task 5: Toxic Spans Detection. The task concerns evaluating systems that detect the spans that make a text toxic when detecting such spans are possible. To address the possibly multi-span detection problem, we develop a start-to-end tagging framework on the top of RoBERTa based language model. Besides, we design a custom loss function which take distance into account. In comparison to other participating teams, our system has achieved 69.03% F1 score, which is slight lower (-1.8 and -1.73) than the top 1 (70.83%) and top 2 (70.77%), respectively.

## 1 Introduction

In recent years, social networks and microblogging sites' popularity have increased, attracting more users. With a huge user base, social media will continue to publish a large amount of user-generated content. As the use of social media increased, other undesirable phenomena and behaviors emerged. Social media users often abuse this freedom to spread abusive or hateful posts or comments. In many cases, the user-generated content is offensive or proactive, and users may have to deal with threats such as cyberattacks or cyberbullying, and other undesirable (Warner and Hirschberg 2012). Therefore, the issue of detecting and possibly limiting the spread of toxic post has become increasingly important.

Although several toxicity or abusive language detection datasets (Wulczyn et al. 2016; Borkan et al. 2019) and models (Borkan et al. 2019; Pavlopoulos et al. 2017; Zampieri et al. 2019) have been released, most of them classify whole comments or documents, and do not identify the spans that make a text toxic. But highlighting such toxic spans can

assist human moderators (e.g., news portals moderators) who often deal with lengthy comments, and who prefer attribution instead of just a system-generated unexplained toxicity score per post. The evaluation of systems that could accurately locate toxic spans within a text is thus a crucial step towards successful semi-automated moderation.

For this reason, SemEval 2021 set up the task Toxic Spans Detection to detect and extract the spans that make a text toxic, when detecting such spans is possible (Pavlopoulos et al. 2021). To address the possibly multi-span extraction problem, we develop a start-to-end tagging framework with custom distance loss, which can tag the start and end position of a toxic span. Based on this scheme, we can effectively deal with the multi-span extraction problem.

The rest of the paper is organized as follows: Section 2 provides system overview. Section 3 describes our approach in detail. Our experiment is discussed in Section 4. We conclude our work in Section 5.

## 2 System Overview

### 2.1 Preprocessing and Word Embedding

The training dataset contains 3 columns:

ID - Contains a unique number to identify each training example.

Spans - Contains a list of indexes that indicates the position of toxic spans.

Text - Contains the text that need to detect and extract the toxic spans.

Note that the spans are not given in text, We transformed the indexes to text first. Besides, we append the "negative" word to the end of each post serving as the indicator. We use word embeddings as input to the model. Word embedding is a distributed vector representation of words (Mikolov et al. 2013), capturing the syntactic and semantic in-

\* Corresponding author.

formation of words. Effective word embedding can get better performance. After comparison, we use the RoBERTa-based pre-training language models as sentence encoder for word embedding.

## 2.2 Sequence Tagging

Sequence tagging as a general methods can be used in wide applications, such as named entity recognition, relation extraction, machine reading comprehension and so on.

The tagging scheme can be divided into BIO (Zheng et al. 2017), BIOES (Huang et al. 2015) and others, in which B denotes the first token of an output span, I denotes subsequent tokens in a span, O denotes tokens that are not part of an output span, E denotes the last token of an output span and S denotes token that is an output span.

## 3 Model Description

Our model has two steps as follows: 1. Concatenate the "negative" word at end of each post. 2. Obtain the word embedding of each token in the post to form the final representation and predict the start and end probabilities for each token as output.

Figure 1 shows the general structure of the system. More details for the systems components are shown in the following subsections.

### 3.1 Embedding Layer

As input sequence  $X$  of length  $T$  is composed of word tokens:  $X = \{x_1, \dots, x_T\}$ . Each token  $x_t$  is replaced with the corresponding vocabulary index  $V(t)$ . The embedding layer transforms the token into vector  $e_t \in R^d$  which is selected from the embedding matrix  $E$  according to the index, where  $d$  is the dimensionality of the embedding space.

In order to indicate the model extract toxic or negative spans, we append the word embedding vector of "negative" to the end of each post. We take the mean of last two hidden layer's weight as word embedding. The example of sentence constructed is also shown in Figure 1.

### 3.2 Tagging scheme

Although the classical BIOES tag based model can obtain competitive result, we think the training dataset is not big enough to learn so many tags. So different the above methods, we apply the start-to-end tagging scheme that predicting start and end probabilities for each token. The different target sequence used by several loss function are as shown in Figure 1.

## 3.3 Loss Function

### 3.3.1 Classical Cross-Entropy Loss

At the beginning, we use the classical binary cross-entropy loss, which creates a criterion that measures the Binary Cross Entropy between the target and the output. The loss can be described as:

$$\ell(x, y) = L = \{l_1, \dots, l_N\}^\top$$

$$l_n = -[y_n \cdot \log x_n + (1 - y_n) \cdot \log (1 - x_n)]$$

### 3.3.2 Label Smoothing Loss

Consider that, we are using roBERTa(Liu et al. 2019) as encoder, which is a large pre-trained language model. and may cause the over-fitting problem. To prevent this, we apply the label smoothing(Szegedy et al. 2015) method and change the '0' in the target sequence to small value 0.025. The computation method is same with cross-entropy loss.

### 3.3.3 Kullback-Leibler Divergence Loss

Besides the handcrafted label smoothing loss, we also tried the KLDivLoss, which is a useful distance measure for continuous distributions and is often useful when performing direct regression over the space of (discretely sampled) continuous output distributions.

The target sequence is the same with the above binary cross-entropy loss. The loss can be described as:

$$l(x, y) = L = \{l_1, \dots, l_N\}$$

$$l_n = y_n \cdot (\log y_n - x_n)$$

where the index  $N$  spans all dimensions of input and  $L$  has the same shape as input.

### 3.3.4 Custom Distance Loss

We notice that the cross-entropy loss pay equal weight to each position's loss, no matter how far the distance between it and the target. To penalize more on the distant false prediction, we propose a custom distance loss, which use an auxiliary sequence that generated by insert equal interval from 0 to 1 center on the '1' target. And use the mean dot product to compute the distance loss.

## 4 Evaluation

### 4.1 Data

The shared task provides trail, training and testing datasets to be used by all participants. The statistics

Figure 1: Start-to-end Tagging Framework

of trail, training and testing dataset can be shown in Table 1.

	Trail	Train	Test
Without span	43	485	394
With span	647	7454	1606
Total	690	7939	2000

Table 1: Datasets for SemEval-2021 Task 5

In this task, we apply the 5-fold cross-validation method and only use the official training data set for training and validating.

## 4.2 Evaluation Measure

To evaluate the responses of a system, we employ the F1 score, as in Martino et al. 2019. Let system  $A_i$  return a set  $S_{A_i}^t$  of character offsets, for parts of the post found to be toxic. Let  $G^t$  be the character offsets of the ground truth annotations of  $t$ . We compute the F1 score of system  $A_i$  with respect to the ground truth  $G$  for post  $t$  as follows, where  $||$  denotes set cardinality.

$$F_1^t(A_i, G) = \frac{2 \cdot P^t(A_i, G) \cdot R^t(A_i, G)}{P^t(A_i, G) + R^t(A_i, G)}$$

$$P^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_{A_i}^t|}$$

$$R^t(A_i, G) = \frac{|S_{A_i}^t \cap S_G^t|}{|S_G^t|}$$

If  $S_G^t$  is empty for some post  $t$  (no gold spans are given for  $t$ ), we set  $F_1^t(A_i, G) = 1$  if  $S_{A_i}^t$  is also empty, and  $F_1^t(A_i, G) = 0$  otherwise. We finally

average  $F_1^t(A_i, G)$  over all the posts  $t$  of an evaluation dataset  $T$  to obtain a single score for  $A_i$ .

## 4.3 Experiments

The model is implemented using Pytorch (Paszke et al. 2019). We experiment with RoBERTa (Liu et al. 2019) based pre-trained language model as encoder, including RoBERTa-base-squad2 (Deepset), twitter-RoBERTa-base-sentiment (Barbieri et al. 2020) and DistillRoBERTa-base (Sanh et al. 2019). And we take the average of last two hidden layers’s weights as embedding. Our model is trained with AdamW (Loshchilov and Hutter 2017) optimizer with initial learning rate 0.00003 and weight decay coefficient 0.012. The max sequence length is 512 and dropout (Srivastava et al. 2014) rate is 0.5 to prevent our model from over fitting. And the threshold is set to 0.5. The final submission which scores 69.03 is equipped with both the binary cross-entropy loss, custom distance loss and voting ensemble mechanism.

## 4.4 Results and Analysis

In order to evaluate the effect of the custom loss function, we compare our approach with its variant.

Variant 1: The variant only use the cross-entropy loss.

Variant 2: The variant only use label smoothing loss.

Variant 3: The variant only use Kullback-Leibler divergence loss.

We take DistillRoBERTa-base as encoder for all of the above experiments. Table 2 show that the variant 2 model has the lowest score, which

Model	F1 score
Variation 1	0.6662
Variation 2	0.6347
Variation 3	0.6618
Our Model	<b>0.6754</b>

Table 2: Performance of Our System and Its Variants

may be caused by the enormous '0' label. Besides, the model with binary cross-entropy loss and custom distance loss obtains the best result. Thus we decide to use the model as our final ensembling element.

#### 4.5 Voting Ensemble

As mentioned above, we tried several RoBERTa based pre-trained language model as encoder. In this section, we will discuss the performance difference between them.

Encoder	F1 score
DistillRoBERTa-base	0.6754
RoBERTa-base-squad2	<b>0.6793</b>
twitter-RoBERTa-base-sentiment	0.6742

Table 3: Performance of Different Encoder

As shown in Table 3, we can find that the overall score's difference is slight. But when we take a closer look at the performance, the result on single example is different. And the RoBERTa-base-squad2 encoder achieved best result, which may be caused by the training method.

Text: "good side of trump? are you kidding me? trump has no good side all bad, he is divisive, a racist and bigot, pathological liar, scammer, tax cheat, sexual pervert,"

Golden Spans: ['pathological liar', 'scammer', 'sexual pervert']

DistillRoBERTa-base: ['racist and bigot', 'sexual pervert']

RoBERTa-base-squad2: ['racist', 'scammer', 'sexual pervert']

twitter-RoBERTa-base-sentiment: ['racist and bigot, pathological liar, scammer', 'sexual pervert']

As shown above, Complementing and correcting each other may improve the overall performance due to the difference. This is exactly what ensemble learning is good at. Ensembling of several models is widely used method to improve the performance of the overall system by combining predictions of

several models, such as as for they provide complementary information.

Considering this, we decide to apply the model ensemble methods, particularly the vote mechanism was applied. In which, if the number of occurrences of one index is bigger than 3 in the all above model's predictions, the index will be add to the final result, otherwise it will be exclude. The ensemble result obtains 69.03% F1 score on the test data set without any rule correction or dictionary based post process. Our model ranks in the top 10 among nearly 100 participating teams with slight lower (-1.8 and -1.73) than the top 1 (70.83%) and top 2(70.77%), respectively.

## 5 Conclusion and future work

In this paper, we propose a start-to-end tagging framework with custom distance loss function for SemEval-2021 Task 5. The performance of our model which is equipped with distance loss and voting mechanism better than its variants. But the distance loss target is assigned manually, which may have low generalization ability to different data set and task. We will try to improve its performance and apply this tagging scheme to other task in future work.

## Abstract

This paper presents our system submission to task 5: Toxic Spans Detection of the SemEval-2021 competition. The competition aims at detecting the spans that make a toxic span toxic. In this paper, we demonstrate our system for detecting toxic spans, which includes expanding the toxic training set with Local Interpretable Model-Agnostic Explanations (LIME), fine-tuning RoBERTa model for detection, and error analysis. We found that feeding the model with an expanded training set using Reddit comments of polarized-toxicity and labeling with LIME on top of logistic regression classification could help RoBERTa more accurately learn to recognize toxic spans. We achieved a span-level F1 score of 0.6715 on the testing phase. Our quantitative and qualitative results show that the predictions from our system could be a good supplement to the gold training set’s annotations.

## 1 Introduction

Toxic messages remain a small but persistent part of online communications (Fortuna and Nunes, 2018; Jurgens et al., 2019). NLP methods have been developed to identify these comments, often relying on deep-language models (Vidgen et al., 2019). However, the part of the message that is specifically toxic is often unknown. Such information is useful not only for validating and explaining the judgments of models (Carton et al., 2018), but can also be useful for moderators to use when making decisions and working with these models in their deployment (Carton et al., 2020; Liu et al., 2021). This paper describes our model<sup>1</sup> and error analysis for SemEval-2021 Task 5: Toxic Spans Detection (Pavlopoulos et al., 2021).

Our model uses a deep learning approach to identify which tokens are toxic. The approach

<sup>1</sup>The code is available at <https://github.com/davidjurgens/offensive-span-detection>.

is motivated by two strands of prior work showing (1) that large language models can effectively serve as sequence-to-sequence (seq2seq) models and (2) that pre-training on a similar task can improve downstream performance (Phang et al., 2018; Gururangan et al., 2020). Here, we treat the toxic-span detection tasks as a seq2seq task, where given a sequence of tokens, the model outputs per-token judgments of whether the token is in the toxic span. Given the limited training data for Task 5, we increase our training data by generating a silver-standard set of span judgments from LIME explanations (Ribeiro et al., 2016) from a model trained to recognize toxic and non-toxic language. These additional judgments are intended to help the model learn the basic span recognition task and identify general toxic language, before fine-tuning on the Task 5 data.

## 2 System Description

Our core system relies on a standard RoBERTa model (Liu et al., 2019) that is trained on a sequence-to-sequence task in two phases. The first phase pretrains the model with heuristically-created spans, gathered from Reddit comments labeled for their toxicity. The second phase fine-tunes this model on the organizer-provided data. Figure 1 shows the overview of the system. All the data used in the paper is in the English language.

### 2.1 Pretraining to Recognize Toxicity

To identify toxic spans, we hypothesize that pre-training the RoBERTa model on a similar task would lead to better downstream performance. Therefore we generate a similar dataset (silver dataset) to the training data (gold dataset) and heuristically label it with spans by using LIME (Ribeiro et al., 2016) on a toxicity classification task.

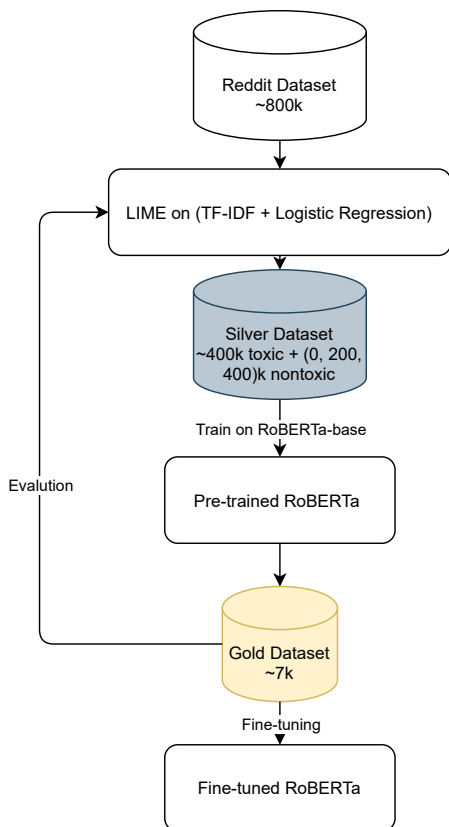

Figure 1: Diagram of our data and architecture. The central hypothesis tested is whether pre-training a RoBERTa model on machine-generated rationales for toxicity could improve performance.

**Data** Silver data was drawn from a sample of all Reddit comments made between January to June 2018. As social media data, these comments contain similar lexical and syntactic patterns as the social media comments data as the gold standard, which was made on the Civil Comments platform. Prior work has shown that pre-training RoBERTa models to recognize this type of social media data improve downstream performance (Nguyen et al., 2020). However, Reddit posts can vary substantially in their length. To avoid introducing confounding effects from pre-training a model on posts of substantially different lengths, we compute the Inter-quartile Range (IQR) of the lengths of Reddit comments and remove all comments identified as outliers. This process effectively removes very long or very short comments. Ultimately, the mean number of words in the training data and Reddit data are roughly similar:  $35.87 \pm 34.92$  words (mean and standard deviation) in the training data, compared with  $36.79 \pm 30.57$  in the Reddit data.

**Identifying Toxic Comments** The Reddit data contains a mix of toxic and non-toxic conversations, which we aim to use for training. To identify toxic conversations, we use the Perspective API to label all comments in the dataset (Wulczyn et al., 2017). The API returns a continuous score reflecting the degree of a comment’s toxicity. This toxicity score is then converted into a binary label to use in training a LIME model to generate rationales for why a comment is (or is not) toxic. We follow the insights from Hua et al. (2020) and set a threshold of 0.7, above which a comment is considered toxic and 0.3, below which the comment is non-toxic. These thresholds were intended to help create easy examples of toxic language for generating rationales as a way of scaffolding the learning for the downstream task. This process led to a labeled dataset of 288.5M comments with binary toxicity labels, of which 9.4% were labeled toxic.

### Generating Heuristically-Labeled Toxic Spans

Our final silver dataset is created by sampling comments from the larger labeled Reddit comments and using a LIME model to generate toxic span labels. LIME is a form of interpretable machine learning that explains the decisions of a classifier using a local approximation to identify which features led to a classification decision. Here, we use a simple logistic regression (LR) model trained on TF-IDF features and use LIME to generate a rationale of the classifier’s decision which identifies which words are contributing to the toxicity decision. The underlying LR model is trained on a balanced sample of 800K toxic/non-toxic comments (not the silver data). This balanced sample is derived in the same way as silver data. The model’s hyperparameters were tuned using 10-fold cross-validation, with the learning rate of 0.01 and strength of the regularization (C) at 1 under L1 loss. In a test of a held-out 200K instances, the model attained a binary F1 of 0.985.

Our silver data is created by generating LIME explanations using the trained LR classifier on a separate 800K comments balanced between toxic and non-toxic. This size is roughly 100x the Task-provided data. In generating explanations, LIME assigns local weights to each token on its weight to drive the correct prediction. To create toxic spans from these continuous-valued weights, we apply a threshold above which we consider the token as the toxic span. The threshold was identified by generating LIME explanations for all of 8629

documents from the Task’s training data and then choosing the threshold that maximized the Span F1 between the 8629 training documents’ toxic spans and the discretized LIME explanations, using a grid search with a step of 0.001 in [0.05,0.50]; the final threshold was set to 0.169.

## 2.2 Model Training

Our model uses a common RoBERTa base and differs according to which data the model is trained on. The pre-training setup trains a RoBERTa model on a seq2seq task where the input sequence of tokens generates a binary sequence denoting whether the input token was inside or outside of a toxic span. Due to the dataset sizes, pre-training was done for one epoch. The fine-tuning setup starts from either the off-the-shelf RoBERTa parameters or from a RoBERTa model initialized through silver-data pre-training. This model is trained in the same way as in pre-training on a binary seq2eq task using the Task-provided data. Models are fine-tuned for 10 epochs and parameters are chosen using the epoch with the best performance on the trial data.

In internal testing, we compared models that have been pre-trained, fine-tuned, or both, using varying amounts of silver data. All hyperparameter choices are reported in the Appendix A.

## 3 Results

Our best model attained a Span F1 of 0.672, and although close in score to the top result (0.708), was ranked 30 in the Task. Surprisingly, this best-performing model did *not* make use of the pre-training on silver data. To better understand the performance, we ran two follow-up analyses to test how different strategies for training affected performances and an error analysis for what were common themes in errors.

### 3.1 Does Pre-training Make a Difference?

In assessing the impact of pre-training, we analyze the submitted model along with five other models: (1) a fine-tuned model using a batch size of 8, (2) a pre-trained only model that makes no use of the Task data, and (3-5) pre-trained and fine-tuned models that use different amounts of silver data. The performances of all models are shown in Table 1.

For the initial comparison, we contrast the fine-tuned model (Table 1, Row 1; denoted FT) with the pre-trained and fine-tuned model on all silver

Model	Batch Size	Silver Data	F1
FT	8	N/A	<b>0.675</b>
FT	16	N/A	0.672 <sup>†</sup>
PT	8	400k/400k (1:1)	0.613
PT + FT	8	400k/0 (1:0)	0.660
PT + FT	8	400k/200k (2:1)	0.660
PT + FT	8	400k/400k (1:1)	0.659

Table 1: Performance at recognizing toxic spans (Span F1) for models trained on just the Task-provided training data (baseline), Pre-Trained (PT) on different amounts and ratios of silver data, and Fine-Tuned (FT) on training data. Ratios denote the number of non-toxic:toxic examples. <sup>†</sup> is the model submitted to the Task.

data (Table 1, Row 6; denoted PTFT). Both models agree on 1281 (65%) of the 2000 test instances. For these agreed cases, both models attain a Span F1 of 0.776—higher than either models regular performance. In these matching predictions, the ground-truth spans have an mean length of 1.13 tokens, mainly concentrated on commonly-labeled offensive words, like “morons”, suggesting that both models are adept at identifying overtly toxic words. In contrast, for the 21 test documents whose spans have  $\geq 5$  words, both models perform poorly with a Span F1 of 0.3489 for the FT model and 0.2077 for the PTFT model.

The FT model performs considerably better than PTFT model on documents with  $\geq 5$  tokens labeled as ground-truth spans, which is likely due to differences between the LIME-labeled data and the Task’s training data. For example, the LIME model generates spans  $\geq 5$  tokens in only 693 of the 800K silver context, suggesting LIME tends to give shorter toxic span labels.

This bias affects the downstream model performance in the test set where 29 of the 2000 test contexts have a span of  $\geq 2$  consecutive toxic words. In those contexts, the FT model achieves a mean Span F1 of 0.523 while the PTFT model has only 0.369. Indeed, the FT model produces spans (average span length: 19.0345) that are  $\sim 224\%$  longer than the PTFT model (average span length: 8.4828). This difference is more obvious than the overall prediction results, as seen in Table 2.

In the remaining cases where the FT and PTFT model predictions differ, the FT model has 296 predictions with a better Span F1 score, of which 216 predictions have longer span. For example, in test context 100, “Stupid is as stupid does Gump was right,” both of the “stupid” tokens are highlighted

Span Size	FT model	PTFT model
Characters	9.30 ± 6.44	7.05 ± 3.48
Tokens	2.14 ± 1.72	1.61 ± 1.00

Table 2: Differences in model prediction length shows that pretraining on LIME-generated toxicity rationales (PTFT) generally produces shorter spans at both span and token levels.

by the FT model, while the PTFT model only labels out the first “stupid”.

However, the tendency of the FT model to predict longer spans does not always yield higher performance. The PTFT model has 237 predictions with better Span F1 scores.

The FT model has a longer span prediction in the 202 of the 237 predictions, but the qualitative results are very different from the above-mentioned example. In multiple cases when the ground-truth spans are empty, the PTFT model can also predict empty spans. However, the FT model has a lower tendency to predict empty spans in those cases. For example, in non-toxic test context 3, “The parallels between the ANC and the Sicilian Mafia are glaring...”, the FT model labels “Sicilian” as toxic, while the PTFT model output is (correctly) empty.

Looking at contexts where there are no underlying toxic spans, the two models perform slightly differently. There are 394 out of 2000 test contexts with empty ground-truth spans. For those contexts, the FT model only gets a mean Span F1 score of 0.058, while the PTFT model gets 0.079.

In contrast to the FT model, the PTFT model has less-accurate predictions on the overtly/commonly toxic spans. For example, there are 430 total “stupid” or “stupidity” related words labeled as toxic by the ground-truth spans. The FT model is able to label 383/430 as toxic, while the PTFT model only labels 331/430. As we know, words like “stupid” can be more contextually-sensitive when compared to other common offensive words. They could be used in a toxicity-neutral way in many contexts. In the PTFT model’s pre-training phase, we fed 400,000 non-toxic documents for the RoBERTa model. These non-toxic documents supplied more non-offensive context for certain toxic words than the small-sized gold dataset. The extra contextual information learned by the pre-trained model can somehow decrease the performance of the PTFT model.

### 3.2 Common Themes in Errors

From the error analysis in the above section, we have noticed that the PTFT model does not perform well when it comes to predicting long toxic spans, empty toxic spans, and toxic phrases. With a deeper dive into the differences between PTFT model predictions and ground-truth spans, we can get a better sense about how is our PTFT model doing and what insights could be recommended for annotators.

In order to perform both qualitative and quantitative error analyses, we randomly sampled 200 test contexts where predictions from the PTFT model do not conform with ground-truth labels. The overall mean Span F1 score on those mispredictions is 0.289; compared to the random sample with a mean of 0.274. We categorize the mistake types from the sampled contexts and provide examples in Table 3.

**Model Errors** The first four categories (Category 1–4) in Table 3 demonstrate the mistakes made by the PTFT model and ground-truth annotations.

Category 1 shows where the PTFT model identifies valid toxic spans not present in ground truth, which accounts for 101 (50.5%) of the model errors in the 200 sampled contexts. In these cases, annotators marked nothing as toxic in 58 contexts. However, most of the overlooked toxic spans are overly-common toxic words like Examples 491 and 1374 in Table 3.

In comparison, in Category 2, there are 81 out of 200 sampled contexts with unmarked toxic span labels in the PTFT model output, in which the PTFT model produced an empty span or an incorrect span as toxic in four cases. Example 642 in Table 3 shows a typical case where a relative rare toxic word, “caca,” is overlooked by the model. In the remaining cases, the PTFT model has shorter predictions than the ground truth toxic spans, matching the low performance on predicting longer toxic spans (§3.1). In some cases, when multiple toxic spans exist in the same document, ground truth only labels one or two spans of them (e.g. Examples 1852 and 1486). While in other cases, ground truth would label more toxic spans (e.g. Example 346). The inconsistencies from ground truth annotations occur more when it comes to the multiple-word labeling, which will be described more in the next analysis for Category 5.

The missing labels from both scenarios are

Category	%	Examples
1. Toxic not labeled by ground-truth spans	50.5	491. this guy is an <b>idiot</b> . I'll disclose I'm male.... 1374. That is a bunch of horse <b>sh*t</b> . 1776. <b>Stupid</b> leftists. <b>Stupid</b> Democrats. I sincerely..
2. Toxic not labeled by the PTFT model	40.5	1852. That's because Floater <b>sucks</b> . That dudes voice is so <b>fucking</b> annoying! 1486. uhhh Hillary Clinton is a <b>serial killer</b> and <b>thief</b> 346. ...Drivers in Anchorage are lazy, <b>stupid</b> and <b>impatient</b> ... 642. What a load of <b>caca</b> !! ...
3. Not toxic but labeled by ground-truth spans	0.5	876. Ergo, America is overrun with the <b>insane</b> .
4. Not toxic but labeled by the PTFT model	13.5	273. Extremist <b>Muslims</b> want to kill infidels. Moderate Muslims cook the extremists a hot lunch. 1802. either you can afford to lose \$1300. in an hour or you're a <b>moron</b>
5. Inconsistent multiple-word/phrase annotation by ground-truth	4	773. Very true. Still <b>sick bastards</b> . 1496. Trump is an <b>impulsive idiot</b> . He will get us all killed. 1776. <b>Stupid</b> leftists. <b>Stupid</b> Democrats. I sincerely believe... 1447. Brooks, would you please join the <b>damn Democrat</b> party and be done with it ?
6. Inconsistent word annotation by ground-truth	41.5	968. ok then you dont use gasoline, plastic or such anything else right??? ya <b>hypocrite</b> bs <b>stupidity</b> as usual 348. ...Hawaii Democrats deny ordinary citizens their constitutional right to self-defense with firearms, including concealed carry... <b>Hypocrites</b> !
7. Inconsistent repeated word annotation by ground-truth	2	413. There is a difference between being tolerant and being <b>stupid</b> . She and her supporters want America to be <b>stupid</b> . 137. I cannot fathom the <b>stupidity</b> of McCain believing any cooperation from the ... The man must be the <b>stupidest</b> person in D.C.
8. Inconsistent sentence annotation by ground-truth	12.5	894. <b>You are a nut ball.</b> 1374.That is a bunch of <b>horse sh*t</b> .

Table 3: An error analysis of 200 predictions of our PTFT model relative to the ground-truth span. All of the sample contexts in the Examples column begin with the context index starting from 0. The first four categories show the differences in between the toxic spans labeling from PTFT model (shaded in blue) and the ground-truth span (bolded). The last four categories show the commonly-seen inconsistencies existing in the ground-truth annotations. Within the last four categories, examples are shown in pairs. Within each pair of examples, the upper example shows the suggested toxic spans based on the majority decisions made by the test context annotation (shaded in yellow) and the ground truth labeling decision by the annotators (bolded). In contrast, the lower example within each category shows where the consistency of annotation breaks compared to the upper example.

straight-forward in their formats and contexts. Besides, there are 20 contexts that both the ground-truth spans and PTFT model missed the toxic span partially or completely.

Generally, ground truth annotation seldom labels non-toxic spans as toxic (Category 3). On the contrary, it is common for our PTFT models to make mistakes on labeling non-toxic spans (Category

4). It happens mostly in the cases when the PTFT model misinterprets the context (e.g. Examples 273 and 1802).

**Inconsistencies in Ground Truth Labels** The last four categories (5–8) in Table 3 show common inconsistencies in annotation decisions, which we hope could aid in improving consistency in future work.

In Category 5, the standard for spans labeling is not consistent for which words are included in the toxic phrase. In some cases, when a sentence is fairly short (< 5 words) and contains toxic words, the ground truth annotation would label out the adjective used for describing the trailing noun (e.g. Example 1469). However, in other cases (e.g. Example 773), the standard would change by skipping the adjectives. Moreover, this inconsistent annotation also occurs in the case when the underlying nouns are almost the same (e.g. Examples 1447 and 1776).

Categories 6 and 7 comprise the majority of the inconsistencies in the annotation standards by the ground truth. These inconsistencies commonly manifest for frequent toxic words. For instance, in Examples 968 and 348, both of the "hypocrite(s)" should be toxic given the context and there is no more than one other toxic word within the document. The omission of common toxic words is the major source for this category. In many cases, the subtle variations of the document context would make it even harder to maintain a unified standard across different annotators. Hence, the introduction of some model-based labeling (or checking) could greatly improve the inconsistencies of this case.

In the sampled contexts, 25 documents consist of only one sentence. Annotators varied in how much of these contexts to label (Category 8), occasionally marking the entire sentence as offensive (20% of these single-sentence contexts), as in Example 894. However, in a few cases (4 of 25), annotators labeled nothing as toxic (e.g. Example 1374). Interestingly, 9 of 25 cases where ground truth either labels the entire sentence or nothing, our PTFT model is able to identify the toxic word(s), suggesting the model is still effective for short contexts.

## 4 Discussion and Future Work

Based on error analysis, our PTFT model suffers from low performance when generating predictions on non-toxic contexts or long toxic spans. A modified error function that rewards for edge-case sce-

narios can potentially improve the PTFT performance. Moreover, during the pre-training, we applied a simple-cutoff on the local weights to make labeling decisions for LIME explanations. The cutoff was determined solely based on evaluations with the Task data. If the LIME labeling could introduce more robust variants in the loss evaluation, the silver data span labeling might be more representative of the Task data's annotation logic.

Through comparing silver data with the gold data, we find the toxicity of some words is influenced by the broader linguistic environment. While the silver and gold data both consist of online comments, their time spans and topics are very different. The gold data uses contexts from 2015-2017 and has a concentration on political news; while the silver data covers 6 months of 2018 with no focused topics. Our qualitative analysis finds that the addition of non-toxic examples in the silver data influenced the model to consider overly common toxic words less toxic than they were in the gold data. Future work is needed to identify the optimal ratio of the toxic and non-toxic samples and to address domain/register differences in the data.

Last, the current approach could invite several natural improvements. For example, in the pre-training phase, we used TF-IDF embedding and logistic regression for the base of LIME explanations. This combination was chosen for its efficiency in the LIME training phase. However, many other embedding and model combinations rendered much better classification results, which may generate better rationales for pre-training.

## 5 Conclusion

We presented our system for SemEval-2021 Task 5 on Toxic Span Prediction. Our initial approach used explainable machine learning (LIME) to generate a heuristically labeled span dataset, which was used to pre-train a RoBERTa model to recognize toxic spans. However, our results show that when fine-tuned on the task data, the resulting model generates slightly shorter explanations and ultimately performs slightly worse than a model trained only on the Task's training data—likely due to bias towards shorter spans generated by LIME. In our subsequent error analysis, we show that the majority of our model's errors (50.5%) are associated with missed annotations in the ground truth, suggesting that actual model performance may be higher in practice.

# WVOQ at SemEval-2021 Task 6: BART for Span Detection and Classification

Cees Roele  
cees.roele@gmail.com

## Abstract

Simultaneous span detection and classification is a task not currently addressed in standard NLP frameworks. The present paper describes why and how an EncoderDecoder model was used to combine span detection and classification to address subtask 2 of SemEval-2021 Task 6.

## 1 Introduction

Task 6 of SemEval-2021 studies the detection of persuasion techniques (Dimitrov et al., 2021). The task considers English language memes, which in subtasks are to be classified, divided into classified fragments having a begin and end, and classified when text is combined with images.

Of the three subtasks described in the paper, the present paper primarily addresses resolving subtask 2:

Given only the "textual content" of a meme, identify which of the 20 techniques are used in it together with the span(s) of text covered by each technique. This is a multilabel sequence tagging task.

The figure below illustrates span detection and classification for three technique classes for a meme.

Figure 1: Span detection and classification: overlapping spans and spans extending over multiple sentences

In the above figure the ellipsis at the end of the sentence denotes the continuation of the second

sentence. Note that *loaded language* and *name calling* both apply to the same span, that is, the word "CRACKHEAD". Note furthermore, that the span for *smears* overlaps with both of these spans and ranges over more than one sentence.

The present paper describes a novel approach to resolving these requirements by generating XML-like start and end tokens to delineate spans. The following illustrates this for the message in figure 1.

```
<SMEARS>
WHY DO THEY KEEP SAYING RELEASE THE
<LOADED-LANGUAGE>
<NAME-CALLING>
CRACKHEAD
</NAME-CALLING>
</LOADED-LANGUAGE>
? "n HUNTER ...
</SMEARS>
```

It attained an F1 score on the test set that is about in the middle of the baseline and the highest ranking score.

The choice of this approach of generating markup to identify spans was made on the basis that it was technically possible, easily understandable at a behavioral level of input and output, and using a model that is pre-trained for dealing with spans. The aim was not so much to attain the highest score as to explore how effective this approach is in a proof-of-concept and what problems need to be overcome to bring it to good performance.<sup>1</sup>

## 2 Background

Propaganda messages are constructed using specific rhetorical techniques. The current task is to identify within a message in what fragment a particular technique is invoked.

<sup>1</sup>The code for the described system is available at: <https://github.com/ceesroele/SemEval-2021-Task-6>.

A simpler task is to identify fragments of a message in which any propaganda technique is used. Effectively, this comes down to classifying any part of a message as being either propaganda or not. It is a sequence labeling problem that can be resolved for example using a BIO tagging format, where BIO stands for Begin, Inside, and Outside. To classify a span of tokens as propaganda we can use B-PROP to designate the begin of the span, I-PROP to indicate the token being inside the earlier begun span, and O to designate a token not being part of a span. (Chernyavskiy et al., 2020).

For our case this approach can be extended by adding new labels for each technique, e.g. B-SMEARS, I-SMEARS, B-NAME-CALLING, B-LOADED-LANGUAGE, and so on for all twenty technique classes. But looking at figure 1 we see that if CRACKHEAD is a token, we have to simultaneously label it as I-SMEARS, B-NAME-CALLING, and B-LOADED-LANGUAGE. The extension of the approach by just adding labels is not applicable to our situation in which spans can overlap.

One solution for this problem is to retain the assumption that each input token is to be tagged, but add virtual depth. This approach was taken for the PPropaganda persuasion Techniques Analyzer (PRta) (Da San Martino et al., 2020). It is based on an architecture where each input token maps to as many output tokens as there are technique classes, plus one extra for *no technique*. Additionally, it uses a complementary output indicating confidence of any propaganda technique being present at the sentence level, which is used as a gate for predicting the presence of any specific techniques.

The sequence labeling method described at the beginning of this section is effectively a sequence-to-sequence translation, where the input and output sequence consist of the same number of tokens. This allows us to match input with output based on position. To generate a marked up version of a message we need to allow an output sequence to have a length that differs from the input sequence.

By using an EncoderDecoder model we can generate arbitrary transformations of an input message including changing its length. This can be used for abstractive dialogue, question answering, and summarization. A state of the art EncoderDecoder model is BART, a denoising autoencoder built with a sequence-to-sequence model. (Lewis et al., 2020).

BART uses a standard Transformer-based neural machine translation architecture to couple a bidirectional encoder with a left-to-right decoder. Pre-training BART was done by first corrupting text with an arbitrary noising function and then training a sequence-to-sequence model to reconstruct the original text.

## 2.1 Data

There are two datasets available for task 6. The first is the Propaganda Techniques Corpus (PTC) dataset from SemEval-2020 Task 11. It consists of about 550 English language news articles in which spans - defined by begin and end positions - have been annotated with one out of 18 propaganda techniques. In practice a number of these techniques have been combined. For example, the three techniques *whataboutism*, *straw men*, and *red herring* have been conflated into the single label *whataboutism, straw men, red herring*. As a result, the dataset has effectively been annotated with 14 labels. Moreover, these composite labels don't identify individual labels in the 2021 dataset, which makes them unsuitable for training. That leaves only 12 usable labels in the PTC.

The 2021 dataset consists of about 660 English language memes. These are short texts consisting of mostly short sentences and relatively many uppercase characters. Here fragments have been identified by start and end indexes and are labeled with one of a total of 20 classes. The differently labeled fragments may overlap, that is, a certain span of text may belong to fragments belonging to different classes.

The table below shows the number of fragments per dataset, the average number of words per fragment, the number of fragments spreading over more than one sentence, and the relative number of uppercase characters in fragments ( $\text{upper} / (\text{upper} + \text{lower})$ ).

Dataset	Spans	Words	> 1	Upper
PTC 2020	5610	8.6	223	0.04
Memes 2021	1497	7.6	224	0.53
Total set	7107	8.4	447	0.14

Table 1: Data

Regarding the data, we make the following observations:

- For 8 of the classes there is data only in the relatively small 2021 memes dataset, which with

many short sentences and a lot of uppercase is structurally different from the PCT 2020 dataset

- For some classes as much as half the characters in their fragments are in uppercase
- The median number of words in a fragment significantly varies per class. E.g. *smears*, *causal oversimplification*, and *whataboutism* have median numbers of words of respectively 16, 20, and 25, while *name calling/labeling*, *loaded language*, and *repetition* have median numbers of words of respectively 3, 2, and 1.
- The median number of sentences by fragments is 1 and for a handful of classes 2.

The above findings will inspire a number of choices specified in the Experimental Setup below.

## 2.2 Pre-training is key

The success of language models like BERT (Devlin et al., 2019) derives in great part from a division of labor and domain. In the first step, a model is trained on a large body of unmarked data. This results in a model that has many linguistic relations represented in its weights, but that by itself is of little use. In the second step, that resulting pre-trained model is fine-tuned with data from a specific domain.

Given the comparative smallness of the two datasets at our disposal, leveraging pre-training can be expected to greatly enhance the quality of predictions.

However, it is worth considering what the pre-training entails. Take BERT. It was trained in part on English Wikipedia articles. But now we are looking at memes full of uppercase characters, containing persuasion techniques that we hope are not used in Wikipedia. Said differently, the data the model was pre-trained on might not be representative for our domain.

More abstract, but no less important, is the method of pre-training. Is the used method of Masked Language Modeling (MLM) supporting our task? We are interested in spans of text, possibly running across multiple sentences. Besides next sentence prediction, BERT's methodology primarily consists of replacing a percentage of individual tokens with a mask token. However effective this may be, it is not optimized for spans.

SpanBERT (Joshi et al., 2020) is effectively BERT trained with a different masking method:

- mask contiguous random spans, rather than random tokens, and
- train the span boundary representations to predict the entire content of the masked span, without relying on the individual token representations within it

SpanBERT outperforms BERT substantially on span selection tasks such as question answering and coreference resolution.

The present paper concerns a specific implementation for span detection and classification. Understanding pre-training helps us understand both why the presented system has a certain success and what its limitations are.

## 3 System overview

### 3.1 Generating markup

As sketched in the Background section, the problem we need to resolve is how to simultaneously represent a span of text and one of a multitude of labels. Our solution is to step away from attempts to map onto a classification structure and instead regenerate the original text, but now with XML-like markup to indicate the start, end, and class of each fragment.

We regenerate the input text using an EncoderDecoder model. Popularly expressed, it reads a text, and then generates a sequence of words. In order to add our markup for fragments we need two help functions, let's call them encipher and decipher. The encipher function takes text plus metadata on fragments and converts this into a string with XML-like markup. We need this to create our training data. The decipher function takes a string including XML-like markup and extracts metadata in the form of start, end, and class from it.

For each of the labels, the names for our technique classes, we create a start tag and an end tag. In order to let the tokenizer treat them each as single tokens, we add all these tags as tokens to the tokenizer.

### 3.2 Using the BART EncoderDecoder model

In principle it is possible to implement Encoder and Decoder on the basis of taking a pre-trained model for each, e.g. RoBERTa for the Encoder and BERT for the Decoder. Finding from a single trial was that in such a setup training went very slow and outcome was dissatisfactory. Instead we

selected BART (Lewis et al., 2020) as an integrated EncoderDecoder model.

BART has a number of pre-training methods that are of interest in trying to understand its performance. Only the first one is part of the pre-training methodology of BERT.

- **token masking**, like BERT
- **token deletion**, random tokens are deleted and the model must decide which positions are missing tokens
- **text infilling**, a number of spans with varying lengths are sampled and replaced with a single mask token. Note that this is different from SpanBERT pre-training where each token of the span is replaced with a mask token.
- **sentence permutation**, sentences are shuffled in random order
- **document rotation**, a token is randomly chosen and the document is rotated to start with that token

We will get back to this when we evaluate the result.

### 3.3 Easy to generalize

Recuperating, we initialize the model by adding start and end tags for each technique class to the tokenizer. We use encipher to create marked up versions of input texts to train the model. To obtain fragments for given inputs we must decipher generated marked up texts to extract meta-data. Besides having markup, the generated text may be different from the input. Directly deriving span positions from the markup tags leads to errors when that happens. This is to some degree mitigated by using an algorithm that searches for the best place of the tag in the original input string.

The novelty of the described system is in using a standard EncoderDecoder model to generate markup. No special architectural changes were made, no domain dependencies were introduced, and only minor pre- and postprocessing is done. It is therefor easy to turn the system into a general purpose span detection and classification system.

## 4 Experimental setup

### 4.1 Data and Training

The articles of the PTC 2020 dataset were reduced to smaller segments on the basis of fragments.

```
for each fragment:
    take all covering sentences
    while another fragment overlaps ..
        .. with any sentence in the segment
    add fragment and those sentences
```

Any sentences remaining, that is, not covered by any fragment, were ignored. The memes of the 2021 dataset were not split.

Mixing the 2020 and 2021 datasets for a single training run led to worse results than having a staged training of first the PTC 2020 data as pre-training and then the 2021 memes data as fine-tuning. For training the datasets were split train:dev:test as 70:20:10. Training was done with a batch size of 8 for 25 epochs.

### 4.2 Framework

The system uses the Seq2SeqModel of Simple Transformers<sup>2</sup>, a task-oriented framework built on top of Hugging Face Transformers<sup>3</sup>. It uses the Hugging Face pre-trained BART model identified with model type "bart" and model name "facebook/bart-base". This is a model consisting of 6 encoder and decoder layers, 16-heads, and 139M parameters.

### 4.3 Configuration

Where training was done mostly with default settings, text generation required improved settings. We want enough tokens in the output for the full input plus markup, we want a relatively low penalty on length, to compensate for the previous setting, we want a relatively high penalty on repetition, and we perform a beam search. Experimentally, we came to the following settings as being optimal:

Parameter	Value
max_length	200
length_penalty	0.4
repetition_penalty	2.0
do_sample	True
num_beams	3
top_p	0.8

Table 2: Seq2SeqModel configuration

<sup>2</sup>See: <https://simpletransformers.ai/>. The used version is 0.60.6. To be able to add begin and end markers as tokens to the seq2seq model a modification was made. It can be found in the github repository for the system discussed here, referred to in the first footnote.

<sup>3</sup>See: <https://huggingface.co/transformers/>. The used version is 4.3.2

## 5 Results

The system’s F1 score of 0.268 on subtask 2 on the test set scores about in the middle between the baseline and the highest ranking score.

Rank	Team	F1 score	Precision	Recall
1	Volta	.482	.501	.464
5	WVOQ	.268	.243	.299
	baseline	.010	.034	.006

Table 3: Subtask 2 scores on the test set

Looking at errors we made the following observations:

- Beginning and end tags in the generated text regularly don’t match.
- Generated text contains changed words and even added words, which leads to faulty identifications of spans.

Why does this happen? First, beginning and end tags are introduced as new tokens in the relatively small datasets we fine-tune with. Transformer models have no notion of syntactic connection between them and standard BART has not been pre-trained to relate these tokens correctly. Second, through its pre-training methodology BART is geared towards relative “freedom” in filling in spans. That’s what makes it suitable for summarization and question-answering. But what we need for markup generation is almost verbatim regeneration of the input.

## 6 Conclusion

The described system for span detection and simultaneous classification offers a proof-of-concept for a novel approach to sequence tagging based on generating a version of a message with markup for labels. Its F1 score on the leaderboard is in the middle between the baseline and the top score.

Drawback of the approach is that two types of systemic errors are introduced: tags lacking a matching tag, and tokens generated that are not in the original message. These are not resolved by fine-tuning the model and they cannot be addressed with the standard configuration parameters of message generation in the sequence-to-sequence model.

Future research should aim at resolving these systemic errors. Matching tags could be addressed through changes in the decoder’s generation algorithm. Having the tokens in the output be the same

as those in the input could be improved by amending the loss function for fine-tuning training of the model.

Only when these two issues are resolved will further optimization of the approach be worth investing effort in.

# HumorHunter at SemEval-2021 Task 7: Humor and Offense Recognition with Disentangled Attention

Yubo Xie, Junze Li, and Pearl Pu

School of Computer and Communication Sciences  
École Polytechnique Fédérale de Lausanne, Switzerland  
{yubo.xie, junze.li, pearl.pu}@epfl.ch

## Abstract

In this paper, we describe our system submitted to SemEval 2021 Task 7: HaHackathon: Detecting and Rating Humor and Offense. The task aims at predicting whether the given text is humorous, the average humor rating given by the annotators, and whether the humor rating is controversial. In addition, the task also involves predicting how offensive the text is. Our approach adopts the DeBERTa architecture with disentangled attention mechanism, where the attention scores between words are calculated based on their content vectors and relative position vectors. We also took advantage of the pre-trained language models and fine-tuned the DeBERTa model on all the four subtasks. We experimented with several BERT-like structures and found that the large DeBERTa model generally performs better. During the evaluation phase, our system achieved an F-score of 0.9480 on subtask 1a, an RMSE of 0.5510 on subtask 1b, an F-score of 0.4764 on subtask 1c, and an RMSE of 0.4230 on subtask 2a (rank 3 on the leaderboard).

## 1 Introduction

Humor, appreciated by people with almost any age or cultural background, is perhaps one of the most fascinating human behaviors. Besides providing entertainment, humor can also be beneficial to mental health by serving as a moderator of life stress (Lefcourt and Martin, 2012), and plays an important role in regulating human-human interaction. As Reeves and Nass (1996) have pointed out, people respond to computers in the same way as they do to real people, which indicates that modeling humor computationally could bring positive effects in human-computer interaction (Nijholt et al., 2003). Despite being universal to human beings, the extent to which people find something humorous varies according to one’s age, gender, or socio-economic

status, making humor a highly subjective experience. This poses many challenges to the field of computational humor. Abundant research has been done to enable computers to automatically decide whether humor is entailed in a given piece of text. Early work (Mihalcea and Strapparava, 2005; Mihalcea et al., 2010) uses manually engineered features to recognize humor in text, while more recent work (Chen and Soo, 2018; Weller and Seppi, 2019) adopts deep learning approaches and pre-trained language models.

SemEval 2021 Task 7: HaHackathon: Detecting and Rating Humor and Offense (Meaney et al., 2021) aims at detecting and rating humor as well as offense in short English text. There are four subtasks involved. Subtask 1a is a binary classification task, predicting if the text would be considered humorous for an average user. Subtask 1b is a regression task and predicts the humor rating of the text if it is considered humorous. Subtask 1c is again a binary classification task and predicts whether the humor rating is controversial, whose ground-truth label is decided based on the variance of the annotators’ ratings. This task also involves offense detection. Subtask 2a predicts how offensive the text is for a general user. All the regression subtasks have scores ranging from 0 to 5.

In this paper, we present our system submitted to SemEval 2021 Task 7. We followed the architecture of DeBERTa (He et al., 2020), an improved version of BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) by using two novel techniques: disentangled attention and decoding enhanced masking. We mainly relied on the disentangled attention mechanism, where the attention weights of the input words are calculated based on their content vectors and relative position vectors. For the four subtasks, we used the same base structure and the only difference is at the output layer, where the classification tasks have two out-

put units and the regression tasks only have one. The pre-trained DeBERTa model has two variants that differ in size. During the evaluation phase, the large version achieved an F-score of 0.9480 on subtask 1a, an RMSE of 0.5510 on subtask 1b, an F-score of 0.4764 on subtask 1c, and an RMSE of 0.4230 on subtask 2a (rank 3 on the leaderboard). In addition, we also experimented with the BERT and RoBERTa models as our baselines, and found them generally under-performed by DeBERTa. Our code has been made publicly available.<sup>1</sup>

## 2 Related Work

Mihalcea and Strapparava (2005) used several human-centric features such as alliteration and synonym to recognize humor in one-liners. Mihalcea et al. (2010) approached the problem by calculating the semantic relatedness between the set-up and the punchline. Morales and Zhai (2017) proposed a generative language model and leveraged background text sources to identify humor in Yelp reviews. Liu et al. (2018) proposed to model sentiment association between elementary discourse units and designed features based on discourse relations. Xie et al. (2020) calculated the uncertainty and surprisal of the set-up and the punchline according to the incongruity humor theory, which were found useful in humor recognition. Recent work also developed neural network based models to recognize humor in text. Chen and Lee (2017) and Chen and Soo (2018) adopted convolutional neural networks, while Weller and Seppi (2019) used a Transformer architecture.

## 3 Dataset

SemEval 2021 Task 7 provides three datasets: the training set (8,000), the validation set (1,000), and the final test set (1,000). Table 1 summarizes the statistics of the three datasets, and lists the respective information of humorous (positive) and non-humorous (negative) examples. Each example is a piece of English text accompanied by four features: `is_humor` (subtask 1a), `humor_rating` (subtask 1b), `humor_controversy` (subtask 1c), and `offense_rating` (subtask 2a). For subtask 1b and 2a, the labels range from 0 to 5. Table 2 gives two samples, one being humorous and the other non-humorous.

<sup>1</sup><https://github.com/yuboxie/semEval-2021-task-7>

	Train	Validation	Test
# positive	4,932	632	615
Avg # tokens	24.48	22.04	26.14
# negative	3,068	368	385
Avg # tokens	25.95	26.12	29.36
# total	8,000	1,000	1,000
Avg # tokens	25.05	23.54	27.38

Table 1: Statistics of the provided datasets. Here the respective information of humorous (positive) and non-humorous (negative) examples are also listed.

For subtask 2a, whose goal is to predict the offense rating of the input text, we also visualize top 200 frequent unigrams for examples with offense rating  $\geq 2$  and  $< 2$ , respectively, illustrated as two word clouds (Figure 1a and Figure 1b). As we can observe, Figure 1a contains words that are expected to appear in offensive text, usually targeting at a specific group of people (e.g., “black”, “gay”, “chinese”, “muslim”, etc.), while Figure 1b contains more ordinary words, which generally do not imply offense.

## 4 System Overview

With the increasingly powerful neural networks such as the Transformer (Vaswani et al., 2017), the performance on many downstream NLP tasks has been greatly improved by fine-tuning large pre-trained language models on smaller but task-specific datasets. Traditional Transformer-based language models such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) use absolute positional embeddings in the input layer, which are added up with the word embeddings and serve as the input to the following Transformer layers. The self attention weights between the tokens are calculated solely based on their hidden representations. However, recent work (Shaw et al., 2018; Dai et al., 2019) has shown that relative position representations are more effective for NLP tasks.

Our system leverages the disentangled attention mechanism from the DeBERTa model (He et al., 2020), where the attention weights between input tokens are calculated based on their content vectors as well as their relative positions. As shown in Figure 2, for each Transformer layer,  $H_i$ ’s are the input representations from last layer, and  $H_i^o$ ’s are the output representations after applying the self attention. Instead of using absolute positional

Figure 1: Word clouds of the data according to the offense rating.

embeddings at the input layer, we create a relative positional embedding table, which is shared across all layers, to represent the relative position between token  $i$  and token  $j$ . More specifically, the index of the relative position between token  $i$  and  $j$  is defined as

$$\delta(i, j) = \begin{cases} 0 & \text{if } i - j \leq -k, \\ 2k - 1 & \text{if } i - j \geq k, \\ i - j + k & \text{otherwise,} \end{cases} \quad (1)$$

where  $k$  is the maximum distance we consider. Similar to normal Transformer attention mechanism, the content representations  $H$  and the relative position representations  $P \in \mathbb{R}^{2k \times d}$  are transformed to queries, keys, and values:

$$\begin{aligned} Q^c &= HW_q^c, K^c = HW_k^c, V^c = HW_v^c, \\ Q^p &= PW_q^p, K^p = PW_k^p. \end{aligned} \quad (2)$$

Then, the attention weight  $A_{ij}$  between token  $i$  and token  $j$  are calculated as follow:

$$A_{ij} = Q_i^c K_j^{cT} + Q_i^c K_{\delta(i,j)}^{pT} + K_j^c Q_{\delta(j,i)}^{pT}. \quad (3)$$

When aggregating the input representations  $H$ , we apply a scaling factor  $1/\sqrt{3d}$  to obtain the output representations  $H^o$ :

$$H^o = \text{softmax}\left(\frac{A}{\sqrt{3d}}\right)V^c. \quad (4)$$

For subtask 1a and 1c, which are binary classification tasks, we use softmax output layer and

cross entropy loss. For subtask 1b and 2a, which are regression tasks, we use mean square error as the loss function. Otherwise, the base structure is the same, and we initialize the model with the pre-trained DeBERTa weights.

## 5 Experimental Setup

We evaluated and compared our system with several baselines on the provided dataset, whose statistics are provided in Section 3. In this section, we are going to elaborate the setup of our experiment.

### 5.1 Baselines

In our experiment, we consider the following approaches as our baselines:

- **Bag of words (BoW)**. In this approach, we neglect the order of the input tokens, and simply add up the word embeddings of the tokens to form the vector representation of the input text. We implemented logistic regression for subtask 1a and 1c, and linear regression for subtask 1b and 2a, using the 300d GloVe word embeddings (Pennington et al., 2014).
- **Convolutional neural network (CNN)**. Convolutional neural networks have been widely adopted in computer vision and image recognition. When applied to NLP tasks, the input is a 2D matrix with each row being the word embeddings of the respective token, and the convolution is operated along the rows, with a

Our system (large)	<b>0.9707/0.9604</b>	0.9446/0.9463	<b>0.9575/0.9533</b>	<b>0.9470/0.9430</b>	<b>0.4923/0.5538</b>

Table 3: Performance of subtask 1a and 1b on the validation / test set.

fixed window size. We follow the CNN model in the work of [Chen and Lee \(2017\)](#), which includes an extra highway layer before the final fully connected layer, allowing shortcut connections with gate functions.

- **Bidirectional long short-term memory (Bi-LSTM).** LSTM ([Hochreiter and Schmidhuber, 1997](#)) has shown to perform quite well in handling sequential inputs, making it suitable for many NLP tasks. Bidirectional LSTM incorporates two LSTMs, one in the forward direction and the other in the backward direction, thus better modeling the context. In this approach, we use a Bi-LSTM with hidden size 200 and one hidden layer.
- **BERT.** BERT ([Devlin et al., 2019](#)) is a deep bidirectional Transformer pre-trained on BooksCorpus and English Wikipedia, with two training objectives: (1) masked language model, where some of the input tokens are randomly masked and are to be recovered by the model; (2) next sentence prediction, where

the goal is to predict if the input second sentence follows the first one. By fine-tuning the pre-trained BERT, the performance of a wide range of NLP tasks can be largely improved, compared with previous models such as LSTMs.

- **RoBERTa.** RoBERTa ([Liu et al., 2019](#)) is an optimized version of BERT, which was trained on bigger datasets and longer sequences. In addition, the next sentence prediction objective was removed, which was found to slightly improve the performance of downstream tasks. RoBERTa reportedly achieved better results than BERT on benchmarks such as GLUE, RACE and SQuAD.

## 5.2 Implementation

All the Transformer-based models in the experiment have two variants that differ in model size. The base version has 12 Transformer layers, 768 hidden units, and 12 multiheads. The large version has 24 Transformer layers, 1024 hidden units,

	Subtask 1c				Subtask 2a

Our system (base)	0.4873/0.4537	<b>1.0000/1.0000</b>	0.6553/ <b>0.6242</b>	0.4873/0.4537	0.5484/0.4653
Our system (large)	0.4943/0.4574	0.9903/0.9032	<b>0.6595</b> /0.6072	0.5016/0.4699	<b>0.4794/0.4516</b>

Table 4: Performance of subtask 1c and 2a on the validation / test set.

and 16 multiheads. We used the Adam optimizer (Kingma and Ba, 2015) with learning rate  $5 \times 10^{-6}$ , and a batch size of 16. All the models were trained until the minimum loss value is reached on the validation set.

### 5.3 Evaluation Metrics

For classification tasks 1a and 1c, we use precision, recall, F-score, and accuracy as the evaluation metrics. For regression tasks 1b and 2a, we use the root mean square error as the evaluation metric:

$$\text{RMSE} = \sqrt{\frac{1}{N} \sum_{n=1}^N (\hat{y}_n - y_n)^2}, \quad (5)$$

where  $\hat{y}_n$  is the predicted value, and  $y_n$  is the ground-truth value.

## 6 Results

The performance of our system and the baselines is shown in Table 3 (subtask 1a and 1b) and Table 4 (subtask 1c and 2a). We show the performance scores on both the validation and the test set. Generally speaking, the large version of our system performs quite well on all the four subtasks, compared with the other models. It can also be observed that, Transformer-based models always outperform the traditional methods by a large margin, except for subtask 1c, where all the models perform poorly and similarly. We conjecture this is because humor controversy is itself a highly subjective task, which is difficult even for humans. We also observe that large version of BERT-like models are generally better than their base counterparts, which is natural since larger models with more parameters usually bring better performance.

Table 5 gives the confusion matrix of our system on the test set in subtask 1a. We can see that in

		Ground-truth		Total
		P	N	
Predicted	P	582	24	606
	N	33	361	394
Total		615	385	1,000

Table 5: The confusion matrix of our system (large) on the test set (subtask 1a). P: Positive, N: Negative.

both positive and negative cases, the system performs quite well and makes only few errors. We manually examined some cases where our system makes a false prediction, and found that when our system predicts humorous but the ground-truth is non-humorous, the input text usually contains a question, e.g.,

*There are 2 kinds of families on Thanksgiving. Which one are you?*

We infer this is because most of the humorous examples in the training set contains a question, usually followed by a short answer serving as the punchline.

## 7 Conclusion

In this paper, we describe our system submitted to SemEval 2021 Task 7. We adopted the disentangled attention mechanism from the DeBERTa model, and participated in all the four subtasks. During the evaluation phase, we got a rank of 3 on the leaderboard for subtask 2a. For future work, we would like to combine human-centric features with the current architecture using the disentangled attention mechanism, and develop a hybrid model. In addition, we plan to expand the provided dataset with extra jokes from various sources such as Reddit forums, hoping to further improve the performance of our system.

## Abstract

This paper introduces the result of Team Grenzlinie's experiment in SemEval-2021 task 7: HaHackathon: Detecting and Rating Humor and Offense in English. This task has two sub-tasks. Subtask1 includes the humor detection task, the humor rating prediction task, and the humor controversy detection task. Subtask2 is an offensive rating prediction task. Detection task is a binary classification task, and the rating prediction task is a regression task between 0 to 5. 0 means the task is not humorous or not offensive, 5 means the task is very humorous or very offensive. For all the tasks, this paper chooses RoBERTa as the pre-trained model. In classification tasks, Bi-LSTM and adversarial training are adopted. In the regression task, the Bi-LSTM is also adopted. And then we propose a new approach named compare method. Finally, our system achieves an F1-score of 95.05% in the humor detection task, F1-score of 61.74% in the humor controversy detection task, 0.6143 RMSE in humor rating task, 0.4761 RMSE in the offensive rating task on the test datasets.

## 1 Introduction

Humorous is one kind most interesting, most has the power, most has the universal significance transmission art. Therefore, humor is one of the ways to improve the quality of daily conversation. In the field of natural language processing, how to make the computer learn humor and improve the quality of human-computer interaction is an important problem. The previous researches task was only to input the humorous corpus into the deep learning network and let the algorithm learn how to generate humorous dialogue. In this case, the sentences are often problematic. Because humor is an abstract concept, in different situations, the degree of humor and the way of humor will be different. Therefore, before the computer learns to generate humorous

sentences, it is an important task for the computer to understand humor and distinguish different degrees and forms of humor.

This paper mainly discusses how to identify these humorous sentences automatically. In SemEval-2021 task 7, subtask1 includes the humor detection task, the humor rating predicts task and the humor controversy detection task (Meaney et al., 2021). Subtask2 is an offensive rating predict task. In the detection task, the Bi-LSTM and adversarial training (Tramèr et al., 2017) is adopted, we also try to use FocalLoss to solve the data unbalance problem. In the regression task, the Bi-LSTM is also adopted. And then we propose a new method named compare method is also adopted.

The rest of the paper is as follows: Section 2 briefly introduces the related work. Section 3 describes the optimization approach to be used in detail. Section 4 describes the experiment process in detail. Section 5 is the conclusion of this paper.

## 2 Related Work

On large corpora, pre-trained models (PTMs) can learn common language representation, which is beneficial for subsequent NLP tasks and can avoid training new models from scratch (Wang et al., 2018). With the development of computing power and the improvement of training skills, the architecture of PTMs is advancing from shallow to deep.

The goal of the first version of PTMs is to learn good word embedding. Since these models are no longer needed by downstream tasks, they are usually very superficial for computational efficiencies, such as skip-gram (Mikolov et al., 2013) and GloVe (Pennington et al., 2014). Although these pre-trained embeddings can capture the semantic meaning of words, they are context-free and cannot capture the advanced concepts in the context, such as polysemy disambiguation, syntactic structure,

semantic role, anaphora, and so on. The second version of PTMs mainly learn context word embedding, such as ELMo(Peters et al., 2018), OpenAI, GPT(Radford et al., 2019) and BERT(Devlin et al., 2018). These learned coders still need to represent words in context through downstream tasks. Besides, various pre-training tasks are proposed to learn PTMs for different purposes.

Given the pre-trained model, downstream algorithms like Random Forest, SVM, Logistic Regression, or single linear layer can be adopted to get the result.

Recent studies have extended the humor detection task to the field of multi-modality and used gesture, speech prosody, and other features in humor detection task(Li et al., 2020). They also began to work on the joint training and integration of humor detection task and humor generation task(Weller et al., 2020). However, these models still regard humor detection as a binary classification task, without considering humor scoring and controversy.

### 3 Methods Description

**Baseline Model** In these tasks, RoBERTa is adopted as the baseline model, and softmax is adopted as the activation function in the classification task. In the regression task first, we try to use ReLU as the activation function, then we use sigmoid as the activation function, and multiply the output of sigmoid by 5. But we find the method without activation function does the best in regression task. If we add ReLU after regression task, the RMSE will reduce 0.1 0.2. So the activation function is not adopted in the baseline model. To avoid the negative output of the model in the scoring model, we need to add ReLU as an activation function in the test phase.

In the regression task, the Mean Square Loss is adopted as the loss function. In classification tasks, we use the CrossEntropy Loss as the loss function.

**Method1: Bi-LSTM** In this paper, all the sub-task use the Bi-LSTM to extract more abundant features. In this model, Bi-LSTM is added after the pre-trained model. [CLS] (classification symbol) always be added before sentence, and use classifier to compute [CLS] representation to get the result. So, there is a problem, that is, the sentence representation from Bi-LSTM will not integrate on symbol [CLS]. But we need the representation of [CLS] for the next step. So the output of Bi-LSTM is sent into a new defined transformer layer, encode

the sentence representation into the symbol [CLS]. Finally, the sentence representation will send into a single linear layer to get the result.

**Method2: adversarial training** Then the adversarial training is adopted to improve the baseline model. Adversarial training is an important way to enhance the robustness of neural networks. In the process of confrontation training, the samples will be mixed with some small disturbances, and then make the neural network adapts to this change, so it has the robustness to the confrontation samples. In the field of the language model, adversarial training improves both robustness and generalization (Morris et al., 2020).

Adversarial training can be summarized as the following maximum and minimum formula,

$$\min_{\theta} \mathbb{E}_{(Z,y) \sim \mathcal{D}} \left[ \max_{\|\theta\| \leq \epsilon} (L(F_{\theta}(X + \delta)), y) \right] \quad (1)$$

Where  $X$  represents the input representation of the sample,  $\theta$  represents the disturbance superimposed on the input,  $F_{\theta}()$  is the neural network function,  $y$  is the label of the sample, and  $L(F_{\theta}(X + \delta)), y$  represents the loss obtained by superimposing a disturbance  $\theta$  on the sample  $X$ , and then comparing it with the label  $y$  through the neural network function.  $\max(L)$  is the optimization objective, that is to find the disturbance that maximizes the loss function. In short, the added disturbance should confuse the neural network as much as possible.

$\min_{\theta} \mathbb{E}_{(Z,y) \sim \mathcal{D}}$  is the minimization formula to optimize the neural network, that is, when the disturbance is fixed, we train the neural network model to minimize the loss of training data, that is to say, the model has certain robustness and can adapt to the disturbance.

In this method, FGM (Fast Gradient Method) (Miyato et al., 2016) is adopted. The idea is very simple, that is, let the direction of disturbance increase along the gradient, and the increase along the gradient means the maximum loss. The formula of FGM is as follows.

$$\delta = \epsilon \cdot \frac{g}{\|g\|_2} \quad (2)$$

Where  $\epsilon$  is a constant, which controls the degree of disturbance rejection.  $g = \nabla X(L(F_{\theta}(X)), y)$ , i.e. the gradient of loss function  $L$  with respect to input  $X$ .

**Method3: FocalLoss** In the classification task, we can see that the data ratio of humorous and non-humorous sentences is close to 2:1, and then in humor’s data, the ratio of controversy and non-controversy is close to 1:1, but We assume that non-humorous sentences are also non-controversy sentences. Therefore, these two tasks are faced with the problem of data imbalance. To solve this problem, we use the FocalLoss (Lin et al., 2017) as the loss function. The FocalLoss is as follows.

$$FocalLoss(p_t) = -\alpha_t (1 - p_t)^\gamma \log(p_t) \quad (3)$$

Where  $p_t$  is the probability of the label  $t$  that is outputted by the classifier.  $N$  is the number of labels.  $\alpha$  and  $\gamma$  are constant.

**Method4: Compare Method** This method is only for humor rating predict task and offensive rating predict task. In the few-shot classification tasks, traditional approach is given a pair of sentences in the same class and given a pair of sentences in different classes. Let the classifier identify whether the pair of sentences is the same class or different classes. So the latent feature of each label in the sentence can be extracted. Unfortunately, this approach can’t be used in regression tasks.

Based on this idea, we proposed the compare method. This method extends the above idea to the regression task. The approach is shown in figure 1. In this model, we input sentence A with rating  $L(A)$ , and sentence B with rating  $L(B)$ , then three different models that realize the function of  $M_{add}$  ( $L(A)$  plus  $L(B)$ ),  $M_{sub\_AB}$  ( $L(A)$  minus  $L(B)$ ), and  $M_{sub\_BA}$  ( $L(B)$  minus  $L(A)$ ). It means to use these models to encode pairs of sentences and output  $Z_{add}$ ,  $Z_{sub\_BA}$ ,  $Z_{sub\_AB}$ . Then put these features into the classifier. Let the output ratings become the addition and the subtraction of the pair of sentences’ rating.

Furthermore, the sentence representation which rating is close to the addition and subtraction of the pair of sentences’ ratings can be used to introduce the  $Z_{add}$ ,  $Z_{sub\_BA}$ ,  $Z_{sub\_AB}$  by minimizing the MSELoss of  $Z_{add}$ ,  $Z_{sub\_BA}$ ,  $Z_{sub\_AB}$  and sentence representation. In this task, this approach is not adopted because of the lack of data.

The three models have the same construction. To simplify the computation, the last layer’s hidden output from RoBERTa is set as the feature of each token. Then these token features are concatenated like "[CLS] (sentence) [SEP] (another sentence) [SEP]". And send the concatenated output to a

single transformer layer to get the [CLS] output for classifying.

The loss function  $C_{loss}$  and the  $Add_{loss}$  is as follows. In the equation, ML is MSELoss and C is our model,  $C(F_A)$  means the output of our model. These loss functions are the loss of the single sentence result and the loss of the result of  $Z_{add}$ ,  $Z_{sub\_BA}$ ,  $Z_{sub\_AB}$ .

$$C_{loss} = ML(C(F_A), L(A)) + ML(C(F_B), L(B)) \quad (4)$$

$$Add_{loss} = ML(C(Z_{add}), L(A) + L(B)) + ML(C(Z_{sub\_AB}), L(A) - L(B)) + ML(C(Z_{sub\_BA}), L(B) - L(A)) \quad (5)$$

## 4 Experiment Setup

**Datasets** First of all, we try to find the relationship between tasks. In the beginning, we think that those with low humor ratings or high offensive ratings may be controversial, but unfortunately, we find many Counterexamples in the datasets. Then we tried to train several tasks together, but the result was not as good as that of training it independently. So we train these tasks independently.

Secondly, in the task of humor scoring and humor controversy detection, only humorous sentences need to be rating predicted and detected. In the data set, only humorous sentences have humor ratings and humor controversy labels. Therefore, how to deal with the label of non-humorous sentences is an important problem. We have tried to set the controversy label of non-humorous sentences to 2, that is, the third category, but this approach will identify humorous sentences as the third category, which will interfere with the model. Therefore, in this paper, we set the rating of non-humorous sentences to 0, and the controversy label to 0, i.e. non-controversy.

**Parameters setting** In this section, the hyperparameter is the same in all subtasks. The optimizer is AdamW with a 3e-5 learning rate and 1e-8 adam epsilon. The pre-trained model has 12 transformer layers and 768 hidden sizes. The max sequence length is 180. The batch size is 8. And weight decay is 0.

## 5 Result

The result of the test datasets is shown in Table 1. Final results in line 1 is results in evaluation

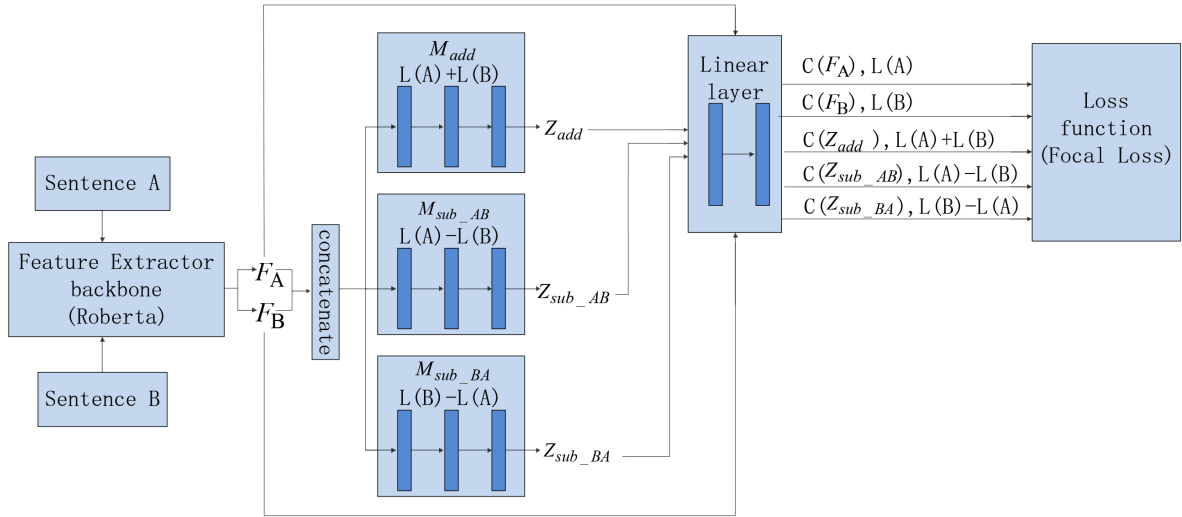

Figure 1: Compare Method Construction

phase. FGM+FocalLoss and compared method are adopted. and other line are the result in post evaluation phase. In this phase, we reduce the learning rate. In table 1, it can be seen that the result of all optimize methods in the controversy detection task is worse than the baseline model. Because we set the non-humorous sentences as non-controversy, This will greatly interfere with the model’s judgment of non-controversy sentences. In the evaluation datasets, i.e. predicted results from non-humorous sentences are used to calculate the F1-score, these approaches do optimize the baseline model. But these approaches do not play an optimization role in the test phase. So we can make this conclusion. Then FGM and Bi-LSTM will make the model extract more abundant features, which will undoubtedly aggravate the interference of non-humorous sentences and reduce the prediction accuracy of the model.

FocalLoss didn’t work as expected and didn’t get better results. Because FocalLoss usually use in the datasets that 0 label is more than 1 label, but in the humor detection task, 1 label is more than 0. Although we adjusted the alpha in FocalLoss to 0.67, FocalLoss still failed to get better results.

FGM optimizes the baseline model in humor detection, humor rating, and offensive rating tasks. and based on FGM, Bi-LSTM does more better in these tasks. Because Bi-LSTM can extract sentence features in more detail, especially bidirectional sequence features. Experiments show that these features are more conducive to downstream tasks.

Finally, Compare Method only optimizes the

offensive rating predict task, but it not good at humor rating predict task, we think the non-humorous sentences. We speculate that non-humorous sentences with a 0 rating interferes with the comparison of two randomly selected sentences in compare method. The number of sentences that select non-humorous sentences for comparison is too large to help the model predict rating, so the auxiliary task interferes with the baseline model.

## 6 Conclusion

This paper introduces the experiment in SemEval-2021 task 7 HaHackathon: Detecting and Rating Humor and Offense. In this article, we propose two main assumptions. The first point is that the model is difficult to obtain the real meaning of the tag according to the change of the 0-5 rating. So the method of adding the auxiliary task on the baseline model was proposed. The auxiliary task is comparing different sentences according to the number proposed by us all to strengthen and supplement this process. This method does the best in offensive rating predict task, achieve 0.4761 RMSE. Second, the output of the pre-training model is similar to the word vector, which needs further processing to be more suitable for downstream tasks. So we try to use Bi-LSTM. Indeed Bi-LSTM does the best, achieve the 95.05% F1-Score in the humor detection task, and 0.6143 RMSE in the humor rating task. These approaches do not play an optimized role in the controversy detection task. The baseline does the best, achieve the 61.74% F1-score. The main reason for this problem lies in the interference

Model	Humor F1	Humor RMSE	Controversy F1	Offensive RMSE
Final results	0.9386	0.6312	0.5455	0.4761 RoBERTa
0.9344	0.6961	0.6174	0.5146	
FGM	0.9481	0.6311	0.5614	0.4847
Bi-LSTM+FGM	0.9505	0.6143	0.5609	0.4956
FGM+FocalLoss	0.9386	-	0.5454	-
Compare Method	-	0.6906	-	0.4761

Table 1: The result of several optimize approach on test datasets

of non-humorous sentences. So there is still room for improvement, such as eliminating the influence of non-humorous sentences, adjust the model parameters and try other pre-trained models. Or try to use a classification model and regression model in machine learning, such as Bayesian or CRF, to process the output of BERT. Therefore, the future work is to find a better way to remove the influence of non-humorous sentences and find a better way to optimize the controversy detection task. And then do more experiments to get better results.

## Abstract

This paper describes our system participated in Task 7 of SemEval-2021: Detecting and Rating Humor and Offense. The task is designed to detect and score humor and offense which are influenced by subjective factors. In order to obtain semantic information from a large amount of unlabeled data, we applied unsupervised pre-trained language models. By conducting research and experiments, we found that the ERNIE 2.0 and DeBERTa pre-trained models achieved impressive performance in various subtasks. Therefore, we applied the above pre-trained models to fine-tune the downstream neural network. In the process of fine-tuning the model, we adopted multi-task training strategy and ensemble learning method. Based on the above strategy and method, we achieved RMSE of 0.4959 for sub-task 1b, and finally won the first place.

## 1 Introduction

Humor, as a highly subjective phenomenon, can be affected by various factors. Automatic humor recognition relies on annotated data to determine whether the text is humorous or not (Mihalcea and Strapparava, 2005). However, such a binary classification does not capture the level of humor, so assessing the level of humor is of great significance (Garimella et al., 2020). Since humor can be influenced by many factors, such as age, and may offend others. Based on such a situation, SemEval-2021 Task 7 focuses on linking humor and offense across different age groups (Meaney et al., 2021). But there are still many challenges to this task. For example, the dataset for the task is small and the texts are short, which does not allow for adequate training. To address these issues, we utilized unsupervised pre-trained language models and fine-tuned these models for specific downstream subtasks. After conducting research and extensive comparative

experiments, the results show that ERNIE 2.0 (Sun et al., 2019b) and DeBERTa pre-trained models performed best on the subtasks. These large unsupervised language models were pre-trained on a large amount of unlabeled data to extract valuable lexical, syntactic, and semantic information from the corpus. Vector representations of text computed by these models are applied to fine-tune the downstream neural networks for the subtasks. The multi-task training and ensemble learning method significantly improve our model’s performance.

The rest of the paper is organized as follows: Section 2 provides a brief description of the related work, and Section 3 describes our proposed approach in detail. In Section 4, the experiments are described in detail and the results are presented. Finally, we summarize the whole paper and discuss future research directions in Section 5.

## 2 Related Work

In the early research of humor and offense detection and evaluation, traditional machine learning methods and n-gram language model were mostly used.

Recent research has shown that unsupervised language pre-trained models using large amounts of unlabeled data have achieved state-of-the-art results in a large number of natural language processing tasks. For example, BERT (Devlin et al., 2018) is a model built based on Transformer Encoder, which is used for downstream tasks by pre-training on the masked language models task and the next sentence prediction task, and then for fine-tuning. Inspired by this approach, many pre-training language models have been proposed. For example, ALBERT (Lan et al., 2019) adopts Factorized Embedding Parameterization and Cross-layer parameter sharing strategies, and adds the sentence order prediction task, so that the model can greatly

Figure 1: Architecture of our model for multi-task training. The public section is shared by all subtasks, while the private section is subtask-specific. First, text is transformed into subwords, and ERNIE 2.0 generates the corresponding contextual vector representation. Then different loss functions are set for each subtask to generate task-specific representations. This is eventually used for classification and regression subtasks in different scenarios.

reduce the number of parameters without lose accuracy compared to BERT. RoBERTa (Liu et al., 2019b) removes the next sentence prediction task and uses dynamic MASK, which is optimized for BERT. DeBERTa (He et al., 2020) improves the BERT and RoBERTa models by using two new techniques. The first one is using Disentangled attention mechanism and secondly, Enhanced mask decoder is used. MT-DNN (Liu et al., 2019a) combines Multi-task Learning and pre-trained models to improve the performance of various natural language processing tasks.

ERNIE 1.0 (Sun et al., 2019a) employs an entity-level and phrase-level mask, the extension of its training corpus and the use of multiple rounds of conversation to replace sentence pair classification further enhance the model’s semantic representation capability. ERNIE 2.0 (Sun et al., 2019b) is an optimized version of ERNIE 1.0, which introduces a large number of pre-training tasks and continuously updates the pre-training model through multi-task learning to help the model learn lexical, syntactic and semantic representations efficiently. ERNIE 2.0 constructs three pre-training tasks, namely word-aware pre-training tasks, structure-aware pre-training tasks and semantic-aware pre-training tasks. The performance of the model is improved by constructing pre-training tasks from multiple perspectives. The ERNIE 2.0 model outperformed BERT and XLNet (Yang et al., 2019) almost across the board on the English task and achieved the best results on 7 GLUE tasks; on the Chinese task, the ERNIE 2.0 model outperformed

BERT across the board on all 9 Chinese NLP tasks.

### 3 Our Approach

#### 3.1 Multi-task training

To mitigate overfitting for specific tasks, we adopt a multi-task training strategy that combines pre-trained language model and multi-task training (as shown in Figure 1). Based on the above strategy, it makes the learned representation generalizable across tasks and improves the performance of various downstream subtasks.

The architecture of our model is shown in Figure 1, with the pre-trained model ERNIE 2.0 as the public section, which is used for generating semantic information common to downstream tasks. and the multi-task training as the private section, where individual subtasks are trained to produce task-specific representations by using different loss functions.

When we fine-tune our model, the input to the model is the data from all subtasks. Words from the text in different subtasks are first processed by tokenizer to generate subwords. After the subwords are transformed into tokens by the mapping of the lexicon, the tokenized sentences are stitched together with [CLS] and [SEP] as the input to the ERNIE 2.0 model to obtain the contextual vector representation corresponding to each token. Multi-task training is a fully-connected layer followed by the ERNIE 2.0 model, and the four downstream subtasks optimize the subtask-specific model by constructing different loss functions for gradient

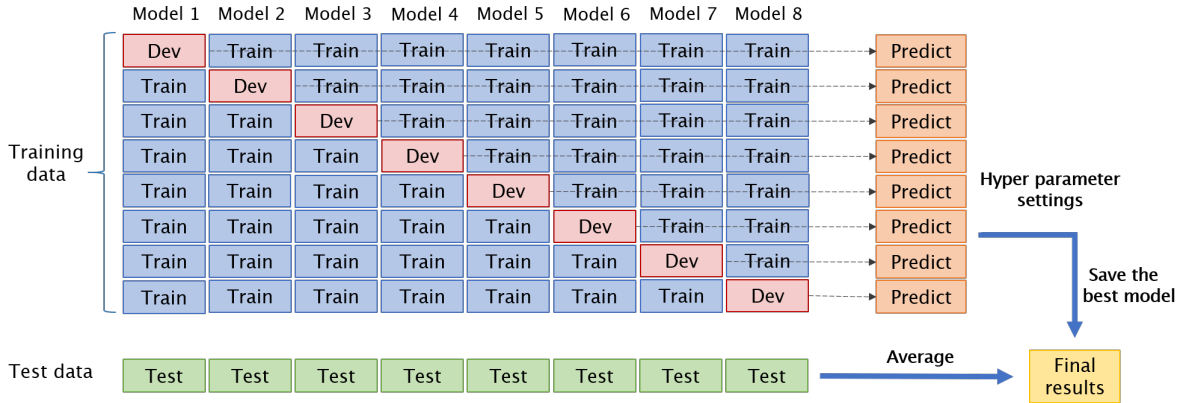

Figure 2: 8-fold cross-validation and ensemble. The training set is divided randomly for 8 times by setting different random seeds. In each division, the training set  $T$  is divided into 8 parts, of which 7 parts are respectively used as the training set and the remaining 1 part is used as the validation set. And finally the average of all saved best models predicted on the test set are the final results.

updating. For the classification task we first use the sigmoid activation function to constrain the output between 0 and 1 before using the BCE loss function, and for the regression task we use the MSE loss function.

### 3.2 Ensemble

We adopt cross-validation for training as a way to improve the robustness of our model, as shown in Figure 2. We first divided the training set eight times by setting different random seeds. Therefore, 8 folds of data are generated, with 7000 training samples and 1000 validation samples in each fold. When fine-tune our model for each fold, the best model for each subtask at each fold of training is saved. For subtask 1a and subtask 1c, the evaluation metric is F1-Score, and for subtask 1b and subtask 2a the evaluation metric is RMSE. finally, we take the mean of all the best saved models after making predictions on the test set as the final results.

## 4 Experiment

### 4.1 Experimental details

All of our experiments were run on the Nvidia Tesla V100. In order to obtain more valuable information from the limited training data and to reduce overfitting to some extent, we adopt the multi-task training strategy and ensemble learning method.

For the training of the per-fold model, we choose the Adam optimizer, set the epoch to 10, and use early stopping strategies according to the performance on the validation set. Considering the small amount of data in the training set, we set a smaller

learning rate for the ERNIE 2.0 model layer and a larger learning rate for the fully connected layer where the subtasks are trained together. Specifically, when fine-tuning our model, we adopt the grid search strategy with the learning rate ranging from  $2e-5$  to  $5e-5$  and the batch size ranging from 32 to 48. Besides, we set the learning rate as a linear function and use a warm-up strategy in the training phase. The ensemble approach we adopt is mainly based on the average prediction results. The specific methods are as follows: for the classification subtask, the prediction probabilities of all base models in each category are averaged, and then the category with the highest probability is taken as the prediction result; while for the regression subtask, the prediction values of all base models are averaged as the final prediction result.

### 4.2 Comparison experiments

In order to verify the effectiveness of our proposed multi-task training strategy based on the ERNIE 2.0 model, we set up two comparison experiments. They are described as follows:

(1) Comparison experiments of multi-task training together and single-task training separately based on ERNIE 2.0 model.

(2) Comparison experiments of single-task separate training based on ERNIE 2.0 and DeBERTa models.

### 4.3 Experimental Results

Table 1 summarizes the results on the validation set of all the models we tried based on the 8-fold cross-validation method. We can see that under

Models	Is_multi_task	Task 1a (F1-Score)	Task 1b (RMSE)	Task 1c (F1-Score)	Task 2a (RMSE)
DeBERTa <sub>xlarge</sub>	False	0.9603	0.4492	0.6598	0.4817
ERNIE 2.0 <sub>xlarge</sub>	False	0.9656	0.4542	0.6388	0.4746
ERNIE 2.0 <sub>xlarge</sub>	True	0.9727	0.4475	0.6566	0.4722

Table 1: The results of different models under the 8-fold cross-validation method. The table describes the results of the DeBERTa and ERNIE 2.0 models on four subtasks in the case of single-task training separately and multi-task training together. For subtask 1a and subtask 1c, the evaluation metric is F1-Score, and for subtask 1b and subtask 2a the evaluation metric is RMSE.

the evaluation metrics of each subtask, The number of parameters in the ERNIE 2.0 model (425M) is less than the DeBERTa model (750M), but the ERNIE 2.0 pre-trained model performs better than the DeBERTa model on several subtasks. Besides, Compared to single-task training, the strategy of using multi-task training shows a significant improvement in performance. Moreover, The impact of ensemble learning method on improving model performance is significant.

## 5 Conclusion

In this paper, we proposed a multi-task training system based on ERNIE 2.0. We describe the architecture of the model and the training process in detail. Besides, we experimentally demonstrate that the strategy performs better with multi-task training compared to single-task training. Moreover, the ensemble learning method makes the model more robust. As a result, we have won the first place in a subtask for the competition of SemEval-2021 task 7. In our future work, we will further explore pre-trained language model and optimize the multi-task training.

## Abstract

Humor and Offense are highly subjective due to multiple word senses, cultural knowledge, and pragmatic competence. Hence, accurately detecting humorous and offensive texts has several compelling use cases in Recommendation Systems and Personalized Content Moderation. However, due to the lack of an extensive labeled dataset, most prior works in this domain haven't explored large neural models for subjective humor understanding. This paper explores whether large neural models and their ensembles can capture the intricacies associated with humor/offense detection and rating. Our experiments on the SemEval-2021 Task 7: HaHackathon show that we can develop reasonable humor and offense detection systems with such models. Our models are ranked third in subtask 1b and consistently ranked around the top 33% of the leaderboard for the remaining subtasks.

## 1 Introduction

Like most figurative languages, humor/offense pose interesting linguistic challenges to Natural Language Processing due to its emphasis on multiple word senses, cultural knowledge, sarcasm, and pragmatic competence. A joke's perception is highly subjective, and age, gender, and socioeconomic status extensively influence it. Prior humor detection/rating challenges treated humor as an objective concept. SemEval 2021 Task 7 (Meaney et al., 2021) is the first humor detection challenge that incorporates the subjectivity associated with humor and offense across different demographic groups. Users from varied age groups and genders annotated the data with the text's humor and have provided an associated score for the same. It is also quite a generic phenomenon that a text might be

\* Authors contributed equally to the work. Names in alphabetical order.

humorous to one and normal/offensive to another. Rarely has it been noticed that the same content is globally accepted as witty. To the best of our knowledge, Meaney et al. (2021) is the first initiative towards annotating the underlying humor as controversial or not. Understanding whether a text is humorous and/or offensive will aid downstream tasks, such as personalized content moderation, recommendation systems, and flagging offensive content.

Large Language Models (LLMs) have recently emerged as the SOTA for various Natural Language Understanding Tasks (Lewis et al., 2019; Raffel et al., 2019; Conneau et al., 2019; Zhang et al., 2020). However, typical day-to-day texts, where these models have shown state of the art performance, are less ambiguous than texts having puns/jokes. Training and evaluating LLMs in the context of highly ambiguous/subjective English texts would serve as an excellent benchmark to figure out the current shortcomings of these models. This paper studies various large language models – BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2019), ERNIE-2.0 (Sun et al., 2019) and DeBERTa (He et al., 2020) and their ensembles – for humor and offense detection tasks. Additionally, we explore a Multi-Task Learning framework to train on all the four sub-tasks jointly and observe that joint training improves the performance in regression tasks.

We have achieved significant performance on all the subtasks and have consistently ranked  $\sim \frac{1}{3}$ <sup>rd</sup> of the total submissions. We were ranked (1) 21<sup>st</sup> with an F-score and accuracy of 94.8% and 95.81% respectively in Task 1a, (2) 3<sup>rd</sup> with an RMSE score of 0.521 in Task 1b, (3) 9<sup>th</sup> with an F-score and accuracy of 45.2% and 62.09% respectively in Task 1c; and (4) 16<sup>th</sup> with an RMSE score of 0.4607 in Task 2. We release the code for models

and experiments via GitHub<sup>1</sup>

We organize the rest of the paper as: we begin with a description of the challenge tasks followed by a brief literature survey in section 2. We then describe all of our proposed models in section 3 with training details in section 4 and present the experimental results in section 5. Finally, we analyze our findings and conclude in section 6, and 7 respectively.

## 2 Background

### 2.1 Problem Description

SemEval 2021 Task 7: HaHackathon: Detecting and Rating Humor and Offense (Meaney et al., 2021) involves two main tasks – humor detection and offense detection. The organizers further subdivide the task into following subtasks:

1. Humor detection tasks:
  - (a) **Task 1a** involves predicting whether a given text is humorous.
  - (b) **Task 1b** requires predicting the humor rating of a given humorous text.
  - (c) **Task 1c** incorporates humor subjectivity by posing a classification problem of predicting whether the underlying humor is controversial or not.
2. **Task 2** is an offense detection task and is posed as a bounded regression problem. Given a text, we need to predict a mean score denoting the text’s offensiveness on a scale of 0 to 5, with 5 being the most offensive.

### 2.2 Related Works

**Transfer Learning** ULMFiT (Howard and Ruder, 2018) used a novel neural network based method for transfer learning and achieved SOTA results on a small dataset. Devlin et al. (2018) introduced BERT to learn latent representations in an unsupervised manner, which can then be finetuned on downstream tasks to achieve SOTA results. Lan et al. (2019); Liu et al. (2019); Sanh et al. (2019); Sun et al. (2019) have proposed several improvements to the BERT model. In this paper, we analyze the effects of using these different base models in the context of humor and offense detection.

<sup>1</sup><https://github.com/aishgupta/Quantifying-Humor-Offensiveness>

**Humor & Emotion Detection** Weller and Seppi (2019) first proposed the use of transformers (Vaswani et al., 2017) in humor detection and outperformed the state of the art models on multiple datasets. Ismailov (2019); Annamradnejad (2020) extended the use of BERT models to humor classification. Fleşcan-Lovin-Arseni et al. (2017) did humor classification by comparing and ranking tweets while Docekal et al. (2020) edit the tweet and rank the extent of humor for the edited tweet on a scale of 0 to 3 (most funny). There has been extensive research in the area of text emotion prediction and generation (e.g., Witon et al. (2018); Colombo et al. (2019); Goswamy et al. (2020); Singh et al. (2021)). Demszky et al. (2020) curated a large scale emotion detection dataset and achieved SOTA results by finetuning a BERT model. However, none of these works delve into humor analysis’ subjectivity, which is a prime focus of this task.

**Sentiment and Pun Analysis** Li et al. (2019); Mal-toudoglou et al. (2020) study BERT based models for sentiment analysis. Ke et al. (2019) uses a combination of sentence embedding, POS tagging and word-level sentiment polarity scores for sentiment classification. Zhou et al. (2020) uses contextualized and pronunciation embeddings for each word and pass these through a neural network to detect and localize pun in the sentence. However, none of these works focus on the subjectivity of the underlying sentiment and pun in the text.

## 3 System Overview

### 3.1 Data

The challenge dataset comprises of a `train` set (labeled 8000 texts) and a `public-dev` set (labeled 1000 texts). Each text input is labeled as 1/0 if it is humorous or not and rated with the offensiveness score on a scale of 0-5. If a text is classified as humorous, it is further annotated with humor rating and classified as controversial or not. For our single-task models (Section 3.2), we train on the `train + public-dev` set after obtaining a suitable stopping epoch by training and validating on the `train` and `public-dev` respectively. For our multi-task models (Section 3.3), we train on 8200 texts sampled randomly from `train` and `public-dev` sets and use remaining 800 text inputs for validation.

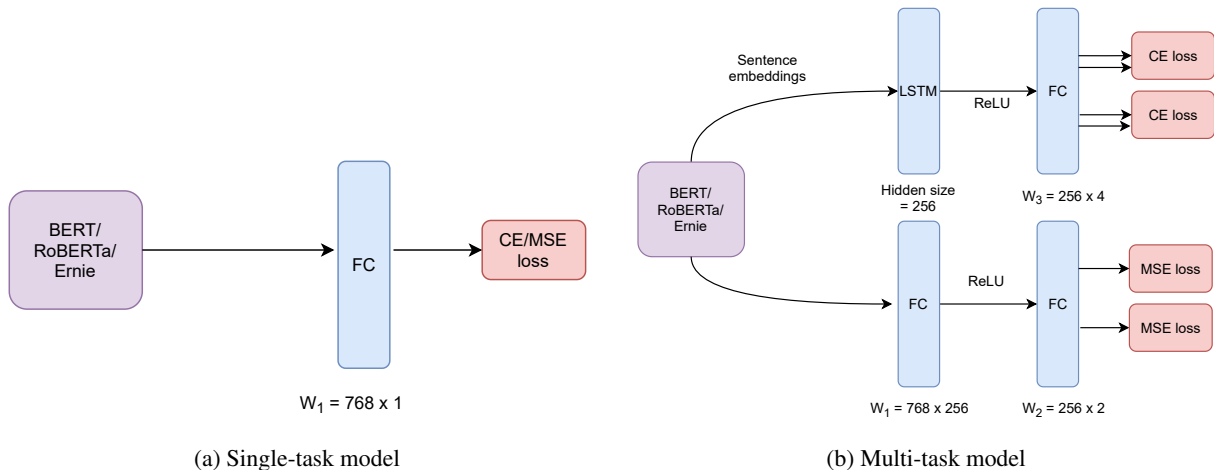

Figure 1: Different Model architectures used for Humor/Offense detection/rating.

### 3.2 Single Task Model

As the tasks are evaluated independently, we have explored LLMs for each task/subtask independently and will be referring to them as single task models. Inspired by [Demszky et al. \(2020\)](#), for each task, we add a classification (for Task 1a, 1c) or a regression (for Task 1b, 2) head on top of the pretrained models like BERT, RoBERTa, ERNIE-2.0, DeBERTa and XLNet and train the model end-to-end (Figure 1a). This ensures that the model learns features solely related to the task, enhancing the performance. Also, as we only add a classification/regression head, the number of learnable parameters does not increase much. This helps us in finetuning the model on such a small dataset for a few number of epochs avoiding overfitting and resulting in better generalization.

### 3.3 Multi Task Learning

[Collobert and Weston \(2008\)](#) demonstrated that Multi-Task Learning (MTL) improves generalization performance across tasks in NLP. The different tasks though uncorrelated, share the same underlying data distribution. This can be of great help for tasks 1b and 1c where labeled instances are far less than for task 1a or 2. Exploiting the fact that all tasks share same data distribution, we propose to learn a model jointly on all the tasks. Specifically, we consider hard parameter sharing among different tasks and parameterize the base models using a neural network, followed by two heads for classification and regression tasks (Figure 1b). Our base model includes LLMs like BERT, RoBERTa, and ERNIE. Contrary to the LSTM layer, which helps in learning features using all the token level embed-

dings, the Fully Connected (FC) layer focuses only on the embedding of [CLS] token. Hence, having these two branches allow the model to focus on different tasks using the same sentence embedding and helps in learning enhanced embeddings for task 1b and 1c with much lesser labeled dataset.

### 3.4 Ensembles

Mostly LLMs differ in their training procedure, and architecture. These big language model frameworks are trained on wide set of datasets for a variety of tasks. Though, they all have comparable performance, they may still capture different aspects of the input. We try to leverage such varied informative embeddings based predictions by combining multiple models trained with different basenet using following strategies:

**Jointly trained Model Embeddings:** All the big language frameworks have shown huge performance improvement on multiple tasks owing to their highly informative latent input embeddings. We propose to learn an ensemble leveraging diverse aspects of the input captured by varied LLMs by concatenating their latent embeddings and mapping them to low dimensional space for task prediction. We use this method in learning ensembles of single task models explained in 3.2.

**Aggregation of Trained Model Predictions:** Joint-training though more informative and powerful, is a computationally intensive approach. Thus as an alternative, we use a weighted averaging of multiple pretrained models without compromising much on the performance.

1. **Weighted Aggregate of Regression Outputs:** For an ensemble of  $k$  models trained

Model	Task1-a		Task1-b	Task1-c		Task2
	F-Score	Accuracy	RMSE	F-Score	Accuracy	RMSE
STM (BERT)	-	-	0.5841	0.5934	0.4829	0.4997
STM (RoBERTa)	0.9523	0.9410	0.5929	<b>0.6242</b>	0.4536	-
STM (ERNIE-2.0)	0.9541	0.9430	0.5546	0.4113	0.5252	0.4716
STM (XLNet)	-	-	0.5656	0.5892	0.5171	-
STM (DeBERTa)	0.9532	0.9420	0.5491	-	-	-
STM (Agg. Ensemble)	<b>0.9581</b>	<b>0.9480</b>	0.5480	0.4520	<b>0.6209</b>	0.4750
MTM (BERT)	0.9374	0.9210	0.5794	0.5080	0.5496	0.5049
MTM (RoBERTa)	0.9477	0.9350	0.5873	0.5479	0.5170	0.5141
MTM (ERNIE-2.0)	0.9530	0.9420	0.5541	0.5389	0.5187	0.4961
STM + MTM (Agg. Ensemble)	0.9520	0.9400	<b>0.5210</b>	0.5321	0.5252	<b>0.4520</b>

Table 1: Metrics on the test dataset for the major models on all the sub-tasks. MTM stands for Multi-Task Model, STM stands for Single Task Model, and Agg. Ensemble is Aggregation Based Ensembling without having to jointly train all the models together.

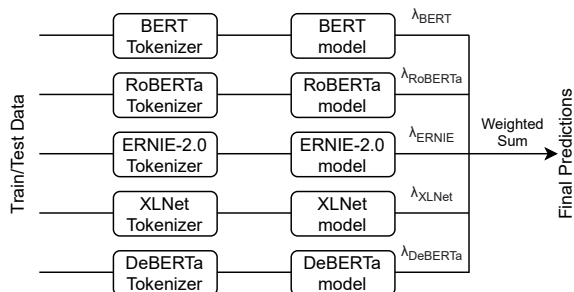

Figure 2: **Weighted-Average Ensembling:** The data is tokenized and then passed to the respective model. A weighted sum is done to obtain the final predictions.  $\lambda_i$  represents the weight for model  $i$ .

using different LLMs as basenet, the aggregate output  $\hat{y}$  is computed as  $\hat{y} = \sum_{i=1}^k \lambda_i \cdot \hat{y}_i$  where  $y_i$  and  $\lambda_i$  represents the output and weight of the  $i^{th}$  model respectively. The weights  $\lambda_i$  are obtained through extensive grid search on the held out validation dataset or set to a  $\frac{1}{k}$  when trained on the entire dataset without a validation set. The complete approach is shown in figure 2.

2. **Voting Based Classification:** This is one of the most popular approach of learning an ensemble and does not involve any hyperparameters or retraining of any of the constituent models. This involves training multiple models independently and using maximum among all the predictions as the final output. For a binary classification task, the final output  $\hat{y}$  is by max-voting across the independent models.

## 4 Experimental Setup

We used Pytorch (Paszke et al., 2019) and HuggingFace (Wolf et al., 2020) library for our models, and Google Colab GPUs for training and inference. We use ADAMW (Loshchilov and Hutter, 2019) and ADAM (Kingma and Ba, 2017) optimizer with initial learning rate of  $2e^{-5}$  for training single task and multi task models respectively. For each of the models we follow a dedicated training pipeline described in subsequent sections.

### 4.1 Data preprocessing

We split the dataset into training and validation data as described in Section 3.1. The sentences are annotated with a [CLS] token in the beginning and given as an input to the model. We performed additional experiments by removing stopwords but noticed a slight deterioration in the performance.

### 4.2 Loss Functions

Task 1a & 1c are instances of binary classification problem and thus have been trained using cross-entropy loss. For predicting humor and offense rating i.e., Task 1b and 2, we have used mean squared error as the loss function.

### 4.3 Training Details

All the models are trained for  $n$  epochs where  $n$  is a hyper-parameter tuned on the validation set using early stopping criteria. For single task models, we split train data into training and validation set to learn the optimal value of  $n$  and then train the model from scratch on train + public-dev

Rank	Task1-a		Task1-b RMSE	Task1-c		Task2 RMSE
	F-Score	Accuracy		F-Score	Accuracy	
Rank-1	0.982	0.9854	0.4959	0.4943	0.6302	0.4120
Rank-2	0.975	0.9797	0.4977	0.4699	0.6279	0.4190
Rank-3	0.960	0.9676	0.5210	0.4699	0.6270	0.4230
Ours	0.948 (21)	0.9581 (21)	0.5210 (3)	0.452 (9)	0.6209 (9)	0.4607 (16)

Table 2: Comparison of our results with those on top of the leaderboard. (\*) indicates our rank on the leaderboard in that task.

set for  $n$  epochs. In case of multi task models, all the tasks do not converge at the same rate. Thus, we train multi task models on randomly sampled 8200 texts from `train + public-dev` dataset and validate on the remaining 800 texts. We use early stopping criteria on validation dataset independently for each task.

## 5 Results

We have trained multiple single task and multi task models using basenet LLMs like BERT, DistilBERT, RoBERTa, XLNet, Albert (Lan et al., 2019), Electra (Clark et al., 2020), DeBERTa, and ERNIE-2.0. We also learned ensembles of single task models by either training a classification/regression head on concatenated input embeddings or using weighted aggregate of the models’ predictions. Apart from this, we also explored voting based ensemble of multi-task models. All our models perform comparably on all tasks and the major models are reported in Table 1. We also compare our best model performance with the top 3 submissions on the leaderboard and report it in Table 2.

## 6 Analysis

### 6.1 Data Augmentation

One recurring issue across all our trained models is the high susceptibility to overfitting. Data Augmentation is a widely accepted solution to reduce overfitting by generating slight variants of the given dataset and is extremely useful for a smaller dataset.

One such approach is Masked Language Modelling (MLM), used to perform context-specific data augmentation (Ma, 2019) and has been used in training LLMs. However, following this data augmentation during training has consistently degraded the performance of our models. We hypothesize that this is due to the mismatch be-

tween the contextual meaning and the associated humor/offense. MLM-based augmentation strategies, with models pre-trained to preserve the sentence’s meaning, fail to capture the associated humor/offense.

Often the selection of words in a sentence is responsible for its humor/offensive rating. Replacing such words by their synonyms can change the humor/offense rating substantially. Hence, using such a data augmentation approach during training will inject heavy noise in the ground truth resulting in deteriorated performance.

### 6.2 Correlation across Tasks

Contrary to our belief, we fail to ascertain any direct relationship between the humor controversy and the offense rating prediction task. We compute the mean offense rating for the texts labeled as controversial and for texts marked as non-controversial. The computed mean values are too close to each other to demonstrate any direct correlation conclusively.

### 6.3 Dataset Size

In literature, finetuning LLMs on small size task specific dataset has shown remarkable task performance. However, our single dedicated task models could not perform better than our multi-task model for Task 1b. We attribute this to relatively small size of supervised dataset available for Task 1b in comparison to other tasks. In our multi task models, though we have lesser labeled text for Task 1b, our sentence embeddings are still updated using the complete available dataset. Thus, our multi task model learns underlying distribution better than single task model owing to join learning and shared parameters for task 1b and 2. We believe that this is the main reason for the enhanced performance of our model on Task 1b which has lesser supervised data available in comparison to Task 1a or 2.

## 7 Conclusion

We have presented several experiments using large language models like BERT, XLNet, etc., and their ensembles for humor and offense detection and rating. We also discuss some of the underlying challenges due to the subjective nature of humor and offense detection task. Using these, we explain why standard training practices used to prevent overfitting, like data augmentation, do not work in this context. Our experiments suggest that even though these models can reasonably capture humor and offense, they are still far from understanding every intricacy arising out of subjectivity. To tackle some of the problems highlighted in this paper, a compelling direction would be online data augmentation by alternating between training the embeddings and generating new texts to preserve the humor/offensiveness. Additionally, pretraining these models on datasets annotated by diverse annotators to capture a more comprehensive world knowledge should further help in generalization.

## Abstract

In this paper we describe the systems used by the RoMa team in the shared task on *Detecting and Rating Humor and Offense (HaHackathon) at SemEval 2021*. Our systems rely on data representations learned through fine-tuned neural language models. Particularly, we explore two distinct architectures. The first one is based on a Siamese Neural Network (SNN) combined with a graph-based clustering method. The SNN model is used for learning a latent space where instances of humor and non-humor can be distinguished. The clustering method is applied to build prototypes of both classes which are used for training and classifying new messages. The second one combines neural language model representations with a linear regression model which makes the final ratings. Our systems achieved the best results for humor classification using model one, whereas for offensive and humor rating the second model obtained better performance. In the case of the controversial humor prediction, the most significant improvement was achieved by a fine-tuning of the neural language model. In general, the results achieved are encouraging and give us a starting point for further improvements.

## 1 Introduction

Detecting humor has become a popular research field at the same time that the bad phenomenon of offensiveness spreading exaggeratedly grows in social media. In this scenario it is very frequent to find out alarming volumes of heterogeneous data such as textual messages, images, advertisements, etc., that harm some age groups, ethnicity, sexual gender or other demographic characteristics (Betul

Keles and Niall McCrae and Annmarie Grealish, 2020). Most of these harmful contents are often masquerade as innocent jokes or simply as a funny content. Therefore, it is crucial to shed light on the commonalities and differences between both phenomena in order to properly addressing the challenge of computationally distinguishing humorous messages from aggressive or offensive ones. Recognizing humorous and offensive utterances on written messages is a very difficult task for human beings and even more for computers (Waseem, 2016). These difficulties increase when the textual messages are isolated from the context in which they are produced. Additional knowledge from gestures, prosody features, visual content, situational environment and sociocultural rules play an important role in how humans properly understand the real meaning behind funny and hateful contents. All this makes humor recognition and offensiveness detection challenging tasks within Natural Language Processing (NLP) and Human-Computer Interaction (HCI). On this line, the *Task 7, HaHackathon: Detecting and Rating Humor and Offense at SemEval-2021* aims at computationally recognizing humor and offensiveness in English tweets (Meaney et al., 2021).

To address the four subtasks launched in *HaHackathon* we propose two distinct architectures which rely on neural language model based representation (*deep-representation*), particularly learned by Transformer architectures. Our first architecture combines the learned representation with a SNN in order to learn in automatically way a metric for discriminating a pair of messages of

the same class from a pair of messages of different classes. Also, we considered applying a graph-based clustering method to each class independently for creating representative prototypes. These prototypes were used to build the training and testing pairs. Our second architecture relied on the principle of fusing representations. For that, the *deep-representation* are mixed with linguistic information (*linguistic-representation*) and given as inputs to a linear regression model which is specialized in predicting humor and offensive scores. The paper is organized as follows: in Section 2 we briefly introduce the description of the four subtasks. Section 3 presents our proposed architectures and gives details about their modules. In Section 4 are described the experiments and results. Finally, we present our conclusions and provide interesting directions that we plan to explore in future work. The source code associated with this paper is online available on GitHub: [https://github.com/mjason98/semeval21\\_humor](https://github.com/mjason98/semeval21_humor).

## 2 Task Descriptions

We investigated the performance of our proposed architectures in the four subtasks introduced in *Ha-Hackathon*: i) given a tweet determining whether it is humorous or not (*subtask 1a*); ii) given a tweet predicting the humor rate in the range of 0 to 5, where 0 indicates that it is not a funny message and 5 indicates that the message is strong humorous (*subtask 1b*); iii) given a tweet determining whether it is considered as controversial (i.e., it is rated with highly variable values of humor from one annotator to another) (*subtask 1c*); the last subtask, iv) given a tweet predicting its offensiveness rating in a range of 0 to 5, where 0 indicates the tweet does not contain any kind of offensiveness and 5 indicates that the message is strong offensive (*subtask 2*).

Organizers provided a dataset for training and test labeled according to the objectives of each subtask. The whole dataset was manually annotated by several annotators in order to minimize the noise in the data and increase the agreement in the annotation procedure. The dataset is composed by 8000 tweets for training and 1000 tweets for testing purposes, respectively. The training set contains 3068 funny and 4932 non-funny tweets. This slight imbalance in the training set imposes an additional difficulty to the learning algorithm for accurately predicting the funny messages. The

problem increases in the task of controversial humor prediction where only 2465 tweets are labeled as controversial and the remainder 5535 are non-controversial. The most complex scenario regarding the data distribution is appreciated in the tasks of humor and offensiveness rating. At a first glance on the Figure 1 can be inferred that the majority of the offensive scores are accumulated in the interval (0,1). As a consequence of that, the tweets which

Figure 1: Histograms of humor and offensiveness score distribution

are not offensive at all or those with scores closer to zero are over-represented whereas the tweets with strong offensive content are under-represented in the dataset. Therefore, from the learning perspective, it is more difficult to score tweets which strong offensive content. Conversely to this scenario, the funniness scores are distributed more uniform. Also, it is important to highlight that tweets with offensive scores greater than 0 in most cases also were scored as funny tweets. This relation reveals the usage of some humor devices as a way for masqueraded offensive messages.

## 3 Our Proposals

In this section we present the proposed models and provide details about their modules. Our models have a modular structure. They are composed of both, an encoder module (*Encoder*) and a prediction module (*Classifier*), which are trained independently. Particularly, we evaluate two distinct methods for the classification module. The first one is based on a Siamese neural network and the second one relies on fusing representations and training a linear regression model.

### 3.1 Encoder Modules

The Encoder plays an important role because it is concerned with learning an abstract representation that vanishes the colinearity between its features

and compresses the textual information on a single dense vector. In our proposal, the encoders are based on Transformer models (TM), specifically on RoBERTa (Liu et al., 2019) and XLNet (Yang et al., 2020) architectures. Moreover, we employed BERTweet (Nguyen et al., 2020) which is based on the structure and pre-training procedure like RoBERTa, but using an English tweets corpus that makes it easier to fine-tune on NLP tasks where the texts are short and informal.

For fine-tuning the TM-based encoders we add up an intermediate layer that receives the vectors from the output sequence of the TM. On this sequence of vectors, we explore three variants for selecting the best way of representing the message: i) the vector in the first position (associated to the *CLS* token), ii) the normalized sum of all vector in the sequence, and iii) the vector in the last position of the sequence. On this layer, we stacked an output layer that makes the final prediction for the targeted task. For that purpose, we follow the strategy proposed in the Universal Language Model Fine-Tuning (ULMFiT) (Howard and Ruder, 2018). For each layer of the TM a different learning rate is set up, increasing it using a multiplier while the neural network gets deeper. This multiplier increases 0.1 points from a layer  $L_i$  to another  $L_{i+1}$ . We use this dynamic learning rate to keep most information from the pre-training at shallow layers and biasing the deeper ones to learn about the specific tasks.

On the humor predicting subtask the BERTweet encoder was employed, whereas for offensiveness rating the three TMs were considered and trained using a multitask learning strategy for predicting offensive scores and irony together. Particularly, for irony detection we used the data proposed in *Task 3: Irony Detection Task at SemEval 2018* (Van Hee et al., 2018).

## 3.2 Classification Modules

In this section we describe the architecture of the two proposed classification modules.

### 3.2.1 SiaNet

To address the humor detection task we propose a SNN (Koch et al., 2015; Bromley et al., 1993) whose functionality lies on extracting features from the input messages, in such a way that a pair of messages belonging to the same class are closer and in case of belonging to opposite class move away w.r.t a distance function. In this work we use the Euclidean distance. The distance learned by this

network is used as a criterion to determine, given an unlabeled message, whether it is more likely to belong to the positive class (e.g. humorous) than to the negative class (e.g. non-humorous). For that purpose, we define in each class a set of prototypes which are used to compare against the unlabeled message. These prototypes are obtained by means of a graph-based clustering method. After having the clusters, for each of them is selected a prototype (real message), which is able to represent the most information contained on that group.

### Prototype Selection Strategy

The SiaNet model requires a pair of messages as input in both training and test phases. During the training stage, pairs of two labeled messages are used, and in the test phase, the label of a new message is predicted considering its similarity with positives (humorous) and negatives (non-humorous) messages. As consequence, the methods employed to obtain the pairs and select the humor and non-humor messages for comparing at the training stage, impact directly on the learning process of the model.

In this work, instead of sampling positive and negative messages randomly, we propose to include an additional step that aims at obtaining prototypical instances (*prototypes*, henceforth) of both classes. For that, we build a graph of  $\beta$ -distance, analogous to the  $\beta$ -similarity graphs proposed in (Garcia, 2005), for the humor ( $G_P$ ) and non-humor ( $G_N$ ) classes. The nodes in the graphs represent the tweets from the training set and the edges joining two nodes are weighted with the distance between them.

In the  $\beta$ -distance's graphs the edges with weights greater than the threshold  $\beta$  are removed, allowing only the closest representations being in the same connected subgraph. Notice that, the representation of the messages associated to nodes are obtained from the Encoder module. Afterwards, we detect communities on the  $\beta$ -distance's graph  $G_P$  and  $G_N$  respectively, using the InfoMap (Edler et al., 2020) algorithm based on the map equation (Rosvall et al., 2009). The map equation is a flow-based and information-theoretic method. By minimizing it over all the possible network partitions, InfoMap reveals important aspects of the network structure with respect to the dynamics on the network.

As result it is obtained a set of subgraphs  $g_P^i \in G_P$  and  $g_N^i \in G_N$  and the nodes they contain with their respective flow values. For each subgraph

$g_C^i$ ,  $C \in [P, N]$  we select the node  $x_{max}$  with the highest flow value. We assume that this node acts as a representative node for  $g_C^i$ , and consequently it is also a prototypical message for the class  $C$ . All prototypical messages for the humorous and non-humorous classes are obtained and defined as Humor Prototype Set ( $P_{Set}$ ) and Non-Humor Prototype Set ( $N_{Set}$ ) respectively. In Figure 2 are depicted the projection of each class messages, and their respective prototypes.

Figure 2: Scatter encoder representations per class with the identified prototypes

### Siamese Neural Net Architecture

The network architecture consists of two input messages and one output that indicates how distant they are according to their representation (Bromley et al., 1993). Both messages are encoded by using the fine-tuned Transformers model (see Section. 3.1). Later, each input is passed through two dense layers (with 64 hidden neurons), which map the encoding to a smaller dimension by learning specific features. We must annotate that both input messages are fed to the same two dense layers (i.e., the new encodings are computed using the same weights in both cases). Later, the representations of the messages are compared to each other through a distance metric. The specific features the model learns to extract, make that messages representations corresponding to opposite classes have a distance greater than the threshold defined in the loss function used. Particularly, we used the *Contrastive Loss* (Hadsell et al., 2006) with a threshold of 0.85, this value was set empirically.

For training the SNN, the dataset needs to be processed for constructing pairs of messages from the same class and pairs of messages from distinct classes. Once defined the sets of prototypes  $P_{Set}$  and  $N_{Set}$  (as described in the Prototype Selection Strategy), we create training examples associated

to each message  $x$  into the training dataset, with  $x \notin P_{Set} \cup N_{Set}$ . For that, we sampled randomly  $k$  *intra-class* examples, by pairing  $x$  with prototypes from its class, and generate  $m$  *inter-class* examples pairing  $x$  with their closest prototypes from the contrary class.

During the test phase, given an unlabeled message, we obtain the encoding of  $z$  by using the Encoder module. After that, we predict the distance of  $z$  with respect to the prototypes in the  $P_{Set}$  and  $N_{Set}$  using the SNN. Based on the previously computed distances, we evaluate two rules for deciding whether  $z$  should be classified under the humorous or non-humorous classes:

i) *Minimum*, we assign  $z$  to the class of its nearest prototype as follows:

$$\hat{y} = \arg \min_i \{SNN(z, x_{i,j})\} \quad (1)$$

where  $x_{i,j}$  is the prototype message  $j$  with label  $i = \{0, 1\}$ .

ii) *Mean*, we assign  $z$  to the class of the Prototype Set with lowest average distance:

$$S_i = \frac{1}{C_i} \sum_{j=1}^{C_i} SNN(z, x_{i,j})$$

$$\hat{y} = \arg \min_i \{S_i\} \quad (2)$$

where  $C_i \in \{|P_{Set}|, |N_{Set}|\}$  and  $x_{i,j}$  is the prototype message  $j$  with label  $i = \{0, 1\}$ .

### 3.2.2 Multiview-based Linear Regression Module

Ensemble methods usually combine data representations or the decisions of multiple models to obtain improved results over those obtained individually. These decisions are made from valuable features extracted by models' intermediate layers, which vary depending on their architecture and the dataset they have been trained on.

Combining all those information into a single prediction unit instead of synthesized predictions, is consistent if we seek to take into account different views of the information, especially when dealing with such complex and subjective tasks as offensiveness detection and in general sentiment analysis are.

We propose to fusing four distinct representations of the tweets and use this mixing deep-features for training a linear regression method. Three of the representations are based on fine-tuned transformer encoders and the other is based on affective features.

## Encoder Settings

Considering the underlying relation between humorous and offensive language observed in the HaHackathon dataset (please, see Figure 1), the relation among offensiveness with other forms of toxic speech (e.g. aggressiveness and hate) presented in (Poletto et al., 2020) and the common usage of figurative devices like irony in social media for communicating indirectly hateful messages (Cignarella et al., 2018; Frenda, 2018). We fine-tuned the RoBERTa-based models on the dataset provided in the shared tasks HatEval 2019 (Basile et al., 2019), OffensEval 2019 (Zampieri et al., 2019), Irony Detection Task at SemEval 2018 (Van Hee et al., 2018) and HaHackathon itself. The fine-tuning was carried out using a smooth learning rate on the Masked Language Modeling (*MLM*) task. We masked randomly 15% of the tokens from each message, and fit them for three epochs, following the strategy proposed in (Liu et al., 2019).

For training the Encoders to address the HaHackathon specific target, the placed intermediate layer after the encoder heads, is fed with the concatenation of the three variants to get the TM output (see Section. 3.1). This layer is the one employed to obtain the message encodings. We combine the offensiveness rating in HaHackathon with the labels of irony in the dataset of *SemEval 2018 Task 3* (Van Hee et al., 2018). This idea relies on the observed relation between humor and offensiveness ratings within the provided data, where many offensive messages can be considered as ironic or harmful forms of humor (see last two examples in Table 4).

To avoid outliers in the dataset for misleading the training process, we employed the *Minkowski error* (Bishop, 1995) in the regression subtask, which is less sensitive to outliers than the standard mean squared error. It is defined as follows:

$$Error_{Minkowski} = \frac{\sum(|y - \hat{y}|)^{kc}}{n} \quad (3)$$

Where  $y$  is the label for one example,  $\hat{y}$  is the predicted value,  $n$  the number of examples and  $kc$  the Minkowski coefficient which we set to 1.4 empirically.

## The Affective Features

Conversely to the three representations above, the Affective Features representation was obtained from a word-level recurrent neural network, trying to capture how affective information from different

dimensions flows along the messages (Kar et al., 2018). For this purpose, we constructed an embedding matrix whose features were based on an affective information set proposed by (Farías et al., 2016) containing basic emotions (i.e., sadness, surprise, fear, etc). The embedding vectors involved 52 components between binary and no binary values, and the vocabulary was built from the affective resources, hence words not expressing emotional charge at all were encoded with the null vector.

The information obtained from this embedding for a message was fed into an BiLSTM (*Bidirectional Long Short Term Memory*) architecture similar to ELMO (Peters et al., 2018). Deeper BiLSTM output was fed, to an intermediate layer to condense the information passed later to the output layers. For training this model we used a multitask approach focusing on predicting how offensive a message is, as well as how funny it is, by using the data provided for HaHackathon.

## Linear Regression

As we can be observed in Figure 3, the encoding provided by transformer models differ regarding the space region in which the offensive features are projected. We can infer that one representation helps the others by providing information not captured simultaneously.

Figure 3: Scatter encoders representations

Considering that, there is no co-linearity between the features extracted from one encoder to another. We hypothesize they can be combined through a parsimonious model to prevent overfitting. Based on that, we decided to employ a Ridge Regression Model, setting the  $\alpha$  hyper-parameter employed for the L2 regularization on the loss function to 1.0. During the experiments we also construct another ensemble based on Recurrent Neural Networks (RNN) which receive all four encodings and treat them as a sequence of the message. The elements of this sequence are weighted through an Addi-

tive Attention layer and combined employing an LSTM layer in order to decide from a time step *i.e.*, from one encoding to another, which of the features must be kept through the entire sequence analysis *i.e.*, all four encodings. The output of this layer is then fed into two parallel output layers to predict whether a message is offensive or not and its offensiveness degree.

The data over-representation for messages with offensiveness rating equal to 0 makes that, from the standpoint of deciding whether a message is offensive or not, the data be balanced (*i.e.*, labeling the messages with offensiveness rating higher than 0 as offensive). This allowed to us using the alternative classification task in the multitask learning approach employed for this model, taking into account that it helps to learn common features among these offensiveness-related tasks.

## 4 Experiments and Results

In this section we describe the conducted experiments for evaluating the performance of our systems on HaHackathon development dataset (*dev-dataset*). For that, we employed the metrics proposed by the task organizers, *F1-score* over the positive class and accuracy (*Acc*) for classification subtasks, and the Root Mean Squared Error (*RMSE*) for regression subtasks.

### Encoder Modules

The SiaNet model and the Ridge Regression model are fed with information of the messages extracted through their respective encoder modules, this makes our first effort focused on tuning them for obtaining the best representation. For both approaches, SiaNet and Ridge Regressor, the encoders were optimized using the RMSprop method (Hinton et al., 2012).

Firstly, for obtaining the multi-viewed representation of the messages, the RoBERTa, BERTweet and XLNet encoders were fine-tuned using (*MLM*) unsupervised learning. For that, we considered three additional related-datasets (Basile et al., 2019; Zampieri et al., 2019; Van Hee et al., 2018) and the HaHackathon dataset itself. Afterwards, since the multi-viewed representation was constructed for rating offensiveness, the three models were trained specifically for this regression task by exploring two main ideas based on multitask learning strategy (*MTL*): i) The first one aims at capturing the

information shared among the four subtasks proposed in the HaHackathon dataset; ii) The second one, aims at capturing the indirect negative speech behind humorous messages, for that we introduced the irony prediction task (*Irony*) combined with offensiveness prediction. Specifically, we used the dataset proposed in (Van Hee et al., 2018) for addressing the irony prediction task.

Table 1 shows the results of applying both strategies for each transformer encoder. As can be observed, by making the model to extract features also useful for irony detection we achieved the best performance. Nevertheless, the first strategy

Model	Strategy		
	<i>HAHA</i>	<i>Irony</i>	<i>No MTL</i>
BERTweet	0.70	0.65	0.81
RoBERTa	0.75	0.63	0.67
XLNet	0.69	0.68	0.70

Table 1: MTL strategies for offensiveness rating subtask. *HAHA* refers to MTL with all HaHackathon subtasks and *Irony* refers to MTL with irony detection task

yields our best result at predicting whether or not a message can be considered as controversially humorous. We also tried to avoid using MTL with the three transformers encoders, fine-tuning them for the offensiveness regression subtask, but in terms of RMSE the performance decreased on 0.07 in average.

Similarly it happened when it was not accomplished the *MLM* fine-tuning. The error was slightly increased for RoBERTa from 0.58 to 0.64 when this stage was avoided and for BERTweet, it increased from 0.65 to 0.91. We hypothesize this technique helped the model to reduce the impact of isolated offensive terms, which may influence the regression stage on messages that are not even offensive.

For fine-tuning the encoder module of SiaNet we explored if it was more convenient to set a single learning rate for the whole model or follow the ULMFiT strategy addressing the humor prediction task. The second approach obtained the best performance in terms of F1-Score/Acc with (0.94/0.92) w.r.t (0.90/0.88) reached by the first one. We also tried to apply MTL to this approach, but this did not yield any improvement, reaching 0.93/0.91.

## Prediction Modules

For classifying unlabeled tweets with SiaNet we evaluated the two methods described in Section 3.2.1 alongside the upper bound of clusters extracted from  $G_P$  and  $G_N$  by InfoMap (50, 250 and 300 clusters) and how the TM output sequence was used according to the strategies described in Section 3.1. Among the combinations resulting from that evaluation, the best-performed was the one involving the *minimum* criterion for labeling the messages, the highest upper bound for allowed instances on  $P_{Set}$  and  $N_{Set}$  respectively (300) and taking the normalized sum of the TM output sequence, reaching under F-Score/Acc the measurements (0.9505/0.9370).

Also, we added Gaussian noise to the encoding inputs for decreasing overfitting when training the Siamese as part of the conducted experiments, resulting on improving the loss in the dev-set from 0.11 when the noise is not added to 0.06.

In the training phase of the Linear Ridge regression method we evaluated the impact of the distinct representations on the performance of our model. Looking at Table 2, we noted that each transformer

model	XLNet	RoB	BT	AF	Off
	+	+	+	+	<b>0.55</b>
	+	+	+	-	0.61
Ridge	-	+	+	-	0.65
	+	+	-	+	0.58
	+	-	+	+	0.59
	-	+	+	+	0.62
LSTM	+	+	+	+	<b>0.55</b>
LSTM-Att	+	+	+	+	0.57

Table 2: Feature representation combination through the ensemble

encoder played an important role in characterizing the messages, also the affective features captured important information about the offensive language, which helped in each combination. The LSTM based models also had a good performance when combining all the representations, especially the one with no attention mechanism.

Summarizing, participating in HaHackathon we addressed the humor prediction task with the SiaNet model. For the humor rating subtask we used the Multiview-based Linear Ridge Regression model, fine-tuning the transformer encoders under the humor and offensiveness rating subtasks simultaneously after applying *MLM*. The controversy

humor prediction subtask was addressed through the BERTweet model using *MTL* with all four sub-tasks from HaHackathon. Finally, the offensiveness rating was predicted by the Multiview-based Linear Ridge Regression, but fine-tuning the encoders with *MTL* and combining offensiveness rating sub-task with irony detection.

## 4.1 Error Analysis

In the humor prediction subtask, we found out that more than 40% of prototypes obtained from the humorous class have the structure *question?argumentation* (Q?A, see Table 3). We hypothesize that some tweets were misclassified as humorous due to sharing this structure with positive prototypes. In fact, within the examples labeled by our architecture as funny when they were not, the ones having this structure represented the 38% of this type of misclassification.

Tweet
What do you call an Asian guy that always shows up before he needs to? Earl Lee
Why did the slave go to college? So he could pickup his Master’s degree.
What do you call a 60-year old whose puberty just started? A late boomer.

Table 3: Prototype tweets annotated as humor with the structure of Q?A

For the offensiveness prediction task, the most critical failures (i.e., absolute difference between the real value and the predicted one) were analyzed from two standpoints: first when the model predicts a lower value than the real one as the first two examples in Table 4 or a higher value as in the last two cases. As we can observed how it happened in the most mispredicted examples, the model gives higher offensiveness values to messages containing phrases that characterize social groups usually being a target of hate spreading or bullying on social media. This is possibly caused by the origin of data used for pre-training the transformer encoders, which were in charge of finding an encoding for the tweets.

## 4.2 Official Results

Regarding the official results on the test set, we made submissions in all four sub-tasks. The baseline proposed by the organizers consisted of a Naive Bayes model with bag of words features

Tweet	Value	Predicted
What do you call a <b>homosexual man</b> on a <b>wheel chair</b> ? A human being	0.15	2.5
What do you call it when two female spies fall in love? <b>Lesbianage</b>	0.6	1.89
Wanna hear a <b>joke</b> ? <b>Women’s rights</b> .	3.35	1.79
What belongs to me but is used the most by others? <b>My ex-wife</b>	1.9	0.43

Table 4: Some examples mispredicted by our model

and Support Vector Regression for the classification and regression subtasks respectively.

In subtask 1a we ranked at place 22<sup>nd</sup> among 58 teams, with F-Score/Acc of 0.948/0.9576, whereas the best system reached 0.982/0.9854. In subtask 1b with a RMSE of 0.5905 and among 50 teams we ranked at 30<sup>th</sup> place and the best system had an RMSE of 0.4959. For subtask 1c we obtained the 10<sup>th</sup> position from 36 teams, our F-Score/Acc was 0.4732/0.6197 and the best system obtained 0.4943/0.6302. Finally, in subtask 2 we were the 14<sup>th</sup> team of 48 in total, with a RMSE of 0.4532 with a difference from the best ranked system of 0.0412.

## 5 Conclusions and Future Work

In this work we presented two models for addressing humor and offensiveness prediction in English tweets. Both models employ the deep-representations learned by Transformers methods for encoding the messages. The first model is based on a Siamese Neural Network combined with a graph-based clustering method. The second model combines feature representations learned by three transformers language models with affective features captured by an BiLSTM-based model. These representations are used to train a linear regression model. The achieved results show that the Siamese architecture outperformed the fine-tuned Transformer models for humor detection task. The performance of this architecture relies on how the tweets are represented by the encoder and the strategy to find the Positive and Negative sets of prototypes. In the second model, the affective features play an important role to determine the offensiveness scores with any combination of features learned by the state-of-the-art language models, showing that they successfully captured underlying affective cues present in offensive and funny speech. We plan to investigate two interesting directions as future works. The first direction is an in-depth study of the harmfulness of humor on human stereotypes taking advantage of the over-

lapping between offensiveness and humor in the HaHackathon dataset. The second one is an exhaustive analysis of clustering methods for building prototypes and how they may influence the learning of the Siamese Neural Network for humor prediction.

## Abstract

We describe MeasEval, a SemEval task of extracting counts, measurements, and related context from scientific documents, which is of significant importance to the creation of Knowledge Graphs that distill information from the scientific literature. This is a new task in 2021, for which over 75 submissions from 25 participants were received. We expect the data developed for this task and the findings reported to be valuable to the scientific knowledge extraction, metrology, and automated knowledge base construction communities.

## 1 Introduction

Counts and measurements are an important part of scientific discourse (Rijgersberg et al., 2011). It is relatively easy to find measurements in text (Foppiano et al., 2019a), but a bare measurement like 17mg is not informative without knowing what it is referring to. For example, it is important to know whether a quantity is 17mg of a medicine dosage or 17mg of concrete additive. Only recently have attempts been made to identify the named entity and property being measured (Hundman and Maamann, 2017). Extracting such information is challenging because the way scientists write can be ambiguous and inconsistent. Furthermore, the location of this information relative to the measurement can vary greatly, and might even be in a different sentence.

Being able to extract measurement information automatically can enable the construction of databases of measured properties. Such databases are important in biomedicine (Hao et al., 2016), engineering (Foppiano et al., 2019a), and other scientific disciplines (Bergmann et al., 2017), but the approaches used for populating these databases do not generalize widely. Furthermore, knowledge graphs (Hogan et al., 2021) frequently aggregate quantitative data reported in the literature and are often

built through a largely manual curation process. Examples include: LITTERBASE<sup>1</sup> (Bergmann et al., 2017), which aggregates observations of marine litter distribution; NeuroElectro<sup>2</sup> (Tripathy et al., 2014), which collects information on electrophysiological properties of neurons; and various model organism databases like the Zebrafish Information Network<sup>3</sup> (Sprague, 2006), which provide summaries of gene information.

Beyond knowledge graphs and curated databases, clinical health contexts often require extraction of measured values for lab results and patient observations. Moreover, scientific research frequently relies on precise measurements for reproducibility of experimental methods (Kaiser, 2018). Measured property extraction could be of value in many other contexts, such as fact checking and news validation or in statistical analysis for public policy (Einav and Levin, 2014).

Research in information extraction and knowledge graph creation has concentrated on forming triples by extracting entities and relations (Konstantinova, 2014). Little attention has been paid to the extraction of measured properties, entities, and conditions or contexts, yet these elements are needed to place measurements into a database and for their subsequent use in comparison and calculation. Units and measures are an important part of the semantic web, though research has largely been focused on ontology design (Rijgersberg et al., 2013). There is, thus, a need for understanding the state of the art on this important task.

The aim of this paper is to introduce the MeasEval shared task for the extraction of counts, measurements, and related context from English-language scientific documents, as well as to present an analysis of the results of participant systems on

<sup>1</sup><https://litterbase.awi.de/>

<sup>2</sup><https://neuroelectro.org/>

<sup>3</sup><http://zfin.org/>

the task.

The rest of this paper is organized as follows. We begin with a description of related work. This is followed by the description of the task itself (Section 3) and the associated data and annotation procedure (Section 4). The evaluation regime is detailed in Section 5 including baselines. Subsequently, we present an analysis of the results of the systems on the task. Finally, we summarize the various participating systems approaches and conclude.

## 2 Related Work

There is a substantial body of work discussing units of measurement, ontologies to describe them, systems designed to extract them, as well as related work on knowledge graphs of numerical attributes. Automated extraction of measured quantities, such as 520 +/- 8 items/kg, is straightforward and many tools exist to perform this task (Foppiano et al., 2019b; Deus et al., 2017; Hao et al., 2016). To build a knowledge graph, we must put these measurements in context. We need to determine the properties being measured (e.g. abundances), the entities that exhibit those properties (e.g. the Maowei Sea), and possible qualifying conditions under which measurements are obtained (e.g. the date and depth of the sampling). These properties, entities, and conditions can then be mapped to those that are used in the knowledge graph, so that the measurements can be normalized into a common system.

There are a number of ontologies that cover units of measurement, such as Quantities, Units, Dimensions, and Types Ontologies (QUDT)<sup>4</sup> and the Ontology of Units of Measure and Related Concepts (OM) (Rijgersberg et al., 2013). These and others are discussed in a survey paper by (Steinberg et al., 2017). Most of these ontologies focus on conversion between different systems of measurement, and on classifying types of measurement or domain of application, but do not necessarily address the “thing” being measured. The Joint Committee for Guides in Metrology’s (JCGM) International Vocabulary of Metrology covers this in slightly more depth, discussing measurement units and quantity values, then talking about quantities themselves, which it defines as a “property of a phenomenon, body, or substance” (Joint Committee for Guides in Metrology, 2012). We find that this nomenclature, while precise, is likely to be con-

fusing to non-metrologists from both an evaluation and annotation perspective, so to support the data annotation process for this task we use a simplified nomenclature.

Metrology research in the Semantic Web community is often focused on ontology alignment for Units of Measurement ontologies. Kaladevi et al. (2016) look at aligning unit ontologies to support merging data across many weather information systems, while Do and Pauwels (2013) more generally look at using MathML for aligning unit ontologies. Efforts around designing linked data models for semantic sensor streams for the Internet of Things also utilize the Units of Measurement ontology for representing measurement information (Barnaghi et al., 2013). None of this work addresses extraction of measurements and their contexts nor building knowledge graphs from such information.

Other research explores creating databases of numeric attributes. Kotnis and Garcia-Duran (2019) infer new values using linear regression for neighboring entities in a knowledge graph. Gupta et al. (2015) use a logistic regression with distributional vectors. Davidov and Rappoport (2010) use a system of averages and boundary values to infer an estimated numeric attribute value. Rather than imputing new values from related entities, MeasEval starts from a value and puts it into the context of measured entities and measured properties, working toward a knowledge representation of numeric data.

## 3 Task Description

MeasEval is an entity recognition and semantic relation extraction task focused on finding counts and measurements, attributes of those quantities, and additional information including measured entities, properties, and measurement contexts.

MeasEval is composed of five sub-tasks that cover span extraction, classification, and relation extraction, including cross-sentence relations. Given a paragraph from a scientific text:

- For each paragraph of text, identify all spans containing quantities (e.g. 12 kg). Quantities are treated as strings, and are not converted or normalized.
- For each identified Quantity, identify the Unit of Measurement (e.g. kg), if one exists. For each Quantity classify additional value Modifiers (e.g. count, range, approximate, mean,

<sup>4</sup><http://www.qudt.org/>

etc.) that apply to the Quantity.

- For each identified Quantity, identify the Measured Entity (e.g. bed inventory) it applies to (if one exists) and mark its span. If an associated Measured Property (e.g. concentration) also exists, identify it and mark its span.
- Identify and mark the span of any Qualifier (e.g. after incubation) that is needed to record additional related context to either validate or understand each identified Quantity.
- Identify relationships between Quantity, Measured Entity, Measured Property, and Qualifier spans using the HasQuantity, HasProperty, and Qualifies relation types.

More detailed definitions can be found by reviewing the MeasEval Annotation Guidelines.<sup>5</sup> We describe each of the elements to be extracted in more detail in the next section.

## 4 Annotated Data

### 4.1 Data Model

As shown in Figure 1, the MeasEval annotation model consists of Quantities, MeasuredEntities, MeasuredProperties, and Qualifiers. A Quantity can be either a count or a measurement, with measurements being composed of a Unit and a Value. Values also can have additional attributes such as “isMean”, “isApproximate”, or “isRange”. Quantities can be directly related to a MeasuredEntity, or can be indirectly related to a MeasuredEntity via a MeasuredProperty. Qualifiers provide additional information that is required to interpret the measurement. These include things like the pressure at which a boiling point was observed, or the depth and location where an ocean sample was taken. Since texts may contain different parts of this information, all relationships are optional. A MeasuredEntity can be related to a MeasuredProperty or a Quantity, a MeasuredProperty can be related a Quantity, and a Qualifier can have a relationship to any span.

### 4.2 Corpus and Annotations

Annotations are drawn from 110 CC-BY licensed articles that have been made previously available by Elsevier Labs.<sup>6</sup> These articles were the ba-

<sup>5</sup><https://github.com/harperco/MeasEval/tree/main/annotationGuidelines>

<sup>6</sup><https://github.com/elsevierlabs/OA-STM-Corpus>

Figure 1: Annotation Model. All relationships are optional.

sis of a previous SemEval task for SemEval 2017 (Augenstein et al., 2017). These 110 articles are distributed evenly across 10 subject areas.

From these 110 articles, the MeasEval dataset includes 428 paragraphs containing 1663 Quantities. These are split into a training data set of 1164 Quantities (313 paragraphs) and an evaluation set of 499 Quantities (135 paragraphs).

All paragraphs were annotated by at least two annotators, then reviewed and reconciled during an adjudication meeting, often including a third annotator. The MeasEval data release included training data, as well as original annotations from multiple annotators for a 248 Quantity subset of the training data. This was to provide deep information on inter-annotator agreement, and also to allow participants to do their own analysis on how their algorithms perform relative to humans.

The inter-annotator agreement (IAA) shows some variation in interpretation when humans are performing this task. The review process serves to resolve much of the disagreement and to ensure that the data is as consistent as possible given the challenging nature of the task. For this subset of data in this IAA set, Table 1 shows Krippendorff’s Alpha values for each class.

Annotation Class	Krippendorff’s Alpha
Quantity	0.943
MeasuredProperty	0.641
MeasuredEntity	0.546
Qualifier	0.334
Unit	0.866

Table 1: Krippendorff’s Alpha scores for subset of data included in Inter-Annotator Agreement dataset.

### 4.3 Data Formats

To increase the usability of the data, multiple formats are provided. The MeasEval data includes a

Figure 2: BRAT Example of a Quantity with related annotations.

text file and a set of annotations for each paragraph of scientific text. Annotations are provided in a tab-separated value (.tsv) file format, and in the BRAT annotation format. The BRAT format is for the purpose of visualization and review, but the official data format for the task is the .tsv, which is used for submissions and evaluation. For .tsv and .txt files, there is one file per paragraph of annotated text, and the .tsv file contains all annotations. For the BRAT files, there are one .ann and one .txt file per annotated Quantity.

For example, given the BRAT annotations illustrated in Figure 2, the data will have a raw text file (S0016236113008041-3153.txt), a BRAT annotation file *per Quantity* (S0016236113008041-3153-1.ann, and S0016236113008041-3153-2.ann), and a tab-separated file containing all annotations from each Quantity (S0016236113008041-3153.tsv).

More detail on each of these formats, including examples, as well as all MeasEval training and evaluation data, inter-annotator agreement annotations, and annotation guidelines can be found on the MeasEval Github repository.<sup>7</sup>

## 5 Evaluation

Evaluation is scored by providing a single SQuAD-style (Rajpurkar et al., 2016) F1 (Overlap) score for each submission, averaged across all nine components of the five subtasks. The 9 components are the Quantity, MeasuredProperty, MeasuredEntity, and Qualifier spans; the Modifier and Unit extensions to Quantity, and the HasQuantity, HasProperty, and Qualifies relationships. The evaluation script also provides a number of other metrics, described below.

In order to effectively evaluate all 9 components of the sub-tasks, it is necessary to first pin all Quantities in a submission to the corresponding Quantities in the gold data. As an example, consider the sentence “The dog weighed 25 pounds, while the average weight of the cats was 9 lbs.” We want to avoid crediting correct MeasuredEntities if asso-

ciated with the wrong Quantity. For example, if a submission listed “dog” as the MeasuredEntity associated with the average weight of 9 lbs, this would be incorrect.

The first pass matches each submission “annot-Set” ID to a corresponding Gold Set annotationId, and propagates this matched identifier across all of the data.

From there, the script calculates Precision, Recall, F-measure, and an Exact Match and SQuAD-style F1 (overlap) score. Exact Match and F1 are averaged across the entire submission. Exact Match is a binary value of 0 or 1, while F1 is a token level overlap ratio of submission to gold spans, where tokenization is done using simple white space delimiters. For components that do not include a span, Exact Match and F1 scores are the same. Relations are also scored with a binary Exact Match and F1 score if the relation types match and both endpoints match either exactly or with some overlap.

Any span, unit, modifier, or relationship found in the gold data, but not the submission, or found in the submission, but not the gold data is included as a “penalty row” with a score of 0 in order to sufficiently penalize both false positives and false negatives when averaging scores. This calculation leads to very fine-grained differences in the distribution of scores in the results tables.

Although not used for calculating leaderboard rankings, the evaluation code can also provide all the same scores micro-averaged by scoring component, by subject area, or by paragraph for further analysis of error. Additional documentation as well as the evaluation code itself can be found on the MeasEval GitHub repository.<sup>8</sup>

### 5.1 Baseline Models

MeasEval also includes two very similar baseline models. Baseline 1 is the best-performing of these, and scores an overall F1 (Overlap) of 0.239 in the evaluation as reported in Tables 2 and 3. Base-

line 1 use spaCy Named Entity Recognition (NER) models for each of the four classes independently. Unfortunately, some training examples need to be thrown away because spaCy’s NER functionality does not support overlapping spans in the same model. Since there is frequently an overlap between MeasEval spans of different types, this necessitates training each annotation type separately, and stripping out edge cases where multiple annotations of the same type intersect.

Baseline 1 generates a deduplicated list of all units in the training data, and checks each Quantity against this list. If there are one or more matches in this comparison, the system returns the “longest last matching” unit, ensuring that cm would be preferred to m in “22 cm” and that s would be preferred to m in “approximately 22 s”. The baseline does not attempt the Modifier component, though could be augmented with a set of regular expressions that search the Quantity string for key phrases and symbols, including “approximately”, “between”, “>”, and “~”.

Once the NER models and unit matching are completed, baseline 1 matches Quantities to MeasuredEntities, MeasuredProperties, and Qualifiers using a knockout match algorithm based on proximity. So each MeasuredProperty matches the nearest Quantity, each MeasuredEntity matches the nearest MeasuredProperty or Quantity, and each Qualifier

matches the nearest span of any type. Baseline 2 is a variant that does much simpler matching, taking each span in the order they appear in the data. Baseline 2 does not appear in the results tables, but scores an overall F1 (Overlap) of 0.223. The code for both baselines is available in a Jupyter notebook on the MeasEval Github repository.<sup>9</sup>

## 6 Results and Discussion

During the 21-day evaluation period (January 10 through 31, 2021), 26 CodaLab users submitted a total of 89 submissions, of which 77 passed validation and were successfully scored by the evaluation script. Given the complexity of the task, we opted to allow for five submissions total during the evaluation, although some collaboration between users meant that some teams were able to effectively submit more than five times. We note that submissions did not calculate scores on sub-tasks, thus making it difficult to overly optimize models using just the overall score. The relatively generous submission allowance does not seem to have presented too much of an over-fitting problem, as scores remain relatively low on all tasks, although the collaboration could have given some participants a slight advantage in the rankings.

Table 2 shows the top submission from each of

<sup>9</sup><https://github.com/harperco/MeasEval/blob/main/baselines/first-baseline.ipynb>

the 19 teams that submitted successfully, as well as the top performing baseline. 10 of the 19 exceed the benchmark of the baseline spaCy model. In addition to the overall F1 scores, Table 2 shows micro-averaged F1 across the four annotation spans as well as Units and Modifiers. Table 3 provides this same breakdown for each of the three relationship types. Team names marked with an asterisk (\*) represent teams which have either submitted system description papers or responded to a request for system information.

The overall top-performing model was at least tied for top performance in five out of 6 of the component scores in Table 2, but interestingly, the second best and third best performing models varied across scoring component. Models that did particularly well at Quantities, Units, or Modifiers, may have had their overall performance reduced by lower performance at the MeasuredEntity and MeasuredProperty spans.

Table 3 shows the scores for the Relation Extraction subtasks: HasQuantity, HasProperty, and Qualifies. These largely align with the annotation span components of the scoring which they are dependent on. In both Table 2 and Table 3 it is worth noting that only 7 teams attempted extraction of Qualifiers and the Qualifies relation, as these were the most difficult aspects of the task.

Top, second, and third place scores per category represented by **bold**, underline, and *italics* respectively.

Figure 3: Visualization of average scores for each scoring component across top score for all participants.

Figure 3 provides a visualization of the distribution of scores for each scoring component from Tables 2 and 3. From this, it is clear that Quantity and Unit are the easiest aspects of the shared task, which makes intuitive sense. The relatively high scores for Modifier is also of interest, as these are the components of the extraction that capture uncertainty and variance in value, which is an important part of the task and not one that we expected to see handled as well as it was. This clearly demonstrates that the various Quantity contextualization subtasks are far more difficult and more work is needed in how best to handle the extraction of related MeasuredEntities, MeasuredProperties, and Qualifiers.

Figure 4 provides a visualization of the distribution of scores for 9 of the 10 subject areas in the corpus. The mathematics subject area has been omitted from this graphic due to under-representation in both the training and evaluation datasets.

## 6.1 Impact of Duplicates

As noted previously, the MeasEval evaluation algorithm was designed toward lenience, and as a result sometimes inflates scores if multiple submission annotations match a single entry in the gold data. This was done to allow submissions to get credit for submitting multiple Quantity annotations that partially matched a single gold data span as well as to generally not penalize systems that might make multiple predictions pinned to the same numeric

Figure 4: Visualization of average scores for each subject area across top score for all participants.

value.

However, allowing duplicates can in some cases result in inflated scores. This is especially evident in cases where submissions contained entries that duplicated entire annotations sets. For a small number of submissions that exhibited annotation set level duplicates, a post-processing routine removed all set level duplicates before final evaluation, resulting in the scores in Table 2 and Table 3.

Additionally, Quantity-level duplicates can also potentially inflate Quantity scores, but should have a neutral impact on other components of scoring. For example, if a system identified the same Quantity two times, but found a different MeasuredEntity for each occurrence, the submission will score extra points associated with the Quantity, and potentially the Unit and Modifiers if those are also correct, but will only get points for the correct MeasuredEntity while being penalized for the incorrect MeasuredEntity. An ablation analysis was performed for the eight submissions covered by system papers, assessing the impact of these duplicates on the Overall F1 (Overlap) metric.

Table 4 gives the extent of duplication for these submissions, the initial overall score from Table 3, the overall score with exact quantity duplicates removed, and the overall score with both exact and overlapping duplicates removed. For example, if the gold data includes the Quantity “approximately 23 mm”, and a submissions included annotation sets with both “23 mm” and “approximately 23 mm”, the exact match duplicate removal would not

drop either score, whereas the overlapping match score would drop whichever occurred last in the submission, whether or not it is the correct answer.

Team Name	F1	Count Exact / Overlap	F1 w/out Exact	F1 w/out Any Duplicates
LIORI	0.519	125 / 32	0.499	0.487
jarvis@tencent	0.473	0 / 11	0.473	0.470
Counts@IITK	0.432	0 / 0	0.432	0.432
CLaC-BP	0.389	0 / 0	0.389	0.389
UPB	0.369	0 / 1	0.369	0.369
KGP	0.278	0 / 0	0.278	0.278
Stanford MLab	0.272	0 / 0	0.272	0.272
CLaC-np	0.241	55 / 0	0.231	0.231

Table 4: Ablation analysis of duplicates and Overall F1 (Overlap) score for each of the eight Teams with System Papers.

The general downward trajectory seen while removing duplicates that are not at the set level is informative. Partly this is due to declining Quantity score from duplicate removal, but some effect is attributable to the possibility that deduplication deletes a correct MeasuredProperty or MeasuredEntity and leaves an incorrect one, given that they may include different values. The ablation analysis simply removes all but the first occurrence, so there is no control over whether removed values are a closer match to the gold data.

## 6.2 Multiple Hypotheses Hypothesis

The results of de-duplication analysis, the relatively low inter-annotator agreement scores, and deeper consideration of the annotation guidelines present an interesting hypothesis. It could be that the different interpretations of the context of a measurement are not automatically right or wrong. It could be that different interpretations are useful in different downstream applications. While it is out of scope in for this task description, future work may look more closely at categorization of the areas where annotators disagreed and systems produced multiple interpretations, to see if there is alignment in the differences and whether there are patterns to the variance.

## 7 Summary of Participating Systems

The MeasEval track at SemEval-2021 received nine system description paper submissions, eight of which are represented in the analysis in Table 4. A ninth paper formulated a new task from the MeasEval dataset focusing on just the relation extraction

part of the problem. One system only attempted the Quantity, Unit, and Modifier parts of the task, while another did not submit any Qualifier spans or Qualifies relationships. Four of the nine systems have released code or models.

There are several points of similarity between the eight main submissions. All but one of the systems are based on the BERT architecture (Devlin et al., 2018) or a derivative, such as SciBERT (Beltagy et al., 2019), BioBERT (Lee et al., 2019), or RoBERTa (Liu et al., 2019). All but one used a pipeline architecture, starting with Quantity extraction. All but one used sequence tagging with a BIO encoding scheme, and four followed the sequence tagger by a Conditional Random Fields (CRF) model to assemble tokens into spans and improve accuracy over simple token-level classifiers. Unit and Modifier extraction was either done using a character-level BiLSTMs, another BERT model, or a rule-based approach. Finally, it was common to see MeasuredEntity, MeasuredProperty, and Qualifier, and sometimes the relation extraction components, stacked together in a multi-task sequence tagging model as a final stage, taking both the original sentences and Quantity spans as input. One system diverged from the sequence tagging approach and used templated question answering techniques to handle the relation extraction along with related spans. Table 5 provides a high-level summary of frequency of architectures and techniques in use by more than one system.

Technique / Model	Submission Count
BERT	3
BioBERT	1
SciBERT	3
RoBERTa	1
CRF	4
BiLSTM Units / Mods	3
Rule-based Units / Mods	3
Dict-based Units / Mods	2
Question Answering	1
Sequence Tagging	7

Table 5: Summary of techniques and architectures used in MeasEval System Description Submissions.

## 7.1 System Specifics

Davletov et al. (2021) (LIORI), achieve their state-of-the-art performance using pre-trained models RoBERTa (Liu et al., 2019) and LUKE (Yamada et al., 2020). They use LUKE to fine-tune an NER model for Quantity extraction, and a RoBERTa-based multi-task model for all other spans. Mod-

ifiers are predicted as Quantity-types. All other spans, including units, are extracted using Question Answering style sequence tagging (start/end logits) without question prompts for each annotation type queried for each extracted Quantity.

This sequential ensemble approach of Quantity-detection followed by either “all-in-one-multi-task” extraction or a staged approach to one or more of the other subtasks proved very common among the top-performing systems.

Cao et al. (2021) (jarvis@tencent), do initial Quantity extraction with an ensemble of a Pointer Net (Vinyals et al., 2015) and a CRF. They use a BERT-based classifier for Modifier tagging and a rule-based system for Units, and then use relation-specific taggers with the same architecture as the Quantity-tagger for all other task components.

Gangwar et al. (2021) (Counts@IITK) similarly tag Quantities with a SciBERT sequence tagger and a CRF model and SciBERT for Modifiers, but use a Character based bidirectional LSTM for Unit tagging. They then encode the Quantity into SciBERT input when tagging MeasuredEntity and HasQuantity, and iteratively mark new spans in the input when tagging then next sub-task, using a rule-base for assembling the necessary relationships. Their performance on Quantity, Unit, and Modifier was near the top performing, but they struggled with MeasuredProperty and HasProperty.

Therien et al. (2021) (CLaC-BP) use SciBERT in a token-level multi-class classifier across all span classes. This is an interesting approach, given the opportunity for joint inference between the various types of spans. However, it penalizes them in that each token in their model can only be one class, while there are cases when a Quantity and MeasuredEntity from one set may be part of, e.g. a Qualifier in another. Quantity spans are then fed to another SciBERT model for Modifier typing, and rule-based systems are used for Units and for the Relations between spans.

Avram et al. (2021) (UPB) use RoBERTa along with a CRF for Quantity extraction. They also tested SciBERT and BERT. They achieved their best results on their dev subset with SciBERT, but their best results on evaluation set came from RoBERTa. They use a BiLSTM to extract Units and classifier Modifiers, and then use a templated Question Answering system as a joint entity and relation extraction system for the remaining subtasks. Unlike LIORI, who did not use prefixes or

suffixes in their question templates, UPB asks more natural language questions of the form “What is the measured property of the quantity \_\_\_?”

[Karia et al. \(2021\)](#) (KGP) also use BioBERT after testing various BERT-based pre-trained models, but depart from many of the other submissions by using a binary classifier rather than BIO tags and CRF layers for Quantity sequence tagging. Modifiers and Units are handled using keywords and dictionary matching, while they use a multi-task BERT model for the remaining components, first finding MeasuredEntity based on the Quantity predictions, then fusing these results for the remaining spans and relations. They also continued refining their approach into the post-evaluation phase, and reported improving their score from an Overall F1 (Overlap) of 0.278 to 0.456.

[Liu et al. \(2021\)](#) (Stanford MLab) only tackle the Quantity, Unit, and Modifier subtasks. Notably, they report building their system for these components from inception to submission in under 48 hours. They use BERT-large for IOB sequence tagging for Quantities, use a similar IO sequence tagging scheme on Quantities to tag Units, and a multi-class classifier to classify Quantities to the appropriate Modifiers. Their system performs well on all subtasks they attempted, even scoring second place overall for Units.

[Lathiff et al. \(2021\)](#) (CLaC-np) diverge from other submissions in their approach. They preprocess their text using GATE and ANNIE, and use custom rules to further clean up tokenization. They treated Stanford Core Dependency Parse trees as graphs to extract subgraphs starting each path query from the CD tokens to identify MeasureEntities, MeasuredProperties and Qualifiers with the use of Graph CNN. They relied on the models from CLaC-BP to map from their tokens to annotation spans for each type in assembling their final submission.

Finally, not shown in Table 1 is [Veyseh et al. \(2021\)](#). They formulated their own task based on the MeasEval data. Although they did not submit a solution during the evaluation period, they have submitted a system description paper describing a novel approach to relation extraction, which they have evaluated on MeasEval sub-task 5. Using our Gold Quantity, MeasuredEntity, MeasuredProperty, and Qualifier spans as input (without annotation sets), they compared their approach to two other baseline models. They encode contextual embeddings, positional embeddings, and entity types

for each annotation span, and perform dependency path reasoning along with an “Information Bottleneck” regularization technique to complete their Relation Extraction task.

## 8 Conclusion

In this paper, we present the design, the data, the evaluation the process, the results, and the systems for MeasEval at SemEval 2021. The shared task is challenging, partly due to the relatively small training data, and partly due to the inter-relationships between many different components of the task. Quantity and Unit identification, and to a lesser extent Modifier typing, appear to be the simplest parts of the task based on average performance, with one participating system building their end-to-end pipeline for these components in under 48 hours. The contextual elements MeasuredEntity, MeasuredProperty, and Qualifier, and their relationships, are far more difficult, which is not surprising given that these are subject to more human annotator disagreement. The challenge of context is especially pronounced in the Qualifier span and Qualifies relationship.

Common components shown in Table 5 include the BERT family of pre-trained neural language models, CRF models, BiLSTMs, and rule-based components. In general, the task does not appear to require whole new novel models and architectures, but rather pipelines and cascading ensembles stitching together various existing methods. There is still room for improvement on this task, and whether progress will come from novel models or creative applications of existing techniques remains to be seen. Work also remains to be done in applying the entities and relationships extracted for this task to the larger end goal of scientific knowledge graph construction and related downstream applications. Future work could be done to further analyze areas of error and disagreement in these annotations, and to investigate entity linking across Quantity, MeasuredEntity, and MeasuredProperty annotation spans to various measurement ontologies and to domain-specific entity and property ontologies.

## Abstract

Understanding tables is an important and relevant task that involves understanding table structure as well as being able to compare and contrast information within cells. In this paper, we address this challenge by presenting a new dataset and tasks that addresses this goal in a shared task in SemEval 2020 Task 9: Fact Verification and Evidence Finding for Tabular Data in Scientific Documents (SEM-TAB-FACTS). Our dataset contains 981 manually-generated tables and an auto-generated dataset of 1980 tables providing over 180K statement and over 16M evidence annotations. SEM-TAB-FACTS featured two sub-tasks. In sub-task A, the goal was to determine if a statement is supported, refuted or unknown in relation to a table. In sub-task B, the focus was on identifying the specific cells of a table that provide evidence for the statement. 69 teams signed up to participate in the task with 19 successful submissions to subtask A and 12 successful submissions to subtask B. We present our results and main findings from the competition.

## 1 Introduction

Tables are ubiquitous in documents and presentations for conveying important information in a concise manner. This is true in many domains, stretching from scientific to government documents. In fact, surrounding text in these articles are often statements summarizing or highlighting some information derived from the primary source of data in tables. A relevant example is shown in Figure 1 from a Business Insider article analyzing the impact of Covid-19 (Aylin Woodward and Gal, 2020). Describing all the information provided in this table in a readable manner would be lengthy and considerably more difficult to understand. Despite their importance, popular question answering (e.g. SQuAD and Natural Question (Rajpurkar et al.,

BUSINESS INSIDER

Figure 1: Surrounding text often highlights some information from the table but does not capture all data. Alternately, the linked text may be subjective or even misleading without the original table to check the claims.

2016; Kwiatkowski et al., 2019)) and truth verification tasks (e.g. SemEval-2019 Fact Checking Task (Mihaylova et al., 2019)) have not focused on tables, being composed solely of written text. This is likely due to their complexity to parse and understand, despite their rich amount of information.

Further, the structure of tables allows much more information to be presented in an efficient manner as humans can interpret meaning in the spatial relationship between cells. However, due to their challenging nature, recent algorithms have been less successful at extracting (Hoffswell and Liu, 2019) and understanding header and data structure in tables (Cafarella et al., 2018). In addition, any hierarchical and nested headers (common in printed documents) increases the difficulty in interpreting data cells, as shown in Figure 2.

In this paper, we propose to bridge this gap with statement verification and evidence finding using tables from scientific articles. This important task promotes proper interpretation of the surrounding article. In fact, the misunderstanding of tables can lead to the reporting of fake news that we see as being all too prevalent today.

	n (% initiated smoking)	Unadjusted

Figure 2: A complex table sourced from (East et al., 2018) with hierarchical column and row structure. Additional difficulty follows from row hierarchy not being delineated by separate columns.

We present the first SemEval challenge to address table understanding. We introduce a brand new dataset of 1980 tables from scientific articles that addresses two challenging tasks important to table understanding:

**A: Statement Fact Verification** Given a statement, determine whether it is *supported*, *refuted* or *unknown* according to the table.

**B: Cell Evidence Selection** Given a statement, select the cells in the table that provide evidence supporting or refuting the statement.

The rest of this paper is formatted as follows: We first discuss related work. We then present a new large table understanding dataset containing close to 2000 tables that is the first to provide evidence labels at the cell level for statements and the first to focus on scientific articles. We provide a detailed analysis of the dataset including several baseline results. We then discuss the performance and approaches of the 19 participants in our challenge and end with an aggregated analysis of participating teams. Finally, we discuss future work.

## 2 Related Work

**Natural Language Inference (NLI)** The table evidence task can be best understood as a variation of the natural language inference task (Dagan et al., 2005), but on tabular data. NLI asks whether one (or more) sentence entails, refutes, or is unrelated to another sentence; our framing asks whether a given table entails, refutes, or is unrelated to a sentence. Several datasets have been created for studying NLI, such as SNLI (Bowman et al., 2015), MultiNLI (Williams et al., 2018), and SciTail (Khot et al., 2018).

**Table QA** This task is also closely related to the problem of search and question answering on ta-

bles. The closest example would be, given a table that is known to contain the relevant information, return cell values that answer a natural language question (Pasupat and Liang, 2015). A variation requires analyzing a collection of tables rather than a single one, along with the natural language question (Sun et al., 2016). Two of the most recent works are TAPAS (Herzig et al., 2020) and TaBERT (Yin et al., 2020), which jointly pre-train over textual and tabular data to facilitate table QA. However, such approaches have previously focused on traditional natural language questions (“What is the population of France?”) rather than inference statements (“France has the highest population in Europe”), which may be entailed, refuted or unknowable from the given table.

**Related Datasets** The works closest to our dataset are TabFact (Wenhu Chen and Wang, 2020) and INFOTABS (Gupta et al., 2020). Both datasets were sourced from Wikipedia tables and contain hypothesis and premise pairs. TabFact has entailment and refute hypothesis types while INFOTABS has an additional “neutral” hypothesis category, much like our “unknown” statements. Both works show that neural models still lag far behind human performance for the fact checking task with tables.

While both datasets have been great at kindling interest in fact verification with tabular data, our dataset differs in two key aspects. First, we source from scientific articles in a variety of domains rather than Wikipedia infoboxes. Scientific tables have very specialized vocabulary and can be more difficult to interpret. Additionally, scientific tables have much more complex structure, like hierarchical column and row headers, rendering the assumption that the first column/row is the header unhelpful. Finally, tables are often directly referenced in scientific text unlike Wikipedia tables that are generally stand-alone. This creates an opportunity to leverage natural statements that depict the original author’s style and intent. The second key differentiator of SEM-TAB-FACTS is the accompanying evidence annotations. We believe the future of fact verification and AI in general will be in cooperation with humans rather than in replacement. Thus, it is essential that models are able to present explanations for decisions on the relationship between the statement and table by showing the most relevant cells in a potentially very large table.

Table 1: Statistics for our SEM-TAB-FACTS dataset.

### 3 Dataset Details

Our dataset consists of two forms of generation: (1) a crowdsourced dataset, and (2) an auto-generated dataset. Table 1 presents the statistics of the dataset. We detail our dataset creation process in the following sections.

#### 3.1 Data extraction and preprocessing

We sourced our tables from scientific articles belonging to active journals that are currently being published by Elsevier and are available on ScienceDirect<sup>1</sup>. We utilized Elsevier ScienceDirect APIs<sup>2</sup> to scrape scientific articles which belong to this list, and satisfy the following criteria: (1) the article is open-access<sup>3</sup>, (2) the article is available under “Creative Commons Attribution 4.0 (CC-BY)” user license<sup>4</sup>, and (3) the article has at least one table. We downloaded 1,920 articles belonging to 722 journals which contained 6,773 tables. We further filtered out complicated tables (e.g. multiple tables in a single table) using hand-written rules to get a set of 2,762 candidate tables from 1,085 articles for annotation. We also extracted sentences mentioning the table within the scientific article as candidate statements, which are corrected and then labeled manually by the annotators.

#### 3.2 Crowdsourced labeling

The manually generated statements were collected using the crowdsourcing platform Appen<sup>5</sup>. We collected five entailed and five refuted statements for each table from the business preferred operators (BPO) on Appen. The BPO crowd is composed of employees hired by Appen on an hourly basis at a constant pay rate determined by Appen. We found

that the workers were much more motivated for the task as they were able to ask questions if needed and we were also able to provide direct feedback to the workers. We initially attempted generating statements with workers from the Appen open-crowd, which is on-demand, but the quality was very poor as it was hard to automatically validate naturally generated statements. Our instructions explicitly lay out 7 types of statements and ask that workers attempt to make one of each type. We encourage the use of different sets of cells whenever possible. The types of statements are aggregation, superlative, count, comparative, unique, all and usage of caption or common sense knowledge. These are derived from the INFOTABS analysis (Gupta et al., 2020). We asked workers to avoid subjective adjectives like “best”, “worst”, “seldom” and look-up statements that only require reasoning with one cell. The pay for each statement set was 75 cents. In total, we collected 10000 statements for 1000 unique tables. See Figure 3 for an example table with its manually generated and natural statements.

Additionally, for our training data, we conducted a verification task to check for grammatical issues and doubly verify the statement label for both the generated and natural in-text statements. The verification task was paid at 3 cents per statement, which equates to 30 cents per table. We restricted the verification task to the workers in the open-crowd from English speaking countries. After verification, we only preserved the statements that were verified to be grammatically correct and the new label matched the original label. Natural statements were also verified in the same process. Although natural statements were generally factually correct, they were sometimes not able to be verified by the referenced table. Additionally, these statements often required rewording to ensure that all parts of the statement can be verified by the table, which was a step taken only for the development and test sets. This left us with 981 tables and 4506 statements. The majority of the removals were due to

Table 2

Data are for 1290 firms across nine East Asian economies. All network data are assembled by the authors, and are cross-sectional for 2008. Table reports country-level statistics on board networks, family networks, state networks, and political networks. Minimum values are everywhere 0. board network counts the amount of board/executive interlocks. Political network counts the amount of board/executive interlocks with politically-connected firms. Family network counts the amount of board/executive interlocks with family-controlled firms. State network counts the amount of board/executive interlocks with state-owned firms.

Country	N	Board network			Family network			State network			Political network

### Original Generated Statements

#### Entailed

- There are 9 different types country in the given table.
- The n value is same for Hong Kong and South Korea.
- There are 4 different types of Networks which contains its own mean, SD and max.
- The least max value is 0 in Political network of Taiwan.
- All the values of SD in Board network is greater than the values of SD in Family network.

#### Refuted

- All the values of SD in Board network is less than the values of SD in Family network.
- There are 4 different types of Networks which contains same mean, SD and max.
- The least max value is 0 in Political network of Thailand.
- There are 7 different types country in the given table.
- The n value is same for Hong Kong and Malaysia.

### Original Related Natural In-text Statements

- Descriptive statistics for each board network type are offered in Table 2, broken down by country.
- For each network interaction, there is considerable variation both across and within countries.

Figure 3: Sample crowd-sourced statements for one table (sourced from (Carney et al., 2020)). Please note that these are the original statements without any further corrections nor rephrasing.

grammatical errors as most BPO workers are not native English speakers. See Table 1 (first row) for detailed statistics of the crowd-sourced training set.

We initially attempted to collect the development and test sets as well as evidence annotations via the same method as the training set. However, we found that the quality was not gold-level and thus we (three of the authors) decided to manually correct the statements and annotate the evidence ourselves. All authors first annotated a small set of 102 statements to test inter-annotator agreement for statement relationship and evidence labeling. Out of 102 statements, we found 5 statements where at least one of three annotators disagreed on the relationship and a further 5 statements where the relationship was agreed but the evidence annotation differed. The other 92 were in complete agreement, indicating high agreement. Therefore, the annotations for the rest of the dev set were annotated by just one person. The test set was annotated fully by one author and the two other authors checked the annotations with all disagreements being resolved. See Figure 4 for a screenshot of the statement annotation correction and evidence annotation interface. See the third and fourth rows of Table 1 for detailed statistics of the dev and test sets.

### 3.3 Automatically generated statements

IBM Watson™ Discovery<sup>6</sup> is an AI-powered search and text analytics engine for extracting answers from complex business documents. One of the available functionalities is a Table Understanding service that produces a detailed enrichment of table data within an html document. We use this service to identify the body and header cells, as well as the *cell relationships*, within our dataset. We then proceed to use a set of templates to automatically create statements about each table. We begin by identifying which cells and columns are numeric and non-numeric using a simple regex. Unlike non-numeric cells, numeric cells and columns are appropriate for specific templates that expect numeric values, such as ‘Value [V] is the maximum of Column [C]’, where every value in column [C] has been identified as numeric. We also generate evidence for some of these templates. The template and evidence generation rules along with their inputs are detailed in Table 2. This process generated 3,512,978 statements from 1,980 tables which were highly skewed in favor of refuted statements. This dataset was then down-sampled to a maximum of 50 statements per table while ensuring a more even distribution between the two classes to form our final released auto-generated dataset. The

Statement: Los Aguanaces 3 other localities has same storage.

Select the cells in the table that support the relationship that you have determined for the above statement. Leave blank if you selected ambiguous or unrelated.

- There are 2+ different, conflicting sets of cells that relate to the statement

Can this table be used for evidence task B? (required)

- Yes
- No
- Need to discuss

Discussion:

Figure 4: Screenshot showing the labeling interface for statement rephrasing, relationship labeling and evidence annotation.

full statistics for the auto-generated training data is shown in the second row of Table 1.

## 4 Evaluation Metrics

### 4.1 Task A: Statement Fact Verification

The goal of task A is to determine if a statement is entailed or refuted by the given table, or whether, as is in some cases, this cannot be determined from the table. We show two evaluation results. The first is a standard 3-way Precision / Recall / F1 micro evaluation of a multi-class classification that evaluates whether each table was classified correctly as Entailed / Refuted / Unknown. This tests whether the classification algorithm understands cases where there is insufficient information to make a determination. The second, simpler evaluation, uses the same P/R/F1 metric but is a 2-way classification that removes statements with the “unknown” ground truth label from the evaluation. The 2-way metric still penalizes misclassifying refuted/ entailed statement as unknown.

### 4.2 Task B: Cell Evidence Selection

In Task B, the goal is to determine for each cell and each statement, if the cell is within the minimum set of cells needed to provide evidence for the statement (“relevant”) or not (“irrelevant”). In

other words, if the table were shown with all other cells blurred out, would this be enough for a human to reasonably determine that the table entails or refutes the statement? The evaluation calculates the recall and precision for each cell, with “relevant” cells as the positive category. For some statements, there may be multiple minimal sets of cells that can be used to determine statement entailment or refusal. In such cases, our dataset contains all of these versions. We compare the prediction to each ground truth version and count the highest score.

## 5 Experiments

We present our baseline experimental setup for each task below.

**Task A** We employ state-of-the-art Table-BERT implementation<sup>7</sup> as proposed by [Wenhu Chen and Wang \(2020\)](#). We utilize Table-BERT’s best performing configuration (Table-BERT-Horizontal-T+F-Template) as (1) using entity-linking to find the relevant columns for a statement, (2) flattening the table by scanning horizontally to form natural statements from the relevant columns and their cell values and (3) classifying the flattened table and the statement using the sentence pair classification

<sup>7</sup><https://github.com/wenhuchen/Table-Fact-Checking>

Input	Template	Evidence	Example Statements
col <sub>i</sub> , col <sub>j</sub>	'The' + col <sub>i</sub> _head + 'is' + col <sub>i</sub> _val + ', when the' + col <sub>j</sub> _head + 'is' + col <sub>j</sub> _val	col <sub>i</sub> _head, col <sub>j</sub> _head, col <sub>i</sub> _val, col <sub>j</sub> _val	The Code is AG3 when the Locality is Los Aguanances3.
col	col_val + 'is in' + col_head	col_val, col_head for en- tailed; col for refuted	AG3 is in Code.
col	unique or same values	col for entailed; None for refuted	Sup./Inf. has the same values.
col[#]	'The maximum of' + col_head + 'is'+val	col[#] for entailed; None for refuted	The maximum of Length(mm) is 2.22.
col[#]	'The minimum of' + col_head + 'is'+val	col[#] for entailed; None for refuted	The minimum of Length(mm) is 1.54.
col[#]	'The mean of' + col_head + 'is' + val	col[#]	The mean of Length(mm) is 1.83.
col[#]	'The median of' + col_head + 'is' + val	col[#]	The median of Length(mm) is 1.73.
col[#]	'The mode of' + col_head + 'is' + val	col[#]	The mode of Length(mm) is 1.54, 1.73, 2.22.

Table 2: Template and evidence rules used for auto-generated ground truth. The examples are derived from Table 4 in Figure 4.

setting in BERT. To overcome the lack of unknown statements in our dataset, we supplement each table with randomly chosen statements from other tables. In Table-BERT, if the entity linking results in no matches, the flattened table is marked as [UNK]. As our dataset contains unknown statements, in such cases we consider all columns to be a match and flatten the entire table.

Using the above process, we perform the following experiments (1) apply the Table-BERT model out-of-the-box (2) re-train Table-BERT model with unknown statement and apply on our test data (3) fine-tune the model in (2) with our manual+auto-generated data and apply on our test data. We also compare these experiments with a majority baseline with entailed as our majority class. The results are presented in Table 3. Applying Table-BERT model out-of-the-box provides some improvement over a majority-baseline. However, when the model is retrained with previously missing unknown statements, the performance improves for three-way classification. Further fine-tuning the model with our training dataset (both manual and auto-generated) provides the best performance on the two-way F1-score.

**Task B** We present the following two baselines for Task B: (1) a random baseline where each cell is marked relevant or irrelevant randomly (2) a simple word-match-based baseline where a cell is marked relevant if it overlaps with the statement. The baseline results are presented in Table 4.

Experiment	Test	
	2-way	3-way
majority-baseline	52.42	42.16
original Table-BERT	56.77	45.58
re-trained Table-BERT	52.96	48.33
+ FT with SEM-TAB-FACTS	56.81	48.24

Table 3: Task A baseline results using F1-score.

Experiment	Dev	Test
random-baseline	21.18	20.47
word-match	49.53	47.39

Table 4: Task B baseline results using F1-Score

## 6 Competition Results

We present two leaderboards for each task<sup>8</sup>. The official leaderboard is from participants who have given us detailed descriptions on their system and affirmed that they did not incorporate any information from the test set that changed their final model. This is a more accurate representation of system quality. The unverified leaderboard is composed of participants who either did not give enough detail or have affirmed that they incorporated some test data information in their final model. The participants did not have access to labels for test data but some teams altered their models upon examining

<sup>8</sup>We made the assumption that teams would not make any use of the test data, as is usually the case for algorithm evaluation, but we did not make this explicit ahead of time and some teams did not realize this was an issue. We decided to have two leaderboards to have a fair comparison for all teams.

Team	3-way F-Score	2-way F-Score
<b>Official Leaderboard</b>		
King001	<b>84.48</b>	<b>88.74</b>
THiFly_Queen	83.76	84.55
RyanStark	81.51	87.22
sattiy	77.32	84.96
BreakingBERT@IITK	69.31	76.81
Volta	67.34	72.89
TAPAS	66.81	73.13
AttesTable	65.59	71.72
Yaouxu	60.76	75.8
Beary-group	58.37	72.56
ok-team	57.79	71.84
SUNLP	47.92	59.58
FishToucher	41.83	52.01
KaushikAcharya	36.23	23.08
<b>Unverified Leaderboard</b>		
Skywalker	92.55	95.15
MagicPai	90.88	94.03
endworld	82.35	88.16
Paima	81.96	88.85
ravikranc	57.90	71.99

Table 5: Task A Leaderboard

the input data in the test set. Although we discouraged this approach, we present the results in hopes it can give some interesting information about how much improvement might be possible with having access to input test data.

19 teams participated in Task A. Of the 14 teams on the official leaderboard, King001 obtained the highest score for task A for both the 2-way (88.74) and 3-way (84.48) F-scores. However, the top three participants have comparable scores. All teams except for the last two beat our best baseline in Table 3. The unverified leaderboard includes 5 teams and contains higher scores than in the official leaderboard. However, due to the reasons outlined above, we cannot say with certainty that the results are reproducible. The full leaderboard results for all participants are in Table 5.

Task B is a much harder task and fewer teams participated in this challenge. Of the 12 teams that participated, 8 are in the official leaderboard. The best score is 65.17 by BreakingBERT@IITK(65.17) which is noticeably lower than the F-scores in Task A. Similarly to Task A the results in the unverified leaderboard are considerably higher. The full leaderboard results for all participants are in Table 6.

We summarize the system details for all participating teams in Tables 7 (Task A) and 8 (Task B). In general, deep learning was the most popular approach used by the participants e.g. BiL-

Team	F-Score
<b>Official Leaderboard</b>	
BreakingBERT@IITK	<b>65.17</b>
Volta	62.95
King001	62.14

MagicPai	88.74
SkyWalker	73.05
endworld	57.85
Paima	51.97

Table 6: Task B Leaderboard

STM with attention, BERT (Devlin et al., 2019) etc. Most of the participants used transformer-based models to train their systems with flavors ranging from general-domain BERT (Devlin et al., 2019) to table-understanding specific versions like TAPAS (Herzig et al., 2020), TaBERT (Yin et al., 2020) and Table-BERT (Wenhu Chen and Wang, 2020). One third of the participants employed some form of ensembling technique in their submission.

Most of the participants have used the manually generated ground-truth in the development of their systems, with only one team not finding it useful. Further, a large percentage of participants have used the auto-generated ground truth in their systems with three teams not finding it helpful in their evaluation.

In terms of external resources, a majority of the participants used external table understanding resources in their systems. Further, most of the participants employed pre-processing techniques like acronym completion, removing special characters, etc... A substantial percentage of participants used techniques like incorporating word embeddings, entity resolution etc. Finally, a large number of participants used TabFact (Wenhu Chen and Wang, 2020) as an external dataset.

We also conducted additional analyses on participant submissions on the official leaderboard. We show through the average confusion matrix for Task A in Table 9 that the Unknown label was the most difficult. In fact, there were more unknown statements incorrectly labelled as entailed than were correctly categorized. Naturally, the statements with the lowest accuracy (< 25%) consist of mainly unknown statements, especially those statements

Team	Description
AttesTable (Varma et al., 2021)	Extended TAPAS to 3 classes by fine-tuning it. Employed a novel way of synthesizing “unknown” samples.
BreakingBERT@IITK (Jindal et al., 2021)	Ensemble models with TAPAS and TableBERT Transformers in a hierarchical two-step method for 3-way classification (unknown vs not unknown first)
Beary-group	Used TAPAS model with TabFact task, and added unique features. Employed preprocessing tricks like k-fold validation and replacing the characters and did hyperparameter tuning.
BOUN (Köksal et al., 2021)*	Used text augmentation techniques such as back translation and synonym swapping on the TAPAS model. Domain adaptation and joint learning using SemTabFacts and TabFact datasets.
endworld	Data Cleaning. Ensemble combining 80 instances of trained TaPas-Large and label smoothing.
FishToucher	Motivated by TaPas, used BERT and enriched the embedding layer with two new token type embeddings: row and column ids* (*The team mistakenly submitted an old model version, see paper for more accurate scores)
Kaushik Acharya (Acharya, 2021)	Parsed statements into candidate logical form; mapped result to handwritten rules, to then execute over relevant cells (identified using string matching and universal dependency parsing)
King001	Trained 20 instances of TaPas, SAT and Table-Bert for an ensemble of 60 models. Used preprocessing like acronym completion, rules to align the table content with the question content, label smoothing.
MagicPai	Multi-model training using models such as TaBERT, tapas.wikisql, tapas.TabFact, tapas_masklm. Finally rule amendments and aligning the distribution of training and test data
ok-team	TAPAS pretrained on TabFact with preprocessing of data (like transforming English numerals to Arabic numerals, removing special characters etc.)
Paima	Fine-tuned TAPAS optimized to perform window scanning on statement-related table data. Pre-processing to reduce abbreviations for table headers, and identifying operation expressions.
RyanStark	Multi-model TaBERT pretrained Model fusion. Pre-processing such as case and abbreviations.
Sattiy (Ruan et al., 2021)	Ensemble of 6 fine-tuned pre-trained models on the augmented data with content snap-shot input. Augmented the data provided by expanding the labels. Used Fast Gradient Method and added disturbance to the embedding layer to obtain a more stable word representation and a more general model.
SkyWalker	Deep learning, LPA rules, TAPAS dataset
SUNLP	BERT for sequence classification, transfer learning
TAPAS (Müller et al., 2021)	Ensemble of TAPAS (BERT-large-like) models: trained with a Mask-LM task on Wikipedia tables, intermediate pre-training data and TabFact data. Hierarchical two-step method for 3-way classification. Added neutral statements during training: random and by removing one of the evidence columns.
THiFly_Queen (Yuxuan et al., 2021)	Ensemble models in a hierarchical two-step method. 8-model to identify unknown statements and 9-model ensemble to classify entailed/refuted. Incorporated different ensemble weights for various statement types (count, superlative, unique).
Volta (Gautam et al., 2021)	Finetuned TAPAS that was pretrained on TabFact. Pre-processing to standardize multiple header rows to a single header.
Yaoxu	Added numeric and enumerate features to TAPAS and also statistic information (such as count) as a new row/column to the table.

Table 7: Descriptions of systems from participants for Task A. \*Note: Team BOUN did not participate in the official leaderboard.

Team	Description
BreakingBERT@IITK	An ensemble of an individual cell-based NLI approach and a similarity approach with the cells and statement
FishToucher	BERT CLS tokens for statement and table cells are used to determine cell relationships to each other, and the statement (for relevant cells)
Kaushik Acharya	Relevant cells are output as part of Task A
RyanStark	BOW approach with rules applied based on word matches in header and data cells.
Volta	Finetuned TAPAS for cell selection. Different models for entailed and refuted statements. Used transfer learning and header standardization.

Table 8: Descriptions of systems from participants for Task B (when provided)

	Refuted	Entailed	Unknown
Refuted	164	81	3
Entailed	46	226	2
Unknown	16	72	43

Table 9: Task A average confusion matrix

that have words overlapping with those in the table. Out of the entailed and refuted statements, ones that require numerical reasoning, like range, count or comparisons seemed to be most challenging. The statements with the highest accuracy ( $> 95\%$ ) generally had most words or numbers exactly overlapping with those in the table. In task B, out of the statements with less than 30% evidence F-score, 86% were ones with a refuted relationship. Conversely, the statements with greater than 70% F-score, 74% were ones with an entailed relationship. This shows that it is more difficult to find the most direct evidence to prove that a statement is refuted by a table than it is to show the positive evidence that a particular statement is supported by it. We believe this is an interesting line of research for future studies.

## 7 Conclusion and Future Works

In this paper, we presented the data and competition results for SEM-TAB-FACTS, Shared Task 9 of SemEval 2021. We created a large dataset via automated and crowdsourced fact verification as well as evidence finding for tables. Our 19 teams had a variety of techniques to tackle this unique but very relevant problem. The evidence finding scores are still quite low and have a large improvement potential. Additionally, the test set may be expanded in future versions of this task with a combination of manually generated, natural, and automated statements.

### Abstract

Recently, there has been an interest in factual verification and prediction over structured data like tables and graphs. To circumvent any false news incident, it is necessary to not only model and predict over structured data efficiently but also to explain those predictions. In this paper, as part of the SemEval-2021 Task 9, we tackle the problem of fact verification and evidence finding over tabular data. There are two subtasks. Given a table and a statement/fact, subtask A determines whether the statement is inferred from the tabular data, and subtask B determines which cells in the table provide evidence for the former subtask. We make a comparison of the baselines and state-of-the-art approaches over the given SemTabFact dataset. We also propose a novel approach CellBERT to solve evidence finding as a form of the Natural Language Inference task. We obtain a 3-way F1 score of 0.69 on subtask A and an F1 score of 0.65 on subtask B.

## 1 Introduction

Textual Inference, also known as natural language inference (Bowman et al., 2015), plays an important role in the study of natural language understanding and semantic representation. Due to the unprecedented amount of information generated over the internet, it becomes essential for machines to comprehend new information based on previous knowledge. Recent social events like political elections and pandemic spread have also shown the need for intelligent fact-checking systems that majorly depends on textual Inference over the scientific data.

Though Textual Inference is well explored, the current works mainly deal with unstructured Evidence in the form of sentences (Dagan et al., 2005).

\* Authors equally contributed to this work. Names in alphabetical order.

Verification under structured and semi-structured Evidence, such as tables, graphs, and databases, remains unexplored. Tables are ubiquitous in documents and presentations for concisely conveying important information; however, Inference on structured data like tables or graphs is much more difficult than simple text format due to complex structure and non-universal schema for the representation of data. Though recently, there has been work on Tabular Inference problems ( Zhong et al., 2020; Cho et al., 2018; Sun et al., 2018; Wenhua Chen and Wang, 2020; Eisenschlos et al., 2020; Pasupat and Liang, 2015; Wang et al., 2018 ) explaining the prediction, evidence finding is still an unexplored area.

Through the SemEval-2021 Task 9 (Wang et al., 2021) we have tried to solve the Tabular Inference problem over scientific tables by providing an answer as well as a solution to our reasoning. In other words, given the structured table data and statement, we aim to classify the statement as entailed, unknown (neutral), or contradiction. In addition, we also aim to classify each cell of the table whether it is relevant or irrelevant in making the aforementioned prediction. Our contribution is three-fold:

- We perform an empirical study of current state-of-the-art models on the SemTabFact dataset for the task of statement verification (see Section 5.1).
- We implement TableSciBERT, TableRoBERTa and develop a heuristic-based classifier. We achieve a 3-way F1 score of 0.69 on statement verification by ensembling TableSciBERT and TAPAS with our heuristic method (see Section 3.1).
- We propose a new model CellBERT, for the task of Evidence finding from the tables. We

achieve an F1 score of 0.65 on Evidence finding by ensembling CellBERT with our heuristic-based approach (See Section 3.2).

The code for all our experiments and pre-trained models are available on GitHub<sup>1</sup>.

## 2 Background

### 2.1 Related Work

Recently, [Wenhu Chen and Wang \(2020\)](#) proposed TabFact, a dataset with 16k Wikipedia tables and 118k human-annotated natural language statements, labeled as either ENTAILED or REFUTED. The authors proposed the TableBERT model for the task of fact-checking. TableBERT uses the pre-trained BERT ([Devlin et al., 2018](#)) model and fine-tunes it using the TabFact dataset as a simple NLI task by linearizing the table along with the fact. The linearized table is then concatenated with the statement which after tokenization is given as input to the BERT model which is used for binary classification to predict the nature of the statement.

The paper also proposed LPA (Latent Program Algorithm) to formulate the table fact-checking as a program synthesis problem. LPA uses reinforcement learning to optimize the task reward of this structured prediction problem directly, as was done in Neural Symbolic Machines (NSM) ([Liang et al., 2016](#)). [Zhong et al. \(2020\)](#) used the combination of the linguistic and symbolic reasoning integrated with an understanding of a given table’s structural format.

[Herzig et al. \(2020\)](#) developed the TAPAS model that performs question-answering over tables without generating logical forms. It uses weak supervision and predicts the answer by selecting table cells and optimally applying aggregation operators (for example: count, sum, average etc.) to the selected cells. An input instance to the model is the combination of the tokenized question and flattened table, separated by an [SEP] token (see Figure 1). In addition to BERT embeddings, TAPAS incorporates the table’s structural information via row, column, and rank embeddings. Since TAPAS uses flattened tables, it also suffers from the limitation of self-attention computation over long input sequences like BERT. Due to this reason, it fails to capture information over large tables or /databases containing/ multiple tables.

### Statement + Caption + Flattened Table

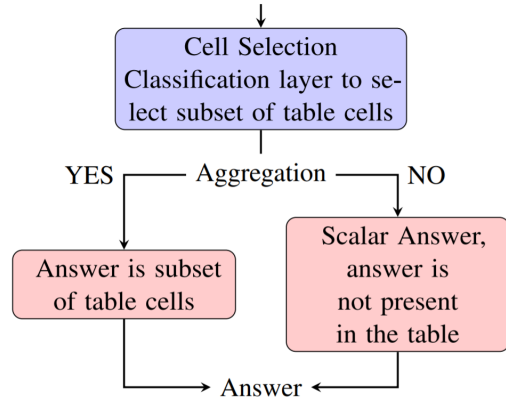

Figure 1: Flow chart explaining the functioning of TAPAS model using the two classification layers.

Besides this, the model’s expressivity is limited to a form of aggregation over a few cells of the table; hence, it fails to handle questions requiring multiple aggregation operations properly.

Recently, [Eisenschlos et al. \(2020\)](#) adapted TAPAS for the task of fact-checking. They introduced two intermediate pre-training tasks learned from the MASK-LM model. The first task is based on counterfactual statements, generated by creating one positive and one negative from every relevant Statement extracted from Wikipedia statements and tables. The second task is based on synthetic statements that generate a sentence by sampling from a set of logical expressions.

Let  $S$  and  $T$  represent the statement/fact and the table, respectively, which are given as input to the model. Furthermore, let  $E_S$  and  $E_T$  represent the corresponding input embeddings. The sequence of statement and the table given by  $E = [E_{[CLS]}; E_S; E_{[SEP]}; E_T]$  is passed through the transformer,  $f$  and a contextual representation is obtained for every token. The entailment probability  $P(S|T)$  is modeled using a single hidden layer neural network obtained by computing the output of [CLS] token:

$$P(S|T) = MLP(f_{[CLS]}(E)) \quad (1)$$

To handle large size tables, Table pruning is done using Heuristic exact match (HEM). In this method, the columns are ranked by a relevance score and added in order of decreasing relevance. Columns that exceed the maximum input length are skipped.

Our task for statement verification differs from the works mentioned above in the aspect that we have a third label, ‘unknown’, where the table fails

<sup>1</sup><https://github.com/vijit-m/TabEval>

to provide any information to infer the Statement. Moreover, no prior work has been performed concerning the task of evidence finding.

## 2.2 Problem Definition

The problem statement is articulated around the following two related subtasks.

**Subtask A - Table Statement Support:** Given a statement/fact, some of which will be directly adapted from the linking text, and a table, determine whether the table’s information supports the Statement. In this classification problem, a statement is assigned one of the following labels:

- **Fully Supported:** Statement is supported by data found within the table (denoted by 1).
- **Refuted:** Statement is contradicted by table (denoted by 0).
- **Unknown:** Not enough information in table to assess statement veracity (denoted by 2).

Mathematically, the problem can be described as, given a table  $\mathbb{T}$  and a statement  $\mathbb{S}$ , we need to learn a mapping  $\mathbb{F}_A$  to the output  $y_A$ , where  $y \in \{0, 1, 2\}$ . See examples in table 1 and table 2.

**Subtask B - Relevant Cell Selection:** Given a statement and a table, determine which table cells form relevant evidence for the Statement (if any). A table cell is evidence for a statement if it helps support or refute a part of the statement. In this subtask each cell of the table is assigned the following labels:

- **Relevant:** the cell must be included (denoted by 1).
- **Irrelevant:** the cell must not be included (denoted by 0).

Mathematically, each cell  $x_{ij} \in \mathbb{T}$  (where  $i, j$  correspond to row and column number respectively), needs to be assigned a value  $y_B \in \{0, 1\}$ . See examples in table 1 and table 2.

Body Sensation	Agoraphobic	Pleasant
number	museum	lovely
palpitation	shop	happiness
heartbeat	boat	Joyous

Table 1: <sup>2</sup> A sample table and statement with correct results for subtask B. **violet:** Relevant Cell, **red:** Irrelevant Cell

Statement	Label
Palpitation is a bodily sensation	Supported
Joyous and boat have same strength	Unknown
Lovely is an agoraphobic situation	Refuted

Table 2: Statements and Labels corresponding to Subtask A

**Corpus Collection:** The training and testing data is sourced from open-access scientific articles with tables using APIs provided by Science Direct for data mining. The data is procured in XML format and each table is also provided in image format since the size and styling of table contents are useful in understanding the table structure. Two separate datasets (with varying complexity) are provided, one in which the statements are automatically-generated, the second one where statements are generated manually by humans. The automatically generated statements are relatively more complex (Wang et al., 2021) and more in number as compared to the Manually generated statements.

**Annotation Process:** Each statement in the SemTabFact dataset is adapted from existing text and verified by at least one human reader. Multiple readers verify a smaller proportion to assess inter-annotator agreement.

**Data Preprocessing:** The Tables in the dataset have multiple sub-columns, unlike the Wikipedia tables in the TabFact dataset. The Training dataset had few errors like label classification errors and Grammatical errors. To overcome this, data is pre-processed and cleaned before feeding it into the models. During the Data Cleaning, statements with no labels are removed, and subcolumns are interpolated to handle the tables’ complex header structure.

The subcolumns are also merged with the table headers in the case of multiple Table headers that improve the results. The tables are provided with surrounding text along with the captions. During preprocessing, the surrounding text is combined with captions which together serve as captions to the subtask A model. Refer to Section 3.1 for our system description for subtask A. (See Appendix A for preprocessing details). We also discuss the result of this step on our model’s performance in Section 6

Figure 2: Approach for Subtask B

### 3 System Description

#### 3.1 Subtask A

Our proposed model for subtask A is an ensemble of TableSciBERT, TAPAS, and a heuristic-based approach. We first use a similarity-based approach to predict and segregate ‘unknown’ statements, and then we predict the remaining statements using an ensemble of TableSciBERT and TAPAS. Given a statement,  $S$  and table,  $T$ , in order to classify whether  $S$  is ‘unknown’ or not, we first calculate the similarity score between  $S$  and each cell  $C \subset T$  using equation 2. Here,  $Sim$  is a similarity function,  $C$  is the content of the cell,  $s_i$  is  $i$ -th token of the statement  $S$  after removing stop words and  $c_j$  is the  $j$ -th token of cell (for handling multi-word cells). We use the nltk library (Bird et al., 2009) to tokenize the statement and cell contents. The similarity function takes as input two tokens and outputs the similarity between them in 0 to 1 (higher score representing more similar). For each token in the statement, we first iterate through all the tokens of the cell and compute the maximum of scores obtained by  $Sim$  function for each token in the cell and the particular token of the statement. We then sum it over all the tokens of the statement to compute the score,  $s_c$ . We obtain the aggregated score,  $s_s$  over the whole table  $T$  by adding score  $s_c$ , of each cell  $c \subset T$  (see equation 3). Refer to Section 4.1 for more information about the types of similarity functions we experimented with.

$$s_c = \sum_i \max_j (Sim(c_j, s_i)), s_i \subset S, c_j \subset C \quad (2)$$

$$s_s = \sum_c s_c, \text{ where } C \subset T \quad (3)$$

We use  $s_s$  as the similarity score between statement  $S$  and table  $T$ . If  $s_s < \lambda_a$ , we label the

statement as ‘unknown’ where  $\lambda_a$  is a hyperparameter. If  $s_s \geq \lambda_a$  we proceed with the two-way classification using our ensemble of TableSciBERT and TAPAS.

Note that these TableSciBERT and TAPAS models were fine-tuned upon two labels only (viz-a-vis Entailed and Refuted). The ensemble is done by applying weighted average upon prediction probabilities of TAPAS and TableSciBERT. TableSciBERT (from TableBERT) was developed by replacing the BERT base model with SciBERT (Beltagy et al., 2019). SciBERT is a pre-trained language model based on BERT, which is fine-tuned upon large scale scientific data. Since the SemTabFact dataset is from scientific articles, using SciBERT makes sense intuitively.

TAPAS and TableSciBERT were trained on the training set (both autogenerated and manual dataset) and the development set. The table pruning method using the Heuristic exact match (HEM) was applied for the large complex tables in an Autogenerated dataset to handle the input embedding size. We also experimented with other transformers models like BioBERT (Lee et al., 2020), CovidBERT<sup>3</sup> but SciBERT gave the best result. Furthermore, we experimented with training them as a 3-label classifier as well. Refer to the Section 3.2 for details.

For training TableSciBERT and other table transformer 3-label variants we augmented the training data with statements having ‘unknown’ label, in order to balance the scarcity of unknown labels in the provided data. The augmentation for a table was done by randomly sampling statements from other tables provided in the dataset having ‘entailed’ or ‘refuted’ as the true label. The motivation behind using this strategy was that these statements served as statements with an ‘unknown’ label for this table. During sampling, we ensured that entailed and

<sup>3</sup><https://huggingface.co/gsarti/covidbert-nli>

refuted statements are equal in number to prevent any bias.

Overall, given a table  $\mathbb{T}$  and statement  $\mathbb{S}$ , the complete pipeline is a two-step process:

- We first perform the binary classification of whether  $\mathbb{S}$  is ‘unknown’ or not using the Similarity heuristic. If the predicted label is ‘unknown’, it is taken as the final prediction; otherwise, we proceed to the next step.
- We use the ensemble of TAPAS and TableSciBERT models to predict the ‘entailed’ or ‘refuted’ label of  $\mathbb{S}$ . Here,  $\mathbb{S}$  are the statements that were NOT classified as ‘unknown’ in the previous step.

### 3.2 Subtask B

For subtask B, we developed an ensemble of two different techniques:

- **CellBERT**: We propose a new method CellBERT as a BERT-base model that is fine-tuned upon an individual cell-based Natural Language Inference Task. We preprocess the training data given to us in Subtask B (which consists of only auto-generated statements) to generate NLI input samples of the form described in Figure 2. Mathematically, given a statement  $S$  and a table  $T$ , we need to label each cell  $c$  in the table as relevant or irrelevant. For CellBERT, each cell’s label is individually determined along with the supporting information of row and column headers. In other words, if the coordinates of a cell  $c$  are given by  $(x, y)$ , where  $x$  is the row number and  $y$  is the column number, the coordinates of the row header and column header cells are given by  $(x, 1)$  and  $(1, y)$  respectively.

The motivation behind using row and column headers information is that these capture the ‘type’ of data present in the cell. The combination of the row header, the cell, and the column header’s contents represent the NLI task’s premise. The hypothesis is taken as the statement provided. Note that using this approach, we ended up with around a million data points to train upon. Due to the unavailability of adequate computational resources, we restricted to using only 0.1% of the preprocessed training data.

- **Similarity**: We observed that Scientific Tables contained many entities for which pre-trained word embeddings are unavailable, and thus supervised approaches like CellBERT, fails to capture the required relationship. To overcome this, we used a cell-wise similarity algorithm, which calculates the score  $s_c$  of each cell  $C$  with the statement  $S$  same as in equation 2. We used  $s_c$  as the similarity score between statement  $S$  and cell  $C$ . If  $s_c < \lambda_b$  we label the cell as ‘irrelevant’, where  $\lambda_b$  is a hyperparameter. Otherwise, we label the cell as ‘relevant’.

## 4 Experiments

### 4.1 Subtask A

Following the TabFact’s TableBERT, we fine-tuned our own TableBERT model on the SemTabFact dataset for Subtask A. We also experimented with mutations of TableBERT by using RoBERTa (TableRoBERTa), XLNet (TableXLNet), and SciBERT (TableSciBERT) as well. We also experimented with implementing BiGRU layers on top of these table transformers. All our experiments were conducted using PyTorch (Paszke et al., 2019) Deep Learning library.

We experimented with a dataset ( $D_1$ ) which contained the Manual dataset along with the Auto-generated statements. A caveat to  $D_1$  was that auto-generated statements that have common tables with the manual dataset were only used. This was done because every model we trained upon only on the manual dataset was overfitting. The overfitting was due to an insufficient number of statements, i.e., 4056 in the Manual Dataset. After preparing the dataset  $D_1$ , we had a total of 72k statements.

For the similarity-based approach, we manually experimented with various non-semantic similarity approaches like edit distance and binary-matching<sup>4</sup> as well as embedding space-based semantic similarity approaches by first computing the word vector. We computed word vectors using GloVe (Pennington et al., 2014), BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019). Cosine similarity and euclidean distance was used to compute similarity between two vectors. The non-semantic based binary-matching approach outperformed others upon the validation set; therefore, we used it

<sup>4</sup>We define binary matching score between two tokens  $t_1$  and  $t_2$  as 1 if the lower-cased, lemmatized and stemmed form of both the tokens is the same otherwise it is taken as 0.

to evaluate our results on the test set. In our final submitted model, SciBERT was fine-tuned for 3 epochs upon the combined dataset  $D_1$  and development dataset, with learning rates as  $5e - 5$ ,  $5e - 6$  and  $1e - 6$  for each epoch. Batch size was kept as 6 with maximum sequence length of 512 tokens. TAPAS was fine tuned upon the auto-generated, manual and development datasets separately for 6, 12 and 5 epochs respectively. Learning rate was kept the same as  $2e - 5$  for each epoch with maximum sequence length as 512. Dropout probability was set to 0.07. For ensemble, we used weights 0.7 and 0.3 for TAPAS and TableSciBERT respectively. We set the hyperparameter  $\lambda_a$  as 2 in our similarity heuristic.

## 4.2 Subtask B

For Subtask B, we preprocessed the dataset into input samples as shown in Figure 2, and fine-tuned a BERT base model. Since the number of statements given corresponding to the auto-generated dataset is large and also accounting for the fact that each cell in the table is a separate input example, the number of tuples of (cell, statement) were very large (over ten million data points). Therefore, only 0.1% of all tuples ( $\approx 30k$  data points) were used to train CellBERT, and the rest of the data was discarded. Note that the 0.1% of the data that we selected to train CellBERT was kept completely balanced with respect to true labels. We also experimented with including and not-including header information during fine-tuning as well. See table 5.

Here as well, for the similarity-based approach, we manually experimented with the same non-semantic similarity approaches like edit distance and binary-matching as well as embedding space-based semantic similarity approaches we used in Section 4.1. In Subtask B too, the non-semantic based binary-matching approach outperformed others upon the validation set, hence we used the same to evaluate our results on the test set. For our final model, the hyperparameter  $\lambda_b$  was set to 1. For CellBERT we fine-tuned a BERT base model for 5 epochs with batch size 16 and learning rate as  $2e - 5$ .

## 5 Results

### 5.1 Subtask A

The organizers use two evaluation metrics for subtask A:

- **3-way-F1:** This is a standard precision/recall evaluation (Three-Way) of a multi-class classification that evaluates whether each statement is classified as Entailed / Refuted / Unknown.
- **2-way-F1:** The second evaluation method is a Two Way method in which statements with the unknown ground truth label are not taken into consideration.

In both methods, first F1 scores are calculated for each table, which is then averaged across all tables for the final F1 score. The results of subtask A on the test set are shown in table 4:

Model	Task A 2-way F1	Task A 3-way F1
<b>(TAPAS+TableSciBERT)-2-Label+Similarity</b>	<b>0.7681</b>	<b>0.6931</b>
BERT-3-Label	0.5963	0.5295
TAPAS -2-Label + Similarity	0.7547	0.6824
SciBERT-2-Label + Similarity	0.6172	0.5534
RoBERTa-3-Label	0.6186	0.5271
(RoBERTa+BiGRU) 3-Label	0.5986	0.5113

Table 4: Test Data Result (Average F1-scores) for subtask A

Confusion Matrix of Test set on (TAPAS+TableSciBERT)-2-Label+Similarity is shown in fig. 3

Figure 3: Confusion Matrix of Testset on (Tapas+TableSciBERT)-2-Label+Similarity.

The best results for subtask A were obtained using (TAPAS+TableSciBERT)-2-Label+ Heuristic-based Similarity with 0.768 as 2-way F1 and 0.693 as 3-way-F1. TAPAS-2-Label+ Heuristic Based Similarity also gave second-best results with 0.755 as 2-way F1 and 0.682 as 3-way-F1. We have experimented with other table transformers like

RoBERTa, BERT, and XLNet, but none of these gave promising results. Models like RoBERTa-3-Label, BERT-3-Label have been trained on the three labels and gave 0.527 and 0.529, respectively, as 3-way-F1. From the experiments, we observed that the models trained on 3 label classification performed poorly in classifying statements with ‘unknown’ label.

## 5.2 Subtask B

The metric used by the organizers calculates the recall and precision for each cell, with “relevant” cells as the positive category. Similar to Task A, the score is averaged over all statements in each table first, before calculating average across all tables. The results for subtask B on test data are shown in table 5. We obtained the best F1 of 0.6517. We have also shown the results of other variants of Cell-BERT, which are classified on the basis of row and column headers (see Table 5).

S.No	Method	F1
1.	Similarity	0.6414
2.	CellBERT	0.5380
3.	CellBERT - DevT	0.6465
<b>4.</b>	<b>CellBERT - DevT + Similarity Ensemble</b>	<b>0.6517</b>
5.	CellBERT (only cell context)	0.4891
6.	CellBERT (cell+row header information)	0.5213
7.	CellBERT (cell+column header information)	0.5199
8.	CellBERT (cell+row+column header information)	0.5380

Table 5: Test Data Result (Average F1-scores) for sub-task B

## 6 Error Analysis

**Subtask A:** On analyzing the training dataset, we realized that many statements require aggregation methods like sum, count, max, and min over the tabular data to determine whether a statement is entailed or refuted (or if it is ‘unknown’). It requires a symbolical understanding of the text that can not be understood using simple NLI based approaches

like Table-BERT and other table transformers. On the other hand, TAPAS outperforms other models primarily due to pre-training on the corpus of synthetic and counterfactual statements, as discussed in Section 2.1.

We noticed that TableSciBERT performed well as compared to other Table Transformers on sub-task A. It makes intuitive sense as the dataset is created from scientific texts and consequently has scientific statements. The organizers also mentioned that the training and testing data is sourced from open access scientific articles with tables using APIs provided by Science Direct for data mining in the task description.

Further, we improved the F1 score on the TAPAS model by 2% by using the multiple header merging technique (See Appendix A). The reason being that the merged headers have more semantic information as they contain the sub-headers too. We have explained the pre-processing step of tables with multiple headers and sub-columns in the Appendix. For 3-way classification, the table transformers gave unsatisfactory results, for example, RoBERTa 3-Label with F1 of 0.527 primarily due to two reasons, first we need complete domain knowledge of the related table to tag a statement to be unknown, and second, no data were available for the unknown label in the training set. We obtain 3-way F1 of 0.693, with (TAPAS+SciBERT)-2-Label+Similarity model, as our similarity heuristic was successfully able to classify 91% of the statements predicted unknown as true unknown labels. This might be possible because many unknown statements in the development and test set are completely independent of the table given.

**Subtask B:** We noticed that CellBERT performs best when header information is included while fine-tuning. An interesting point to note is that CellBERT trained only on autogenerated dataset provides an F1 score of 0.538, whereas when it was later fine-tuned upon the Development Dataset which had Manual based dataset (CellBERT-DevT), it boosted the results on the test set to F1 score of 0.646. The reason being the Test Dataset being a Manual based dataset, whereas the earlier CellBERT model was trained on the more complex autogenerated dataset.

The heuristic-based Similarity approach was performing surprisingly well on the test set as well,

giving us a comparable result of 0.641 F1. Although both the approaches are entirely different, the scores are comparable. This motivated us to analyze each method’s predictions, but we could not come up with a convincing hypothesis for what might be the reason for this observation. However, we noticed a common trend in both methods. When the number of cells in a table is large, and the number of relevant cells is very less, both models failed to identify relevant cells in such cases. In other words, both models had difficulty in identifying true positives.

## 7 Conclusion

This paper attempts a solution to an under-explored but essential problem: Statement Verification and Evidence Finding with Tables. There have been various works related to a binary classification of statements. Still, evidence finding for these classifications is a difficult and novel challenge. We are successfully able to present an ensemble of TAPAS model, table transformer-based TableSciBERT, and similarity heuristic trained for subtask A with 2-way F1 of 0.768 and 3-way F1 of 0.693. In subtask B, we implemented the CellBERT - DevT+ Similarity Ensemble method as our best model with an F1 score of 0.652.

In the future, we plan to progress in implementing new models that can tackle both linguistic and symbolic reasoning. We aim to extend the TAPAS model to 3 labels, requiring large data for training in unknown labels for good results. In the case of subtask B, we are planning to experiment with other NLI techniques and models. Besides, we will be looking into using more data for training CellBERT and other NLI models as well.

## Appendix

### A Preprocessing of the Multiple Header files

The provided dataset had many Tables with multiple headers and subcolumns, as shown in table 6.

Since most of our models take a single header as input only and with an equal number of columns in every row, we had to convert such tables to suit our input type. There were two processes involved for preprocessing such Tables.

**Intrapolation:** For one table, we would calculate the maximum numbers of columns in the Table and then interpolate all other rows with less columns to eventually have an equal number of columns in every row. Resulting table 7 obtained by interpolation of table 6 is shown below

ExperMatter	UserB		UserC	
	Base1	Base2	Base1	Base2
Gold	5.6		7	8
Silver	3.4	6.7	8.0	6.7

Table 6: Table with multiple headers and subcolumns

ExperMatter	UserB	UserB	UserC	UserC
	Base1	Base2	Base1	Base2
Gold	5.6		7	8
Silver	3.4	6.7	8.0	6.7

Table 7: Table after Intrapolation

**Header Merging:** Since the input our model has to be a single header file we had to merge such rows as shown below. Final table obtained after Preprocessing is shown in table 8.

ExperMatter	UserB	UserB	UserC	UserC
	Base1	Base2	Base1	Base2
Gold	5.6		7	8
Silver	3.4	6.7	8.0	6.7

Table 8: Table after preprocessing

### B Other Experiments with training data

We have also provided the results for 2-way F1 on the development set, which we have created out of the training dataset in table 9 were trained on only two labels. We divided both the Manual and Auto-generated training data into Train and Dev set with a split of 90 : 10, respectively. Various combinations of Train and Dev data were used to train different models. The models given in table 9 were trained on only two labels as both of the training datasets do not contain unknown labels, and this is also the reason why we have not shown 3-way F1.

TAPAS model gave us the best here too, with an F1 score of 97.1 when the Autogenerated train set and Dev set were used, while it gave us the best F1 score of 76.7 when the Autogenerated + Manual train set and Manual Dev set were used. We have not included any of the models trained only on the Manual train dataset because the provided Manual data is very small in numbers and the results of any model trained on manual train set were not very promising. Clearly TAPAS outperforms all the models and gives the best results on both the Datasets.

Model	Train set	Dev set	Metrics (On Dev set)			
			Precision	Recall	F1	Accuracy (%)
<b>TAPAS</b>	<b>Auto</b>	<b>Auto</b>	<b>99.4</b>	<b>94.7</b>	<b>97.1</b>	<b>94.32</b>

## Abstract

Disagreement between coders is ubiquitous in virtually all datasets annotated with human judgements in both natural language processing and computer vision. However, most supervised machine learning methods assume that a single preferred interpretation exists for each item, which is at best an idealization. The aim of the SemEval-2021 shared task on Learning with Disagreements (LE-WI-DI) was to provide a unified testing framework for methods for learning from data containing multiple and possibly contradictory annotations covering the best-known datasets containing information about disagreements for interpreting language and classifying images. In this paper we describe the shared task and its results.

## 1 Introduction

The assumption that natural language (NL) expressions have a single and clearly identifiable interpretation in a given context, or that images have a preferred labels, still underlies most work in NLP and computer vision. However, there is now plenty of evidence that this assumption is just a convenient idealization; virtually every project devoted to large-scale annotation has found that genuine disagreements are widespread.

In NLP, that annotator/coder disagreement can be genuine—i.e., resulting from debatable, difficult, or linguistic ambiguity—has long been known for anaphora and coreference (Poesio and Artstein, 2005; Versley, 2008; Recasens et al., 2011).<sup>1</sup> But in recent years, we have also seen evidence that disagreements among subjects/coders are common with virtually every aspect of language interpretation, from apparently simple aspects such as part-of-speech tagging (Plank et al., 2014b), to more

complex ones like semantic role assignment (Dumitrache et al., 2019), to subjective tasks such as sentiment analysis (Kenyon-Dean et al., 2018), and to the inferences that can be drawn from sentences (Pavlick and Kwiatkowski, 2019).

In computer vision, as well, the assumption that gold labels may be specified for items has proven an idealization (Rodrigues and Pereira, 2018)—in fact, possibly even more than for NLP. In many widely used crowdsourced datasets for computer vision, different coders assign equally plausible labels to the same items. The problem of disagreement among coders, including experts, on the classification of noisy image data has arisen in many CV applications. This includes classification of astronomical images (Smyth et al., 1994), medical image classification (Raykar et al., 2010), and numerous others (Sharmanska et al., 2016; Rodrigues and Pereira, 2018; Firman et al., 2018).

Many AI researchers have concluded that rather than attempting to eliminate disagreements from annotated corpora, we should preserve them—indeed, some researchers have argued that corpora should aim to collect all distinct interpretations of an expression (Smyth et al., 1994; Poesio and Artstein, 2005; Aroyo and Welty, 2015; Sharmanska et al., 2016; Plank, 2016; Kenyon-Dean et al., 2018; Firman et al., 2018; Pavlick and Kwiatkowski, 2019). Poesio and Artstein (2005) and Recasens et al. (2012) suggest that the best way to create resources capturing disagreements is by preserving *implicit* ambiguity—i.e., having multiple annotators label the items, and then keeping all these annotations, not just an aggregated ‘gold standard’. A number of corpora with these characteristics now exist (Pasonneau and Carpenter, 2014; Plank et al., 2014a; Dumitrache et al., 2019; Poesio et al., 2019; Rodrigues and Pereira, 2018; Peterson et al., 2019)

Much recent research has explored the question of whether corpora of this type, besides being more

<sup>1</sup>See also the analysis of disagreements in OntoNotes and word senses in Pradhan et al. (2012), Pasonneau et al. (2012), and Martínez Alonso et al. (2016).

accurate characterizations of the linguistic reality of language interpretation and image categorization, are also better resources for training NLP and computer vision models, and if so, what is the best way for exploiting disagreements in modeling. [Beigman Klebanov and Beigman \(2009\)](#) used information about disagreements to *exclude* items on which judgements are unclear (‘hard’ items). In the CrowdTruth project ([Aroyo and Welty, 2015](#); [Dumitrache et al., 2019](#)) information about disagreement is used to *weigh* the items used for training. [Plank et al. \(2014a\)](#) proposed to use the information about disagreement to *supplement* the gold label during training. Finally, methods were proposed for training directly from the data with disagreements, without first obtaining an aggregated label ([Sheng et al., 2008](#); [Rodrigues and Pereira, 2018](#); [Peterson et al., 2019](#); [Uma et al., 2020](#)). Only limited comparisons of these methods have been carried out ([Jamison and Gurevych, 2015](#)), and the sparse research landscape remains fragmented; in particular, methods applied in CV have not yet been tested in NLP, and vice versa.

The objective of SemEval-2021 Task 12, Learning with Disagreements (LE-WI-DI), was to provide a unified testing framework for learning from disagreements in NLP and CV using datasets containing information about disagreements for interpreting language and classifying images. The expectation being that unifying research on disagreement from different fields may lead to novel insights and impact AI widely.

## 2 Task organization

In order to provide a thorough benchmark for methods for learning from disagreements, we identified five well-known datasets for very different NLP and CV tasks, all characterized by providing a multiplicity of labels for each instance, by having a size sufficient to train state-of-the-art models, and by evincing different characteristics in terms of the crowd annotators and data collection procedure. We found or developed near-state-of-the-art models for the tasks represented by these datasets. Both ‘hard’ and ‘soft’ evaluation metrics were employed ([Uma et al., n.d.](#)).

The shared task was set up on the CodaLab Competitions platform,<sup>2</sup> which enables training and uniform evaluation on these datasets, such

<sup>2</sup><https://www.microsoft.com/en-us/research/project/codalab/>

that the crowd learning adaptations of the base models proposed by participants to the task would be directly comparable.

In this section, we briefly introduce the five datasets included in the benchmark and our evaluation criteria. We also elaborate on the setup of the shared task.

### 2.1 Data

There are by now quite a few datasets preserving disagreements, and covering many levels of language interpretation; remarkably, none of these has ever been used for a shared task like the one we are proposing, and the majority of them have never been used for a shared task at all. Our shared task has aimed at leveraging this diversity. The datasets included are outlined in this section and their characteristics are summarized in Table 1. Figure 1 shows the observed agreement of each dataset.

Figure 1: Observed Agreement for each dataset

#### 2.1.1 The Gimpel et al. POS corpus

One widely used resource for developing disagreement-aware NLP models is the dataset of Twitter posts annotated with POS tags collected by [Gimpel et al. \(2011\)](#). [Plank et al. \(2014b\)](#) mapped the Gimpel tags to the universal POS tag set ([Petrov et al., 2012](#)) and collected at least five crowdsourced labels per token from 177 annotators. This dataset contains 14K training examples (English words/tokens) annotated by 177 annotators. Each item was annotated between five and 177 times, 16.38 times on average. For this shared task, we selected 8.3K, 3K, and 3.1K tokens as training, development and test sets respectively.

#### 2.1.2 The pDIS corpus

The *Phrase Detectives* corpus ([Poesio et al., 2019](#)) is a crowdsourced coreference corpus collected

	POS	PDIS	HUMOUR	IC-LABELME	CIFAR-10H
Number of items	14,000	96,305	18,002	10,000	10,000
Number of crowd workers	177	1,741	272	59	2,457
Number of categories	12	2	2	8	10
Average annotations per item	16.37	11.87	5.00	2.50	51.10

Table 1: Summary of dataset characteristics

with the *Phrase Detectives* gamified online platform (Poesio et al., 2013).<sup>3</sup> We use PDIS, a simplified version of the corpus containing only binary information status labels: Discourse New (the entity referred to has never been mentioned before) and Discourse Old (it has been mentioned). PDIS consists of 542 documents, for a total of 408K tokens and over 96K markables. These documents were annotated by game players who produced an average of 11.87 annotations per markable.

Forty-five of the documents (5.2K markables), collectively called PD<sub>gold</sub>, additionally contain expert-adjudicated gold labels. This subset of PDIS was designated as the test set. The training and development datasets consist of 473 documents (and 86.9K markables) and 24 documents (4.2K markables) respectively.

### 2.1.3 The Humour dataset

The comprehension and appreciation of humour is known to vary across individuals (Ruch, 2008), making disagreement over the perceived funniness of jokes an appealing subject of study. For our training data, we used the corpus of Simpson et al. (2019), which consists of 4,030 short texts (3398 jokes, mostly based on puns, and 632 non-jokes such as proverbs and aphorisms). 28,210 unique pairings of these texts were presented to five crowdsourcers each, who indicated which text in the pair (if either) they found to be funnier. The goal is to learn a model that can predict binary pairwise labels that can predict which of two short texts is funnier.

The 4,030 text instances were split into 60% (2,418 texts, 9,916 unique pairs) for the training set and 20% (806 texts, 1,086 unique pairs) for the development set. Since this dataset has already been published, we constructed a new test dataset along similar lines: 1,000 short texts (all punning jokes) were paired in 7,000 different ways, and each of these 7,000 pairs was then presented to five crowd workers for a preference judgement.<sup>4</sup>

<sup>3</sup><https://github.com/dali-ambiguity>

<sup>4</sup>US-based workers from Amazon Mechanical Turk were

### 2.1.4 The LabelMe corpus

Much research on learning from disagreements was motivated by computer vision datasets, so we intended to include some of these, too. Possibly the most widely used such corpus is the LabelMe dataset<sup>5</sup> (Russell et al., 2008). It classifies outdoor images according to 8 categories: *highway, inside city, tall building, street, forest, coast, mountain or open country*. Using Amazon Mechanical Turk, Rodrigues and Pereira (2018) collected an average of 2.5 annotations per image from 59 annotators for 10K images in this dataset.

We randomly selected 5K, 2.5K, and 2.5K images for training, development, and testing respectively, careful to keep the label proportions in each subset close to the proportions in the 10K dataset.

### 2.1.5 The CIFAR-10H corpus

Krizhevsky’s (2009) CIFAR-10 dataset consists of 60K tiny images from the web, carefully labelled and expert-adjudicated to produce a single gold label for each image in one of 10 categories: *airplane, automobile, bird, cat, deer, dog, frog, horse, ship, and truck*. Peterson et al. (2019) collected crowd annotations for 10K images from this dataset (the designated test portion) using Amazon Mechanical Turk, creating the CIFAR-10H dataset<sup>6</sup> which we use for this shared task.

We randomly selected 7K, 1K, and 2K images for training, development and testing respectively. We kept as much data as we could for training without jeopardizing the evaluation process, as the base model was found to be sensitive to data size. As with the original dataset, each subset we created contains an equal number of images per category.

## 2.2 Evaluation metrics

While recent research questions the assumption that a single ‘hard’ label (a gold label) exists for every

employed, paid in line with the federal minimum wage.

<sup>5</sup><http://labelme.csail.mit.edu/Release3.0>

<sup>6</sup><https://github.com/jcpeterson/cifar-10h>

item in a dataset, the models proposed for learning from multiple interpretations are still largely evaluated under this assumption, using ‘hard’ measures like accuracy or class-weighted  $F_1$  (Sheng et al., 2008; Plank et al., 2014a; Martínez Alonso et al., 2015; Sharmanska et al., 2016; Rodrigues and Pereira, 2018). For reference and comparison reasons, we also evaluate the models produced for this shared task using  $F_1$ .

However, a way of evaluating models as to their ability to capture disagreement is needed, especially for datasets with substantial extent of disagreement. The simplest ‘soft’ metric of this type is to evaluate ambiguity-aware models by treating the probability distribution of labels they produce as a **soft label**, and comparing that to the full distribution produced by annotators, using, for example, cross-entropy. This approach was adopted in, *inter alia*, (Peterson et al., 2019; Uma et al., 2020). Peterson et al. (2019) tested this approach on image classification tasks, generating the soft label by transforming the item annotation distribution using standard normalization. In this shared task we also use standard normalization to produce soft labels for the humour dataset. Uma et al. (2020) show that the choice of soft label encoding function depends on the characteristics of the dataset. For POS and IC-LABELME, they show that a softmax function over the annotator distribution is preferable over standard normalization. On the other end, for PDIS, training a soft-loss model using the posterior probability produced by Hovy et al.’s (2013) MACE probabilistic aggregation model as a soft label produces predictions that are most accurate with respect to the gold.

Therefore, in this shared task we used different soft label encoders to generate soft labels from annotator distributions for the test data.

### 2.3 Task setup

CodaLab was the designated site for hosting SemEval-2021 competitions.<sup>7</sup> LE-WI-DI was run in two main phases:

**Practice phase.** In the practice phase, the goal was to train models for each task to learn from crowd annotations, given (1) the training data (consisting of raw and preprocessed input data and crowd annotations), (2) the development data with no labels, and (3) the base models (discussed in Section 3). While participants were encouraged to start with the

<sup>7</sup>Our competition can be found at <https://competitions.codalab.org/competitions/25748>.

base models and extend them, we did not make this mandatory. Participants could test the performance of their models on the development set by making predictions on the given development input data and then uploading their submissions to CodaLab for preliminary testing. We permitted up to 999 submissions in this phase. The ‘leader board’ was made public to allow participants not only to see how their models performed, but also to compare the performance of their model to those submitted by other participants.

**Evaluation phase.** The evaluation phase was the official testing phase of the competition. In this phase, we released test data (without labels) but we also released the gold labels and crowd annotations for the development set to facilitate quick offline testing and refining of models and model selection. The number of submissions for this phase was limited to ten submissions per participant to prevent the participants from fine-tuning their models on the test data.<sup>8</sup> The allowed number of submissions was later increased to 999 to more encourage submission attempts. The leader board was also kept public in this phase. Each participant could see the best model of each of the tasks using each of the evaluation metrics.

**Post-campaign evaluation.** As our aim was to make this benchmark available beyond the competition to researchers developing disagreement-aware models, we included a third, post-evaluation phase to allow lifetime access to the data. Researchers participating in this phase will be able to access the same data as in the evaluation phase and test their models on the test data for the various tasks.

## 3 Base models and baselines

In order to encourage the participants to focus on the development of methods for learning from disagreement, as opposed to achieving higher performance by developing better models, we provided ‘base’ models for each of the tasks represented by the aforementioned corpora. In this section, we briefly discuss the baseline models for each task that we provided. In Section 5, we report the results using these base models and two crowd learning approaches: majority voting and the soft loss method (Peterson et al., 2019; Uma et al., 2020).

<sup>8</sup>This proved unnecessary as the inherent difficulty of the shared task was enough of a deterrent.

**The pos tagging model.** The POS tagger is a bi-LSTM (Plank et al., 2016) with additional use of attention over the input word and character embeddings, as used in Uma et al. (2020).

**The pDIS classification model.** The model for this task was developed by comparing architectures from two models: a state-of-the-art coreference model and a state-of-the-art IS classification model. We combined the mention representation component of Lee et al.’s (2018) coreference resolution system with the mention sorting and non-syntactic feature extraction components of the IS classification model proposed by Hou (2016)<sup>9</sup> to create a novel IS classification model that outperforms Hou (2016) on the pDIS corpus. The training parameters were set following Lee et al. (2018).

**The humour preference learning model.** We use as base model for this task Gaussian process preference learning (GPPL) with stochastic variational inference, as described and implemented by Simpson and Gurevych (2020). As an input vector to GPPL, we first take the mean word embedding of a text, using 300-dimensional word2vec embeddings trained on the Google News corpus (Mikolov et al., 2013). Then, we compute the frequency of each unigram in the text in a 2017 Wikipedia dump, and each bigram in the text in a Google Books Ngram dataset. Finally, we concatenate the mean unigram and bigram frequencies with the mean word embedding vector to obtain the input vector representation for each short text. The GPPL model is trained on pairwise labels from the training set to obtain a ranking function that can be used to score test instances or output pairwise label probabilities. As a Bayesian model, it takes into account sparsity and noise in the crowdsourced training labels, and moderates its confidence accordingly. Hence, it is a strong baseline for accounting for disagreement among annotators. This same GPPL approach set the previous state of the art on the humour dataset (Simpson et al., 2019).

**The LabelMe image classification model.** For this task, we replicated the model from Rodrigues and Pereira (2018). The images were encoded using pretrained CNN layers of the vgg-16 deep neural network (Simonyan et al., 2013). This encoding is passed into a feed-forward neural network layer

<sup>9</sup>This model was developed for fine-grained information status classification on the ISNOTES corpus (Markert et al., 2012; Hou et al., 2013).

with a ReLU activated hidden layer with 128 units. A 0.2 dropout is applied to this learned representation which is then passed through a final layer with softmax activation to produce the model’s predictions.

**The CIFAR-10 image classification model.** The trained model provided for this task is the ResNet-34A model (He et al., 2016), a deep residual framework which is one of the best performing systems for the CIFAR-10 image classification. We made available to participants the publicly available Pytorch implementation of this ResNet model.<sup>10</sup>

## 4 Participating systems

Unfortunately, we observed a dramatic difference in the number of participants that signed up to the competition (over 100 groups), the number of groups that participated in the trial phase, and the number of groups that submitted a run for official evaluation.<sup>11</sup> Only one group, UOR, submitted in the evaluation phase (Osei-Brefo et al., 2021). However, they did submit models for each of the tasks, and did adopt a learning from disagreements approach.

**pos tagging.** For POS tagging, UOR developed a novel POS tagging model by fine-tuning the BERT language model (Devlin et al., 2019). The (tweet, token) pairs were encoded in the form

[CLS] Tweeted text [SEP] Token [SEP]

where the ‘[CLS]’ token was added for classification and the ‘[SEP]’ token separated the tweet from the token under consideration. To learn the class for the token, the learned classification token was passed through a single feed-forward neural network layer with softmax activation. The output of this layer represented the probabilities of the token belonging to each of the 12 classes.

To extend this model for crowd learning, UOR added an adaptation of the crowd layer from Rodrigues and Pereira (2018). Rather than compute a single loss from the crowd layer as Rodrigues and Pereira (2018) do, UOR compute a joint loss from both the crowd layer and the base model (without the crowd layer bottleneck).

<sup>10</sup><https://github.com/KellerJordan/ResNet-PyTorch-CIFAR10>

<sup>11</sup>Two participating groups cited an inability to come up with a novel crowd learning paradigm as the reason they did not submit for official evaluation.

**PDIS classification.** For this task, UOR also used a fine-tuned BERT together with [Rodrigues and Pereira’s \(2018\)](#) crowd layer. Each (document, markable) pair was encoded as follows:

[CLS] + Document + [SEP] + Markable + [SEP]

where the ‘[CLS]’ and ‘[SEP]’ tokens are used in the same manner as in POS tagging.

**Humour preference learning.** For humour preference learning, the participant submitted predictions using the base model without modifications.

**LabelMe image classification (IC-LABELME).** For this task, UOR adapted the [Rodrigues and Pereira \(2018\)](#) crowd layer to the base model.

**CIFAR-10H image classification (IC-CIFAR10H).** For IC-CIFAR10H, the crowd labels were aggregated into hard labels using majority voting. However, UOR combined [Zagoruyko and Komodakis’s \(2016\)](#) WideResNet model, which has been shown to outperform [He et al.’s \(2016\)](#) ResNet with the novel Sharpness-Aware Minimization (SAM) optimization technique, proposed by [Foret et al. \(2020\)](#), that has been shown to efficiently improve model generalization, especially on noisy, singly labelled data.

## 5 Results and discussion

Table 2 contains the results of various models discussed in Sections 3 and 4 on this shared task when evaluated based on the hard metric (i.e., the class-weighted  $F_1$  with respect to the gold labels) and the soft metric (the cross-entropy between the soft labels for each task—see Section 2.2—and the model prediction for that task). The best results for each task are highlighted in bold.

UOR concentrated their effort on the IC-CIFAR10H dataset, on which they did achieve good results and outperformed the baseline (see below). In the other datasets, their official results at the end of the evaluation phase were less competitive.

With the POS and PDIS datasets, the model proposed by UOR, adding a crowd layer on top of BERT, achieved substantially worse results than training from a label aggregated using majority voting or training using a soft-loss function, both according to the hard evaluation metric ( $F_1$ ) and the soft metric (CE). The ranking between soft-loss method, aggregation, and crowd layer with POS is consistent with that obtained by [Uma et al. \(n.d.\)](#), but the results obtained by UOR are much worse for reasons that will require further investigation. (With PDIS,

[Uma et al. \(n.d.\)](#) obtain comparable results with soft-loss functions and with the crowd layer.) More generally, the results show that although the hard label (the majority voting aggregate of the annotator distribution) and the soft label (a probability distribution encoding of the annotator distribution) were drawn from the same annotator distribution with this dataset, given the same base model, training by targeting the soft label (base model + soft loss) outperforms training using majority voting aggregates (base model + majority voting) regardless of which evaluation metric is used to compare the models.

For the humour preference learning task, again, the base model outperforms UOR’s submission on both metrics, but in this case the difference in performance between GPPL and UOR is much less substantial with the hard metric, although it remains large according to the soft metric. This large difference may be due to a technical issue that requires further investigation, since UOR’s submission was also supposed to have been produced by the same base system. A possible reason for poor cross-entropy error is the use of discrete labels, which are heavily penalized for overconfidence by cross-entropy error. On this soft metric, the Bayesian probabilistic approach of GPPL may have advantages over approaches with poorer calibration, which remains to be explored in future work. The GPPL approach therefore remains the state of the art with this dataset.

For IC-LABELME, again, soft-loss training achieved better hard and soft scores than both aggregation training with majority voting labels and the UOR extension of the base model using a crowd layer adapted from [Rodrigues and Pereira \(2018\)](#). The finding that the UOR group’s adaption of the [Rodrigues and Pereira \(2018\)](#) crowd layer yielded lower  $F_1$  than training using majority voting is unexpected, given that in [Rodrigues and Pereira \(2018\)](#); [Uma et al. \(2020\)](#) and [Uma et al. \(n.d.\)](#), the crowd layer, particularly the DL-MW variant, was shown to be a competitive approach to learning from crowds and always outperforms majority voting. However, UOR’s crowd layer does achieve better soft evaluation (cross-entropy) scores than majority voting.

There is one dataset, however, on which UOR outperformed the two baselines: IC-CIFAR10H. For this dataset, UOR used [Zagoruyko and Komodakis’s \(2016\)](#) WideResNet image classifier trained using majority voting aggregated labels and

Task	Model	Hard score (F <sub>1</sub> )	Soft score (cross-entropy)
POS	base model + majority voting	0.753	2.263
POS	base model + soft loss	<b>0.767</b>	<b>1.084</b>
POS	UOR (BERT + Crowd Layer)	0.125	2.331
PDIS	base model + majority voting	0.906	0.397
PDIS	base model + soft loss	<b>0.928</b>	<b>0.273</b>
PDIS	UOR (BERT + Crowd Layer)	0.474	0.830
HUMOUR	base model (GPPL)	<b>0.557</b>	<b>0.728</b>
HUMOUR	UOR	0.513	3.697
IC-LABELME	base model + majority voting	0.806	2.833
IC-LABELME	base model + soft loss	<b>0.833</b>	<b>1.691</b>
IC-LABELME	UOR (base model + Crowd Layer)	0.784	1.769
IC-CIFAR10H	base model + majority voting	0.646	2.610
IC-CIFAR10H	base model + soft loss	0.698	1.052
IC-CIFAR10H	UOR (WideResNet + SAM)	<b>0.769</b>	<b>0.827</b>

Table 2: Results on the benchmarks and participant submissions on all the tasks using F<sub>1</sub> (higher is better) and cross-entropy (lower is better)

Foret et al.’s (2020) SAM optimization technique. The results show that WideResNet outperforms ResNet with this task both according to the hard metric and the soft metric. Interestingly, this is the one dataset in which the Deep Learning from Crowds approach of Rodrigues and Pereira (2018) works best according to Uma et al. (n.d.), outperforming both soft-loss training and majority voting training. It would thus be interesting to understand if the performance of UOR’s model could be further increased by adopting one of these methods.<sup>12</sup>

## 6 Conclusion

This shared task presented the first unified testing framework for learning with disagreements. The datasets include sequence labelling, three classification tasks, and preference learning, hence provide a testbed for a wide range of challenges when learning from multiple annotators. We proposed to evaluate not just the ‘hard’ performance against a gold standard, but also the ability to predict the distribution of different interpretations of the data—that is, the alternative labellings provided by different annotators. The results show the benefit of soft loss functions that account for the distribution of labels in the training data. However, modelling alternative

<sup>12</sup>As a postscript, we should note that after the end of the official competition we did carry out an investigation of the reasons for the poor performance of UOR’s models on the tasks other than IC-CIFAR10H. Some points emerging from the discussion are presented in the participants’ paper for the shared task.

interpretations of data remains an under-researched topic in NLP and computer vision. To encourage future work on learning with disagreements, the shared task and datasets will remain available for evaluating new methods.

## Abstract

This paper presents the Source-Free Domain Adaptation shared task held within SemEval-2021. The aim of the task was to explore adaptation of machine-learning models in the face of data sharing constraints. Specifically, we consider the scenario where annotations exist for a domain but cannot be shared. Instead, participants are provided with models trained on that (source) data. Participants also receive some labeled data from a new (development) domain on which to explore domain adaptation algorithms. Participants are then tested on data representing a new (target) domain. We explored this scenario with two different semantic tasks: negation detection (a text classification task) and time expression recognition (a sequence tagging task).

## 1 Introduction

Data sharing restrictions are common in NLP datasets. For example, Twitter policies do not allow sharing of tweet text, though tweet IDs may be shared. The situation is even more common in clinical NLP, where patient health information must be protected, and annotations over health text, when released at all, often require the signing of complex data use agreements.

The Source-Free Domain Adaptation shared task presents a new framework that asks participants to develop semantic annotation systems in the face of data sharing constraints. A participant’s goal is to develop an accurate system for a target domain when annotations exist for a related domain but cannot be distributed. Instead of annotated training data, participants are given a model trained on the annotations. Then, given unlabeled target domain data, they are asked to make predictions. This is

a challenging setting, and much previous work on domain adaptation does not apply, as it assumes access to source data (Ganin et al., 2016; Ziser and Reichart, 2017; Saito et al., 2017; Ruder and Plank, 2018), or assumes that labeled target domain data is available (Daumé III, 2007; Xia et al., 2013; Kim et al., 2016; Peng and Dredze, 2017).

Two different semantic tasks in English were created to explore this framework: negation detection and time expression recognition. These represent two common types of classification tasks: negation detection is typically formulated as predicting an attribute of a word or span given its context, and time expression recognition is typically formulated as a named entity tagging problem. Both of these tasks have previously been run as shared tasks, and had at least two different domains of data available, and we had access to experienced annotators for both tasks, allowing us to annotate data in a new domain.

Negation detection is the task of identifying negation cues in text. This task has been widely studied by previous work (Chapman et al., 2007, 2001; Harkema et al., 2009; Sohn et al., 2012) including the development of a variety of datasets (Uzuner et al., 2011; Mehrabi et al., 2015). However, there are still large performance losses in the cross-domain setting (Wu et al., 2014).

For negation detection, we provided a “span-in-context” classification model, fine-tuned on instances of the SHARP Seed dataset of Mayo Clinic clinical notes, which the organizers have access to but cannot currently be distributed. (Models were approved to be distributed, as the data is de-identified.) In the SHARP data, clinical events are marked with a boolean polarity indicator, with values of either asserted or negated. As development

	Source Collection	Source Domain	Instances	Negated instances
train	SHARP Seed	Mayo Clinic clinical notes	10,259	902
dev	i2b2 2010	Partners HealthCare clinical notes	5,545	1,115
test (unlabeled)	MIMIC III	Beth Israel ICU progress notes	622,703	-
test (labeled)	MIMIC III	Beth Israel ICU progress notes	9,580	958

Table 1: Size of the negation detection datasets. The train set is never distributed to the participants.

	Source Collection	Source Domain	Documents	Time entities
train	THYME	Mayo Clinic clinical notes	278	18,020
dev	TimeBank	News	99	2,231
test (unlabeled)	-	Food security	47	-
test (labeled)	-	Food security	17	1,900

Table 2: Size of the time expression recognition datasets. The train set is never distributed to the participants.

data, we used the i2b2 2010 Challenge Dataset, a de-identified dataset of notes from Partners HealthCare. The evaluation dataset for this task consisted of de-identified intensive care unit progress notes from the MIMIC III corpus (Johnson et al., 2016).

Time expression recognition has been a key component of previous temporal language related competitions, like TempEval 2010 (Pustejovsky and Verhagen, 2009) and TempEval 2013 (UzZaman et al., 2013). For this task, we followed the Compositional Annotation of Time Expressions (SCATE) schema (Bethard and Parker, 2016) used in SemEval 2018 Task 6 (Laparra et al., 2018). As in negation detection, previous works have also observed a significant performance degradation on domain shift (Xu et al., 2019).

For time expression recognition, we provided a sequence tagging model, fine-tuned on de-identified clinical notes from the Mayo Clinic, which were available to the task organizers, but are difficult to gain access to due to the complex data use agreements necessary. (Models were approved to be distributed, as the data is deidentified.) The development data was the annotated news portion of the SemEval 2018 Task 6 data whose source text is from the freely available TimeBank. For evaluation, we used a set of annotated documents extracted from food security warning systems.

The main impact of this task is to drive the NLP community to address the serious challenges of data sharing constraints by designing new domain adaptation algorithms that allow source data and target data to remain separate, rather than assuming they can be shared freely with each other.

## 2 Data and Resources

In this section, we describe both negation detection and time expression recognition tasks, the models fine-tuned on a difficult-to-obtain set of annotated data, the development data representing a new domain on which participants can explore their approaches for domain adaptation, and the test data representing another new domain on which the systems developed by participants are evaluated. Details of the different data sets can be found in Tables 1 and 2.

### 2.1 Negation detection

The negation detection track asks participants to classify clinical event mentions (e.g., diseases, symptoms, procedures, etc.) for whether they are being negated by their context.

For example, the sentence:

- (1) *Has no diarrhea and no new lumps or masses*

has three relevant events (diarrhea, lumps, masses), two cue words (both *no*), and all three entities are negated. This task is important in the clinical domain because it is common for physicians to document negated information encountered during the clinical course, for example, when ruling out certain elements of a differential diagnosis.

This task can be treated as a “span-in-context” classification problem, where the model jointly considers both the event to be classified and its surrounding context. For example, a typical transformer-based encoding of this problem for the *diarrhea* event in the example above looks like:

- (2) *Has no <e> diarrhea </e> and no new lumps or masses .*

**Pre-trained model** Participants were provided with a “span-in-context” classification model, trained on the 10,259 instances (902 negated) in the SHARP Seed dataset of de-identified clinical notes from Mayo Clinic, which the organizers had access to but cannot currently be distributed. In the SHARP data, clinical events are marked with a boolean polarity indicator, with values of either ASSERTED or NEGATED.

**Development data** Participants could use as development data the i2b2 2010 Challenge Dataset, a de-identified dataset of notes from Partners Health-Care, containing 5,545 entities labeled with an assertion status in the set {ASSERTED, NEGATED, UNCERTAIN, HYPOTHETICAL, CONDITIONAL, FAMILYRELATED}. We provided scripts that extracted i2b2 entities and simplified the label set to {NEGATED, NOTNEGATED}. Since the i2b2 2010 dataset consisted of notes from two sources, Partners and MIMIC III, the latter of which overlaps with our proposed test set, our script also filtered the development instances to contain only those from the Partners notes.

**Test data** During the testing period, participants were provided with the raw text of 622,703 instances drawn from the MIMIC III corpus<sup>1</sup>, which contains manually de-identified progress notes for patients from the intensive care unit of Beth Israel Deaconess Medical Center, with entities of interest already identified. From this, we manually annotated 9,580 instances of which 958 were negated.

## 2.2 Time expression recognition

The time expression recognition track, which represents a sequence-tagging task, uses the fine-grained time expression annotations that were a component of SemEval 2018 Task 6 (Laparra et al., 2018). For example:

- (3) In 

MONTH-OF-YEAR
January

 of 

YEAR
2009

, she experienced acute onset lower abdominal pain 

NUMBER
four to five

PERIOD
hours

AFTER
after

 her meal.

This task can be treated as a sequence classification problem, as in other named-entity tagging tasks.

<sup>1</sup><https://mimic.physionet.org/>

**Pre-trained model** Participants were provided with a sequence tagging model, trained on the 18,020 time expressions in the clinical portions of the SemEval 2018 Task 6, that were available to the task organizers, but are currently difficult to gain access to due to the complex data use agreements.

**Development data** Participants could use as development data the annotated news portion of the SemEval 2018 Task 6 data. The source text is from the freely available TimeBank<sup>2</sup>, and the 2,231 time entity annotations were from the freely available SCATE GitHub repository<sup>3</sup>.

**Test data** During the testing period, participants were provided with the raw text of 47 reports drawn from food security warning systems<sup>4</sup> and asked to predict time expressions. From this, we used 17 documents that included 1,900 time entities, annotated by two independent annotators and an adjudicator.

## 3 Evaluation Metrics

Negation detection was evaluated using the precision/recall/ $F_1$  of the negated class, as used in most published work. Time expression recognition was evaluated using the standard precision/recall/ $F_1$  previously used for the entity-finding portion of SemEval 2018 Task 6.

In both cases, the metrics are defined as:

$$P(S, H) = \frac{|S \cap H|}{|S|}$$

$$R(S, H) = \frac{|S \cap H|}{|H|}$$

$$F_1(S, H) = \frac{2 \cdot P(S, H) \cdot R(S, H)}{P(S, H) + R(S, H)}$$

where  $S$  is the set of items predicted by a system and  $H$  is the set of items manually annotated by humans.

## 4 Baseline Systems

To provide a comparison benchmark, we proposed two baselines for both negation detection and time expression recognition:

<sup>2</sup><https://www.cs.york.ac.uk/semeval-2013/task1/index.php%3Ffid=data.html>

<sup>3</sup><https://github.com/bethard/anafora-annotations>

<sup>4</sup>Like the UN World Food Programme <https://www.wfp.org/> or the Famine Early Warning Systems Network <https://fews.net/>.

Sub-task	System	source			dev			test		
		<i>P</i>	<i>R</i>	<i>F</i> <sub>1</sub>	<i>P</i>	<i>R</i>	<i>F</i> <sub>1</sub>	<i>P</i>	<i>R</i>	<i>F</i> <sub>1</sub>
Negation	Src-Trained	-	-	0.820	0.851	0.818	0.834	0.917	0.516	0.660
Negation	Dev-Tuned	-	-	-	-	-	-	0.908	0.611	0.730
Time Expression	Src-Trained	0.967	0.968	0.968	0.775	0.768	0.771	0.849	0.746	0.794
Time Expression	Dev-Tuned	-	-	-	-	-	-	0.827	0.782	0.804

Table 3: Performance of the baselines on the source domain, where **Source-Trained** (*Src-Trained*) was trained, and the two target domains (dev and test). For **Dev-Tuned**, dev set was also used for training.

**Source-Trained** Models pre-trained on only the source train data, i.e., the models that the organizers shared with the participants as explained in Section 2.

**Dev-Tuned** Models pre-trained on the source data (i.e., **Source-Trained**) and then fine-tuned on the labeled dev data.

All baselines were built on RoBERTa (Liu et al., 2019) using the HuggingFace Transformers library.<sup>5</sup>

Table 3 shows the performance of the baselines on negation detection and time expression recognition respectively. In both cases, there is a big drop in the performance of **Source-Trained** when it is applied to out-of-domain datasets. Using the development data to continue training the model (**Dev-Tuned**) provides some improvement for both tasks, but it is still far from in-domain performance.

## 5 Participating Systems

Since our goal was to see a set of experiments as varied as possible, we did not impose any constraint on the approaches participants could submit, including the use of any of the unlabeled or labeled data provided. The task had 9 participants that submitted 20 unique runs in total, as shown in Table 4. For each task, 2 submissions per team were allowed. There were 5 participants and 8 submission in **negation detection**, and 7 participants and 12 submissions in **time expression recognition**. Only 3 participants took part in both tasks.

### 5.1 Negation detection

*BLCUFIGHT-1* tried a self-training method fixing the top classifier so only the feature extractor was updated. Then, they ran an ensemble of 3 models. *BLCUFIGHT-2* built an unlabeled dataset selecting

<sup>5</sup><https://github.com/huggingface/transformers>.

2,000 instances from the development set, 2,000 from the test set and 2,886 from the training set. They used that unlabeled dataset progressively to continue fine-tuning the distributed model (for 2 epochs) following a self-learning approach. They additionally selected some negative prefixes and negative words as rules. The final predictions were obtained from an ensemble of 5 models.

*UArizona-1* used the development data to continue fine-tuning the distributed model (for 10 epochs). Then, they randomly sampled 3,000 examples from unlabeled test data and performed 2 self-learning iterations, using a 0.95 threshold to filter the pseudo training examples.

*IITK-1* also adapted the model with pseudo labels obtained from a sample of 25,000 instances from the test data. They selected predictions with low entropy as the pseudo training examples, performed data-augmentation on the selected instances, and used the resulting set to continue training the distributed model. *IITK-2* applied an adaptive version of this approach by slowly increasing the entropy threshold after each epoch and filtering again the training instances.

*MedAI-1* and *MedAI-2* followed a self-learning strategy preceded by a negation-aware pre-training process. For the latter, they built a dataset applying some heuristics on the test data. First, they manually collected a dictionary including negation cues, such as “not”, “no”, “no longer”. Second, they selected the nouns within a 3 token window around occurrences of the negation cues. Finally, they labeled the cue-noun pairs as negated instances.

**Observations:** Self-learning was the most widely applied technique (6 out of 8 submissions). 3 submissions extended this with heuristics, 2 submissions extended it with data augmentation, and 2 applied it with a model ensemble. Only 2 submissions leveraged the development set of which only 1 used the labeled data. All the

<sup>†</sup> We did not receive feedback for these submissions.

Table 4: Some details on the tasks submissions. For each submission, the table reflects the **task** (*neg.* stands for negation) where it participates, if it uses the *unlabeled* or *labeled* development data (**dev data**), if it uses the *unlabeled test data*, if participants carried out some manual or heuristics-based **annotation**, if **other** source of data is used and the **main techniques** applied. List of abbreviations in the *main technique* column: *act-learn* for active learning, *dt-augm* for data augmentation, *ens* for ensemble, *heur* for heuristics, *neg-train* for negation-aware pre-training, *sf-learn* for self learning, *sf-train* for self training, *teach* for mean teacher.

submissions but one used the unlabeled test data to produce a training set for the target domain, either in the form of pseudo-labeled instances (5 submissions) or by heuristic-driven annotation (2 submissions). No submissions used additional resources.

## 5.2 Time expression recognition

*BLCUFIGHT-1* and *BLCUFIGHT-2* proposed an unsupervised mean-teacher framework that updates the model in a self-learning manner. Additionally, they used a set of string-matching heuristics derived from the development set, e.g., “spring” or “summer” for Season-Of-Year, and “decades” for Period. *BLCUFIGHT-1* ensembled 2 models for a better robustness.

*Self-Adapter-1* and *Self-Adapter-2* generated pseudo training examples by running the provided model on the test documents and selecting the sentences where the highest words’ entropy was lower than 0.1. In *Self-Adapter-1*, they combined the

predictions of both a fixed version and a trainable version of the model. *Self-Adapter-2* used only the trainable model. In both submissions, the trainable model was updated by applying 3 iterations of the *sloughing trick*, i.e., training the model iteratively with the pseudo-labels obtained by the model of the previous iteration.

*PTST-UoM-1*, also following a self-training approach, built, for each unlabeled input sentence, a chart containing high probability label sequences produced by the distributed model and applied it as a supervision signal. They used the labeled development data for tuning some of the hyperparameters.

*UArizona-1* combined active learning and data augmentation. They ran 5 iterations of the following steps: 1) predict the unlabeled test data and then select 32 sentences with high entropy calculated as the sum of the entropy of all tokens in the sentence; 2) manually label time entities in the 32 sentences; 3) for each manually labeled time entity, generate

5 additional training examples using 5 new words with same entity type; 4) train the model on the resulting dataset. The same method was used by *UArizona-2*, but, in this case, they fixed some errors in the manual annotations.

*KISNLP-1* and *KISNLP-2* used the development labeled data as a fine-tuning resource, which was complemented by a data augmentation process. They did not use the unlabeled test data, nor any other resource.

*YNU-HPCC-1* and *YNU-HPCC-2* also used the labeled portion of the development set. They fine-tuned 4 popular transformer-based pre-trained models: RoBERTa, BERT (Devlin et al., 2019), DistilBERT (Sanh et al., 2020) and ALBERT (Lan et al., 2020). The final prediction was given by hard voting strategy, integrating the results of the 4 models along with **Source-Trained**.

**Observations:** Self-learning (5 submissions) and data augmentation (4 submissions) were the most commonly followed approaches. 2 submissions extended a self-learning technique with manually created heuristics. Only 3 submissions proposed ensemble methods. In this task, the development set was more frequently exploited and 4 submissions made use of the labeled data to continue fine-tuning the provided model. The test set was manually annotated by 2 submissions that followed an active learning approach, along with some additional resources. 4 submissions did not use the unlabeled test data.

## 6 Evaluation Results

Tables 5 and 6 shows the performance of the systems described in Section 5 on negation detection and time expression recognition. For comparison, the tables also include the performance of the baselines described in Section 4.

### 6.1 Negation detection

As shown in Table 5, 7 out of 8 submissions on negation detection outperform **Source-Trained** but only 4 performed better than **Dev-Tuned**.

The best results were obtained by *MedAI-1* and *MedAI-2*, achieving 16.2 and 9.2 percentage points of  $F_1$  more than **Source-Trained** and **Dev-Tuned**, respectively. These model had a large recall improvement (14.5 points more than **Source-Trained** and 24.0 more than **Dev-Tuned**) at the expense of a slight degradation in precision.

System	$P$	$R$	$F_1$
MedAI-1 <sup>†</sup>	0.902	<b>0.756</b>	<b>0.822</b>
MedAI-2 <sup>†</sup>	0.902	<b>0.756</b>	<b>0.822</b>
UArizona-1 <sup>+†</sup>	0.880	0.680	0.767
BLCUFIGHT-2 <sup>*†</sup>	0.913	0.616	0.736
IITK-2 <sup>†</sup>	0.876	0.624	0.729
Boom-1	0.929	0.597	0.727
IITK-1 <sup>†</sup>	<b>0.939</b>	0.566	0.706
BLCUFIGHT-1	0.528	0.639	0.578
Dev-Tuned	0.908	0.611	0.730
Source-Trained	0.917	0.516	0.660

Table 5: Official results (ranked by  $F_1$ ) on negation detection. Superscripts indicate that the submission used: \*unlabeled dev, +labeled dev or †unlabeled test data

*IITK-1* and *Boom-1* outperform both baselines in terms of precision but obtain a worse recall than **Dev-Tuned**.

The 3 best submissions on this task (*MedAI-1*, *MedAI-2* and *UArizona-1*) make use of some kind of labeled data. In the case of *MedAI-1* and *MedAI-2*, this data belongs to the target test domain, which could explain the good results of these 2 submissions. *BLCUFIGHT-2*, the next best performing system and the only other one that outperforms both baselines, also applies some manual supervision in the form of hand-crafted rules.

In general, self-learning proved to be an effective technique for negation detection, especially in terms of recall, while data-augmentation also shows recall improvements in some cases. As usual, ensemble models are helpful. Including some manual supervision drove the largest gains.

### 6.2 Time expression recognition

Table 6 shows that for time expression recognition, 9 out of 12 submissions outperformed **Source-Trained** and only 3 obtained a better performance than **Dev-Tuned**. The gains were generally smaller than on negation detection, with the best models being only 2.1 percentage points of  $F_1$  above **Source-Trained** and 1.1 percentage points above **Dev-Tuned**.

As in negation detection, the best performing system (*BLCUFIGHT-1*) utilizes some form of manual supervision. In this case, they apply a set of manually created string matching heuristics in combination with a *self-learning* approach that is boosted by a model ensemble.

In this task, the use of the labeled development

System	$P$	$R$	$F_1$
BLCUFIGHT-1* <sup>†</sup>	0.847	0.785	<b>0.815</b>
Self-Adapter-1 <sup>†</sup>	0.873	0.757	0.811
BLCUFIGHT-2* <sup>†</sup>	0.834	0.787	0.810
YNU-HPCC-2 <sup>+</sup>	0.817	0.791	0.803
Self-Adapter-2 <sup>†</sup>	0.839	0.760	0.797
PTST-UoM-1 <sup>++</sup>	<b>0.901</b>	0.713	0.796
UArizona-1 <sup>†</sup>	0.786	0.804	0.795
UArizona-2 <sup>†</sup>	0.783	<b>0.807</b>	0.795
Boom-1	0.869	0.732	0.795
KISNLP-1 <sup>+</sup>	0.810	0.777	0.793
KISNLP-2 <sup>+</sup>	0.798	0.764	0.781
YNU-HPCC-1 <sup>+</sup>	0.872	0.655	0.748
Dev-Tuned	0.827	0.782	0.804
Source-Trained	0.849	0.746	0.794

Table 6: Official results (ranked by  $F_1$ ) on time expression recognition. Superscripts indicate that the submission used: \*unlabeled dev, +labeled dev or <sup>†</sup>unlabeled test data

set is more frequent. 5 of the submissions made use of this data, but none obtained better results than **Dev-Tuned**, although *YNU-HPCC-2* got a close  $F_1$  score. In the case of *PTST-UoM-1*, this explained by the fact that they only consulted this set to fine-tune the hyperparameters of their model, although this strategy was enough to obtain the best precision among all systems. The approach of *KISNLP-1* and *KISNLP-2* is the same as **Dev-Tuned** but combined with some data-augmentation, resulting in a drop in performance. This may be caused by only using the development set to perform the augmentation since, after all, it belongs to a different domain than the test documents. *YNU-HPCC-2* is the only submission, along with *YNU-HPCC-1*, that utilized other pre-trained transformers, in an ensemble mode, besides the model provided.

*UArizona-1* and *UArizona-2* are the only submissions that tried an *active learning* strategy. The approach performed slightly better than **Source-Trained** but worse than **Dev-Tuned**. This contrasts with the best performing model on negation detection that also implemented a manual annotation process on test data, but it is explained by the much more complex annotation scheme of time expressions. *UArizona-2* obtains the best recall on the task.

*Self-Adapter-1* is the only submission that outperforms **Dev-Tuned** without using any kind of manual supervision. The only difference with re-

spect to *Self-Adapter-2*, that did not perform as well, is that the original model trained on the source domain is consulted to produce pseudo-examples in every iteration of their self-learning technique. This seems to counteract a possible degradation of the predictions caused by updating the model with pseudo-labels.

## 7 Future directions

Self-learning and data augmentation were the most frequently used techniques. Some systems, including the best performing ones, incorporated some kind of manual supervision in the form of active-learning, hand-crafted heuristics or semi-automatically building a training set. This suggests that future work on source-free domain adaptation will focus on acquiring data instances for the target domain either automatically or manually, and use such data to continue fine-tuning the source-domain model.

Any new approaches will have to address some fundamental challenges. Errors in the generation of pseudo-labels propagate in successive self-learning iterations degrading the performance. Continual fine-tuning on data from a new domain can lead to catastrophic forgetting, especially if the data is restricted to certain instances like those drawn from high-confident predictions of the source model. Manually supervised approaches, such as active learning, do not necessarily solve these problems due to the complexity of some annotation schemes, like in time expressions recognition, and the reduced number of labels that this methods can yield.

Some of the experiments carried out during this task have approached these issues and should be taken as an starting point for future research.

## 8 Conclusion

In this paper, we have described the Source-Free Domain Adaptation shared task held within SemEval-2021. In this task, participants were asked to adapt a given model to a target domain when the access to both labeled and unlabeled source data is restricted. In contrast to previous tasks on domain adaptation, participants were only provided with a trained model and the target unlabeled data. Systems were evaluated on two tasks, negation detection and time expression recognition, that are paradigmatic examples of two common types of machine-learning problems in natural language processing: text classification and sequence

labeling.

9 participants took part in the challenge with 20 different systems. In negation detection, 8 submissions were received from 5 participants while 7 participants submitted 12 runs for time expression recognition. 3 participants presented approaches for both tasks. 7 out of 8 submissions for negation detection and 9 out of 12 submissions for time expression recognition outperformed the model trained on the source domain. Compared to the same model fine-tuned on the development data, 4 systems in negation detection and 3 in time expression recognition showed a better performance.

This is the first time that such a framework is formally designed and aims to draw the community's attention to a challenging problem that seriously affects the deployment of NLP models to real-life scenarios, like health institutions.

The scripts and the code of the baselines, along with the development and test data, can be obtained from the task's GitHub repository.<sup>6</sup> The trained models are available in the HuggingFace model hub for both negation detection<sup>7</sup> and time expression recognition.<sup>8</sup> The CodaLab<sup>9</sup> leader-board of the of the post-evaluation phase will continue to accept submissions indefinitely.

## Abstract

Domain adaptation assumes that samples from source and target domains are freely accessible during a training phase. However, such assumption is rarely plausible in the real-world and may cause data-privacy issues, especially when the label of the source domain can be a sensitive attribute as an identifier. SemEval-2021 task 10 focuses on these issues. We participate in the task and propose novel frameworks based on self-training method. In our systems, two different frameworks are designed to solve text classification and sequence labeling. These approaches are tested to be effective which ranks the third among all systems in subtask A, and ranks the first among all systems in subtask B.

## 1 Introduction

Deep neural networks have achieved remarkable success in a variety of applications across different fields while with huge expense of laborious large-scale training data annotation. To avoid expensive data labeling, domain adaptation (DA) methods were proposed to fully utilize previously labeled datasets and unlabeled data on hand in a transductive manner, which obtained promising results in sentiment analysis, part-of-speech tagging, machine translation, etc. (Glorot et al., 2011; Yang and Eisenstein, 2014; Chu and Wang, 2018)

Unsupervised Domain Adaptation (UDA) aims to reduce the domain shift between labeled and unlabeled target domains. Early works (Blitzer et al., 2006; Pan et al., 2010) learnt domain-invariant features to link the target domain to the source domain. Along with the growing popularity of deep learning, plenty of works benefited from its powerful representation learning ability for domain adaptation. Those methods typically minimized the distribution discrepancy between two domains (Plank et al., 2014), or deployed adversarial training (Ganin and Lempitsky, 2015; Bousmalis et al., 2016; Li et al., 2018).

However, a crucial requirement in the methodology of these methods is that all samples from both domains are freely available during the training process, which is inefficient in data transmission and may violate the data privacy policy. For example, it is not allowed to share tweet texts according to Twitter policies, though tweet IDs can be shared. The situation is even more common in clinical NLP, where patient health information must be protected, and annotations over health text, when released at all, often require the signing of complex data use agreements.

SemEval 2021 task 10 focuses on the problem of source-free domain adaptation for semantic processing. Subtask A of task 10 is negation detection which aims to classify clinical event mentions (e.g., diseases, symptoms, procedures) for whether they are being negated by their context. Traditional systems, such as one of the first algorithms NegEx (Chapman et al., 2001) was based on rules. Subsequently, syntax-based methods were developed (Huang and Lowe, 2007; Mehrabi et al., 2015). In recent years, some researchers explored new generation of transfer learning models (BERT) to solve this task (Khandelwal and Sawant, 2019), outperforming the previous state-of-the-art systems by a significant margin.

Subtask B of task 10 is time expression recognition which aims to find time expressions in text. It is a sequence labeling task as (Laparra et al., 2018) described in their work. A few of works combined traditional machine learning with rules achieved good performances (Olex et al., 2018). Some studies got character-level contextual embeddings (Xu et al., 2019) and applied to this task, yielding major performance improvements over the previous state-of-the-art.

In this paper, we propose two different unsupervised frameworks for each subtask in source-free setting. For negation detection task, we design a framework which obtains pseudo labels with high

confidence by using reliable pseudo labels as prototypes. For time expression recognition, we design an unsupervised teacher-student framework with Mean Teacher.

## 2 System description

For subtask A, we used a pseudo-labeling training method. To reduce the uncertainty from the pseudo labels, we only chose those with high confidence to fine-tune the model. Finally, we ensembled 5 models to make the model have better robustness and results. For subtask B, we started by data pre-processing. Then, we enlarged the training set with pseudo-labeled sentences, which were predicted on the test set by teacher model. In addition, Mean Teacher helps to generate better pseudo labels. Finally, we used the ensemble model to make predictions and add manual expressions. Each module will be introduced in detail in the following sections.

### 2.1 subtask A: Negation detection

#### 2.1.1 Pre-processing

Samples in the test data was split by punctuation to a single sentence which included the entity being detected. This was done to avoid the impact of the irrelevant context. All white spaces were removed.

#### 2.1.2 Architecture

For negation detection, we utilized the RoBERTa-base (Liu et al., 2019) pretrained model fine-tuned on the 10,259 instances (902 negated) in the SHARP Seed dataset which is different from the target domain. To adapt the source domain to the target domain, we kept the feature extractor of the source model fixed and trained the classifier module by using pseudo labels with high confidence (He and Zhou, 2011). It aims to learn a domain-specific classifier learning module.

Our model is composed of two parts, the first part is Adaptive Prototype Memory (APM) (Kim et al., 2020), which provides pseudo labels with high confidence for the target model. The second part is the target model where parameters of the feature extractor are fixed, i.e., does not participate in training. The overall architecture of our model is shown in Fig.1

**Pseudo Labeling:** Pseudo labeling (Lee et al., 2013) was originally proposed for semi-supervised learning. Since Pseudo labeling is a simple and efficient method, it gains popularity in other trans-

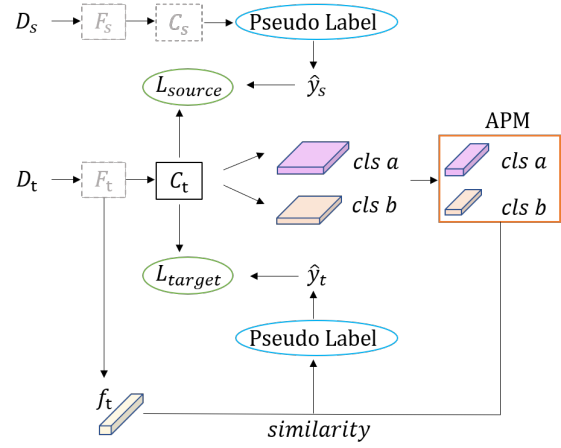

Figure 1: Overall flow of subtask A framework. In the figure, **D**, **F**, **C** and **L** represent Data, Feature extractor, Classifier and Loss, respectively. The subscripts **s** and **t** indicate whether they come from the source domain or the target domain. Dashed lines indicate fixed model parameters.

ductive learning problems like **Domain Adaptation**. The main idea is to label unlabeled data with the maximum predicted probability and perform fine-tuning together with labeled data. For this task, we don't have labeled training data, so our method uses a more reliable pseudo-labels to fine-tune the model.

**APM:** To obtain reliable pseudo labels, prediction uncertainty is measured by self-entropy, i.e.,  $H(x) = -\sum p(x)\log(p(x))$ . The smaller the entropy is, the more confidence of the prediction is. First of all, we calculated the normalized self-entropy of target samples.

$$H(x_t) = -\frac{1}{\log N_c} (x_t) \log(l(x_t))$$

where  $N_c$  refers to the number of classes,  $l(x_t)$  is the output of the target classifier,  $x_t$  represents the samples from the target domain. The next step is to select the reliable part among all target samples, i.e., the part with smaller entropy. In order to minimize the influence of incorrect pseudo labels, we chose 20% as a threshold to get reliable samples. So the top 20% target samples of the smaller entropy are stored in the APM.

Based on prototypes from APM module which can represent each class, we can assign labels to unlabeled target data according to similarity score:

$$S(x_t) = \frac{1}{|M_c|} \sum_{p_c \in M_c} \frac{p_c^T f_t}{\|p_c\|_2 \|f_t\|_2}$$

where  $c$  represents two classes, i.e., “negated” or “not negated”,  $f_t$  and  $p_c$  stand for the embedded feature of target data and prototype respectively.

**Loss Function:** Pseudo labels generated by the first part are used to train the classifier of the target model. During the training process, to avoid the influence of unstable pseudo labels, our loss consists of two parts. One is the loss of the source classifier, and the other is the loss of the trainable target classifier.

$$L_{total}(D_t) = (1 - \alpha)L_{source}(D_t) + \alpha L_{target}(D_t)$$

At the beginning, loss of the source classifier accounts for a large proportion, it is added for regularization, because the generated label may be unstable. With the increase of training steps, the proportion of source decreases gradually, while the proportion of the loss of the target classifier increases.

### 2.1.3 Ensembling

To obtain a more robust model, we trained five models by changing the hyper parameters, and integrated the five models by voting ensemble method. Test data were passed through the ensembled model as the final output of the system.

## 2.2 Subtask B: Time expression recognition

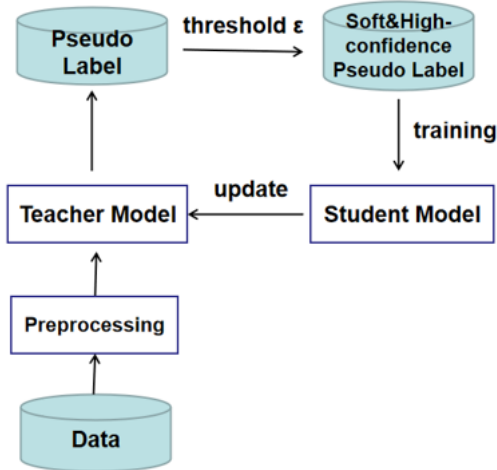

Figure 2: Overall flow of subtask B framework

### 2.2.1 Pre-processing

- Denoising: Since the first two lines of the development set text are the descriptions of the file name and would not appear in the test set, we removed the first two lines of all verification set texts.

- Training set: Development set and randomly selected partial test set.

### 2.2.2 Teacher and Student architecture

The main part of our system for subtask B is the teacher-student framework (Liang et al., 2020), which is an unsupervised method. Specifically, The teacher model is initialized by student model. To avoid losing too much information of other classes, we proposed to use soft labels. Recall that for the  $n$ -th token in the  $m$ -th sentence, the output probability simplex over  $C$  classes is denoted as:

$$[f_{n,1}(X_m; \theta), \dots, f_{n,C}(X_m; \theta)].$$

After the teacher model generated soft labels from training set (let denote  $\{S_m = [s_{m,n}]_{n=1}^N\}_{m=1}^M$  the soft pseudo-labels generated from teacher model), in order to further address the uncertainty in the data, we selected tokens based on the prediction confidence. That is to say, we selected a set of high confidence tokens from the  $m$ -th sentence by

$$H_m = \{n : \max_c s_{m,n,c} > \epsilon\},$$

where  $\epsilon \in (0, 1)$  is a tuning threshold. The high confidence selection essentially enforces the student model to better fit tokens with high confidence, and therefore is able to improve the model robustness against low-confidence tokens. Loss1 is denoted as:

$$Loss1 = \frac{1}{M} \sum_{m=1}^M \ell_{KL}(S_m^{(t)}, f(X_m; \theta))$$

where  $\ell_{KL}(\cdot, \cdot)$  denotes the KL-divergence-based loss:

$$\ell_{kl}(S_m, f(X_m; \theta)) = \frac{1}{|H_m|} \sum_{n \in H_m} \sum_{c=1}^C -s_{m,n,c} \log f_{n,c}(X_m; \theta).$$

### 2.2.3 Mean Teacher

In our architecture, we also added Mean Teacher loss to update student model. Mean Teacher (Tarvainen and Valpola, 2017) is a simple but effective method to improve teacher model performance. After the weights of the student model have been updated with gradient descent, the teacher model weights are updated as an moving average of the student weights as follows:

$$\theta'_t = \alpha\theta'_{t-1} + (1 - \alpha)\theta_t,$$

where  $\alpha$  is a smoothing coefficient hyperparameter. Loss2 denote Mean Teacher loss (same as the formula in 2.2.2), but  $\ell_{KL}(\cdot, \cdot)$  denotes:

$$\ell_{kl}(S_m, f(X_m; \theta)) = \frac{1}{N} \sum_{n=1}^N \sum_{c=1}^C -s_{m,n,c} \log f_{n,c}(X_m; \theta).$$

Accordingly, the student model can be optimized by minimizing the loss (consists of Loss1 and Loss2).

The process described above is repeated periodically to train the student model. Eventually, early stopping is adapted to prevent student model from overfitting.

#### 2.2.4 Post-processing

- **Ensembling:** Ensemble has shown its power on effectively improving the robustness and accuracy of each individual prediction (Opitz and Maclin, 1999; Rokach, 2010). By ensembling predictions from models with different hyper-parameters or architectures, we can get better results than each individual model. In our system, we set different hyper-parameters on learning rate and random seed. In this case, two ensemble model generate predictions individually and we take the union of the two independent predictions as model predictions.
- **Manual rules:** Through observation on the data, we obtained a set of feature words which appear frequently. Specifically, we labeled feature words “daily” and “annual” with “Calendar-Interval”, label “minutes” and “decades” with “Period”, label “ago” and “before” with “Before” etc.

### 3 Experiments

#### 3.1 Data

SemEval 2021 Task 10 released the training, development and test dataset.

For subtaskA, the development data is the i2b2 2010 Challenge Dataset, a de-identified dataset of notes from Partners HealthCare, containing 2886 unlabeled train instances (entities in sentence context), and 5545 dev instances with a corresponding labeling for with negation status. The test data is from the MIMIC III corpus v1.4, which is much

	Train	Dev	Test
Positive	-	1115	958
Negative	-	4430	8622
Total	2886	5545	9580

Table 1: Data distribution of subtask A.

messier than the development data. The detailed statistics are shown in Table 1.

For subtask B, we found that the category labels were severely imbalanced. Specifically, the training set and the dev set have label types which are not mutually exclusive. In addition, the dev set labels is mainly distributed in Month-Of-Year, Day-Of-Month, Period, etc., while the test set labels are mainly distributed in Month-Of-Year, Season-Of-Year, Year, etc.

#### 3.2 Evaluation Metrics

F1, Precision and Recall were used to evaluate the performance of both subtask A and subtask B. The evaluation will verify whether the predicted “label” is the same as the desired “label” which is annotated by human workers, and then calculate its F1 scores, precision and recall.

#### 3.3 Experimental Details

**Hyper-Parameters of subtask A.** Since we were training the model with unlabeled data, we added the same amount of dev and test data as train data to fine-tune the model to get better results. We use an Adam optimizer to tune the parameters with learning rate = 5e-5, max seq length = 128, batch size = 32, seed = 40 and we trained each model for 2 epochs. Then we used the APM module to get  $M = 400$  prototypes which represents each class. By computing the similarity between each target sample and all prototypes in APM, we obtained 8658 pseudo-labels with high confidence.

**Hyper-Parameters of subtask B.** For subtask B, we trained our two ensemble model (each with three models) on unlabeled data with seed = 32,42, learning rate = 2e-5,2.5e-5,3e-5, we trained each model for 5 epochs with early stopping. We also used an AdamW optimizer to tune the parameters with epsilon = 1e-6, batch\_size = 16.

### 4 Results

The performance of our system and the task baselines for both subtasks are shown in following tables.

Model	F1	Precision	Recall
Baseline	0.660	0.917	0.516
Baseline(fine-tuned)	0.730	0.908	0.611
SFDA w/o $L_{source}$	0.674	0.874	0.548
SFDA w/o APM	0.686	0.927	0.545
SFDA	0.717	<b>0.936</b>	0.581
SFDA+ensemble	<b>0.736</b>	0.913	<b>0.616</b>

Table 2: Results of different ablation experiments for subtask A. All the models are trained on training data, development data and test data.

Table 2 shows the results of several ablation experiments. Compared with models without APM or  $L_{source}$ , we found that adding both together improved the performance of the model. The voting ensemble model of single models trained with extra development and test data outperforms all other models and achieves the highest F1 score.

Model	F1(dev)	F1(test)
SFDA(t) w/o $L_{source}$	0.838	0.661
SFDA(t) w/o APM	0.814	0.717
SFDA(t)	0.859	0.707
SFDA(t)+ensemble	<b>0.873</b>	0.720
SFDA(t+d) w/o $L_{source}$	0.864	0.689
SFDA(t+d) w/o APM	0.851	0.668
SFDA(t+d)	0.868	0.718
SFDA(t+d)+ensemble	0.870	<b>0.725</b>

Table 3: Results of models trained on different data sets. SFDA(t) refers to the model trained on train data and SFDA(t+d) represents the model trained on both train data and development data.

Table 3 shows the results of models trained on different data sets. Since we don't need labeled data to train the model, we added development and test data to train the model. Compared with our final model which was trained on three data sets, models trained on fewer data sets, i.e., only on train data or on both train data and development data perform less well.

Figures 3 and 4 show the confusion matrix of the classification results of baseline model and our model on the test dataset. This corresponds to *Baseline* and *SFDA+ensemble* in Table2, respectively. Compared with baseline, we predicted more true positive samples. However, the false prediction of negative samples as positive has increased. As a result, the recall and F1 score of our model have been improved, but the precision has decreased a little.

Figure 3: The confusion matrix of the baseline model

Figure 4: The confusion matrix of our model

Table 4 shows the results of several ablation experiments. Without soft labels, we can find that F1 score drop significantly. A possible explanation is that the soft labels preserve more information and generate better labels. Based on soft labels, MT and manual rules marginally improve the F1 scores. Finally, the ensemble model (MT+soft+rules) outperforms all other models and achieves the highest F1 score.

Table 5 shows the results of our model trained on dev set. Compared with the dev set, the F1 of the test set dropped by an average of 2%.

**Error analysis.** For subtask A, we conducted statistics and analysis on the classification results of Baseline model and our best model. There are 474 sentences that both Baseline model and our best model predict correctly. The entity being detected usually follow the word that express negative

<sup>1</sup>Model pre-trained on only the source data (official provided).

<sup>2</sup>Model pre-trained on the source data and then fine-tuned on the dev set (official provided).

<sup>3</sup>Here MT refer to Mean Teacher.

Model	F1	Precision	Recall
Baseline <sup>1</sup>	0.794	0.849	0.746
Baseline(fine-tuned) <sup>2</sup>	0.804	0.827	0.782
MT <sup>3</sup>	0.755	0.747	0.763
soft	0.807	0.859	0.761
MT+soft	0.801	0.854	0.754
MT+soft+rules	0.812	<b>0.863</b>	0.767
MT+soft+rules(ensemble)	<b>0.815</b>	0.847	<b>0.785</b>

Table 4: Results of different ablation experiments for subtask B. Our models are trained on training set.

Model	F1(dev)	F1(test)
Baseline	0.746	0.794
Baseline(fine-tuned)	-	0.804
MT	0.767	0.747
soft	0.815	0.791
MT+soft	0.813	0.799
MT+soft(ensemble)	<b>0.832</b>	<b>0.814</b>

Table 5: Results of subtask B. Our models are trained on dev set.

meanings in these sentences closely. e.g. "... *no* <e>erythema </e>...", "... *denies* <e>chest pain </e>..." ... There are 116 sentences that our model predicts correctly but the baseline predicts incorrectly. In this part, there are some long-distance keywords or parallel phrases. e.g. "... *No tobacco, EtOH, or* <e>IV drug use </e>". There are 348 sentences that are not predicted correctly by both models. For these, we consider to add some hand-craft rules to improve the results of the model.

For subtask B, we conducted a manual error analysis. For the raw text "*during the harvest season*", both our model and baseline model incorrectly labeled "harvest" with "Season-Of-Year" instead of "harvest season", "harvest" is just the activity, though if it instead said "harvest season", we would annotate that whole thing as a "Season-Of-Year". For the raw text "*February (27,661)*", baseline model incorrectly label "27" with "Day-Of-Month" while our model didn't, which proves the effectiveness of our architecture. In addition, we list a detailed description of the recall of subtask B in Table 6.

## 5 Conclusion

We introduce two different frameworks which are both based on self-training method for text classification and sequence labeling in SemEval 2021 task 10, in order to address the problems of source-

free, labeled training data scarcity. In subtask A, we used a metric learning method, combining pseudo labeling with prototype network and achieve good results. In subtask B, we employed teacher-student framework, and then we propose to use high-confidence soft labels to further improve the self-training. Our system takes third place in subtask A and first place in subtask B.

In future, we would like to introduce adversarial training and more data augmentation approaches in our model to further facilitate source-free domain adaptation.

## Abstract

There is currently a gap between the natural language expression of scholarly publications and their structured semantic content modeling to enable intelligent content search. With the volume of research growing exponentially every year, a search feature operating over semantically structured content is compelling. The SemEval-2021 Shared Task NLP CONTRIBUTIONGRAPH (a.k.a. ‘the NCG task’) tasks participants to develop automated systems that structure contributions from NLP scholarly articles in the English language. Being the first-of-its-kind in the SemEval series, the task released structured data from NLP scholarly articles at three levels of information granularity, i.e. at sentence-level, phrase-level, and phrases organized as triples toward Knowledge Graph (KG) building. The sentence-level annotations comprised the few sentences about the article’s contribution. The phrase-level annotations were scientific term and predicate phrases from the contribution sentences. Finally, the triples constituted the research overview KG. For the Shared Task, participating systems were then expected to automatically classify contribution sentences, extract scientific terms and relations from the sentences, and organize them as KG triples.

Overall, the task drew a strong participation demographic of seven teams and 27 participants. The best end-to-end task system classified contribution sentences at 57.27% F1, phrases at 46.41% F1, and triples at 22.28% F1. While the absolute performance to generate triples remains low, in the conclusion of this article, the difficulty of producing such data and as a consequence of modeling it is highlighted.

## 1 Introduction

Traditional search models over scholarly communication are now changing toward Knowledge Graph (KG) models operating on structured fine-grained

scholarly content offering enhanced contextual search results. Several initiatives exist to this end: Google Scholar, Web of Science (Birkle et al., 2020), Microsoft Academic Graph (Wang et al., 2020), OpenAIRE Research Graph (Manghi et al., 2019), Open Research Knowledge Graph (Auer, 2018), Semantic Scholar (Fricke, 2018) to name just a few. These KG models differ in their content, their level of detail, etc., as they represent diverse aspects of scholarly communication.

Text, of course, is of seminal importance to Science. It is as important as experimentation itself; unpublished research lacks validity. Seen in another angle, it is hard to imagine a medium other than discourse that can convey a comprehensive picture of the scholarly investigation. For the wider research audience, it is interesting to read the full “stories” of Science.

Nonetheless, since scientific literature is growing at a rapid rate (Johnson et al., 2018) and researchers today are faced with this publications deluge (Landhuis, 2016), it is increasingly tedious, if not practically impossible to keep up with the research progress even within one’s own narrow discipline. In this regard, among the existing scholarly knowledge structuring initiatives, the Open Research Knowledge Graph (ORKG) (Auer et al., 2020) is posited as a solution to the problem of keeping track of research progress minus the cognitive overload that reading dozens of full papers impose. It aims to build a comprehensive KG that publishes the research contributions of scholarly publications per paper, where the contributions are interconnected via the graph even across papers. The ORKG digital library (DL) framework can be accessed here <https://www.orkg.org>.

Motivated by the availability of a next-generation DL, we present the SemEval-2021 NLP-CONTRIBUTIONGRAPH (NCG) Shared Task as a step in the easier knowledge acquisition of contri-

butions for researchers - *the automated structuring of the unstructured article contributions*. To this end, via the NCG task, we have formalized the building of such a scholarly contributions-focused graph over NLP scholarly articles as an automated task. In the subsequent paper, we detail our task in terms of its resources, organization, participants, and evaluations.

## 2 Data

The NCG Shared Task comprised a dataset of NLP scholarly articles annotated for their contributions. The contributions were structured to be integrable within KG infrastructures such as the ORKG (Jaradeh et al., 2019) that capture research overviews. The contributions were annotated in three different information granularities, i.e. (1) *Contribution sentences*: a set of sentences about the article’s contribution; (2) *Scientific terms and relations*: a set of terms and relational predicates in the contribution sentences; and (3) *Triples*: semantic statements that pair the terms with a predicate, modeled toward subject-predicate-object RDF statements for KG building. This latter set of annotations formed the actual graph. Inspired after article sections, the Triples were organized under three (mandatory) or more of 12 total information units (IUs), viz. RESEARCHPROBLEM, APPROACH, MODEL, CODE, DATASET, EXPERIMENTALSETUP, HYPERPARAMETERS, BASELINES, RESULTS, TASKS, EXPERIMENTS, and ABLATIONANALYSIS.

### 2.1 Data Annotation Scheme

A trial annotation stage preceded the annotation of the Shared Task dataset. In this stage, an annotation scheme was prescribed. This involved specifying the annotation data granularities and the 12 IUs for organizing the triples. Observations were also obtained about the position in the articles where the authors generally stated the contribution. The trial annotations were conducted in two steps: a pilot annotation step (D’Souza and Auer, 2020) followed by an adjudication step (D’Souza and Auer, 2021). The resulting scheme itself was called the NLPCONTRIBUTIONGRAPH (NCG) scheme.

For the trial stage, a relatively small dataset of 50 articles uniformly distributed across five NLP tasks, i.e. machine translation, named entity recognition, question answering, relation classification, and text classification, were selected.

Overall, after the pilot annotation task the follow-

ing core question was answered. Could a scheme be defined such that it would encompass all annotation decisions of the task? In reality, it was found that the scheme could only define high-level annotation decisions such as: where in the article could the contribution information generally be found? E.g., the title, the abstract, a few lines in the Introduction, the first few lines of the Results section. This still entailed making subjective decisions such as if the model is not described in the Introduction then the first few lines of the model description section would need to be annotated. The scheme also specified the 12 IUs for organizing the structured triples. The choice of the specific IU for organizing the triples was based on the closest section title.

After the two-step trial annotation stage, the intra-annotation agreement between the pilot and adjudication steps, in terms of F1, was 67.92% for sentences, 41.82% for phrases, and 22.31% for triple statements indicating that with increased granularity of the information, the annotation adjudication was greater (2021).

The trial annotations were made by a postdoctoral researcher in Computational Linguistics. The same experienced annotator also annotated the full dataset. Next, we explain the NCG data with a focus on the KG and then offer two supporting examples as illustrations of the data.

### 2.2 Understanding our Knowledge Graph

The NCG KG used two levels of knowledge systematization: 1) At the root, it defined a dummy node called CONTRIBUTION. And following the root node, 2) it defined the 12 nodes introduced earlier and generically referred to as Information Units or IUs. Each scholarly article’s annotated contribution triple statements were organized under three (mandatory) or more of these IU nodes, depending on whether they applied to the article. Next, we provide details about each IU.

**RESEARCHPROBLEM** The research challenge addressed by a contribution. In other words, a focus of the research investigation or the issue for which a research solution was proposed.

**APPROACH or MODEL** The contribution of the paper as the solution proposed for the research problem. This unit was called APPROACH when the solution was proposed as an abstraction, and was called MODEL if the solution was proposed in practical implementation terms. Further, in case the solution was not referred to as approach or

model in the article, the reference was normalized as either APPROACH or MODEL. E.g., references like “method” or “application” were normalized as APPROACH; on the other hand, references like “system” or “architecture,” were normalized to MODEL. This unit captured only proposed system highlights.

**CODE** The contribution resource; the link to the software on an open-source hosting platform such as Gitlab or Github or on the author’s website.

**DATASET** Like CODE, this a contributed resource in the form of a dataset.

**EXPERIMENTALSETUP or HYPERPARAMETERS** Details about the platform including both hardware (e.g., GPU) and software (e.g., Tensorflow library) for implementing the machine learning solution; and of variables, that determine the network structure (e.g., number of hidden units) and how the network is trained (e.g., learning rate), for tuning the software to the task objective. It was called EXPERIMENTALSETUP only when hardware details were provided.

**BASELINES** The systems that a proposed APPROACH or MODEL were compared with.

**RESULTS** The main findings or outcomes reported in an article for the RESEARCHPROBLEM.

**TASKS** The APPROACH or MODEL, particularly in multi-task settings, are tested on more than one task, in which case, this unit was defined to capture all the experimental tasks. Unlike the earlier units, the TASKS IU was a container for more than one of the earlier mentioned IUs. Specifically, each task listed in TASKS could include one or more of the EXPERIMENTALSETUP, HYPERPARAMETERS, and RESULTS as sub-information units.

Furthermore, since it is common in NLP for tasks to be defined over datasets, experimental tasks are often synonymous with the experimental datasets, therefore this unit was also applied in articles where the datasets were explicitly listed instead of the task names.

**EXPERIMENTS** The second container information unit, like TASKS, defined to include one or more of the previous discussed units as sub-information units. This unit encapsulated several TASKS themselves and consequently, the units that TASKS encapsulated, i.e. EXPERIMENTALSETUP and RESULTS, or a combination of APPROACH, EXPERIMENTALSETUP and RESULTS.

**ABLATIONANALYSIS** A form of RESULTS that describes the performance of components in an APPROACH or MODEL.

### 2.3 Data Examples

Below, we show two examples of two different IUs, viz. RESEARCHPROBLEM and MODEL, respectively, as illustrations of our data.

```
{
  "has research problem" : [
    [ "Statistical Machine Translation",
      { "from sentence": "Learning Phrase
        Representations using RNN Encoder -
        Decoder for Statistical Machine
        Translation"} ],
    [ "SMT", "phrase - based SMT", { "from
      sentence" : "Along this line of
        research on using neural networks
        for SMT , this paper focuses on a
        novel neural network architecture
        that can be used as apart of the
        conventional phrase - based SMT
        system ."} ]
  ]
}
```

Figure 1: Annotated data in JSON format for the RESEARCHPROBLEM Information Unit for the paper “Learning Phrase Representations using RNN Encoder–Decoder for Statistical Machine Translation.”

**Example 1** In this example, the RESEARCHPROBLEM IU is modeled for the following reference paper: *Learning Phrase Representations using RNN Encoder–Decoder for Statistical Machine Translation* (Cho et al., 2014). We show two formats of our data: the JSON format (see Fig. 1) with all three annotated information granularities; and the triples format (see Table 1) showing only the annotated data for a KG. In the JSON data, the dummy root node CONTRIBUTION is left unspecified, however, it is specified in the triples. For this data, three phrases that named the research problem were annotated. The phrases were attached to the dummy root node by the predicate “has research problem.” Further, in the JSON data, following the predicate “from sentence,” the selected contribution sentences are listed.

**Example 2** In this example, a subpart of the MODEL IU is annotated for the following reference paper: *Convolutional Neural Network Architectures for Matching Natural Language Sen-*

(Contribution, has, Statistical Machine Translation)
(Contribution, has, SMT)
(Contribution, has, Phrase - Based SMT)

Table 1: Annotated RESEARCHPROBLEM Information Unit contribution data as triples. This data is obtained from the JSON data shown in Fig 1.

tences (Hu et al., 2014). See Fig. 2 for the JSON format and Table 2 for the triples data.

## 2.4 Data Statistics

Overall, the NCG Shared Task dataset had 50 articles in the trial data, 237 articles in the training data, and 155 articles in the test data. The trial data articles uniformly spanned five tasks, the training data spanned 24 tasks, and the test data spanned 10

tasks. For the Shared Task itself, participants were encouraged to merge the trial and training datasets. Thus, the overall training data had 287 articles representing 29 unique tasks. The training and test tasks were mutually exclusive except for one, i.e. ‘natural language inference.’ Table 3 shows further detailed statistics of the NCG dataset in terms of each of the annotated information granularities.

Our full dataset is publicly released online (D’Souza et al., 2021).

## 3 Task Description

Our comprehensive NCG Shared Task formalism was as follows. Given a scholarly article  $A$  in plaintext format, the goal was to extract (1) a set of contribution sentences  $C_{sent} = \{C_{sent_1}, \dots, C_{sent_N}\}$ , (2) a set of scientific knowledge terms and predicates from  $C_{sent}$  referred to as entities  $E = \{e_1, \dots, e_N\}$ , and (3) to organize the entities  $E$  as a set of (subject,predicate,object) triple statements  $T = \{t_1, \dots, t_N\}$  toward KG building organized under three or more of the 12 total IUs.

**Task Evaluation Phases.** The task comprised three evaluation phases, thereby enabling detailed system evaluations.

*Evaluation Phase 1: End-to-end Pipeline.* In this phase, systems were tested for the comprehensive end-to-end KG building task described in the formalism above. Given a test set of articles  $A$  in plaintext format, the participating systems were expected to return: (1) a set of contribution sentences  $C_{sent}$ , (2) a set of scientific knowledge terms and predicates from  $C_{sent}$ , i.e. entities  $E$ , and (3) the entities in  $E$  organized in a set of triple statements  $T$  toward KG building. System outputs were evaluated for the three aspects and overall.

*Evaluation Phase 2, Part 1: Phrases and Triples.* In this phase, systems were tested only for their capacity to extract phrases and organize them as triples. Given a test set of articles  $A$  in plain-text format and contribution sentences  $C_{sent}$  from each article, each system was expected to return: (1) the entities  $E$ , and (2) the set of triple statements  $T$ .

*Evaluation Phase 2, Part 2: Triples.* In this phase, systems were tested only for the triples formation task. Thus, given gold entities  $E$  for the set of  $C_{sent}$ , systems were expected to form triple statements  $T$ .

Dataset	<i>info-units</i>	<i>sentences</i>	<i>entities</i>	<i>total triples</i>	<i>total unique triples</i>	<i>subject</i>	<i>predicate</i>	<i>object</i>

Table 3: NLPCONTRIBUTIONGRAPH Shared Task 2021 Overall Corpus Statistics

## 4 Task Setup

**Online Competition** We used the CodaLab platform for running the competition online <https://competitions.codalab.org/competitions/25680>. For the convenience of the participants, the task was divided into four phases. In the Practice phase, which began on Aug 16, 2020, we released the participant kit that included the full training dataset along with the Python code of the official scoring program <https://github.com/ngc-task/scoring-program>. In the Evaluation phases that lasted from Jan 10 till Feb 1, 2021, we provided the participants with masked versions of the test set based on the current evaluation phase. The test set annotations in each phase were uploaded to CodaLab and were not available to the participants. To obtain results, the participants were expected to upload their system outputs to CodaLab where they were automatically evaluated by our script and reference data stored on the platform. In each evaluation phase, teams were restricted to make only 10 submissions and only one result, i.e. the top-scoring result, was shown on the leaderboard.

Before the task began, our participants were onboarded via our task website <https://ngc-task.github.io/>. Further, participants were encouraged to discuss their task-related questions via our task Google groups page at <https://groups.google.com/forum/#!forum/ngc-task-semeval-2021>.

**The NCG Data Collection of Articles** Our base collection of scholarly articles was downloaded from the publicly available leaderboard of tasks in AI called <https://paperswithcode.com/>. While *paperswithcode* predominantly represents the NLP and Computer Vision research fields in AI, we restricted ourselves just to its NLP papers. From their overall collection of articles, the tasks and articles in our final data were randomly selected. The raw articles’ pdfs needed to undergo a two-step preprocessing before the annotation task. 1) For pdf-to-text conversion, the GROBID parser (GRO,

2008–2020) was applied; following which, 2) for plaintext pre-processing in terms of tokenization and sentence splitting, the Stanza toolkit (Qi et al., 2020) was used. The resulting pre-processed articles could then be annotated in plaintext format. Note, our data consists of articles in English.

**Evaluation Metrics** The NCG Task participating team systems were evaluated for classifying contribution sentences, extracting scientific terms and relations, and extracting triples (see specific details in Section 3). The results from the three evaluations parts were also cumulatively averaged as a single score to rank the teams. Finally, for the evaluations, the standard precision, recall, and F1-score metrics were leveraged.

This completes our discussion of the NCG task in terms of its dataset definition and overall organization description. In the remainder of the paper, we shift our focus to the participating teams. Specifically, we describe the participating systems and examine their results for the NCG task.

## 5 Participating System Descriptions

The NCG Shared Task received public entries from 7 participating teams in all. In this section, we briefly describe the teams’ systems in terms of the three parts of the NCG task, i.e. contribution sentence classification, scientific terms and relations extraction, and triples extraction.

### 5.1 Contribution Sentence Classification

To identify the contribution sentences from articles, systems adopted one of two strategies: a binary classification objective, or a multi-class classification objective. In the first strategy, sentences were either classified as contribution sentences or not. In the second strategy, sentences were classified in a 13-class classification task as one of the 12 IUs or as a non-contribution sentence. Next, we describe these strategies. Note, the asterisk superscripts against team names, where present, correspond to \*\*\* 3rd best, \*\* 2nd best, and \* 1st best systems in the Shared Task, respectively.

**Binary Classifiers** Team YNU-HPCC (Ma et al., 2021) employed BERT as a *binary classifier* to classify the contribution sentences. Team INNOVATORS (Arora et al., 2021) also employed a BERT-based *binary classifier* wherein each instance was a set of 10 sentences with additional sentences as context features to the model. Team KnowGraph@IITK\*\*\* (Shailabh et al., 2021) used the standard SciBERT + BiLSTM architecture (Beltagy et al., 2019) as a *binary sentence classifier*. Team UIUC.BioNLP\* (Liu et al., 2021) employed BERT-based *binary sentence classifier* with features that handled sentence characteristics w.r.t. their context in the article - specifically, its closest preceding topmost and innermost section headers and its position in the article.

**Multi-class Classifiers** Team DULUTH (Martin and Pedersen, 2021) framed a *13-class multi-class classification* task. They employed deBERTa (He et al., 2020) as their classifier. Team ECNUICA (Lin et al., 2021) employed three pre-trained transformer models, viz. RoBERTa (Liu et al., 2019), SciBERT (Beltagy et al., 2019), and BERT (Devlin et al., 2019) as an ensemble classifier. They formulated a multi-class classification task as well. The features to BERT models are the original sentence, contextual information as previous and next sentence to the original sentence, and a sub-title of the paragraph with the separator token ([SEP]) in between. Team ITNLP\*\* (Zhang et al., 2021) employed a BERT-based multi-class classifier that leveraged sentence context and the paragraph heading as additional features.

These binary and multi-class sentence classifiers, were also adapted to our following dataset characteristics.

### 5.1.1 Contribution sentences data imbalance

Characteristically, of all the sentences in training data scholarly articles, only 10% were annotated as contribution sentences. Thus, our dataset presented an imbalanced classification task.

Teams YNU-HPCC, DULUTH, KnowGraph@IITK\*\*\* and UIUC.BioNLP\* trained their classifiers on the given data. While INNOVATORS and ITNLP\*\* downsampled the non-contribution sentences. INNOVATORS established a threshold based on cumulative contributing sentence bigram scores as a filter; ITNLP fixed the ratio of positive to negative samples as an integer and tuned the value.

### 5.1.2 Differing tasks coverage between the training and the test datasets

Since only one task was in common between the training and the test datasets, this meant that systems trained only on the training data would be applied on articles from nine new tasks as test data. To this end, Team ECNUICA hypothesized that if the classifier could *see*, i.e. somehow be trained on, the test data tasks, its performance could be boosted. They, thus, adopted the strategy of re-training their classification ensemble with silver-labeled test data instances. This followed the standard setup of training the classifier on the actual training data, applying it to the test data, and incrementally retraining the classifier leveraging the few confidently classified test instances. The instances were marked as silver training data only when all three ensemble classifiers predicted the same class.

### 5.2 Scientific Terms and Relations Extraction

After identifying the contribution sentences, systems then had to extract their scientific terms and relational predicates.

**Sequence Labeling Systems** Majority, i.e. six, of the seven participating systems adopted a sequence labeling approach.

1. Team YNU-HPCC used a pre-trained BERT model for sequence labeling of each token, obtaining embeddings for each token in the sequence, with softmax and argmax top layers which were shared across all tokens.
2. Team DULUTH trained a feature-based maximum-entropy Markov model (MEMM) to predict scientific terms in the contribution sentences.
3. Team ECNUICA extracted entities using RoBERTa (Liu et al., 2019) with a CRF layer and a BIO sequence labeling scheme. The input sequences to RoBERTa are modified with sub-title information.
4. Team KnowGraph@IITK\*\*\* extracted phrases in the sentence by adding BiLSTM layers to the SciBERT + CRF model as a sequence labeler. To mark phrase boundaries, they used the BILUO scheme.
5. Team ITNLP\*\* employed the standard BERT-based model, however, in a sequence labeling setting. They trained ten different models

by 10-fold cross-validation and used a voting count threshold scheme to extract the final set of entities.

6. Team UIUC\_BioNLP\* used a BERT-CRF model for phrase extraction and type classification (Souza et al., 2019). They employed the BIO scheme to distinguish the scientific terms vs. predicate phrases.

**Rule-based System** Team INNOVATORS leveraged an unsupervised rule-based approach for phrase extraction. Using spaCy (Honnibal et al., 2020), they obtained dependency parses for each sentence. They then implemented a set of dependency tree node traversal heuristics for phrase extraction based on the dependency parses.

### 5.3 Triples Extraction

1. Team YNU-HPCC first classified the scientific terms in subject, predicate, and object roles using three binary BERT classifiers. These triples from each contribution sentence were then organized as the 12 IUs leveraging a 12-class *contribution* sentence classifier. This team, however, did not participate in the end-to-end evaluation task.
2. Team DULUTH applied Stanford Core NLP’s dependency parser (Chen and Manning, 2014) to generate a dependency parse for each contribution sentence. They used the dependency parse structures to assign subject, relation, and object phrase roles to the extracted scientific terms. These were then organized as triples per IU obtained by their 13-class sentence classifier. *The overall end-to-end pipeline system score achieved by this system is 28.38%.*
3. Team INNOVATORS implemented a set of rules based on the dependency parses to form triples from the extracted scientific terms. They used a CNN-based architecture for classifying the *contribution* sentences as the 12 IUs. *Their end-to-end score was 32.05%.*
4. Team ECNUICA approached the triples formation task in two steps: i) they formed triple candidates based on the scientific term sequence order in the sentence. Additionally, they employed a set of predefined predicates when the predicates were not directly found in the sentence. ii) They then employed a SciBERT-based binary classifier to classify the triples as true or false candidates. *Their overall end-to-end system score was 33.35%.*
5. Team KnowGraph@IITK\*\*\* addressed the RESEARCHPROBLEM, CODE, BASELINES and ABLATIONANALYSIS IUs by a heuristics-based approach. For the remaining eight IUs triples, they followed a 3-step approach: i) identify predicates from the scientific terms using a binary SciBERT+BiLSTM classifier; and ii) formed triples by arranging the terms and predicates in exact order as they appear in the original sentence; and iii) employ an 8-class SciBERT + BiLSTM classifier to classify the triples. *Their overall end-to-end system score was 37.83%.*
6. Team ITNLP\*\* extracted triples as follows: i) they formed all possible triples candidates from the classified scientific terms; and ii) employed a binary BERT classifier for true or false candidates. Prior to BERT classification, they perform the negative candidate triples downsampling as follows: by artificially generating them using random replacement (RR) of one of the arguments of the true triples with a false argument; and by random selection (RS) of triples where no argument is a valid pair of another. Additionally, each of their system components obtained boosted performances with the Friendly Adversarial Training strategy (Zhang et al., 2020). *Their overall end-to-end system score was 47.03%.*
7. Team UIUC\_BioNLP\* categorized the triples into six types based on our dataset characteristics. Four of the six types were: structuring intra-sentence information; linking sentence information to IU; linking IU to the root node; and structuring inter-sentence information. The first two of the four broad types were further subdivided into two based on whether the predicate was found in the sentence or was the term “has.” Each of the six types were addressed by a specifically trained BERT classifier. *They obtained an overall end-to-end system score of 38.28% within the task deadline and 49.72% a day later after fixing phrase component offset errors.*<sup>1</sup>

<sup>1</sup>Per the task timeline, i.e. within the Phase 1 end-to-end system evaluation, the team achieved 38.28% F1 within the

## 6 Shared Task Results

In this section, we present the results of the seven participating teams’ systems.

The results in Table 4 show the cumulative scores of the participating teams in each of the three evaluation phases in our Shared Task. We refer the reader to Section 3 for a detailed description of the three evaluation phases. In each phase, Teams were officially ranked by these scores. Next, we examine the scores by the individual extraction

task deadline due to an error in their submission offsets for phrases. Thus, they are officially 2nd after the ITNLP team within the Shared Task timeline for Phase 1.

tasks that constituted building the NLPCONTRIBUTORGRAPH per article.

### 6.1 Contribution Sentences Classification

As a first step toward building the NLPCONTRIBUTORGRAPH, systems were evaluated for identifying contribution sentences. This was done only in the Evaluation Phase 1 of the Shared Task, i.e. the phase that tested the end-to-end systems. These results are shown in Table 5 under column “Sentences.” This subtask attained a high score of 57%. The top two teams, i.e. UIUC\_BioNLP\* and ITNLP\*\*, differed by only 1 point. Comparing these performances to a baseline, a default system

would return all titles as candidate contribution sentences. This results in a score of 10.78% F1 at 90% precision and 5.7% recall. In contrast to the 1 sentence per article result in the default computation, our actual data averages at 17 sentences per article. Thus the default score was computed on a significantly underestimated data sample as also reflected by its low recall. Nevertheless, the top systems significantly outperform this default score with both systems averaging at 20 sentences per article. The least score was also significantly better than the default at 38.1% F1 at an average of 12 sentences per article.

With F1 less than 60%, the task shows itself challenging. Some teams ascribed this to the dataset characteristic that contribution sentences constituted only a minority of the sentences in the article (<10%) and thus, overall, presented imbalanced data. To address this they downsampled the data. However, from the two participant systems that used a downsampling strategy, it could not be conclusively verified as an effective strategy since these systems performed on opposite ends of the performance spectrum. On the other hand, *incorporating the closest section header and sentence position as features in the BERT model showed itself an effective and reliable strategy for sentence classification*. This modeled the dataset better since the sentences were annotated from a few sections and the sentences were usually close to the section header. The system UIUC\_BioNLP\* that incorporated such features outperformed all other systems including the ones with the downsampling strategy, i.e. ITNLP\*\* and INNOVATORS.

Finally, how did bootstrapping the test data as silver-labeled data impact model performance? Team ECNUICA that adopted this strategy did not obtain a balanced harmonic mean between their precision and recall achieving the highest recall among all teams of 82.48% and the lowest precision of 26.21%. Thus this strategy did not show itself too effective and reliable.

## 6.2 Scientific Terms and Relations Extraction

These results are shown in Table 5 under column “Phrases” for the end-to-end systems. The highest F1 obtained on this task was 46.41%. However, this score was impacted by the pipeline setup such that the low performance in sentence classification impacted the performance in this stage. We conducted a separate evaluation phase to control for this as-

pect. In other words, we examined how would the systems perform only on extracting terms and relations given gold contribution sentences? These results are shown in Figure 3 (a). In fact, the bar chart offers a perspective on the significant differences in system performances when applied on automatically extracted sentences versus gold data. The systems showed the same performance ranking order in both settings. This is a somewhat expected result since none of the systems implemented any specific noisy sentence handling strategy in which case performance differences may have risen. In conclusion, the best result was 46.4% F1 in the end-to-end setting and was 78.6% F1 when given gold sentences.

Notably, the pipeline systems were 10 points lower for extracting phrases than for sentences.

## 6.3 Triples Extraction

The final extraction task to build the NCG per article was to form triples from the extracted terms and relations. These results for the pipeline systems are shown in Table 5 under column “Triples.” The best performance was 22.28% F1 and the 2nd best was significantly lower at 13.79% F1. To evaluate system performances purely for extracting triples, thereby cancelling out the effect of the pipeline setup, additional evaluations were conducted wherein gold data were incrementally made available to the system. These results are shown in Figure 3 (b). Given only the gold sentences, the best team attained 43.44% F1; given gold terms and relations in addition, they achieved 61.29% F1. A score of 61.29% F1 is a strong performance on a still fairly difficult task given the annotation decision subjectivity that may have crept into the data thereby producing considerable variations in annotation patterns. This is discussed in Section 7.

### Identifying only the Information Unit Labels

We conducted a meta-evaluation for identifying the set of IU labels per article. These results are shown in Table 5 under column “Information Units.” The top two teams were tied at 72.93% F1 with the second best score at 60.54% F1. Like sentence classification, a default system could be implemented for this task as one that output just the three mandatory IUs, i.e. RESEARCHPROBLEM, MODEL, and RESULTS for all articles. The scores from this default system were 69.01% F1, 81.67% precision, and 59.76% recall. It is 9 points better than the 2nd best. When given gold sentences, systems could

be evaluated for identifying just the IUs since the classification were dependent on the underlying sentences. These results are shown in Fig. 4.

A notable exception in the results is that the IU classification score by Team INNOVATORS remained unchanged regardless of pipelined or gold sentences as input. This is because their downsampling heuristic once designed did not rely on the underlying data when filtering. It is likely that the new gold sentences information was not used at all.

Figure 4: Information Unit identification results in *Evaluation Phase 1: End-to-end Pipeline with Pipelined Sentences* (blue bars) and *Evaluation Phase 2, Part 1 and Part 2 with Gold Sentences* (red bars)

## 7 Discussion

Finally, we conclude our Shared Task paper with a discussion on the perceived limitations of our dataset that can potentially be addressed in future work. Thereby, a new dataset will present new opportunities to evaluate systems on this novel task.

**Single Annotator Annotations** The NCG Shared Task dataset was annotated by a single annotator. Further, the design of the annotation scheme was supported by only an intra-annotator consensus agreement score for that annotator. Since this work is the first-of-its-kind in proposing an initial scheme, and given the complex nature of this annotation task with the need to design a model within a realistic timeframe, our annotation procedure is well-suited.

However, as discussed in our related work (D’Souza and Auer, 2021), in the next stage, we advocate for a blind, multi-stage, and multi-annotator annotation process for the NCG scheme, recognizing it as a potentially better annotation model. We find that such a process

while incorporating multiple worldviews could better address annotation inconsistencies that may have crept in in our current dataset.

**Non-uniform Distribution of Articles** As discussed earlier, our combined training dataset had 29 tasks and the test data had 10 tasks. However, these tasks did not have a uniform distribution of articles in our data. In the training data, the number of articles per task ranged from a maximum of 101 in one task, i.e. “natural language inference,” to a minimum of one article in seven tasks - 58.62% of the training data tasks had less than 5 articles. The test dataset, on the other hand, followed a more uniform distribution than the training data ranging from a maximum of 32 articles to a minimum of seven articles at an average of 15.5% articles per task. While our training dataset had over 200 articles, it may not have been sufficiently representative to learn uniform patterns. Thus in a new version of the dataset, a more uniform representation of the tasks will be attempted.

## 8 Conclusions

We have detailed the NLPCONTRIBUTIONGRAPH Shared Task that entailed structuring research contributions in NLP articles as structured KGs. This task is the first-of-its-kind to be organized in the SemEval series. It attracted a strong participation demographic of 27 participants and seven teams - BERT transformer models were a popular choice among the participant systems in two different capacities, i.e. as classifiers or sequence labelers. Our task also saw the use of traditional parsers such a dependency syntax parsing technology. Further, some systems leveraged a hybrid approach including a combination of heuristics and machine learning. While the end-to-end task performance was low showing the task considerably challenging, each individual subtask toward obtaining an NCG, i.e. contribution sentence classification, scientific terms and relations extraction, and triples formation, demonstrated high performances in the subtask-only evaluation setting, i.e. when given gold data from the previous stage. The best system adopted a hybrid approach which seemed the most effective strategy for building the NCG.

The NCG dataset is publicly available (D’Souza et al., 2021) and a KG overview of a structured form of our paper is here <https://www.orkg.org/orkg/comparison/R74774>.

## A Per Information Unit Evaluations

Table 7 shows triple extraction F1 scores for each of the IUs. The scores from each of the three evaluation phases in our Shared Task are separated by slash symbols. Recall that from the second evaluation phase, the gold data were made available to the systems starting with sentences (*Evaluation Phase 2, Part 1: Phrases and Triples*) followed by the terms and relations additionally (*Evaluation Phase 2, Part 2: Triples*).

Comparing the performances across IUs, we see the CODE IU was the easiest to extract. In *Phase 1*, the best F1 was 83.33%. In both *Phase 2, Part 1* and *Part 2*, the best F1 was 100.0%. This is an expected result for CODE to be easiest to extract since it had the simplest annotation patterns; an example is depicted in Fig. 5.

		Training Data	Test Data
1	CODE	1.0	1.03
2	RESEARCHPROBLEM	2.78	2.13
3	DATASET	13.78	22.5
4	APPROACH	15.55	17.61
5	MODEL	18.06	20.14
6	ABLATIONANALYSIS	18.82	21.19
7	BASELINES	20.13	15.3
8	RESULTS	23.31	23.0
9	HYPERPARAMETERS	23.78	19.78
10	EXPERIMENTALSETUP	27.53	27.47
11	TASKS	34.63	-
12	EXPERIMENTS	54.65	39.06

Table 6: Average no. of triples per Information Unit

Table 6 shows the average number of triples per IU reflecting, in a sense, their complexity. We hypothesize that the more the triples, the more complex the extraction task. Comparing these numbers with the results in Table 7, we see that 5th ranked IU, i.e. MODEL, showed the next easiest to extract after CODE, at 38.14% F1, in the end-to-end setting. Following which, we see that the 2nd ranked IU, i.e. RESEARCHPROBLEM, obtained an F1 of 35.79%. Nevertheless, confirming our hypothesis, we found a negative correlation ( $r -0.65$ ) between the training data triples size per IU and the end-to-end system performances, i.e. for IUs with fewer triples the extraction score is higher for most IUs. The negative correlations were progressively stronger from *Part 1* to *Part 2* in *Evaluation Phase 2* ( $r -0.75$  and  $r -0.79$ ), respectively.

## Abstract

We propose a cascade of neural models that performs sentence classification, phrase recognition, and triple extraction to automatically structure the scholarly contributions of NLP publications in English. To identify the most important contribution sentences in a paper, we used a BERT-based classifier with positional features (Subtask 1). A BERT-CRF model was used to recognize and characterize relevant phrases in contribution sentences (Subtask 2). We categorized the triples into several types based on whether and how their elements were expressed in text, and addressed each type using separate BERT-based classifiers as well as rules (Subtask 3). Our system was officially ranked second in Phase 1 evaluation and first in both parts of Phase 2 evaluation. After fixing a submission error in Phase 1, our approach yielded the best results overall. In this paper, in addition to a system description, we also provide further analysis of our results, highlighting its strengths and limitations. We make our code publicly available at <https://github.com/Liu-Hy/nlp-contrib-graph>.

## 1 Introduction

With the deluge of scientific publications in recent years, keeping pace with the literature and managing information overload have become increasingly challenging for researchers. There is a growing need for tools that can automatically extract and structure semantic information from scientific publications to facilitate advanced approaches to information access and knowledge curation (Shen et al., 2018).

The field of natural language processing (NLP) has witnessed an enormous growth in recent years with advances in deep learning, and there are increasing efforts in developing methods to extract scholarly knowledge from NLP pub-

lications (QasemiZadeh and Schumann, 2016; D’Souza and Auer, 2020b). One such effort is NLPContributions, an annotation scheme for describing the scholarly contributions in NLP publications and a corpus annotated using this annotation scheme (D’Souza and Auer, 2020b). This corpus has been proposed for training and testing of machine reading models, whose output can be integrated with the Open Research Knowledge Graph framework (ORKG) (Jaradeh et al., 2019). ORKG formalizes the research contributions of a scholarly publication as a knowledge graph, which can further be linked to other publications via the graph. The goal of the NLPContributionGraph (NCG) shared task (D’Souza et al., 2021) is to facilitate the development of machine reading models that can extract ORKG-compatible scholarly contribution information from NLP publications. The shared task consists of three subtasks (see D’Souza et al. (2021) for a more detailed description):

- Subtask 1: Identification of contribution sentences from NLP publications
- Subtask 2: Recognition of scientific terms and relations in contribution sentences
- Subtask 3: Extraction and classification of triples that pair scientific terms with relations

In this paper, we describe our contribution to NCG shared task. We built a cascade of neural classification and sequence labeling models based on BERT (Devlin et al., 2019). For subtask 3, we characterized triples based on whether and how their elements are expressed in text, and employed different models for each category. We also explored rule-based heuristics to improve model performance. Our models had the best overall performance in the shared task (57.27%, 46.41%, and 22.28%  $F_1$  score in subtasks 1, 2, and 3, respectively). The results are encouraging for extracting

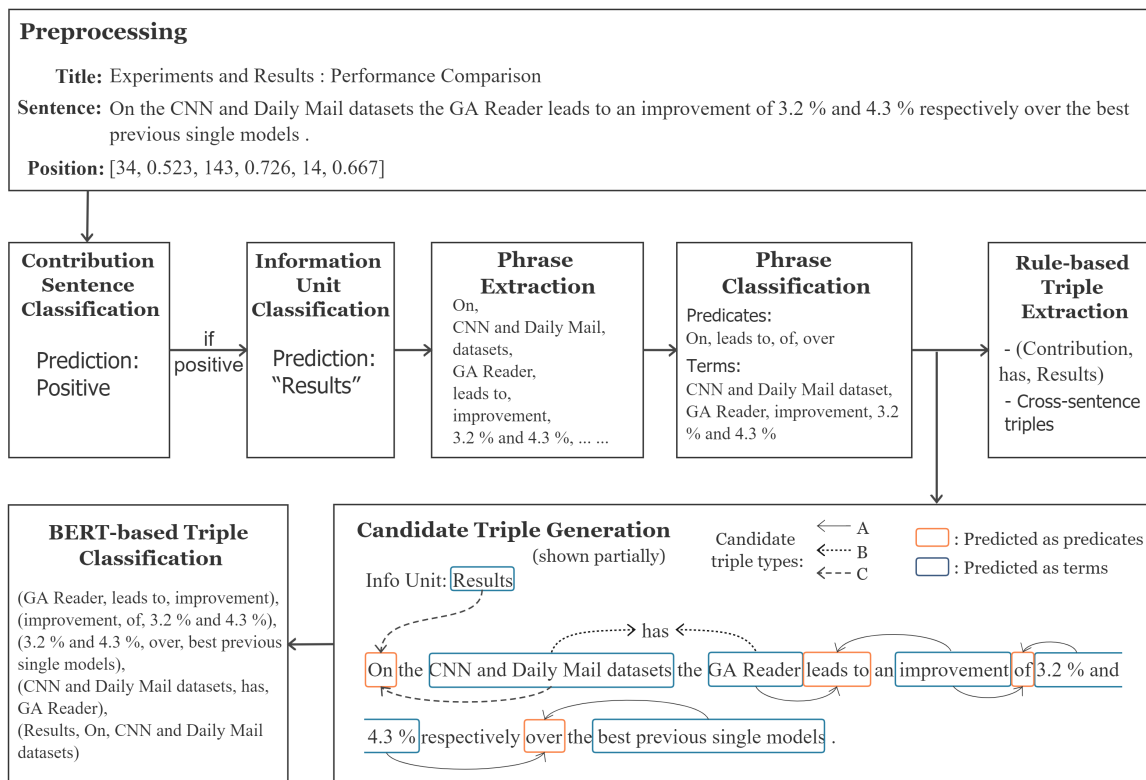

Figure 1: End-to-end system diagram.

scholarly contributions from scientific publications, although there is much room for improvement.

## 2 System Overview

In this section, we first describe our data preprocessing steps. Next, we discuss our models for each subtask, and the experimental setup for our end-to-end system (Phase 1). We provide an overview of the system in Figure 1 and provide examples for illustration, when necessary.

### 2.1 Data preprocessing

The participants of the shared task were provided three kinds of input: a) plain text files of the publications converted from PDF using Grobid<sup>1</sup>, b) sentences and tokens identified using Stanza (Qi et al., 2020), and c) triples and source texts organized by their information units (e.g., APPROACH) in JSON format.

#### 2.1.1 Identifying headers and positional information

One major preprocessing step was to identify section headers in the publications and associate them

with individual sentences. For sentence classification (subtask 1), we incorporated the topmost and innermost section headers associated with a sentence into its representation. The topmost header indicates the general role that a sentence plays in the article, while the innermost header provides more specific context for the sentence. For example, one topmost/innermost header pair is EXPERIMENT/DATA SET AND EXPERIMENT SETTINGS.

In the absence of explicit section information in the input, we used rule-based heuristics to extract these headers. With the first heuristic (Heuristic1), we simply identified the sentences following blank lines in plain text files as section headers. In Heuristic2, we first identified candidate headers as sentences that contain fewer than 10 words, have the first letter capitalized, do not end with several stopwords (*by, as, in, that, or and*), do not contain question marks in the middle or end with some punctuation (comma, colon or full stop). Next, we determined the case format used for headers in the publication by counting the occurrences of each case format type (e.g., all uppercase: EXPERIMENTAL SETUP). Among the headers that conform to the determined case format, we dis-

<sup>1</sup><https://grobid.readthedocs.io/>

tinguished topmost headers as those that contain several lexical cues (e.g., *background, method*) and are shorter than 5 words. Finally, we associated each sentence with the nearest preceding topmost and innermost header.

To incorporate headers into the sentence representation, we join the topmost and innermost header together with a colon between them and refer to it as the “title” of the sentence. In the case where a sentence is directly governed by a top-level header or it is a header itself, the title consists of the topmost header only.

We characterize the position of each sentence in the document with a combination of numeric features:

- The offset of the sentence in the entire paper.
- The offset of the sentence with respect to its topmost header.
- The offset of the sentence with respect to the header extracted using Heuristic 1.

Each of these offset features are divided by the number of sentences in the corresponding discourse (entire paper or the section) to extract a proportional sentence position feature. Thus, for every sentence, a total of six positional features (three offsets, three proportional sentence positions) are computed.

### 2.1.2 JSON Parsing

We created two additional models to assist with triple extraction: a) a multi-class sentence classifier that labels each sentence with a single information unit and b) a binary phrase classifier that labels phrases as scientific terms vs. predicates (described below). To train these models, we extracted additional information from JSON files. First, we matched the contribution sentences with the source text in the JSON files to get the information unit labels of the sentences. Second, we aligned the phrases with the triples in the same information unit, and determined whether each phrase is a predicate or term based on its location in the triple.

## 2.2 Subtask 1: Contribution Sentence Classification

We built a binary classifier to determine whether each sentence describes a contribution of the publication. Our analysis revealed that this decision was not simply based on the semantics of the sentence, but also its position in the document. On

one hand, the section header associated with the sentence provides important clues about the role of the sentence in the larger context. For example, the header “Related Work” indicates that sentences in this section are likely to discuss the contributions of prior research. On the other hand, some parts of the documents are naturally more salient than others (e.g. title, abstract, the first few lines of each section), where authors tend to summarize the most important information. To operationalize these insights, we designed a model that captures the information about the sentence, its topmost and innermost headers as well as its position in the document, as discussed above.

We used a BERT model to encode the sentence and its title (i.e., concatenated headers) separately and concatenated their textual representation together with the positional features to obtain a sentence representation. We then fed this representation into two dense layers, and used a final softmax layer for classification (Figure 2).

Figure 2: Sentence classification model architecture

## 2.3 Subtask 2: Phrase Recognition

Subtask 2 is similar to a named entity recognition (NER) task, although the participating systems were only required to extract relevant text spans and not to categorize them. One major difficulty with this subtask is that phrases do not align neatly with sentence constituents (e.g., noun phrases) and they vary greatly in length and in what counts as their boundaries (e.g. *best results* and *our best results* are both valid phrases).

For this subtask, we used a BERT-CRF model for phrase extraction and type classification (Souza et al., 2019). The raw text of the sentence is taken

as the model input. A BIO scheme that incorporates phrase types (scientific term vs. predicate) is used (e.g., B-Predicate, I-Term, O). The probabilities produced by the BERT model are fed into a Conditional Random Field (CRF) layer (Lafferty et al., 2001) for end-to-end training. We note that while phrase type classification is not necessary for subtask 2, we perform it since it is useful for our subtask 3 model, described next.

## 2.4 Subtask 3: Triple Extraction

Subtask 3 involves organizing phrases into triples. In information extraction, semantic triples are typically composed of subject, predicate, and object terms each corresponding to specific textual spans. This is not always the case in this subtask. While in most cases all three terms are extracted from a single sentence, a non-negligible number of triples consist of at least one phrase that does not come from the sentence (e.g. (TASKS, has, *Coreference resolution*), where the subject is an information unit and the predicate is not a sentence element).

To better understand triple characteristics, we categorized them into several types based on their composition, and created separate relation classification models for each type. The triple categorization is presented in Table 1. For each type, we list their functions in information organization, their proportion to all triples, along with some examples. We note that input to the training process for triple extraction varies by the type of the triple (described for each type in Section 2.4.2).

### 2.4.1 Information Unit Classification

To aid triple extraction, we modified the binary classification model that we trained for subtask 1 to further classify contribution sentences by their information units (multi-class classification). The process of labeling contribution sentences with information units was briefly described in Subsection 2.1.2.

In analyzing the information units, we identified two special pairs (MODEL vs. APPROACH and EXPERIMENTAL-SETUP vs. HYPERPARAMETERS). In the dataset, no document contains both units of a pair. The decision of which unit to choose is made at the document level. Therefore, we merged the labels of similar units before feeding the examples into the multi-class classification model.

After classification, we used lexical rules to split these units. Our rules were based on the following

observations. First, the MODEL vs. APPROACH distinction seems related to how the authors mention their work in the abstract and section headers of the paper. Second, EXPERIMENTAL-SETUP is often used instead of HYPERPARAMETERS when the hardware or the framework used in the study is specified (e.g. *V100 GPU, Pytorch*).

We did not recognize CODE information units using this model, since we found that such sentences can be identified with a very high accuracy using a simple rule based on presence of a URL in the sentence.

### 2.4.2 Neural models for triple extraction

We extract triples of type A, B, C and D (Table 1) by formulating them as neural relation classification tasks. All the classifiers are vanilla BERT classifiers (one linear layer followed by softmax). For each type, we observed the patterns in the training data, and addressed the most common ones. Ignoring the less frequent patterns inevitably led to a lower recall ceiling in our models.

**Type A** This type, in which all triple elements are mentions in the sentence, represents the majority of the triples. The corresponding model classifies the triples as a whole (“triple classification”). To the best of our knowledge, little research has been done on relation classification among three phrases; however, the Transformer model at the core of BERT is versatile enough to succeed in a wide range of tasks. As our training examples, we take every combination of a predicate and two terms in a sentence as a candidate triple, and train a model that predicts whether the three phrases constitute a triple or not. We encode the relation between three phrases by marking their boundaries in the sentence, as shown in Example 1. We use angle brackets to enclose predicates, and square brackets to enclose terms.

- (1) *In this paper* , we explore an alternate `[[ semisupervised approach ]]` which does `<< not require >> [[ additional labeled data ]]`.

**Type B** To identify triples of type B (two terms from the sentence and the relation type one of has, name, or None), we classify the relation between each pair of terms in a sentence that are not related by a type A triple. We found that 96% of these triples preserve the order of the two terms in the sentence, so we also preserve the order for extraction.

	Composition	Examples	Role	Pct.
Type A	Three phrases in a sentence	( <i>Deep - ED</i> , obtain, <i>BLEU score</i> )	Organize the semantics of a sentence.	57%
Type B	Two terms in a sentence with an added predicate <i>has</i> or name	( <i>ByteNet Decoder</i> , has, <i>30 residual blocks</i> )	Organize the semantics of a sentence.	7%
Type C	Information unit (subject), and two phrases in a sentence (predicate and object)	(HYPERPARAMETERS, use, <i>cross - entropy loss</i> )	Link a sentence to its information unit.	9%
Type D	Information unit (subject), <i>has</i> (predicate), and a term in the sentence (object)	(HYPERPARAMETERS, has, <i>starting learning rate</i> )	Link a sentence to its information unit.	9%
Type E	CONTRIBUTION (subject), <i>has</i> (predicate), information unit (object) OR CONTRIBUTION (subject), fixed (predicate), and a phrase (object) for the information units RESEARCH PROBLEM and CODE	(CONTRIBUTION, has, RESULTS), (CONTRIBUTION, has research problem, <i>neural machine translation</i> )	Link the “Contribution” node of each paper to an information unit.	9%
Type F	Cross-sentence triples	( <i>Positional Encoding</i> , inject, <i>some information</i> )	Structure the information across sentences	3%

Table 1: Triple types, their roles, and frequency. Types A-D are addressed using neural models and Types E-F with rules. 6% of triples do not fit in these categories and are not shown.

**Type C** Type C triples involve an information unit name as the subject along with a predicate and object from the sentence. We found that 89% of these triples take the first predicate and the first term in a sentence as their predicate and object respectively. Furthermore, in 98% of these sentences, the first predicate precedes the first term. Therefore, we classify each sentence whose first predicate precedes the first term, to predict whether a triple of this type can be extracted from the sentence. To train this classifier, we prepend the information unit name to the sentence text with a colon in between, as in Example 2 (*Model* is the information unit).

(2) *[[ Model ]]: In this work , we << introduce >> [[ a new type of linear connections ]]* for multi - layer recurrent networks .

**Type D** Type D triples are similar to Type C, but instead of a predicate phrase from the sentence, they involve the non-sentence predicate *has*. We found that 95% of these triples in the training set take the first term in the sentence as their object, and the first predicate in the sentence, if one exists, almost always follows the first term. Therefore, we classify each sentence that conforms to this pattern, to predict whether the information unit name and the first term constitute a *has* relation. We prepend the info unit name to the sentence in the same way

as in Type C.

### 2.4.3 Rule-based triple extraction

Triples of type E and F are extracted using heuristic rules. For type E, the subject is always CONTRIBUTION. The predicate can be *has*, in which case the object is the name of an information unit. If the related information unit is CODE or RESEARCH PROBLEM, the predicate is a fixed predicate (*Code* or *has research problem*, respectively) and the object is a phrase from the sentence. These rules use phrase and information units identified in earlier steps (Sections 2.3 and 2.4.1, respectively).

We developed the following rules to extract cross-sentence triples (type F):

1. If the first sentence has a single entity, and the second sentence has at least 2 entities, we assign the entity in sentence 1 as the subject and the first and second entities in sentence 2 as the predicate and object, respectively. We add this triple to the list only if both subject and predicate are noun phrases, which prevents many false positives. We also add the corresponding triple in the form of INFO-UNIT-*has-subject* (e.g. MODEL-*has-Encoder*). In many sentences that follow this rule, the first sentence is a section header.

	Avg F <sub>1</sub>	Information Units			Sentences			Phrases			Triples		
		F <sub>1</sub>	P	R	F <sub>1</sub>	P	R	F <sub>1</sub>	P	R	F <sub>1</sub>	P	R
Our system	49.72	72.93	66.67	80.49	57.27	53.61	61.46	<b>46.41</b>	42.69	50.83	<b>22.28</b>	22.30	22.26
IAA	52.82	<b>79.73</b>	78.83	80.65	<b>67.44</b>	67.25	67.63	41.84	45.36	38.83	<b>22.28</b>	23.76	20.97

Table 2: End-to-end performance (Evaluation Phase 1). IAA: intra-annotator agreement.

- If the two sentences each contain a single term and sentence 1 term is a substring of sentence 2 term or if sentence 1 term is an acronym of sentence 2 term, we create the following triple: *term 1-name-term 2*. We extract a term’s acronym by combining the initials of each token in the entity. An example of a term pair that follows this rule is (*GLUE, General Language Understanding Evaluation*).

These rules are applied to consecutive sentences only. In the training set, we found 812 triples that follow these rules, 649 (80%) of which could be identified correctly using these rules.

## 2.5 Experimental Setup

We implemented our models using Simple Transformers<sup>2</sup>. We used SciBERT (Beltagy et al., 2019) as the pre-trained language model. To train our models, we used a batch size of 16, and empirically found the best learning rate for each model between  $10^{-5}$  and  $10^{-4}$ . One exception was that in our sentence classification model (subtask 1), we used a fixed learning rate of  $10^{-5}$  to fine-tune the BERT, and a larger learning rate between  $5 \times 10^{-5}$  and  $10^{-3}$  for the dense layers. We used the AdamW optimizer (Loshchilov and Hutter, 2017) and the polynomial decay scheduler with the power of 0.5. We ran the experiments on a Google Cloud VM instance, using a Tesla V100 GPU.

## 3 Results

All the subtasks were evaluated on F<sub>1</sub> scores, and among them, triple extraction is evaluated by the micro-average of F<sub>1</sub> scores on each information unit. In the end-to-end evaluation (Phase 1), the participants were provided with the raw input to perform all three subtasks sequentially. We were officially ranked second in Phase 1, due to a submission error that resulted in phrase extraction F<sub>1</sub> of zero. Our correct submission achieved an average F<sub>1</sub> of 49.7%, the best score among all participating teams. Table 2 shows our performance in Phase 1,

<sup>2</sup><https://github.com/ThilinaRajapakse/simpletransformers>

and the intra-annotator agreement (IAA) on each subtask (D’Souza and Auer, 2020a).

We observe that, although the performance of our system on sentence classification is lower than human performance (57.27% vs. 67.44% F<sub>1</sub>), using its own sentence predictions, our system outperforms human annotators on phrase recognition (46.41% vs. 41.84% F<sub>1</sub>), and reaches comparable performance to human annotators on triple extraction. We also note that our system generally performs better in terms of recall than precision.

We were officially ranked first in both parts of Evaluation Phase 2. In Part 1, the participants were provided with the sentences labels to conduct phrase recognition and triple extraction sequentially; in Part 2, both the sentence labels and the phrase labels were provided to extract triples. We essentially followed our method in Phase 1 on phrase recognition and triple extraction, but made several attempts to improve the performance, which we discuss in Section 4. Our results in both parts of the Phase 2 evaluation are shown in Table 3. Compared to Phase 1 evaluation, we observe a significant improvement in phrase recognition (46.41% vs. 78.57% F<sub>1</sub>) in Part 1 and in triple extraction (22.28% to 43.44% and 61.29% F<sub>1</sub>) when ground truth contribution sentences and phrases are provided.

## 4 Performance Analysis

In this section, we analyze the performance of several components of our system and compare different schemes for entity representation and triple extraction. We also discuss some possible methods for improvement based on our shared task results and follow-up experiments.

### 4.1 Contribution Sentence Classification

We conducted ablation experiments to evaluate the effect of features for contribution sentence classification. Table 5 shows the model performance on the 10% validation set when using all features, using either the title or the position features together with the sentence, and using the sentence only.

	Information Units			Phrases			Triples		
	F <sub>1</sub>	P	R	F <sub>1</sub>	P	R	F <sub>1</sub>	P	R
Part 1	82.49	76.84	89.02	78.57	76.86	80.35	43.44	45.06	41.94
Part 2	82.49	76.84	89.02	-	-	-	61.29	65.19	57.82

Table 3: Performance in phrase and triple extraction (Evaluation Phase 2). Note that we focused only on triple extraction in Part 2, therefore the information unit extraction performance remains the same.

Unit name	Research problem	Approach	Model	Code	Dataset	Experimental Setup	Hyperparameters	Baselines	Results	Tasks	Experiments	Ablation analysis
F <sub>1</sub>	94.64	24.14	86.22	87.50	80.00	58.29	72.61	91.45	94.65	90.48	83.16	90.68

Table 4: Information unit classification performance.

Settings	F <sub>1</sub>	P	R
Sentence + title + position	65.11	63.96	66.30
Sentence + title	63.87	61.00	67.03
Sentence + position	52.28	46.38	59.89
Sentence only	51.39	49.00	54.03

Table 5: Results of ablation experiments on contribution sentence classification task.

We observe the title information significantly improves the performance, and the position features are also helpful, to a lesser extent. Combining the title and the position features gives the best performance on contribution sentence classification.

## 4.2 Information Unit Classification

In Evaluation Phase 2, the ground truth labels for contribution sentences increased the performance of our base model on information unit classification from 72.93% to 76.84% F<sub>1</sub>. To further improve our method, we ensembled 45 multi-class sentence classifiers by averaging their output (using *bagging*), which increased the F<sub>1</sub> score to 78.65%. Next, we improved our rules for distinguishing the special pairs (MODEL vs. APPROACH and EXPERIMENTAL-SETUP vs. HYPERPARAMETERS) by adjusting the lexical cues with more careful observation of the data, which results in our final performance (82.49% F<sub>1</sub> in Table 3).

For further analysis, we evaluated the classification performance on each information unit, as shown in Table 4. The related confusion matrix is shown in Fig. 3. We observe that severe confusion mainly occurs between MODEL vs. APPROACH and EXPERIMENTAL-SETUP vs. HYPERPARAMETERS, pairs that we grouped together in neural classification. This shows that while our sentence classification model has good accuracy, there is still much room for improvement in the rule-based differentiation of similar units.

Figure 3: Confusion Matrix

The differentiation between MODEL and APPROACH is particularly challenging. While some papers aim at discussing an abstract idea and some focus on system implementation, most papers fall in the gray area between them. We also attempted neural classification on the abstracts to deal with this issue, but the result were not satisfactory.

## 4.3 Phrase extraction and classification

**Specific BIO VS. simple BIO** Alternative to our method of using specific BIO tags to indicate phrase types (Subsection 2.3), we also used another scheme (“simple BIO”), in which we only used (B, I, O) tags to mark phrase boundaries.

With this scheme, we first trained a BERT-CRF model to extract the phrases, and then trained a binary BERT classifier to predict phrase types. The sentence along with the phrase marked by special tokens is fed into the BERT model for binary clas-

Settings	Phrase extraction			Phrase classification		
	F <sub>1</sub>	P	R	F <sub>1</sub>	P	R
Specific BIO	76.09	75.57	76.62	98.13	98.00	98.25
Simple BIO	77.13	76.33	77.95	98.27	98.70	97.85
Simple BIO + ensemble	78.57	76.86	80.35			

Table 6: Phrase extraction and classification performance. We take *predicate* as the positive label to calculate the F<sub>1</sub> score for phrase classification.

sification. The performance comparison of these schemes is shown in Table 6. While both schemes are effective, simple BIO outperforms specific BIO in phrase extraction by a small margin, so we used this scheme in Evaluation Phase 2.

The difference may be due to the noise in phrase types. Specifically, there is a good number of gerund phrases, on which the predicate-term differentiation is challenging. Moreover, in some cases, a verb phrase is used as a term to form triples. Combined with the relatively low intra-annotator agreement, these observations suggest that uncertainty and noise in the data affects the performance of the models. Note that the specific BIO scheme eliminates the need for a separate phrase classification model, making it preferable when the training and inference speed is a concern.

**Error analysis and improvement** We investigated the wrong predictions of our phrase extraction model, and found that most errors are due to boundary detection issues. For example, in one sentence, the model predicts *all layers of representation* as a phrase, while *all layers, of, representations* are annotated as three separate phrases. The opposite situation also occurs, when the model predicts a single unit as separate phrases. Another type of boundary error occurs when the model cannot predict correctly whether to include a non-core phrase element, like an adverb, in the phrase or not (e.g., it predicts *see that* whereas the annotated phrase is *also see that*). We believe that a relaxed boundary match evaluation can be considered for this task.

We attribute these errors to the uncertainty in semantic granularity, and attempted to alleviate the problem by ensembling. We get 12 bootstrap samples from the training data, and on each sample, we train the model and save its snapshot after each epoch from the 3th epoch to the 10th epoch, to get a total of 96 submodels. To aggregate their predictions, we extract a phrase in a sentence only if it is predicted by more than N submodels, where

N is a hyperparameter around 48. We present the result in Table 6 for comparison. We observe that ensembling noticeably improved phrase extraction (from 77.13% to 78.57% F<sub>1</sub>).

#### 4.4 Triple extraction

**Triple vs. pairwise classification** In addition to triple classification method (Subsection 2.4.2) to extract type A triples, we also used pairwise classification for this task. In this scheme, we considered every (subject, predicate, object) triple as a composition of two (predicate, term) pairs, or “candidate pairs”, and used a neural model to predict whether the two phrases in the pair are associated. After prediction, we reconstructed triples from the predicted pairs using rules. If a predicate is predicted to be associated with two terms, we combine them into a triple while preserving the order of the two terms in the sentence (subject first). If one predicate is associated with more than two terms, we only extract the triples in which the predicate is located between the two terms in the sentence. With only a few exceptions, we confirmed the effectiveness of these reconstruction rules; in other words, the performance of the pairwise scheme depends mainly on the classification accuracy on candidate pairs.

We compared the performance of the two schemes for type A triple extraction on the 10% validation set. We also attempted to address the imbalance of class labels resulting from both schemes by downsampling and class weight adjustment.

Settings		F <sub>1</sub>	P	R
No adjustment	Pair	91.33	91.23	91.43
	Triple	75.95	70.58	82.20
Downsampling	Pair	91.31	89.09	93.63
	Triple	80.04	79.43	80.66
Class weight	Pair	91.30	88.93	93.79
	Triple	<b>80.37</b>	81.35	79.42

Table 7: Performance of the pairwise classification scheme.

In the pairwise classification scheme (Table 7),

	F1	P	R
No adjustment	<b>87.54</b>	85.93	89.22
Downsampling	75.59	62.32	96.04
Class weight	83.35	74.94	93.89

Table 8: Performance of the triple classification scheme.

there is a 11% drop in the F1 score from the candidate pair classification to triple prediction, which is not unexpected as the model needs to correctly classify *both* of the candidate pairs to correctly predict a triple.

Table 8 shows the performance of the triple classification scheme, which achieves better performance compared to the pairwise classification scheme (87.54% vs. 80.37% F<sub>1</sub>). We also observed that the best performance was obtained without dealing with the imbalanced data. It seems that despite constituting a small portion of the dataset (9.7%), the number of the positive samples is large enough for the model to learn useful patterns.

**Type-specific performance** We also evaluated our deep learning methods for the extraction of the four types of triples, as shown in Table 9.

Type	F1	P	R
A	87.54	85.93	89.22
B	55.56	88.24	40.54
C	83.33	77.96	89.51
D	75.86	78.11	73.74

Table 9: Performance of triple extraction on each type.

Whereas our models for Type A, C, and D perform generally well, our model for Type B is far less accurate. Type B is a little special among the four types in that it requires the prediction of relation types. The type *has* is more difficult to predict than *name*, because the sentence often lacks semantic clues about the belonging or inclusion relationship between the two terms. A plausible idea is to incorporate *has* into the input, but it is difficult to do so without breaking the grammatical integrity of the sentence. We leave this improvement for future work.

**Coordination in triple extraction** A common problem we observed in our triple extraction models is the failure to account for coordination between terms. Example 3 shows a sentence with the terms in bold, and the two type C triples associating

them. Our model only extracts the first triple, and misses the second.

- (3) *The MoE consists of a **number of experts**, each a simple feed - forward neural network, and a **trainable gating network** which selects a sparse combination of the experts to process each input.*

(APPROACH, consists of, *number of experts*)

(APPROACH, consists of, *trainable gating network*)

We attempted to address this issue in post-processing, and used Stanza dependency parser (Qi et al., 2020) to detect coordination of words in phrases. If one phrase is used in a triple, we generated a parallel triple by replacing the term with the other. While this method improves recall (from 57.57% to 58.41%), it also led to precision errors (from 65.15% to 61.77%), its overall effect being negative (from 61.13% to 60.04% F<sub>1</sub>). We plan to refine this approach in future work.

## 5 Conclusion

We developed a system to generate structured representations of research contributions described in NLP publications in a manner compatible with the ORKG framework, achieving the top performance in the NCG shared task. We combined a cascade of state-of-the-art BERT-based classification and sequence labeling models with rule-based methods. In particular, we proposed a novel approach for triple extraction, where we tackled triples with different characteristics using different relation classification methods. We also explored various alternatives to the components in our end-to-end system to analyze the contribution of individual components.

In future work, we plan to improve the differentiation of similar units (e.g., MODEL vs. APPROACH), improve the extraction of type B triples, and address coordinated triples more thoroughly. We did not attempt to extract approximately 6% of the triples that did not fit in our classification (Table 1). These often involve nested information units, and we also hope to explore them in more depth in future work.

# KGP at SemEval-2021 Task 8: Leveraging Multi-Staged Language Models for Extracting Measurements, their Attributes and Relations

Neel Karia\*, Ayush Kaushal\*, Faraaz Mallick\*  
Department of Computer Science and Engineering  
Indian Institute of Technology Kharagpur  
{karianeel, ayushkaushal, faraazrm}@iitkgp.ac.in

## Abstract

SemEval-2021 Task 8: MeasEval aims at improving the machine understanding of measurements in scientific texts through a set of entity and semantic relation extraction sub-tasks on identifying quantity spans along with various attributes and relationships. This paper describes our system, consisting of a three-stage pipeline, that leverages pre-trained language models to extract the quantity spans in the text, followed by intelligent templates to identify units and modifiers. Finally, it identifies the quantity attributes and their relations using language models boosted with a feature re-using hierarchical architecture and multi-task learning. Our submission significantly outperforms the baseline, with the best model from the post-evaluation phase delivering more than 100% increase on F1 (Overall) from the baseline.

## 1 Introduction

Most scientific experiments are accompanied by relevant measurements, which help researchers to quantify their observations and qualitative arguments. Measurements also play a pivotal role in summarizing large experiments, and provide a brief idea of the results obtained. It is customary for scientists to present their research in the form of scientific papers. Nowadays, with thousands of papers being published digitally every year, it is extremely difficult to go through every single paper in order to get the desired data. The most popular electronic open-access repository of e-prints, arXiv, currently has 1,867,929 articles<sup>1</sup>. The sheer vastness of this number suggests just how important it is for us to automate the task of extracting measurement-related information from research papers (Singh et al., 2016).

\*Equal contribution.

<sup>1</sup>as of 9<sup>th</sup> April, 2021

A thorough understanding of the measurements not only requires the numerals, but also the context in which the quantities occur. Moreover, the entities and the properties measured along with the qualifiers that condition the measurements are crucial for understanding the measurement. MeasEval (Harper et al., 2021) is a semantic relation extraction task focused on obtaining 9 different entities pertaining to counts, measurements and qualifying attributes of these quantities in a collection of excerpts from research papers in English. Figure 1 shows an example of a quantity along with its attributes and relations from this dataset.

We propose a three-stage pipeline to address this task. The first stage uses a pre-trained BERT model (Devlin et al., 2019) to detect quantity spans from sentences. Receiving the detected spans as inputs, the second stage obtains the units and modifiers using extracted units and modifier keywords. Finally, the third stage receives the quantity spans from the first stage and uses another pre-trained language model over each quantity-span-conditioned sentence to obtain quantity-span-aware contextualized representations for each sub-token in the sentence. These representations are then used to detect the measured entity corresponding to each quantity (if any). The predictions from the measured entity task are then fused with the individual representations for each sub-token. These representations are used to detect the measured property and the qualifiers in a multi-task learning setting (Ruder, 2017).

Our submission surpassed the baseline by a significant margin and ranked 3<sup>rd</sup> for the Unit task. Our current best model delivers 516.7%, 436.8%, and 296.4% F1 (Overlap) (Mei and Radev, 1979) gains for Measured Entity, Measured Property and Qualifier tasks respectively, over the baseline.

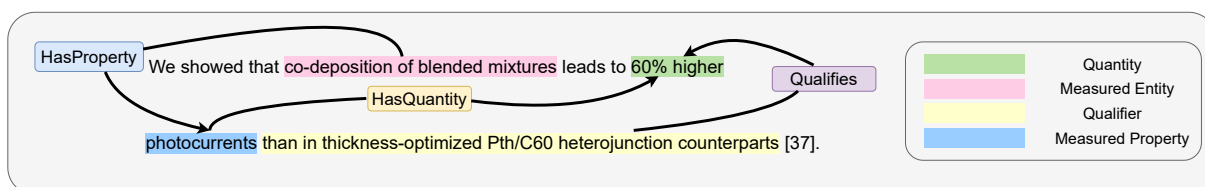

Figure 1: Visualization of Annotated Dataset

## 2 Related Works

Understanding and extracting information from scientific documents has been receiving increasing interest (Tsai et al., 2006; Nadeau and Sekine, 2007). Extracting units of measurement from scientific documents was previously studied via regular expressions and supervised classifiers (Berrahou et al., 2013; Sevenster et al., 2015).

In the orthogonal direction, there has been rapid progress in understanding natural language using deep pre-trained language models (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2020; Yang et al., 2019), which has led to a general improvement across multiple tasks. The sequence labelling (Lample et al., 2016; Panchendrarajan and Amaesan, 2018) and span prediction (Luo et al., 2020; Pang et al., 2019) tasks for natural language have also received great interest recently. We build upon these systems.

## 3 Problem Statement

We are given a set of **documents**  $D = \{(d_i)_{i=1}^n\}$ . Every document  $d_i \in D$ , consists of various **Quantity** (Q) spans  $Q_i = \{(q_i^j)_{j=1}^m\}$ . Every  $q_i^j \in Q_i$ , can have a **Unit** of measurement (e.g. *cm*, *ml*) associated with it. Also every  $q_i^j \in Q_i$  is associated to some (or no) **Modifiers** (Mod) which provide information about the type of Q (e.g. whether it is a range of values, whether it denotes the Median of a set of values, etc.)<sup>2</sup>. For every  $q_i^j \in Q_i$ , there can exist a corresponding **Measured Entity** (ME)  $e_i^j$ . Some Qs do not have any ME, e.g. in ‘3413 women’, the measurement is 3413 and ‘women’ is the ‘unit’ of 3413 and **not** its ME (according to “S0006322312001096-1177.tsv”). Similarly in ‘three occasions’, the measurement is ‘three’ and ‘occasions’ is its ‘unit’ and not its ME (according to “S0165587612003680-1078.tsv”). If a  $q_i^j$  has a corresponding ME  $e_i^j$ , it can also have an associated **Measured Property** (MP)  $p_i^j$ . Finally, the

<sup>2</sup><https://github.com/harperco/MeasEval/tree/main/annotationGuidelines>

Qs, MEs and MPs can have a number of **Qualifiers** (Qual)  $qual_i^j$  providing additional information about them.

The problem also introduces three relations, namely **Qualifies** (QS), **HasProperty** (HP), and **HasQuantity** (HQ). These relations are defined between Qs, MEs, MPs and Quals as binary classification functions ( $f(x, y) \rightarrow (0, 1)$ ):

- $QS(x, a) = 1, \iff$  the Qual,  $a$ , *qualifies* the element  $x$ , where  $x$  is a Q, ME or MP.
- $HP(p, e) = 1, \iff$  the MP,  $p$ , is *associated* with the ME,  $e$ .
- $HQ(y, q) = 1, \iff$  the Q,  $q$ , is *related* to element  $y$ , where  $y$  is an ME or MP.

The problem statement consists of 5 sub-tasks. We deal with identifying all Q spans in the documents in sub-task 1, followed by detecting the Units and Mods for each identified Q in sub-task 2. In sub-tasks 3 and 4, we identify the ME, MP, and Qual spans, corresponding to the extracted Qs. Finally in sub-task 5, we identify the relationships HQ, HP, and QS between the detected Q, ME, MP, and Qual spans. Figure 1 shows the annotation procedure to be followed (Stenetorp et al., 2012).

## 4 System Overview

We model all the previously described sub-tasks as supervised learning problems. Firstly, we perform a minimal pre-processing of sentence segmentation and number normalization on the documents. Then, Stage 1 handles sub-task 1 and the Stage 2 handles sub-tasks 2 respectively, and the remaining ones are handled by Stage 3 of our pipeline.

Before proceeding to describe our approach, we describe the baseline model, provided by the task organizers. The baseline treats the detection of Q, ME, MP and Qual spans all as sequence labeling problems. It uses the spaCy Entity Tagger model (Honnibal et al., 2020) to extract all these four spans. The Units for these Qs are obtained by

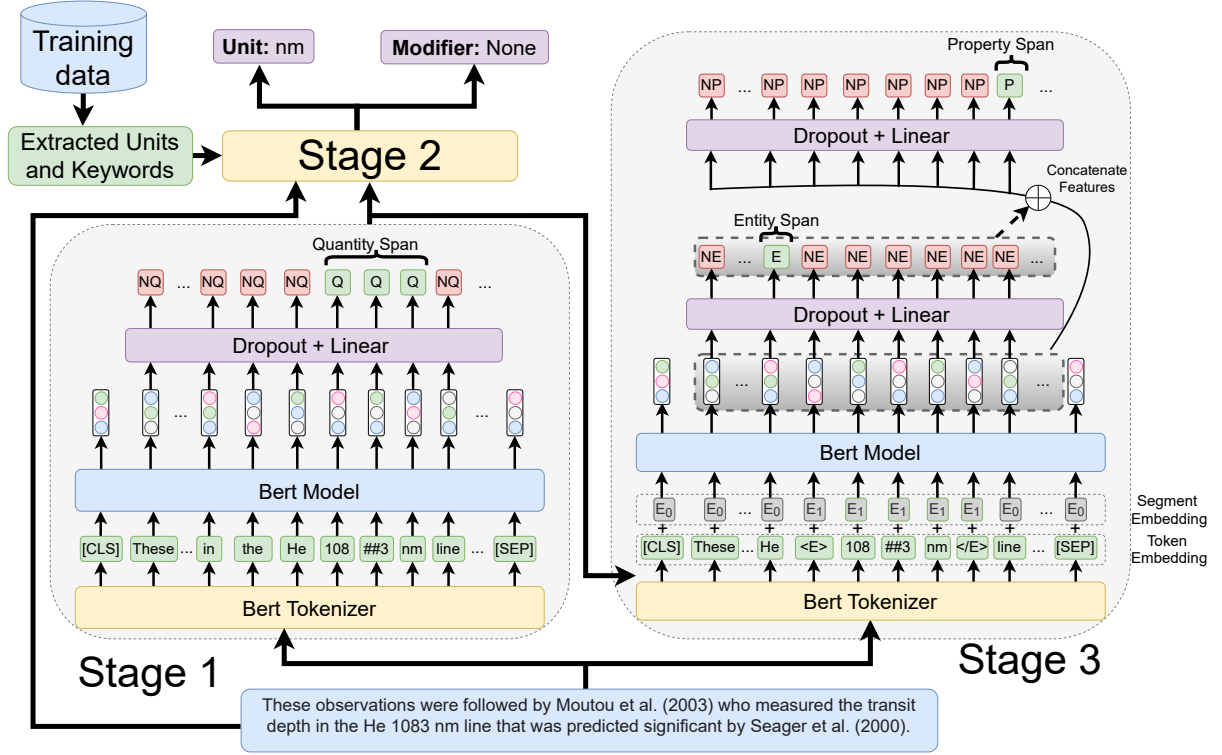

Figure 2: Overview of our Pipeline

matching the largest Units in these predicted spans with those from the train dataset.

#### 4.1 Stage 1

Similar to the baseline, we treat the Q spans learning problem as a sequence labelling problem. This is an intuitive step as it can detect multiple spans within the same text segment while being significantly cheaper in terms of the computation cost. Specifically, for a given sentence  $s$ , the input to our model is  $[CLS] s [SEP]$ . It is sub-word tokenized (Wu et al., 2016) to get the one-hot sub-token sequence  $w_0, w_1 \dots w_n$ . These sub-tokens are then fed to BERT to obtain the contextualized representations  $x_0, x_1 \dots x_n$  as follows.

First the word vectors are obtained using the Embedding  $E$  and Positional-Embedding  $E_{pos}$ :

$$x_j^{(0)} = w_j E + E_j^{pos} \quad (1)$$

Then these vectors are passed through  $L$  layers of transformer encoder (Vaswani et al., 2017) to obtain the contextualized representation. Each transformer encoder layer  $l$  receives the output vector sequence  $\{(x_j^{(l-1)})_{j=0}^n\} = x_0^{(l-1)}, x_1^{(l-1)} \dots x_n^{(l-1)}$  from the previous layer  $l - 1$  and computes the

output representation  $\{(x_j^{(l)})_{j=0}^n\}$  as follows:

$$\{(z_j^{(l)})_{j=0}^n\} = LN(MSA(\{(x_j^{(l-1)})_{j=0}^n\}) + \{(x_j^{(l-1)})_{j=0}^n\}) \quad (2)$$

$$\{(x_j^{(l)})_{j=0}^n\} = LN(\{(z_j^{(l)})_{j=0}^n\} + \{((W_2^l)^T f((W_1^l)^T z_j^{(l)} + b_1^l) + b_2^l)_{j=0}^n\}) \quad (3)$$

Here  $MSA$  is Multi-headed Self Attention and  $LN$  denotes Layer Norm.  $W_2^l, W_1^l, b_1^l, b_2^l$  are trainable parameters and  $f$  is the activation function.

The final contextualized representations  $\{(x_j)_{j=0}^n\} = \{(x_j^{(L)})_{j=0}^n\}$  are the outputs of the  $L^{th}$  transformer layer. Finally, these representations  $x_j$  (excluding  $j = 0, j = n$  for  $[CLS], [SEP]$  tokens) are each classified to a binary label:

$$(y_j^{NQ}, y_j^Q) = W_c^T x_j + b_c \quad (4)$$

Here  $W_c$  and  $b_c$  are learnable parameters and  $(y_j^{NQ}, y_j^Q)$  are the logits. This formulation of our problem can also be treated as the popular BIO tagging scheme excluding the 'B' beginning tag. This is then used to greedily match the largest contiguous span of sub-tokens with positive labels.

## 4.2 Stage 2

This stage receives the Q span predictions from Stage 1 as input and uses a method similar to the baseline, to obtain the Units. We extracted the set of Units occurring in the annotated Qs, from the documents in the dataset. However, in scientific documents, often combinations of units are present (e.g.  $Kgms^{-2}$  is a combination of ‘Kg’, ‘m’ and ‘s’). Our future work includes extending our approach to be exhaustive to handle such complex combinations of units.

To obtain the keywords for modifiers, given a Q span, we extracted the set of tokens occurring inside the span as well as in the neighboring window of 10 characters, on either side of the actual span. We discarded stopwords, punctuation marks and numbers. Then, we calculated the rate of co-occurrence between the remaining set of tokens and the Mods in the train dataset. This helped us to obtain keywords acting as significant cues for the respective Mod classes. Examples include “approximately” for IsApproximate, “greater than” for IsRange, etc. Another challenge with the sub-task is the presence of similar sets of keywords corresponding to multiple Mod types. For example, the Mods ‘IsMean’ and ‘IsMeanHasTolerance’ are very similar with the slight difference that keywords corresponding to the Mod ‘IsMeanHasTolerance’ contain the additional symbol, ‘±’. We adopted a hierarchical approach in order to detect such minute differences and correctly identify the type of Mod for every Q span, e.g. IsMeanHasTolerance is True when IsMean and HasTolerance are both true. We started by detecting a general Mod class, and gradually used extra cues to classify the span into more specific Mod classes such as {IsMeanHasSD, IsMeanHasTolerance, IsRangeHasTolerance, IsList}.

## 4.3 Stage 3

The input to this stage is the sentence-quantity tuple  $\langle s, q \rangle$  and our objective is to detect the spans for ME, MP and Qual. There could be multiple Qs in a single sentence. We treat detecting ME, MP, and Qual as three sequence labeling sub-tasks in a multi-task learning setting.

We create a modified sentence  $s'$  where the Q span  $q$  inside the sentence is enclosed within a special start marker  $\langle E \rangle$ , and a special end marker  $\langle E \rangle$  (Baldini Soares et al., 2019; Kaushal and Vaidhya, 2020; Zong et al., 2020). We additionally have

a special segment embedding for the Quantity ( $q$ ) portion of the quantity-context encoded sentence  $s'$ , different from the remainder of the sentence. We input  $s'$  and corresponding segment embeddings to BERT and obtain quantity-aware contextualized vectors  $\{v_1, v_2 \dots v_n\}$  for each of the  $n$  sub-tokens in  $s'$ . We then obtain the ME task logits  $e_i$ , for each sub-token vector  $v_i$ :

$$e_i = W_e^T v_i + b_e \quad (5)$$

Here  $W_e^T$  and  $b_e$  are learnable parameters. Now, as per the annotation rules of the task, a Q will have an associated MP only if an ME related to the given Q exists. Hence, for predicting the MP, we extract features from the ME task logits and concatenate them with each sub-token vector  $v_i$  as follows:

$$r = [\max_{i=1}^n e_i; \text{mean}_{i=1}^n e_i] \quad (6)$$

$$p_i = W_p^T [v_i; r] + b_p \quad (7)$$

Here  $W_p^T$  and  $b_p$  are learnable parameters,  $\max$  and  $\text{mean}$  are element-wise operations and  $p_i$  is the logit of the  $i^{\text{th}}$  sub-token for the MP sub-task. Here  $;$  denotes concatenation. Similarly, we obtain the logits  $qu_i$  corresponding to the Qual task, for every sub-token vector  $v_i$  of the sentence  $s$ , as follows:

$$qu_i = W_{qu}^T [v_i; r] + b_{qu} \quad (8)$$

Here  $W_{qu}^T$  and  $b_{qu}$  are learnable parameters. The model is trained with the following combined multi-task learning objective:

$$\text{Loss}(s, q, (y_i^e)_{i=1}^n, (y_i^p)_{i=1}^n, (y_i^{qu})_{i=1}^n) = \sum_{j=1}^n (\mathcal{L}(e_j, y_j^e) + \mathcal{L}(p_j, y_j^p) + \mathcal{L}(qu_j, y_j^{qu})) \quad (9)$$

Here  $(y_i^e)_{i=1}^n, (y_i^p)_{i=1}^n, (y_i^{qu})_{i=1}^n$  are ground truths for each sub-token for the ME, MP and Qual sub-tasks respectively;  $\mathcal{L}$  is the softmax cross-entropy loss (Dunne and Campbell, 1997).

Similar to Stage 1, we greedily match the longest contiguous positive labeled spans for each of the three sub-tasks and obtain the ME span  $e$ , MP span  $p$  and Qual span  $qu$  corresponding to the input Q span  $q$  for the sentence  $s$ . Here  $(q, e, p, qu)$  forms an annotation set which is then post processed to generate the relations HP, HQ and QS on this annotation set as per their definitions in §3.

Model	Precision	Recall	F1

Table 2: Multi-Task Results.  $F1_{ME}$ ,  $F1_{MP}$ , and  $F1_{Qual}$  are the F1 measures on the ME, MP, and Qual tasks respectively.

#### 4.4 Domain Specific BERT

Domain specific language model weights lead to a significant performance boost (Müller et al., 2020; Nguyen et al., 2020; Lee et al., 2019; Vaidhya and Kaushal, 2020; Beltagy et al., 2019). SciBERT (Beltagy et al., 2019), BioBERT (Lee et al., 2019), and RoBERTa-BioMed (Liu et al., 2020; Gururangan et al., 2020) performed relatively well as they are pre-trained on scientific documents in domains relevant to our task.

### 5 Experiments and Discussion

All experiments were performed using PyTorch (Paszke et al., 2019) and HuggingFace’s transformers (Wolf et al., 2019). Optimization was done using Adam (Kingma and Ba, 2014). We include the complete set of experimental parameters in §D.

#### 5.1 Development Phase

After dividing the 5 sub-tasks into 3 stages, we worked on each stage individually. We trained the models exclusively on the train dataset and used the trial dataset for validation and hyperparameter tuning. We used the F1, Precision and Recall metrics for each token in the sequence labeling sub-

Model	$F1_{ME}$	$F1_{MP}$	$F1_{Qual}$

RoBERTa-BioMed	<b>0.577</b>	0.473	0.232
SciBERT	0.556	0.486	0.188
BioBERT	0.575	<b>0.501</b>	0.297

Table 3: Stage 3 Results

tasks, for evaluating individual components over the validation set during the development phase.

Table 1 shows the performances of various BERT models in Stage 1. We observe that BioBERT delivers the best F1 score, followed by BERT-base and RoBERTa-BioMed. Much to our surprise, BERT-Large and SciBERT performed worse than BERT-base despite their large size (Li et al., 2020) and domain specificity.

In order to understand the role of each component of our model in Stage 3, we perform various ablation studies as shown in Table 2. First, we experiment with various combinations of multi-task learning with the three tasks - ME, MP and Qual. We observe that multi-task learning can lead to significant gains on all three tasks. Only the multi-task combination of ME and Qual led to performance reduction. Multi-task training all three tasks together nearly gives the best performance on all three metrics. We attribute this gain in performance to the inter-related natures of the three sub-tasks.

Secondly, we study the importance of segmentation and concatenation of features. We create BERT X, which doesn’t add separate segment embeddings for the Q span, and BERT Y which does not concatenate the ME logit features for predicting MP and Qual spans. From Table 2, we observe that BERT X has a significant reduction in performance for all the three sub-tasks upon excluding the segment embeddings, as the model input doesn’t have a clear demarcation between the Q span portion and non-Q span portion of the sentences. We also observe a reduction in performance for MP and Qual for BERT Y, showing the importance of fusing the logits of ME for the former two sub-tasks.

Similar to Stage 1, we experiment with various BERT models as shown in Table 3. Here we observe that RoBERTa-BioMed, BioBERT and BERT-large perform the best for ME, MP and Qual respectively. BERT-Base performs the worst for all of them. All the models except BioBERT have significantly lower  $F1_{Qual}$  than BERT-Large. Each model produces an  $F1_{ME}$  score greater than 0.5.

#### 5.2 Post-Evaluation Phase

The evaluation was done using the official script<sup>3</sup>. The classification and relation extraction sub-tasks were both evaluated by a binary match score and the span identification tasks by a SQuAD style (Ra-

Table 4: Test Set Performance

jpurkar et al., 2016) overlap score. The leaderboard ranking was based on a global F1 score averaged across all sub-tasks.

For our official submission, we selected BioBERT as it achieved the best F1 score in Stage 1 and near-best performance for the tasks in Stage 3. Minor discrepancies in the submission format involving the annot-id reference, quotes, whitespace-sensitivity and utf-8 encoding, not detected by the evaluation script were fixed in the post-evaluation phase. Table 4 shows the final performance of our models. After proper conversion to the desired format during the post-evaluation phase, we also evaluated various other BERT models along with our best model, BioBERT. BioBERT delivers the best performance of 0.456 F1 (Overall) followed by RoBERTa-BioMed and SciBERT. BioBERT also performs best on 7 of the 9 individual tasks.

### 5.3 Future Work

Stage 3 of our pipeline operates at a sentence-level, so for a given Q span, it does not capture the ME, MP, and Qual spans occurring across sentences. However, our approach can be easily extended to consider the nearby sentences or even the entire document (at the cost of computation speed).

The identification of exact word boundaries for the span identification tasks is crucial. Treating these tasks as sequence labeling problems and greedily matching for spans can lead to a few problems. For example, if a sub-token occurring within a long span is mislabeled, then the span is split into two components. In the future, we can explore leveraging contrastive learning (Chen et al., 2020) to improve the predictions for exact word boundary match. We can have transition based labeling layers such as Conditional Random Fields (CRFs) (Wallach, 2004) over the more popular BIO/BIOES sequence tagging schemes (Yang et al., 2018).

Lastly, while the multi-staged approach is fairly interpretable at the intermediate outputs of Q spans,

it also leads to a few issues. The predictions for MP, ME and Qual spans in Stage 3 are heavily dependent on the Q spans from Stage 1, and there does not exist any mechanism to rectify errors in Stage 1 later, in our approach. There is also an exposure bias (Schmidt, 2019; Galloway et al., 2019) as the model is trained on the ground truth, while tested on the predicted Q spans. Moreover, we believe that having common weights between the BERT models of Stage 1 and Stage 3 will not only make our approach faster and lighter, but also more performant through multi-task learning.

## 6 Conclusion

In this paper, we present our system details for the SemEval 2021 Task-8: MeasEval which is aimed at extracting entity and semantic relations pertaining to counts and measurements. We use a multi-staged approach where we first identify the quantity spans using BERT, then the units and modifiers for these predicted quantity spans by intelligent templates that leverage extracted units and modifier keywords. Finally we input the quantity-aware sentences to another BERT model to predict ME, MP, and Qual in a multi-task learning settings with feature re-use. Our submission achieved the second runner up position on the leaderboard for the Unit-identification sub-task and it showed the highest improvement in the post-evaluation phase, with an F1 (Overall) score only 0.063 lower than the highest score across both the phases.

## Acknowledgments

We would like to thank the MeasEval organizers, especially Corey Harper, for their constant support and for clearing our doubts. We would like to thank Aadarsh Sahoo for the insightful discussions. We would also like to thank the Department of Computer Science and Engineering, IIT Kharagpur, for providing us with the computing resources.

## A Appendices

Following is the overview of the appendix.

- §B – We provide implementation details: codebases, trained models and detail dependencies.
- §C – We provide details of the dataset in shared task, its statistics and annotation set for the task.
- §D – We detail the experimental settings and hyperparameters.

## B Code and Dependencies

We will make our code public <sup>4</sup> with instructions to replicate our systems. We also release our pre-

<sup>4</sup><https://github.com/Ayushk4/SE-T8>

trained model for our submissions <sup>5</sup>.

All experiments were performed using PyTorch (Paszke et al., 2019) and HuggingFace’s transformers (Wolf et al., 2019) libraries. The optimization was done using Adam optimizer (Kingma and Ba, 2014). We used git for reproducibility setup. In Table 7 we list all the dependencies used in our codebase. We include a step-by-step guide to setup and run the codebase in our README file present within the code also with details to set up our environment.

## C Dataset Details

We experiment on the dataset provided by the task organizers, consisting of gold annotations (Harper et al., 2021) for the set of scientific documents in English which are released here<sup>6</sup>. These scientific documents are a subset of the Elsevier Labs OA-STM-Corpus available publicly<sup>7</sup>.

**Basic Annotation Set:** The basic annotation set consists of 4 types of spans and 3 types of relations between them. The span types are Quantity (counts and measurements), Measured Entity (the item whose measurement/count is provided by the Quantity spans), Measured Property (the property of the Measured Entity, whose measurement is provided by the Quantity spans) and Qualifier (special circumstances which affect a particular measurement). These spans are related using three types of Relations - HasQuantity (relates a Measured Entity or a Measured Property to a Quantity), HasProperty (relates a Measured Entity to a Measured Property) and Qualifies (relates a Qualifier to any Measured Entity, Measured Property, or Quantity).

Hyperparameter	Set of Values
Learning Rate	$\{3e - 4, 3e - 5, 3e - 6, 3e - 7\}$
Number of Epochs	$\{5, 10, 15, 20\}$
Batch Size	$\{4, 8, 16, 24\}$

Table 10: Sets of Hyperparameters

**Statistics:** The complete dataset is divided into three parts: train, trial and eval. We train on the train set. Trial is used for validating and Eval is the held-out test dataset on which the final performance of the models are evaluated. In Table 5, we list the dataset statistics for the spans of each type. In Table 6, we list the dataset statistics related to the various relations - (HP, HQ, QS).

## D Experimental Settings

**Preprocessing:** We sentence tokenize every document using the NLTK sentence tokenizer. we observed that phrases such as “Fig. 1”, “Table. 2” and “et al. ”, along with a few others, caused sentences to be tokenized at wrong intervals (due to the presence of “.”). We detected and re-joined the instances for such phrases.

**Normalization:** We normalized the dataset by replacing all numerals by the same digit - 0. The helped our model identify the Q spans better. We observed that without normalization, the F1 (Overlap) Score for Q spans decreased considerably (from 0.844 to 0.790).

**Training and Hyperparameters:** The model take  $\approx 20$  seconds per epoch on Tesla P100. The number of parameters are same as BERT. Table 9 lists the HuggingFace model names corresponding to the BERT models we used. We validated our models using F1 metrics for Stage 1 and Stage 3 over the trial dataset. In Table 10 we share the sets of hyperparameters that we explored whereas in Table 8 we mention the **best** set of hyperparameters that we obtained.

# DPR at SemEval-2021 Task 8: Dynamic Path Reasoning for Measurement Relation Extraction

## Abstract

Scientific documents are replete with measurements mentioned in various formats and styles. As such, in a document with multiple quantities and measured entities, the task of associating each quantity to its corresponding measured entity is challenging. Thus, it is necessary to have a method to efficiently extract all measurements and attributes related to them. To this end, in this paper, we propose a novel model for the task of measurement relation extraction (MRE) whose goal is to recognize the relation between measured entities, quantities and conditions mentioned in a document. Our model employs a deep translation-based architecture to dynamically induce the important words in the document to classify the relation between a pair of entities. Furthermore, we introduce a novel regularization technique based on Information Bottleneck (IB) to filter out the noisy information from the induced set of important words. Our experiments on the recent SemEval 2021 Task 8 datasets reveal the effectiveness of the proposed model.

## 1 Introduction

One of the key indicators of scientific writing is the quantities description of various experiments and results. While the mentions of all measurements could provide a rigorous understanding of the topic, it might make the reading and automatic processing of the text more difficult. As such, designing effective methods to recognize the mentions of measurements and also the conditions in which they are valid is necessary. According to the definition of the SemEval 2021 Task 8 (Harper et al., 2021), a measurement might consist of the following components: (i) Measure Entity: A span referring to an entity that one of its properties has been measured and its value is provided in the document; (ii) Measured Property: A span referring to the characteristics of an entity that has been measured; (iii)

[ME1] samples [/ME1] have been generated with Coronin and Dystrophin proteins. In the filtration experiments, some of them with a [PR1] diameter[/PR1] [QT1] less than 2 mm [/QT1] have been filtered out using [QT2] 200-degree [/QT2] filtering [ME2] radiation [/ME2], resulting in [QT3] 20% [/QT3] [ME3] utilization [/ME3]. These results are obtained in a [QL1] dry climate [/QL1].

Figure 1: A document annotated with the measured entities (i.e., [ME]), quantity (i.e., [QT]), measured property (i.e., [PR]) and qualifier (i.e., [QL]) (best viewed in color).

Quantity: A span in the document that refers to a value and possibly it comes with a unit; and (iv) Qualifier: A span referring to a condition in which more information about the Quantity, Measured Property or Measured Entity is provided. Figure 1 shows a sample document annotated with the aforementioned entities. In this paper, we collectively name all of these four types as measurement component.

As it is shown in the provided example, documents might contain multiple entities, properties, quantities and qualifiers that are scattered in different parts of the document. As such, finding which measurement components are associated with each other is not straightforward. In this paper, this task is called measurement relation extraction (MRE) that aims to recognize what is the relationship between two given measurement components. More specifically, the following relation types are considered: (i) Has-property: Indicates the selected property is one of the characteristics of the selected entity; (ii) Has-Quantity: Indicates the selected quantity is provided for the selected entity or property; (iii) Qualifies: Indicates the selected qualifier provides more information about the selected entity or quantity; (iv) None: Indicates that there is no

relation between the selected measurement components. For instance, in the given example document in Figure 1, the following relations between different measurement components exist: (1)  $ME_1$  has property  $PR_1$ ; (2)  $PR_1$  has quantity  $QT_1$ ; (3)  $ME_2$  has quantity  $QT_2$ ; (4)  $ME_3$  has quantity  $QT_3$ ; and (5)  $QL_1$  qualifies  $ME_3$ ;

Finding the relation between a pair of measurement components is challenging and it requires consideration about the position of the given entities and the context in which they are used. Generally, this task can be formulated as a typical Relation Extraction (RE) task whose goal is to identify the semantic relation between two given named entity mentions. For RE, it has been shown that contextual information such as dependency path between the two given entities is important. As such, in this paper, we also aim to exploit the contextual information for a pair of measurement entities to predict the relation between them. To this end, the main question to answer is how we can extract the contextual information that is helpful for this task. One simple solution is to use the dependency path between the two measurement components. However, this might not be perfect due to various reasons such as lack of high-quality dependency parser designed especially for scientific domain and the fact that the dependency tree is ignorant of the downstream task (i.e., MRE) thus might not be efficient to extract important context from. Therefore, in this paper, we aim to propose a novel method to dynamically infer the important context for the MRE task. More specifically, we introduce a deep architecture to infer which words should be selected from the given document to form the important context from which the relation between the given measurement components can be inferred. The proposed deep architecture exploits a translation-based perspective to achieve this goal.

In addition, in this paper, we propose a novel method to efficiently regularize the representations of the input words based on the inferred important context. In particular, our method is based on the Information Bottleneck (IB) theory in which the inferred context is treated as information bottleneck to exclude noisy information in the input document representation. We conduct extensive experiments on the SemEval 2021 Task 8 dataset. Our experiments reveal the effectiveness of the proposed model for the task of MRE.

## 2 Model

**Task Definition:** The input to the model is the document  $D = [w_1, w_2, \dots, w_n]$  consisting of  $n$  words and also the positions of the two entities of interest,  $w_s$  and  $w_o$  where  $s$  and  $o$  are the indices of the first (i.e., subject) and the second (i.e., object) entities, respectively. The input document is annotated with the label  $l$  from the set  $L = \{\text{hasQuantity, hasProperty, qualifies, None}\}$ . Our proposed model for this task consists of four major components: (1) Input encoder to convert the input text into high dimensional word vectors; (2) Dependency Path Reasoning: This component employs the word vector representations and extract a path between the two entity mentions in the given document; (3) Regularization: This component employs the extracted dependency path as the information bottleneck to filter out noisy information from the input document; (4) Prediction: Finally the regularized representations of the dependency path will be used to make the final prediction. The rest of this section provides details for the aforementioned components.

### 2.1 Input Encoder

To represent each word  $w_i$  in the input document  $D$ , we use the concatenation of the following components: **Contextualized Embedding**, We feed the input document  $D$ , i.e.,  $[CLS]w_1w_2 \dots w_n[SEP]$  to the pre-trained BERT<sub>base</sub> transformer and take the hidden states of the last layer of the BERT model, i.e.,  $E = [e_1, e_2, \dots, e_n]$ , as the contextualized word embedding of the input document. Note that for the words that have multiple word-pieces, we take the average of their word-piece embeddings obtained from the BERT model. **Position Embedding** For each word  $w_i$ , we compute its distance to the subject  $w_s$  and the object  $w_o$ , i.e.,  $d_s^i = \|i - s\|$  and  $d_o^i = \|i - o\|$ , respectively. The distances are represented using high dimensional vectors  $e_i^s$  and  $e_i^o$  obtained from randomly initialized embedding tables. During training, the embedding tables are being updated. **Entity Type Embedding** The type of the two entities (i.e., Quantity, Measured-Entity, Measured-Property, and Qualifier) are represented using high dimensional vectors obtained from randomly initialized embedding tables. The embedding tables will be fine-tuned during training.

The concatenation of the aforementioned embedding vectors, i.e.,  $X = [x_1, x_2, \dots, x_n]$ , are used

to represent the words of the input document. It is noteworthy that since the parameters of the pre-trained  $BERT_{base}$  are fixed during training, in order to tailor the contextualization of the word embeddings to this task, we feed the vectors  $X$  to a Bi-directional Long Short-Term Memory (BiLSTM) network and we use the hidden states of the BiLSTM neurons, i.e.,  $H = [h_1, h_2, \dots, h_n]$ , as the final vector representations of the input document  $D$ . The vectors  $H$  will be used by the subsequent components.

## 2.2 Dependency Path Reasoning

To find the dependency path between the subject and the object entities, we employ a translation-based perspective. More specifically, given the vector representations of the subject entity, i.e.,  $h_s$ , and the object entity, i.e.,  $h_o$ , the dependency path should be represented using the vector  $P$  such that using this vector, the subject representation  $h_s$  is transferred (i.e., translated) to the object representation  $h_o$ , under the operation  $\Phi$ . Formally,  $h_o = \Phi(h_s, P)$ . Using this definition, we can define the path representation by  $P$  by exploiting the inverse operation  $\Phi^{-1}$ , i.e.,  $P = \Phi^{-1}(h_s, h_o)$ . After obtaining the path representation  $P$ , we compare it with the representations of the other words of the document  $D$  to assess their likelihood to be included in the dependency path. Concretely, the similarity between the vector  $h_i$  and the vector  $P$  could be used to estimate the probability of the word  $i$  to be used in the dependency path. However, one limitation of this method is that the likelihood of the word  $w_i$  is computed regardless of the other words  $w_j$  where  $j \notin \{i, s, o\}$ . To address this issue, we propose to compute the likelihood of the word  $w_i$  based on the interaction between the representation of the word  $w_i$ , i.e.,  $h_i$ , the representations of the other words, i.e.,  $h_j$  for  $j \notin \{i, s, o\}$ , and the path representation  $P$ . To this end, we first compute a vector representation for the words  $w_j$  by applying  $MAX\_POOL$  operation on all words  $w_j$  for  $j \notin \{i, s, o\}$ :  $\bar{h}_{-i} = MAX\_POOL(h_1, h_2, \dots, h_j)$ . Afterwards, we apply the function  $\Phi^{-1}$  on the vectors  $P$  and  $\bar{h}_{-i}$ :  $\hat{h}_i = \Phi^{-1}(\bar{h}_{-i}, P)$ . The vector  $\hat{h}_i$  represents the path for transferring (i.e., translating) the vector  $\bar{h}_{-i}$  to  $P$ . As such, the similarity between  $\hat{h}_i$  and  $h_i$  could reveal how important is the word  $w_i$  to convert the representation of the context  $w_j$  for  $j \notin \{i, s, o\}$  to the representation of the depen-

dency path  $P$ . Therefore, we use this similarity, i.e.,  $Sim_i = \left\| \hat{h}_i - h_i \right\|$ , as the score of the word  $w_i$  to be included in the dependency path. The words that their score is above a pre-defined threshold will be used as the inferred dependency path.

It is worth noting that to learn the function  $\Phi^{-1}$ , in this work, we use a feed forward neural network. In particular, the concatenation of the vectors  $h_s$  and  $h_o$  are fed into a 2-layer feed forward neural network with  $|P|$  neurons at the final layer:  $P = FF([h_s : h_o])$ , where  $[:]$  represents concatenation and  $FF$  represents the feed-forward neural network. To train the  $FF$  network for the RE task, we use the vector  $P$  to predict the probability distribution  $P_\Phi(\cdot|D, t, a)$  using another feed-forward network  $FF_2$  whose final layer dimension equals the number of labels, i.e.,  $|L|$ . We use negative log-likelihood to train the  $FF$  and  $FF_2$  networks:  $\mathcal{L}_\Phi = -\log(P_\Phi(l|D, t, a))$  where  $l$  is the gold label.

Finally, to represent the induced path, we take the max-pooled representation of the words in the path:  $h_P = MAX\_POOL(h_1, h_2, \dots, h_p)$  where  $p$  is the number of words in the induced dependency path. The path representation  $h_p$  will be used by the subsequent components.

## 2.3 Regularization

Although the induced dependency path from the previous component is intended to contain the important information for the RE task, it might still contain some noisy information due to the contextualization in the input encoder. To overcome this noisy information, in this work, we propose to exploit the induced path as the information bottleneck (IB) (Tishby et al., 2000). IB’s goal is to reduce the mutual information between the input and the bottleneck, meanwhile, to increase the mutual information between the bottleneck and the output. For the second goal, the bottleneck (i.e., the dependency path representation  $h_p$ ) will be used by the prediction component, and the increase of its mutual information with the output is enforced by reducing the training loss (e.g., negative log-likelihood). To fulfill the first goal, i.e., decreasing the mutual information between the input and the bottleneck, we resort to a contrastive learning paradigm to estimate the mutual information between two high-dimensional vectors using the classification loss of a binary-discriminator. More specifically, the path representation  $h_p$  is concatenated with the

max-pooled representation of the input document  $D$ , i.e.,  $h_d = \text{MAX\_POOL}(h_1, h_2, \dots, h_n)$ , and this concatenation, i.e.,  $h_{pos} = [h_p : h_d]$ , serves as the positive sample for the contrastive learning. To construct the negative samples, we first take the max-pooled representation of a randomly chosen document  $D'$  from the same mini-batch, i.e.,  $h_{d'} = \text{MAX\_POOL}(h'_1, h'_2, \dots, h'_m)$  where  $h'_i$  is the representation of the  $i$ -th word in the document  $D'$  and  $m$  is the total number of words in  $D'$ . Afterwards, the concatenation of  $h_p$  and  $h_{d'}$  is employed as the negative sample:  $h_{neg} = [h_p : h_{d'}]$ . Finally, a feed-forward discriminator is employed and trained to distinguish the positive samples from the negative ones, i.e.,  $\mathcal{L}_{disc} = \log(1 + e^{(1-D(h_{pos}))}) + \log(1 + e^{D(h_{neg})})$ . By adding the discriminator loss  $\mathcal{L}_{disc}$  to the final loss function and decreasing it, the estimated mutual information between the input and the bottleneck (i.e., the path representation  $h_p$ ) is decreased too.

## 2.4 Prediction

To make the final prediction on the relation between the given subject and object entities, we employ the representations of the induced dependency path (i.e.,  $h_p$ ), the subject entity (i.e.,  $h_s$ ), and the object entity (i.e.,  $h_o$ ) to construct the final vector  $V = [h_p : h_s : h_o]$  where  $[:]$  represent concatenation. The vector  $V$  is finally consumed by a feed-forward neural network to predict the distribution  $P(\cdot|D, t, a)$ . The loss function to train the main RE task is thus defined as:  $\mathcal{L}_{pred} = -\log(P(l|D, t, a))$  where  $l$  is the gold label. The overall loss function to train the entire model is:  $\mathcal{L} = \mathcal{L}_{pred} + \alpha\mathcal{L}_\Phi + \beta\mathcal{L}_{disc}$  where  $\alpha$  and  $\beta$  are the trade-off parameters.

## 3 Experiments

### 3.1 Dataset, Hyper-Parameters & Baselines

In order to demonstrate the effectiveness of the proposed model, i.e., Dynamic Path Reasoning (DPR), we evaluate it on the recent SemEval 2021 Task 8 dataset. This dataset provides measurement annotation for 233 training documents, 65 development documents, and 130 testing documents, all in English. Note that we do experiments only on the train and trial set (as the gold entities are not available for test set). Also, we evaluate the model only for relation extraction, not the entire task (as such, we did not make a submission during MeasEval evalu-

ation phase). More specifically, for each document, the positions of the measured entities, measured properties, quantities, and qualifiers are provided. Furthermore, for each measurement component, its relations with the other components or extra information (e.g., unit of quantity) is available. Note that in our experiments, we do not use the *annotation set* information which indicates which components belong to the same measurement.

We fine-tune the hyper-parameters of the proposed model on the development set of the SemEval 2021 Task 8 dataset. The model with the best performance on the development set is evaluated on the test set. Based on our experiments, the following hyper-parameters are selected: 50 dimensions for the position embedding and entity type embedding; 200 dimensions for the hidden layer of the BiLSTM and all feed-forward networks; 0.1 and 0.05 for the trade-off parameters  $\alpha$  and  $\beta$ ; 0.7 for the threshold in the dynamic path reasoning component; Adam optimizer with learning rate 0.3; batch-size 50; and early stopping with the patience of 10.

To comprehensively evaluate the proposed model, we compare its performance against the following baselines: (i) Sequential Models, specifically we compare with **BiLSTM** which takes the non-contextualized word embeddings of the input document (i.e., GloVe) and encode the sequence of the words. Moreover, we also compare with **BERT** model fine-tuned during training for the MRE task. (ii) Structure-aware models, these models employ the structure of the input document (e.g., dependency trees of the sentences). Specifically, we compare with iDepNN (Gupta et al., 2019) which employs the dependency trees of the sentences of the document. This baseline adds an edge between the roots of the trees to create a connected graph, Furthermore, it prunes the tree along the dependency path between the two entities of interest. Finally, we compare our model with **LSR** which dynamically infer a graph structure for the input document using the representations of the entities and other words on the dependency path between the entities.

### 3.2 Results

The results on the test set are presented in Table 1. There are several observations from this table. First, the proposed model significantly (with  $p < 0.01$ ) outperforms the baselines. It indicates the importance of using dynamic path reasoning and also the

Model	Precision	Recall	F1
<b>BiLSTM</b>	65.3	71.1	68.1
<b>BERT</b>	70.4	71.8	71.1
<b>iDepNN</b>	69.4	75.0	72.4
<b>LSR</b>	72	75.9	73.9
<b>DPR (Ours)</b>	70.1	83.4	<b>76.2</b>

Table 1: Performance on Test set

proposed regularization method. Second, Comparing the structure-aware and sequence-based baselines, it is evident that the structure of the input document is necessary for achieving better results. However, between the iDepNN and the LSR baseline, the latter has better performance due to its capability of inferring the structure of the document instead of relying on external parse trees as in iDepNN. Finally, this experiment shows that using the pre-trained language model BERT substantially improves the performance compared to a sequence-based model that utilizes GloVe embedding. This is on par with the recent advancement on NLP using contextualized word embeddings.

### 3.3 Ablation Study

In this section, we provide more insight into the effectiveness of different components of the proposed model. The major two components in our model are dynamic path reasoning and regularization. To study their importance, we evaluate the performance of the following baselines on the development set of the SemEval 2021 Task 8 datasets: (i) **Full<sup>-DPR</sup>**, this baseline completely removes the dynamic path reasoning component. More specifically, the vector  $h_p$  is removed from the final prediction vector  $V$  and the loss function  $\mathcal{L}_\Phi$  is also removed from the overall loss function  $\mathcal{L}$ ; (ii) **Full<sup>DPRS</sup>**, this baseline employs the dynamic path reasoning component. However, to compute the similarity score  $Sim_i$ , instead of considering the context if the word  $w_i$ , it directly computes the score by  $Sim_i = \|P - h_i\|$ ; (iii) **Full<sup>-Reg</sup>**, this model completely remove the regularization component, i.e., by removing the loss function  $\mathcal{L}_{disc}$  from the overall loss function  $\mathcal{L}$ ; (iv) **Full<sup>dot</sup>**, this ablated model preserves the regularization component. However, instead of using Information Bottleneck, it directly decreases the similarity between the path representation, i.e.,  $h_p$ , and the input document representation, i.e.,  $h_d$ , by replacing the  $\mathcal{L}_{disc}$  by  $\mathcal{L}_{\lceil \sqcup} = h_p \cdot h_d$ .

The results are presented in Table 2. This table shows that all components of the proposed model

Model	Precision	Recall	F1
<b>Full</b>	73.2	86.7	79.4
<b>Full<sup>-DPR</sup></b>	71.1	79.1	74.9
<b>Full<sup>DPRS</sup></b>	70.2	82.3	75.8
<b>Full<sup>-Reg</sup></b>	72.9	80.6	76.6
<b>Full<sup>dot</sup></b>	73.8	76.4	75.1

Table 2: Performance of the ablated models on the development set

are necessary to achieve the highest performance. More specifically, the dynamic path reasoning has the highest impact on the performance as removing it will hurt the most. Also, it shows that the consideration of the context to compute the score for each word to be included in the induced path is necessary. Finally, it shows that regularization is helpful for exclude noisy information from the input. More interestingly, replacing the IB with a dot product to enforce the regularization hurts more than removing the regularization itself. It indicates the necessity of using IB for regularization.

## 4 Related Work

Measurement Relation Extraction (MRE) is one specific formulation of the general Relation Extraction (RE) task. In the literature, RE has been tackled by feature-based methods (Zelenko et al., 2003; Zhou et al., 2005; Sun et al., 2011; Nguyen and Grishman, 2014; Nguyen et al., 2015c) and advanced deep learning models (Zeng et al., 2014; Wang et al., 2016; Lee et al., 2017; Zhang et al., 2017; Nguyen et al., 2019; Jin et al., 2018; Veyseh et al., 2020b). Recently, structure-aware deep models have shown significant improvement for RE (Peng et al., 2017; Song et al., 2018; Xu et al., 2015; Liu et al., 2015; Miwa and Bansal, 2016; Nguyen and Grishman, 2018a; Zhang et al., 2018). For a thorough review of the prior works, refer to the recent work (Gupta et al., 2019; Nan et al., 2020; Veyseh et al., 2020a)

## 5 Conclusion

We proposed a new model for the MRE task. The introduced model employs a dynamic path reasoning component which induces important context words to predict the relation between two measurement components. Furthermore, we proposed a novel regularization method based on Information Bottleneck to exclude noisy information from the input. Our experiments on the SemEval 2021 Task 8 reveal the effectiveness of the proposed model.

## Abstract

MeasEval aims at identifying quantities along with the entities that are measured with additional properties within English scientific documents. The variety of styles used makes measurements, a most crucial aspect of scientific writing, challenging to extract. This paper presents ablation studies making the case for several preprocessing steps such as specialized tokenization rules. For linguistic structure, we encode dependency trees in a Deep Graph Convolution Network (DGCNN) for multi-task classification.

## 1 Introduction

Scientific articles contain many quantities which have to be linked to their measured entities. Identifying quantities may seem as simple as digit recognition, but numbers alone are not informative. The entities and properties being measured, while crucial information, are difficult to extract. SemEval 2021 Task 8 (Harper et al., 2021) is a semantic relation extraction task consisting of 5 subtasks: identifying *quantities* and their *modifying* attributes, identifying *measured entities* and their *properties* as well as *qualifying* attributes, if specified.

Recent reports on the strong performance of purely neural models for NLP tasks often underreport the data preprocessing and postprocessing steps that accompany them. Preprocessing significantly influences overall performance. Typical NLP preprocessing steps include sentence splitting and tokenization, sometimes followed by task relevant gazetteer annotation, possibly named entity recognition (NER), part-of-speech (POS) tagging and dependency parsing. These preprocessing steps are so common that many different packages perform them, such as Stanford CoreNLP (Manning et al., 2014), spaCy<sup>1</sup>, and NLTK (Bird et al., 2009).

<sup>1</sup><https://spacy.io/models>

Linguistically inspired features are, however, not regularly exploited and we present here one attempt at encoding dependency information for the structural task of linking quantities with their measured entities, measured properties or qualifiers.

We approach the MeasEval task as a multi-class classification task using a Deep Graph Convolution Neural Network (DGCNN) (Zhang et al., 2018), treating the dependency parse tree as a graph to convolve over. We explore tokenization variants, as well as encodings of the dependency relations using node2vec (Grover and Leskovec, 2016) and UMAP (McInnes et al., 2018) techniques.

## 2 Problem Statement

The MeasEval (Harper et al., 2021) task consists of 5 (not independent) sub-tasks covering span detection, classification and relation extraction across multiple sentences<sup>2</sup>. Given a paragraph of scientific content in English, a system should: 1) label quantity spans (Q) where Q can be simple count or a numerical value with a unit. 2) if there is a unit it should be labelled as Unit(U), and a Q should be classified into one of the types (*count*, *approximate*, *range*, *list*, *mean*, *median*, *medianHasSD*, *meanHasTolerance*, *rangeHasTolerance*, *hasTolerance*) as Modifier(mod). 3) for each Q, systems should identify the span of a measured entity (ME) if one exists and also any measured properties (MP). 4) Identify any spans of qualifiers (QL) that record additional detail related to Q, ME or MP. 5) Label the relationships between Q, ME, MP and QL spans using HasQuantity(HQ), HasProperty(HP) and Qualifies relation types.

## 3 System Overview

**Motivation:** Unlike named entity detection tasks, MeasEval’s ME or MP detection depends on quan-

<sup>2</sup><https://competitions.codalab.org/competitions/25770>

ties and their relation to other tokens within a sentence. Since dependency parse trees are capable of providing approximations of semantic relationships between predicates and their arguments, we opted to generalize over different dependency parse trees to obtain latent path representations to distinguish between different semantic connections that quantities have with MEs or MPs. To encode this path representation we use a Graph Convolutional Networks (GCN) (Kipf and Welling, 2017) in the form of a DGCNN (Zhang et al., 2018), to operate directly on the dependency graph to capture higher order neighborhood information in the form of embeddings. This embedding is used for classifying the relationship type between the tokens to detect one of the 6 classes explained in Section 3.2.2

Our system has 3 main phases: preprocessing, input creation and training a GCN model and post processing respectively. Each phase communicates with the next through CoNLL format (Tjong Kim Sang and De Meulder, 2003) files.

### 3.1 Phase-I: Preprocessing

We preprocess data using the GATE (Cunningham et al., 2013) modules: ANNIE Tokenizer, ANNIE Sentence splitter, and Stanford Parser (POS tags and dependency graphs (de Marneffe et al., 2006)). Special tokenization rules added are:

**mixed character protection** prevents splitting tokens of differing character types into different tokens, e.g.  $\delta 13CTOC \not\rightarrow \delta, 13, CTOC$

**split mathematical symbols** preserves the usual ANNIE tokenization for  $5 \leq 2\theta/^\circ \leq 80$  into seven tokens ( $5, \leq, 2\theta, /, ^\circ, \leq, 80$ )

**number normalization** decimal numbers are prevented from being split into 3 tokens. Number words are also identified as numbers

**abbreviation period** common abbreviations in scientific journals are recognized as integral tokens including the abbreviation period, e.g. *e.g., Fig., sp., spp.* This improves sentence splitting and tokenization

**list and interval protection** scientific articles frequently report on intervals expressed in different ways and on lists of variable lengths. Both do not usually receive proper parse assignments, because the group as a whole plays a role in the text. To improve the dependency

relation assignments, we manually assign the POS tag ‘CD’ to the groupings:

CD (: | - | to) CD  
 CD (, CD)\* and CD

**unit gazetteer** composed from different sources<sup>3</sup> listing 4280 units

### 3.2 Phase-II: Input creation and GCN training

We train a DGCNN (Zhang et al., 2018) as a multilayer neural network that operates directly on a graph to induce node embeddings with properties of their neighborhood. DGCNN takes  $(A, I)$  as input, where  $A \in \mathbb{R}^{n \times n}$  is an adjacency matrix and  $n$  is equal to the number of nodes in the graph  $G$ .  $I \in \mathbb{R}^{n \times c}$  is an information matrix, associating  $c$  feature values with each of the  $n$  nodes. A single layer of DGCNN captures information according to:

$$Z = f(\hat{D}^{-1}AIW) \quad (1)$$

where  $\hat{D}$  is a diagonal degree matrix with  $\hat{D}_{ii} = \sum_j A_{ij}$  (capturing the branching factor of node  $i$ ) and  $W \in \mathbb{R}^{c \times c'}$  is a trainable parameter matrix.  $f$  is a nonlinear activation function and  $Z \in \mathbb{R}^{n \times c'}$ . Higher order neighborhood information is obtained by stacking multiple DGCNN layers:

$$Z^{t+1} = f(\hat{D}^{-1}AZ^tW^t) \quad (2)$$

where  $Z^0 = I$ ,  $Z^t \in \mathbb{R}^{n \times c_t}$  is the output of the  $t^{th}$  graph convolution layer,  $c_t$  is the size of the output vector of layer  $t$  and  $W^t \in \mathbb{R}^{c_t \times c_{t+1}}$ .

We model a dependency tree as graph  $G = (V, E)$ , where  $V$  are tokens and  $E$  are directed dependency relations. We ensure  $(v, v) \in E$  for all  $v \in V$ . To represent paths in the dependency graph between any two nodes, we add explicit reverse links (to *nsubj* from governor to dependant we add *rnsbj* from dependant to governor).

#### 3.2.1 Input creation

The DCNN classifier predicts six output classes, as defined in Section 3.2.2 for token pairs  $(t_1, t_2)$ , the *subgraph center points*.

The following sections show how (i) candidate token pairs are created, (ii) the smallest subgraph containing  $t_1$  and  $t_2$  is extracted, (iii) each subgraph  $SG$  is represented by  $(A_{SG}, I_{SG})$

<sup>3</sup><http://www.ibiblio.org/units/index.html>, [https://en.wikipedia.org/wiki/Metric\\_units](https://en.wikipedia.org/wiki/Metric_units)

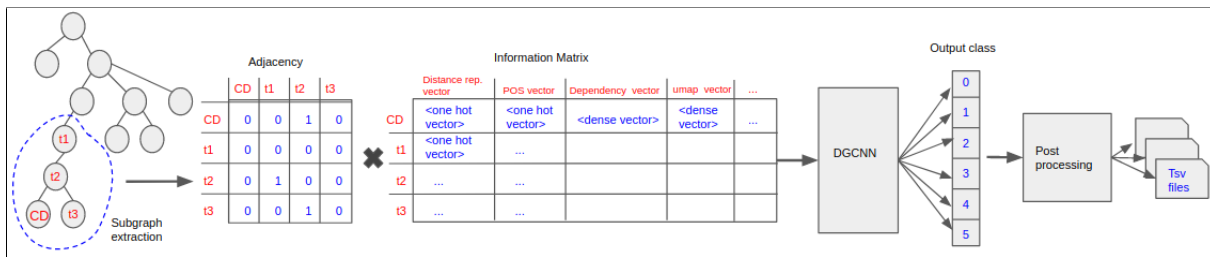

Figure 1: System Architecture from phase-II to phase-III

**Subgraph center point candidates:** In all pairs  $(t_1, t_2)$ ,  $t_1$  has to be a CD (a candidate for a quantity).<sup>4</sup>

In principle, all nodes in the graph are candidates for  $t_2$ , but we empirically set a limit of five on the connecting path length.

**Subgraph extraction** For each  $(t_1, t_2)$ , we select a subgraph containing only the shortest path recursively:  $SG_1$  contains all neighbors of  $t_1$ .  $SG_{k+1}$  contains  $SG_k$  and all neighbors of  $SG_k$ . We select the first subgraph that contains  $t_2$ .

**Adjacency matrix representation** The adjacency matrix  $A \in \mathbb{R}^{n \times n}$  is a binary matrix. Dependency relations from governor to dependant are one-to-many and all rows in the matrix are interpreted as dependants, the columns as governors.

**Information matrix** The information matrix  $I$  is a  $n \times c$  matrix, where  $c$  is size of the concatenated values for the five explicit or latent features associated with each vertex in our system:

**DISTANCE FEATURE** We use the Double Radius Node Label (DRNL) (Zhang and Chen, 2018) to calculate a combined distance of a node  $v_i$  to both subgraph centre nodes within the information matrix as one hot vector as follows:

Nodes  $t_1$  and  $t_2$  carry the label 1. For each  $v$  in the subgraph we calculate labels representing distance using the following hashing function:

$$f(v) = 1 + \min(d_{t_1}, d_{t_2}) + \lfloor \frac{d}{2} \rfloor \times (\lfloor \frac{d}{2} \rfloor + [d\%2] - 1) \quad (3)$$

where  $f(v)$  assigns labels to all nodes  $v$ ,  $d_{t_1}$  and  $d_{t_2}$  are distances of  $v$  with respect to  $t_1$  and  $t_2$  respectively.  $d = d_{t_1} + d_{t_2}$ ,  $\lfloor d/2 \rfloor$  is the integer quotient and  $[d\%2]$  is the remainder of  $d$  divided by 2.

<sup>4</sup>Note that the gold relations connect text spans, not necessarily tokens. The classifier attempts to predict relations between tokens and the postprocessing phase maps the results to spans.

POS FEATURE encoded as a one hot vector

WORD EMBEDDING from the PubMed ELMo model (Peters et al., 2018) of size 1024.

DEPENDENCY PATH EMBEDDING represents the dependency path of each node within the subgraph from  $t_1$  (base node)  $(p(v, t_1))$ . We create *dependency embeddings* of size 128 from dependency sequences in the training data using node2vec (Grover and Leskovec, 2016). Given a graph  $G$ , node2vec<sup>5</sup> uses a random walk procedure from each node  $v \in G$  to produce  $s$  sequences of length  $l$ , and uses these sequences for training node2vec. We embed dependency sequences instead of node sequences to produce embeddings for each dependency relationship type (i.e. we use node2vec to produce embeddings for edges instead of nodes). To represent  $p(v, t_1)$  we concatenate dependency embeddings for each dependency along the dependency path. Given our empirical limit,  $p(v, t_1) \in \mathbb{R}^{5 \times 128}$  and for smaller subgraphs we pad with 0's.

UMAP EMBEDDING As either a complement, or a replacement to dependency embeddings, we experimented with the UMAP dimension reduction technique (McInnes et al., 2018). We trained UMAP as a supervised learning approach feeding dependency embeddings along with class labels and reduced dependency path embeddings to 2 dimensions.

### 3.2.2 Training the DGCNN model

Input  $(A, I)$  was used to train an off the shelf implementation of Deep Graph Convolution Neural Networks (DGCNN)<sup>6</sup> with CrossEntropyLoss<sup>7</sup> as its loss function and with class weights calculated

<sup>5</sup><https://github.com/aditya-grover/node2vec>

<sup>6</sup>[https://github.com/muhanzhang/pytorch\\_DGCNN](https://github.com/muhanzhang/pytorch_DGCNN)

<sup>7</sup><https://pytorch.org/docs/stable/generated/torch.nn.CrossEntropyLoss.html>

by  $1/\text{total\_num\_datapoints\_within\_class}$ . We trained the system for 6 epochs with a batch size of 100 in a cuda environment with 6 output classes to predict.

**Class labelling:** Center points  $(t_1, t_2)$  are predicted to fall into one of six classes:

**Class 0:**  $t_1$  is not part of a gold Quantity (Q) span<sup>8</sup>; **Class 1:**  $t_1$  is within a Q span but  $t_2$  is not within any gold span; **Class 2:**  $t_1$  and  $t_2$  are in the same Q span (e.g. 5 kg); **Class 3:**  $t_1$  is within a Q span and  $t_2$  is any token within the ME span belonging to the same annotation set as  $t_1$ ; **Class 4:**  $t_1$  is within a Q span and  $t_2$  is any token within the MP span belonging to the same annotation set as  $t_1$ ; **Class 5:**  $t_1$  is within a Q span and  $t_2$  is any token within the QL span belonging to the same annotation set as  $t_1$ .

### 3.3 Phase-III: Postprocessing

The six classifier classes predict relations between two tokens, while the gold standard annotates relations between text spans. The required mapping to competition output requires several postprocessing steps.

**Prediction ranking** When multiple  $t_2$  with the same class are predicted for a particular  $t_1$  we choose  $t_2$  with the highest probability.<sup>9</sup>

**Span mapping** For each prediction  $(t_1, t_2) \in \text{ClassY}$  we record the token offset for  $t_2$  as span for ClassY in our system output unless the BERT model from (Therien et al., 2021) finds a neighbouring token with the same predicted class, in which case they are merged into the same span.

**Detecting units** Once quantity spans are determined, any measurement gazetteer entry within it was labelled as a unit.

**Predicting quantity modifiers** We used another pretrained BERT model from (Therien et al., 2021) to predict modifiers for each quantity span.

## 4 Results and Analysis

We split the combined training and trial datasets randomly into 75% training and 25% validation set resulting in 233 and 80 documents in our training and validation set respectively.

<sup>8</sup>Not all CDs are part of a gold quantity (e.g. Fig. 5).

<sup>9</sup>We exclude predictions for  $(t_1, t_2)$  where  $t_2$  carries POS tags among *IN*, *DT*, *CD*, *PUNCT*.

We experimented with different preprocessing and feature representations using the official Meas-Eval evaluation script. DGCNN training parameters were fixed for all the experiments.

Table 1 shows development results, the first row (in italics) shows the competition system. The first column (T) indicates the influence of the list and interval protection step: *c* indicates it is included, *n* indicates it is not included. We observe that not including it returns slightly better results, offset by a high rate of duplicates<sup>10</sup>.

We experiment with different path length limits (column 4: H). While a length limit of 8 showed better results on the development data than our competition limit of 5, the same is not true for the test data (see Table 2), where there is no equivalent recall gain.

T:	S:	H:	P	R	F1	EM	O	
<i>c</i>	<i>s</i>	<i>u</i>	5	.586	.466	.520	.281	.328
<i>c</i>	<i>s</i>	<i>u</i>	8	.563	.503	.532	.288	.336
<i>n</i>	<i>s</i>	<i>u</i>	5	.567	.485	.522	.291	.334
<i>n</i>	<i>s</i>	<i>u</i>	6	.591	.487	.535	.301	.344
<i>n</i>	<i>s</i>	<i>u</i>	8	<b>.654</b>	<b>.529</b>	<b>.585</b>	<b>.337</b>	<b>.387</b>

Table 1: Development results. P:precision, R:recall, F1:F1-score, EM:exact match, O:F1 (Overlap)

Table 2 shows competition and post-competition results on test data. The initial competition system is in italics, in bold are the revised results after the organizers removed duplicates.

T:	S:	H:	P	R	F1	EM	O	
<i>c</i>	<i>s</i>	<i>u</i>	5	<b>.546</b>	<b>.323</b>	<b>.406</b>	<b>.217</b>	<b>.241</b>
<i>c</i>	<i>s</i>	<i>u</i>	5	.554	.347	.427	.232	.258

Table 2: Competition results

Results on the test data are significantly lower, indicating overfitting. Post-competition ablation in Table 3 shows that UMAP, for instance, was not effective. Overlap determined competition rankings.

T:	S:	H:	P	R	F1	EM	O	
<i>c</i>	<i>s</i>	<i>u</i>	5	.691	.313	.431	.241	.264
<i>c</i>	<i>s</i>	<i>u</i>	5	.539	.446	.448	.275	.306
<i>c</i>	<i>s</i>	<i>u</i>	8	.614	.310	.412	.227	.249
<i>c</i>	<i>s</i>	<i>u</i>	8	.480	.477	.478	.263	.296

Table 3: Post competition results

<sup>10</sup>Only in the first row of Table 2 are duplicates removed, all other reported results have duplicates and thus overreport slightly.

	Q	ME	MP	U	Mod	HQ	HP
csu5	<b>.889</b>	<b>.057</b>	<b>.007</b>	<b>.495</b>	<b>.408</b>	<b>.028</b>	<b>0.</b>

cs_5	.830	.177	.177	.449	.484	.167	.053

Table 4: F1 overlap scores of annotation types on competition test data. Q:Quantity, ME:Measured Entity, MP: Measured Property, U:Unit, Mod:Modifier, HQ: Has Quantity, HP: Has Property

Analysing performance for the different labels in Table 4 shows that our system is not yet mature and needs adjusting. The potential of the DCGNN for the tasks is demonstrated by the high results for quantity (Q) and acceptable results for units (U), which are in line with stronger systems. The comparatively low performance for measured entities (ME) and measured properties (MP) demonstrates that the multi-class labelling approach needs better support. We will consider approaches from the literature (Yao et al., 2018), (Sun et al., 2019), (Hong et al., 2020), (Gupta et al., 2016).

HasQuantity and HasProperty received no attention during development and consistently scored 0 for runs with UMAP, see Table 4.

**Combined tokens:** When  $CD(CD),*$  and  $CD$  is followed by *respectively*, each list item corresponds to a different entity/property (e.g. *This compares to signatures of accelerated electron precipitation from peaked electrons and “inverted-V” electrons, which occur on 9.8 and 3.4% of MEX orbits, respectively.*) As per gold annotation, 9.8 and 3.4% are 2 different Qs both with “MEX Orbits” as ME and “signatures of accelerated electron precipitation” as MPs. We generate *9.8 and 3.4%* as a single Q and “Signatures” as ME, leading to several false negatives. Documents S0032063312003054-2458, S0016236113008041-3257, S0378112713005288-1916 caused this error.

**Math equalities** Our system does not protect math environments such as *...tetragonal unit cell with  $a=4.1816(4)$  Å and  $c=10.0322(6)$  Å...* in document S0022459611006116-1351. Consequently,  $a$  is labelled as a determiner (DT). As determiners are not part of gold labels,  $a$  is eliminated in postprocessing when it should have been labelled as an MP in this case and also in document S0022459611006116-1257.

**Calculations with measurements** Our custom tokenizer does not handle calculations, as in “...re-

*vised average base reaction rate (from  $k_1 = 2 \times 10^{-9}$  to  $k_1 = 1 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$ )...*” in document S0019103512003533-3908. The gold annotation for Q is ( $k_1 = 2 \times 10^{-9} \text{ to } k_1 = 1 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$ ) and ME is *average base reaction rate*, where we return “ $2 \times 10$ ” as a Q with “average” as ME, “ $1 \times 10$ ” as Q with “reaction” as ME and “9” (split by symbol “-”) as separate quantities with ME as “reaction”, incurring false positive errors.

**Duplication of Quantities** Lists of quantities including units are not combined with our custom tokenizer, thus for *for 4.5 kg and 6 kg samples* in document S0016236113008041-3257, we stipulate two different quantities. This results in duplication of quantities in our submission.<sup>11</sup>

**Units** The gold standard annotates for instance *thin shale barriers* (S1750583613004192-1126), *das* (S037842901300244X-1654),  $\% \Delta E/E$  (S0301010413004096-767), and *KLoC* (S016412121300188X-3207) as units. These are not included in our gazetteer list of 4028 units, incurring false negative errors.

## 5 Conclusions

The MeasEval task is a challenging task that can benefit from a variety of tools in a well integrated system. The small data size limits a true appreciation of the challenges involved but ablation studies suggest that tokenization variations influence precision and recall differently and should be carefully considered in application systems. Also, a umap reduction suggested a ca 1% performance boost on validation data, but incurs a ca 5% loss on test data, showing signs of overfitting. The subgraph classifier proved effective only for quantity and unit prediction. Ablations show that larger subgraphs and longer paths lead to performance degradation, making a case for more task oriented locality features. Duplicates have to be removed.

While the unusual complexity of the classification task and the limited size of the dataset prohibits very general conclusions, we showed that DCGNNs offer an interesting way to encode dependency information but that it has to be supported by several domain inspired contributions to work for all task components effectively.

<sup>11</sup>This duplication of labels was removed by the organizers for the official ranking.

## Abstract

This paper explains the design of a heterogeneous system that ranked eighth in competition in SemEval2021 Task 8. We analyze ablation experiments and demonstrate how the system components, namely tokenizer, unit identifier, modifier classifier, and language model, affect the overall score. We compare our results to similar experiments from the literature and introduce a grouping algorithm developed in the post-evaluation phase that increased our system’s overall score, hypothetically elevating our competition rank from eight to six.

## 1 Introduction

The MeasEval 2021 shared task involves identifying related groups of the four annotation types seen in Table 1, identifying relations linking the annotations of each group, and providing additional information (units and modifiers) for quantities (see (Harper et al., 2021)). Our system learns to classify tokens, groups tokens of the same class into spans and further groups related spans using a distance-based heuristic, providing a baseline for systems that attempt to learn these groupings.

## 2 Data

The data comprises excerpts from scientific articles of different disciplines: Astronomy, Engineering, Medicine, Agriculture, Biology, Chemistry, Earth Science, Computer Science, and Mathematics. The limited data (see Table 1), the wide range of topics involved, and the idiosyncrasies of each scientific field’s vocabulary make the task difficult. In fact, the task organizers report a high degree of inter-annotator disagreement for certain annotation types. Krippendorff’s alpha (Hayes and Krippendorff, 2007) for each annotation type is also shown in Table 1, underlining that annotating Measured Properties, Measured Entities, and Qualifiers poses a substantial degree of ambiguity, even to humans.

Annotation	Frequency	$\alpha$
Quantity (QA)	1164	.94
Unit (U)		.86
MeasuredEntity (ME)	1148	.54
MeasuredProperty (MP)	742	.64
Qualifier (QL)	276	.33

Table 1: Frequency of training data annotations and their Krippendorff’s Alpha

The training data contains a total of 298 excerpts containing 1164 different quantities. We refer to groupings of annotations as complete data-points (see Figure 1).

All complete data-points contain one quantity and at most one annotation span of each other type. A summary of complete data-point frequencies is provided in Table 2.

Annotations present	Frequency
QA	11
ME,QA	361
ME,MP,QA	512
ME,QL,QA	50
ME,MP,QL,QA	225
MP,QA	4
MP,QL,QA	1

Table 2: Frequency of different complete data-points in the training data

## 3 System

Our system is a pipeline of different machine learning and rule-based modules. We use SpaCy<sup>1</sup> for sentence splitting and tokenization and we fine-tune a SciBERT model<sup>2</sup> to classify each token into one of *Quantity* (QA), *Measured Entity* (ME), *Measured Property* (MP), *Qualifier* (QL), or *Other* (O).

<sup>1</sup><https://spacy.io/>

<sup>2</sup>SciBERT uses the same model architecture and pretraining objective as BERT (Devlin et al., 2019), but it is pre-trained on a large corpus of scientific text (Beltagy et al., 2019).

Figure 1: An example of a complete data point with corresponding annotations

During a first postprocessing phase, the token level output of the classifier is merged into spans of adjacent annotations of the same type. We feed the spans annotated as QA to a second SciBERT classifier to determine their modifier class (see Section 3.4). A distance-based heuristic groups the classified spans into complete data-points.

All of the system’s deep learning components are implemented using PyTorch (Paszke et al., 2017). Our models use simple (linear + softmax) classification on top of BERT’s implementation from the HuggingFace library.<sup>3</sup> Pre-trained weights are obtained from HuggingFace’s Model Hub.<sup>4</sup> Our competition SciBERT models are optimized by Adam (Kingma and Ba, 2015) using a constant learning rate of  $5e-6$  (the rest of Adam’s parameters are set to PyTorch’s defaults). The competition system’s token classifier is fine-tuned on all the training data for 5 epochs, while the modifier classifier is fine-tuned on all the training data for 3 epochs.

### 3.1 Preprocessing

**Tokenization** We modify SpaCy’s tokenizer to make several symbols individual tokens. As illustrated in Tables 3 and 4, our tokenizer separates apart mathematical symbols as well as suffixes *Rp*, *Rs*, *mH*, *RRh*.

Prefix	= $\sim \pm - \leq > < \geq$
Infix	= $\sim \approx \bullet : \% ( ) \rightarrow + - \pm , > <$
Suffix	<i>Rp</i> <i>Rs</i> <i>mH</i> <i>RRh</i>

Table 3: Tokenization rules added

The tokenization rules split apart tokens that contain annotations of different types (see Table 4).

**Gold span to token conversion** The token-level objective used to fine-tune SciBERT requires mapping the gold span annotations onto tokens. However, the gold standard annotations don’t always coincide with our token spans. Some gold annotation boundaries are in error (e.g. *oss rate* instead

<sup>3</sup><https://huggingface.co/transformers>

<sup>4</sup>The SciBERT models we refer to are fine-tuned from ‘scibert\_scivocab\_cased’ and the BERT model we refer to is fine-tuned from ‘bert-base-cased’.

SpaCy tokens	Modified tokens
$\sim$ 2-3, mA, /, cm2	$\sim$ , 2, -, 3, mA, /, cm2
$\sim$ 0.40-0.45, V	$\sim$ , 0.40, -, 0.45, V
$\sim$ 27%	$\sim$ -, 27, %
(ratio, CaP=1.67)	(,ratio, CaP, =, 1.67,)

Table 4: Tokenization examples

of *loss rate*) and some are deliberate (e.g. *beach* as the annotated part of the token *beaches*).

Of the 3330 gold spans that we convert to token-level training samples, only 48 are off by one character, and 2 are off by more than one character. The remaining token level annotations perfectly match the gold spans in character offset. We therefore convert gold annotations to token annotations naively, projecting gold span annotation onto the token span with the least character differences and obtain mappings as illustrated in Figure 2a.

**Sentence splitting** Scientific text makes frequent use of acronyms (e.g. *fig.*) which confuse SpaCy’s default sentence splitter. We use exclusion rules for frequent abbreviations and special tokens that end in punctuation. We also exclude symbols from starting a sentence, as well as tokens not preceded by a period.

### 3.2 Token Classification

We fine-tune SciBERT to classify tokens into the five output categories QA, QL, MP, ME, and O, where O indicates no annotation for a token. This module processes one document at a time, taking a list of sentences as input, where each sentence is a list of tokens. The output of the classifier is the token annotations for each of the sentences it receives.

**Input** The special token *[CLS]* is followed by tokenized sentences separated by *[SEP]*.

**Token classification** We use a linear layer followed by softmax for the token level multi-class classification into the five label categories from SciBERT output

**Out of vocabulary tokens** SciBERT’s Word-Piece tokenizer (Wu et al., 2016) splits unknown

tokens into *subwords* for which it has embeddings. We distribute a token’s gold annotation over all subwords within its span (see Figure 2b). To calculate the loss between gold standard and predicted tags, we use cross-entropy. Finally, to predict the class of a token that SciBERT breaks, we take the majority class of its subwords, breaking ties using the class of the first subword, contrary to (Devlin et al., 2019), who always use the class of the first subword.

### 3.3 Token Span Creation

After token classification, we group any adjacent tokens labelled with the same class into a single span for that label. If the label for a token differs from the label of its neighbors, it forms a span by itself.

### 3.4 Modifiers

In addition to the five classes discussed so far, MeasEval 2021 also annotates 10 modifier categories<sup>5</sup> for quantity spans: *IsApproximate*, *IsCount*, *IsRange*, *IsList*, *IsMean*, *IsMedian*, *IsMeanHasSD*, *IsMeanHasTolerance*, *IsRangeHasTolerance*, *HasTolerance*, or *NOMOD*.

For instance, the underlined quantity in Example 1 has a modifier class of *HasTolerance* triggered by  $\pm$ .

(1) ... constrain the CTB at 93.90 $\pm$ 0.15 *Ma*

To determine a quantity’s modifier class, we fine-tune a second SciBERT model. Using the *[CLS]* token as a representation for a quantity’s span, the model classifies the span into one of the 11 categories.

Our model predicts at most one modifier per quantity span, which fails in certain examples with more than one modifier. The training data contains 552 quantities with modifiers and 37 of those quantities have two modifiers assigned to them. In competition, our system ranked third for the modifier class.

### 3.5 Unit identification

We identify units in quantities using a simple rule-based algorithm. No unit is predicted when a quantity span ends in a number or when its predicted modifier is *IsCount*. Otherwise, mark the unit as the string of characters starting from the last occurring numerical character in the quantity span to the

<sup>5</sup>We add an 11th *NOMOD* which indicates the absence of a class.

end of that quantity span. Example 1 highlights the unit in a gray box.

## 3.6 Span Grouping

We present two approaches for grouping annotation spans into datapoints. The first approach is our original competition algorithm, the second is an improved, post-competition version. Each approach works from lists of token spans (as described above) and outputs a list of groupings. Groupings approximate complete data points.

### 3.6.1 Original

Our competition system creates candidate groupings for each quantity in a first pass by adding at most one measured entity, one measured property, and one qualifier span to the group if they occur within the same sentence as the group’s quantity. A span cannot be assigned to multiple groups. Next, we calculate the character distance between each group’s quantity and any still unmatched annotations that are at most one sentence away. The list of distances is sorted and the closest missing annotation within one sentence distance is added. While this algorithm creates some correct complete datapoints, it has two major drawbacks: one measured entity cannot be used for multiple groups and we do not rank the matches to achieve the best fit for all the quantities. When used in our competition system, this algorithm generates 1626 True positives, 892 false positives, and 1504 false negatives.

### 3.6.2 Span++

In the post evaluation phase, we tested a new algorithm that accounts for token distance during the grouping process. First, the algorithm initializes candidate groups for each quantity. Then, each quantity span is paired with each measured entity span and the shortest token distance between the spans is calculated. The measured entity from the closest pair is added to its quantity’s group and the pair is removed from the list. This is repeated for all measured entities that are within a 68 token distance from their quantity. Measured entities farther away are discarded. Then, the same matching process is used for measured properties and qualifiers with cutoff distances of 26 and 25 tokens respectively. Using identical settings to our original submission, we evaluate the performance of our new algorithm (called ‘span++’ in Table 5). We obtain consistently better overlap f1-scores. While this algorithm supersedes its predecessor, it still

a)	Tokens:	<i>Model</i>	<i>Cl</i>	<i>assumes</i>	<i>a</i>	<i>constant</i>	<i>photoelectron</i>	<i>heating</i>	<i>efficiency</i>	<i>of</i>	<i>96</i>	<i>%</i>	
	Gold tags:	ME	ME	O	O	MP	MP	MP	MP	O	QA	QA	
b)	SciBERT tokens:	<i>Model</i>	<i>Cl</i>	<i>assumes</i>	<i>a</i>	<i>constant</i>	<i>photo</i>	<i>##electron</i>	<i>heating</i>	<i>efficiency</i>	<i>of</i>	<i>96</i>	<i>%</i>
	Expanded tags:	ME	ME	O	O	MP	MP	MP	MP	MP	O	QA	QA

Figure 2: (a) Converting span annotations of Figure 1 to token annotations. (b) If SciBERT tokenizer breaks a token, we assign its gold tag to all of its sub-tokens

fails to account for multiple quantities having the same measured entity. When used in our competition system, this algorithm generates 1728 True positives, 778 false positives, and 1402 false negatives.

### 3.7 Relations

Our system uses predefined rules to determine the relations between annotations in a data-point. If there is a measured entity and no measured property, then the measured entity HasQuantity, otherwise, when both are present, the measured entity is assigned HasProperty and the measured property is assigned HasQuantity. Anytime a qualifier is added to a span, we stipulate that it qualifies the quantity.

## 4 Results

Our submission ranked eighth in competition (listed as rank 7 on the CodaLab leaderboard). Our system is robustly above average on all categories (see Table 5) with strong performance in quantity overlap score (tied for 2nd), qualifier overlap score (2nd), modifier overlap score (3rd), and qualifies overlap score (3rd).

Table 5 shows competition and post-competition results. Our competition system is called *CLaC-BP* and the competition winner is listed under *top ranked*. The first six entries of Table 5 show results for ablation experiments.

Our competition system had a non-zero dropout probability, therefore, we cannot recreate its exact performance for the benchmarking of our ablations. The system labelled **Full** was run with zero dropout probability and is otherwise identical to our competition system. All ablated systems are compared to this baseline.

**Noticeable differences** The first comparison in row 2 substitutes our fine-tuned SciBERT model for a fine-tuned BERT base model for token classification. SciBERT outperforms BERT for every

category except quantity and unit.

In row 3 we assess our modified tokenizer, by substituting it with SpaCy’s default tokenizer. The performance is near identical to our baseline system in every category.

The third and fourth systems were trained without modifiers and without units respectively. Overall, the system without units performed worse than the system without modifiers. This is, however, to be expected as there are 905 units and only 552 modifiers, i.e. units account for more overlap score.

Finally, the last comparison showcases the improvements when using *span++*.

## 5 Discussion

Our system’s modular pipeline allows us to assess the components in ablation studies and the various experiments we perform are informative about the task.

Compared to BERT base, SciBERT pretraining gives a solid advantage to all categories, except quantities and units. Not surprisingly, Table 5 shows a greater increase in precision than recall and the exact matches (EM) and F1 overlap (O) scores rise significantly.

Comparing SciBERT’s and BERT’s performance on the token level objective (Table 6) used during fine-tuning, we see that SciBERT yields greater precision for all competition categories, while BERT yields higher recall for all but *other*. In addition, the token level evaluation is not fully commensurate with the task evaluation, as the significant second task of grouping different spans is not fully assessed.

Our system might benefit from a more precise token level classifier due to its grouping algorithm: it is reasonable to assume that it performs better when more of the detected spans are correct (high precision system) and performs worse with a greater number of incorrect spans (high recall system).

Substituting SpaCy’s tokenizer into our system does not make much difference because SciBERT’s WordPiece tokenizer will break any unknown to-

kens, however they are tokenized, into subwords at inference time. Yet, because the classifier output is projected onto input tokens, SpaCy’s failure to separate certain tokens (see Table 4) might be responsible for the very small degradation when using the SpaCy tokenizer.

Addressing the modifier categories with a separate SciBERT model is successful and allows our system to benefit from several rule-based transition phases. While the task is not well understood (see the overall low performances and the high inter-annotator disagreement), we believe this type of architecture to be more beneficial than end-to-end systems, as we can pinpoint weaknesses and experiment more easily. This is demonstrated by the sizeable improvement of results when implementing a simple distance measure constraint for the grouping step. Once such features have been identified as effective, their encoding in the classifier becomes possible.

## 6 Summary

Measurements are ubiquitous in scientific articles, yet have so far not been addressed. The MeasEval task is an opportunity to combine different subtasks and experiment how best to combine them. Our system approaches the MeasEval task in a modular fashion: preprocessing, two classifications, and postprocessing. It breaks the task into two, first a

classification of the relations for measured entities, measured properties, and qualifiers and second a classification of modifiers. SciBERT, trained on scientific articles, yields better performance than BERT in our experiments, mainly due to improvements in precision. The differences, however are small. Before, between, and after the two classification steps are a number of rule-based modules that create the classifier input and piece together the classifier output for submission. Several experiments on variations in these rule-based accessories suggest their usefulness and ways to improve our results.

## Abstract

This paper describes our system for verifying statements with tables at SemEval-2021 Task 9. We developed a two-stage verifying system based on the latest table-based pre-trained model GraPPa. Multiple networks are devised to verify different types of statements in the competition dataset and an adaptive model ensembling technique is applied to ensemble models in both stages. A statement-slot-based symbolic operation module is also used in our system to further improve the performance and stability of the system. Our model achieves second place in the 3-way classification and fourth place in the 2-way classification evaluation. Several ablation experiments show the effectiveness of different modules proposed in this paper.

## 1 Introduction

Verifying whether a statement is entailed, refuted, or unknown with the given table is a challenging task, which requires the system to understand the statement and table jointly and reasons from the two information resources. The studies on this task could benefit several downstream applications, e.g. fake news detection. Recently, with the release of a large-scale dataset for table-based fact verification named TABFACT (Chen et al., 2019), this task received several studies. Verifying statements based on tables is a challenging task since the researches on understanding tables are not enough compared with works on free-texts, and the methods to train models understanding free-text and table jointly need further studies as well.

While TABFACT contains a huge number of statements and tables, the tables in the TABFACT dataset are relatively simple since they do not have hierarchical column heads as tables in scientific papers do and the contents in the tables are easier to understand compared to the tables in scientific

papers as well. In the SemEval task 9 (Wang et al., 2021), the goal is to develop a system that can verify statements (**subtask A**) and find evidence (**subtask B**) based on the tables extracted from scientific tables. Our team is more interested in the verifying task and only participated in subtask A. Different from data in TABFACT, in subtask A, we are also required to classify a new type of statement that cannot be entailed or refuted based on the given table, named “unknown” type. Since no statements of this type are given in the training data, the classification of this type of statement becomes a core difficulty of the subtask.

This paper describes our two-stage table-based verifying system based on the latest table-based pre-trained language model GraPPa (Yu et al., 2020). The system leverages the model ensembling technique to ensemble different verifying models which are designed to solve different types of statements in the dataset in both two stages of the system. The statement-slot technique is also used to capture and solve a small part of the data by symbol calculation, which helps to increase the performance and stability of our system. Our system achieves a two-way score of 84.55 and a three-way score of 83.76 in subtask A respectively.

## 2 Related Work

### 2.1 GraPPa

GraPPa is a pre-trained model for table-based semantic parsing task, proposed by Yu et al. (2020). It is pre-trained on the synthetic question-SQL pairs with a novel text-schema linking objective, where the SQL queries are generated by a synchronous context-free grammar(SCFG). The text-schema linking objective makes the model predict the syntactic roles of the columns in the SQL to encourage the model to notice the link between

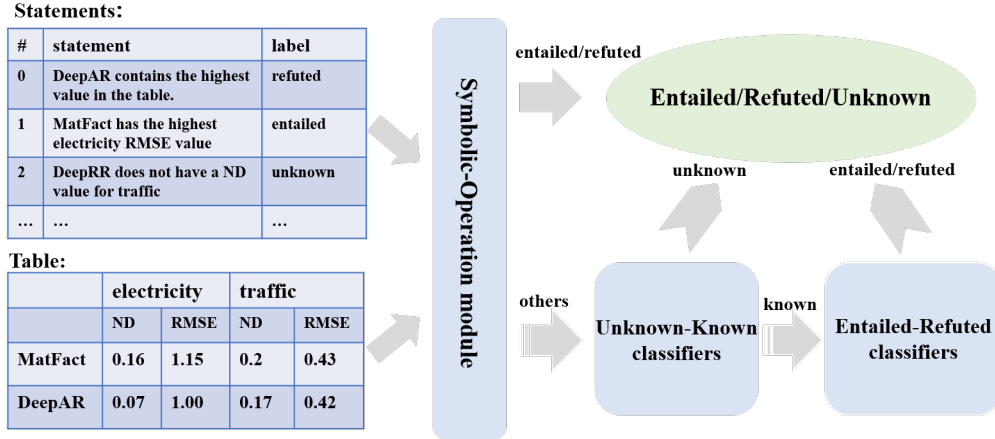

Figure 1: The flowchart of the system. Statements and tables are first sent into the symbolic-calculation module, where statements with simple sentence structures are verified by symbol calculation. Statements that are not processed by the calculator are then sent into the two-stage deep-learning-based verifying system, where the first stage’s models verify whether the statement cannot be verified by the given table, and the second stage’s models verify whether the statement can be entailed by the given table.

natural language phrases and the corresponding logical form constituents.

The authors of GraPPa use 475k synthetic examples to pre-train GraPPa. On four popular semantic parsing benchmarks, GraPPa consistently achieves state-of-the-art results, which shows the powerful table understanding ability of GraPPa. In this work, we find that GraPPa’s ability of understanding tables can also be migrated to the table-based fact verification task and achieves great performance on this task.

## 2.2 Mixture-of-Experts layer

In Shazeer et al. (2017) the authors proposed a sparsely mixture-of experts layer applied on the stacked LSTM model which achieves new state-of-the-art results on language modeling and machine translation benchmarks with lower computational cost and larger model capacity. In this work, we applied this MoE layer on the top of the GraPPa model as a part of our verifying system.

## 3 System Description

This section mainly describes the details of the two-stage table-based verifying system. The first stage classifies unknown type statements from the other two types of statements, while the second stage further classifies the entailed type statements from refuted type statements. We find that the proposed two-stage system works better than a direct three-way classification system, because 1) no unknown type statements are provided in the

train set, which brings difficulty to the training process of the three-way classification system; 2) the two-stage system is closer to the processing procedure of human since you have to decide whether the table knowledge is enough to entail or refute the given statement before the further reasoning. Before the two-stage deep-learning-based system, a symbolic-calculation module is added to capture and process some statements with simple sentence structures. The symbolic-calculation module has the features of low recall and high precision and is used to process some numerical type statements (the verifying process involves numerical operations) since we find that the deep-learning-based system is unstable when processing such type of statements. The flowchart of the whole system is displayed in Figure 1.

### 3.1 Statement-table joint encoder

In both stages of our system, multiple binary classifiers are ensembled together to verify statements. All of the binary classifiers used in the system are constructed based on the table-based pre-trained model GraPPa. In the system, the GraPPa model works in two way: 1) encoding the statement and the pruned table by following the table-BERT method and the table pruning algorithm proposed in Chen et al. (2019); 2) encoding the statement and each row of the table separately by the same method. While the first way is the standard encoding method of NLI tasks, we found the second way

also has its advantages and will explain later. After encoding the table and statement by GraPPa, multiple networks are devised to do reasoning based on the encoded representations. The following sections provide further details of these models, named pruned-table-based models and whole-table-based models separately.

Figure 2: The structure of verifying model is based on the types of statements. An MLP manager activated by the softmax function takes the joint representation as input and outputs the probability distribution that the statement belongs to different types of statements. Multiple MLP experts process the joint representation and output the classification logits, which are further averaged by the statement type probability from the manager to achieve the final classification logits.

### 3.2 Pruned-table-based models

As introduced before, we simply substitute BERT by GraPPa in the Table-BERT method to get the joint representation of the statement and table. Multiple networks are devised to process the joint representation: 1) a simple linear layer, same as Table-BERT; 2) three MLP processing different types of statements (statements that need to count rows/columns, statements related with the superlative operation, other statements) with a softmax activated MLP manager outputs the probability that the statement belongs to each type of statements. The final output distribution is the weighted average of different MLP experts’ output distribution; 3) same structure as 2), but the statements are separated based on the language style (natural/artificial) and the MLP manager is trained based on the natural statement ids provided in the train set; 4) sparsely MoE layer introduced in Shazeer et al. (2017) with applying the implementation on <https://github.com/davidmrau/mixture-of-experts>. Figure 2 shows the basic model structure of networks 2) and 3).

### 3.3 Whole-table-based models

As serialized tables obtained by language template are usually too long to be encoded by transformer-

based model, the above methods use a table pruning algorithm to choose statement-related columns from the table, while the algorithm is not perfect and it may discard some useful columns in tables. Even if the pruning algorithm chooses all the related columns, the pruned serialized table may still be too long. The whole-table-based models regard the table as the set of rows and serialize each row by the same method. Then each row is concatenated with the statement and sent in GraPPa to get the representation of tokens in the statement and each row. Two different reasoning networks are applied after the encoding process. The first one is a simple attention network across all tokens in the statement and table, the final output distribution is produced by the following:

$$Q = RR^T, Q' = \text{softmax}(Q), F = Q'R \quad (1)$$

$$\mathbf{att} = RW_a + \mathbf{b} \quad (2)$$

$$\mathbf{out} = \text{MLP}(F^T \mathbf{att}) \quad (3)$$

where  $R \in \mathbb{R}^{n \times e}$  is the representation matrix of all the tokens in the table and statements,  $n$  is the product of row numbers and the maximum token numbers of the concatenation between the statement and different rows,  $e$  is the embedding size. Softmax is applied to the attention matrix, where  $Q'_{ij}$  represents the  $j^{\text{th}}$  token’s contribution to the  $i^{\text{th}}$  token.  $F$  is the attended representation matrix, and  $\mathbf{att}$  is the importance score of tokens in statement and table achieved by a linear layer where  $W_a \in \mathbb{R}^{e \times 1}$  and  $\mathbf{b} \in \mathbb{R}^{e \times 1}$  are trainable parameters. Follow the equation 3, the representations are further aggregated by the importance score and sent into an MLP classifier to get the output distribution.

Another choice of reasoning network is the GAT network proposed in Liu et al. (2019) to aggregate evidence from different sources. GAT hierarchically aggregates information (first in token-level and then in sentence-level) which is more reasonable compared to the simple attention network mentioned before. For the convenience of presentation, all the models mentioned in this section are named and listed in Table 1.

### 3.4 Adaptive model ensembling

An adaptive model ensembling technique is applied to both stages of our verifying system, where

Model	Description
Table-GraPPa	GraPPa with a linear layer
NumGuide	GraPPa with three MLP experts for verifying different numerical type statements
StmtGuide	GraPPa with two MLP experts for verifying statements with different language styles
MoE	GraPPa with sparsely MoE layer (8 MLP experts)
RowAtt	GraPPa with attention layer across all tokens
RowGAT	GraPPa with GAT aggregation module

Table 1: Name and description of models used in the system

different weights of models are searched in different subsets of the development set. Such ensembling technique works well in our system since models work differently on different types of data (e.g. A model may perform better on shorter statements while B model may perform better on longer statements). In the first stage, the weight of each model is searched on two subsets of development set based on the length of the statement and serialized table (we found that some models have a better performance on longer input sequences than others, and set 300 words as the threshold).

In the second stage, the type of each statement is first recognized by some language features and then the model weights are searched on each subset of the development set. Three types of statements are defined: 1) “count” type statements, in which the model needs to count the specific rows or columns in the table; 2) “superlative” type statements, in which the model need to find the maximum or the minimum value of one row/column; 3) “same/different” type statements, which the model need to decide whether some cells’ value are the same or different. The first two types of statements are recognized by statement slots, while the third type is recognized by trigger words (“same”, “different”, “equal”). We apply the weights searched from the development set on these three statement types and simply do averaging ensemble to the rest of the statements. The ensembling weights are searched on the development set without the participation of models trained with train and development set, while we replaced some models with the version that retrained on both train and development set in the evaluation period and direct applied the weights searched on the development set. More details of the models involved in ensembling are presented in the appendix.

Type	Statement slot
Count	there be () value(s) in the table
Count	there be () different ()
Superlative	() lowest () in the table be ()
Superlative	() has highest value(s) of ()

Table 2: Examples of the statement slots used in the system

### 3.5 Statement-slot based symbolic-calculation module

To further increase the performance and the stability of the system, a statement-slot-based symbolic-calculation module is developed to solve some numerical type statements which are relatively difficult to deep models. The symbolic-calculation module is added before the two-stage system with a low recall and high precision. Several statement slots are devised to capture “count” and “superlative” type statements. After the capture, the symbolic-calculation module parses the table and extracts the corresponding rows/columns based on a designed entity linking algorithm, and then do the related logical calculation based on the category of the statement and the parsing result of the table. Table 2 shows some examples of the statement slots used in our system.

### 3.6 Training method

In the first stage, the unknown type training data are created from three source: 1) from other tables’ statements under the same XML file, 1685 statements in total; 2) automatic generated statements by language templates, 1378 statements in total; 3) the statements from the related scientific papers (extracted from the related papers of training set tables, near the references of the tables by programming), 1272 statements in total. All of the statements in the train set are used as the known type data to train

models. Training processes are stopped when models reach the highest accuracy on the development set.

In the second stage, we first use the train set to train models and stop the training process at the maximum development set accuracy checkpoint and the minimum development set loss checkpoint. Then we add the development set into the train set and retrain some of the models, stopping at a fixed epoch to make the most use of data.

Almost all of the models are trained with the cross-entropy loss function except the NumGuide, StmtGuide, and MoE. For the NumGuide, we use trigger words to recognize the “counting” and “superlative” types statements in the train set and use the recognition result as labels to calculate the cross-entropy between the manager’s output and labels. For StmtGuide, we used the provided natural statement ids in the train set to calculate the cross-entropy between the manager’s output and labels. For MoE, an extra loss mentioned in Shazeer et al. (2017) is applied to avoid the local optimum. The extra loss functions mentioned above are simply added on the origin cross-entropy loss with a weight of 0.01. Models in the second stage are pre-trained on the TABFACT dataset before further trained on the competition dataset. More details about model training can be found in the appendix.

## 4 Evaluation

To evaluate our proposed verifying system, we perform two ablation studies regarding the adaptive ensembling method and the statement-slot-based symbolic-calculation module used in our system on both the development set and test set.

Table 3 shows the evaluation of our system on both development set and test set, compared with different ways of ensembling. We found that the adaptive ensembling on both stages achieves the highest two-way and three-way scores on the development set, while it only improves the three-way classification performance on the test set and slightly regresses on the two-way classification. We assume that it may be because of the difference between the data distributions of the development set and the test set.

Besides the ablation experiment on ensembling, we also perform an ablation experiment on the statement-slot-based symbolic-calculation module. Table 4 shows the result of the ablation experiment. The result of the experiment shows that the pro-

posed symbolic-calculation module increases the performance on both the development set and test set by around 5 percent, which shows the benefit of the symbolic-calculation module on verifying numerical type statements.

Ensembling type	Dev set		Test set	
	2-way	3-way	2-way	3-way
W+W	<b>87.81</b>	<b>86.93</b>	84.55	<b>83.76</b>
W+A	86.77	86.09	84.92	82.45
A+W	86.50	84.31	<b>85.41</b>	81.58
A+A	85.46	83.47	85.22	81.41

Table 3: Ablation experiment regarding the ensembling in the two stages of the system, where **W** refers to the adaptive ensembling and **A** refers to the simple averaging ensembling. The sequence of the letter refers to the ensembling setting of two stages, e.g. W+A means the first stage applies adaptive ensembling and the second stage applies average ensembling.

Ensembling type	Dev set		Test set	
	2-way	3-way	2-way	3-way
w/ sym-cal	<b>87.81</b>	<b>86.93</b>	<b>84.55</b>	<b>83.76</b>
w/o sym-cal	82.31	82.36	78.94	77.79

Table 4: Ablation experiment regarding the symbolic-calculation module (sym-cal). The result of the experiment shows that the proposed symbolic-calculation module consistently improves the performance on both the development set and the test set.

## 5 Conclusion

This paper describes our two-stage verifying system developed for SemEval-2021 Task 9, which leverages the latest table-based pre-trained model GraPPa. The two-stage verifying structure allows us to develop more targeted models on both stages of the system. Multiple reasoning networks are applied behind the GraPPa model, and an adaptive model ensembling technique is used in both stages of the system. A statement-slot-based symbolic-calculation module is also added at the top of the whole system to further improve the performance and stability of the system. Ablation experiments show the effectiveness of the methods proposed in the paper.

## A Weight searching in adaptive ensembling

We use a grid search method to search the weight of each model in adaptive ensembling. The searching algorithm can be expressed as follows:

1. Initialize total weight  $T=15$  (larger  $T$  may cause overfitting on the dev set and larger searching cost as well).
2. Generate all possible weight combinations  $L$ , where every element  $\mathbf{W}$  in  $L$  needs to satisfy the constraint:  $\sum_{i=1}^n W_i = T$  where  $n$  is the number of models joining in the ensembling.
3. For each  $\mathbf{W}$  in  $L$ , apply the normalized weights  $\mathbf{W}/T$  on models' results on the dev set to get the accuracy of ensembling. Save the set of weights with the highest accuracy as the best weights. If multiple sets of weights achieve the same best accuracy, calculate the variance of each set of weights and choose the set with the lowest variance as the best weights.

## B Models involved in adaptive ensembling

The following sections introduce the details of models involved in the two-stage ensembling. We revised the entity linking algorithm proposed in [Chen et al. \(2019\)](#) to get better-pruned tables. The new algorithm works better on some models, while we found some models with the origin entity linking algorithm also perform well and we keep them as a part of ensembling. In the following description, the model applies the revised entity linking algorithm if not mentioned specially.

For the simplicity of presentation, we define the following usage of symbols: a "+" symbol added behind the name of the model means the model is trained on train set and stopped when reaching the maximum accuracy on dev set; a "-" symbol added behind the name of the model means the model is trained on train set and stopped when reaching the minimum loss on dev set; no symbol added behind the name of the model means the model is trained on both train and dev set and stopped at fixed epochs.

### B.1 Models involved in the first stage's ensembling

A total of 8 models participate in the first stage's ensembling, while some models are trained by bi-ased CE loss (we adjusted the weight of different classes with 1.5:1 for unknown and other classes) to reach a more balance recall and precision. They are: 1) Table-GraPPa+ ;2) RowGAT+; 3) RowAtt+; 4) MoE+; 5) StmiGuide+; 6) RowAtt+ trained with weight added to the loss function; 7) Table-GraPPa+ trained with weight added to the loss function; 8) RowGAT+ trained with weight added to the loss function.

### B.2 Models involved in the second stage's ensembling

A total of 9 models participate in the second stage's ensembling, they are: 1) Table-GraPPa; 2) StmtGuide; 3) Table-GraPPa+ with origin entity linking algorithm; 4) MoE; 5) RowGAT; 6) NumGuide; 7) RowAtt; 8) MoE-; 9) Table-GraPPa with origin entity linking algorithm.

When searching the ensembling weights on the dev set, we simply do the following replacements: change Table-GraPPa with Table-GraPPa+; change StmtGuide with StmtGuide+; change MoE with MoE+; change RowGAT with RowGAT+; change NumGuide with NumGuide+; change RowAtt with RowAtt+; change Table-GraPPa with origin entity linking algorithm with Table-GraPPa- with origin entity linking algorithm. Ensembling weights are searched on these models without training on the dev set and directly apply to the corresponding model trained on both train and dev sets.

## C More details about model training

All models are trained with AdamW optimizer (implemented by Huggingface) with a warmup ratio be 0.3 and learning rate be  $2e-5$ , and all models in the second stage are pre-trained first on the TABFACT dataset.

# TAPAS at SemEval-2021 Task 9: Reasoning over tables with intermediate pre-training

Thomas Müller, Julian Martin Eisenschlos, Syrine Krichene

Google Research, Zürich

{thomasmueller, eisenjulian, syrinekrichene}@google.com

## Abstract

We present the TAPAS contribution to the Shared Task on Statement Verification and Evidence Finding with Tables (SemEval 2021 Task 9, Wang et al. (2021)). SEMTABFACT Task A is a classification task of recognising if a statement is entailed, neutral or refuted by the content of a given table. We adopt the binary TAPAS model of Eisenschlos et al. (2020) to this task. We learn two binary classification models: A first model to predict if a statement is neutral or non-neutral and a second one to predict if it is entailed or refuted. As the shared task training set contains only entailed or refuted examples, we generate artificial neutral examples to train the first model. Both models are pre-trained using a MASKLM objective, intermediate counter-factual and synthetic data (Eisenschlos et al., 2020) and TABFACT (Chen et al., 2020), a large table entailment dataset. We find that the artificial neutral examples are somewhat effective at training the first model, achieving 68.03 test F1 versus the 60.47 of a majority baseline. For the second stage, we find that the pre-training on the intermediate data and TABFACT improves the results over MASKLM pre-training (68.03 vs 57.01).

## 1 Introduction

Recently, the task of Textual Entailment (TE) (Dagan et al., 2005) or Natural Language Inference (NLI) (Bowman et al., 2015) has been adapted to a setup where the premise is a table (Chen et al., 2020; Gupta et al., 2020). The Shared Task on Statement Verification and Evidence Finding with Tables (SemEval 2021 Task 9, Wang et al. (2021)) follows this line of work and provides a new dataset consisting of tables extracted from scientific articles and natural language statements written by crowd workers. In this paper, we discuss a system for tackling task A, which is a multi-class classification task that requires finding if a statement is

entailed, neutral or refuted by the contents of a table. The training set contains only entailed and refuted examples and requires data augmentation to learn the neutral class. Additionally, this data set is composed of English language data and requires sophisticated contextual and numerical reasoning such as handling comparisons and aggregations.

A successful line of research on table entailment (Chen et al., 2020; Eisenschlos et al., 2020; Gupta et al., 2020) has been driven by BERT-based models (Devlin et al., 2019). These approaches reason over tables without generating logical forms to directly predict the entailment decision. Such models

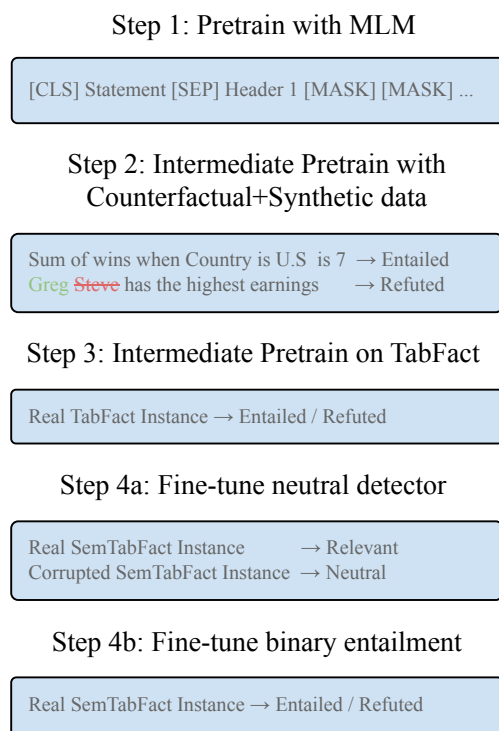

Figure 1: Overview of the training pipeline use in our system. We use intermediate pre-training on *Counterfactual+Synthetic* data (Eisenschlos et al., 2020) and then fine-tune on TABFACT (Chen et al., 2020).

are known to be efficient on representing textual data as well reasoning over semi-structured data such as tables. In particular, TAPAS-based models (Herzig et al., 2020) that encode the table structure using additional embeddings, have been successfully used to solve binary entailment tasks with tables (Eisenschlos et al., 2020).

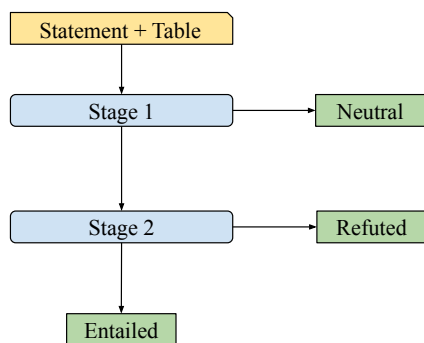

Figure 2: Overview of the complete system. Stage 1 classifies into neutral and non-neutral statements. Stage 2 into entailed and refuted. Both stages are based on binary TAPAS classifier models.

To address multi-class classification entailment we decompose the main task into two sub-tasks and use two TAPAS models as described in Figure 2. A first model classifies the statement into neutral or non-neutral, and a second into entailed or refuted. The two models are learned separately: we created artificial neutral statements to fine-tune the first model. Examples are extracted by randomly pairing statements and tables from the SEMTABFACT training set. We also generate harder examples by creating new tables from the original tables by removing columns that contain evidence to refute or entail the statement. This procedure is discussed in Section 3.

We follow Eisenschlos et al. (2020) and pre-train the two TAPAS models with a MASKLM objective (Devlin et al., 2019) and then with counterfactual and synthetic data as shown in Figure 1. We additionally fine-tune both models on the TABFACT dataset. Details are given in Section 4.

We find that our artificial neutral statement creations out-performs a majority baseline and that pre-training help for both the first and the second stage. Our best models achieve 68.03 average micro f1-score on the test set.

## 2 Related Work

**Entailment on Tables** Recognizing textual entailment (Dagan et al., 2010) has expanded from a text only task to incorporate more structured data, such knowledge graphs (Vlachos and Riedel, 2015), tables (Jo et al., 2019; Gupta et al., 2020) and images (Suhr et al., 2017, 2019).

The TABFACT dataset (Chen et al., 2020) for example, uses tables as the *premise*, or source of information to resolve whether a statement is entailed or refuted. The TAPAS architecture introduced by Herzig et al. (2020) can be used to obtain transformer-based baselines, as shown in Eisenschlos et al. (2020), by using special embeddings to encode the table structure. Zhang et al. (2020); Chen et al. (2020) also use BERT like models but obtain less accurate results due possibly to not using table-specific pre-training.

**Intermediate Pre-training** Our system relies on intermediate pre-training, a technique that appears in different forms in the literature. Language model fine-tuning (Howard and Ruder, 2018), or domain adaptive pre-training (Gururangan et al., 2020) are useful applications for domain adaptation. In a similar manner than Pruksachatkun et al. (2020), we use the *Counterfactual+Synthetic* tasks from Eisenschlos et al. (2020) to improve the discrete and numeric reasoning capabilities of the model for Table entailment.

**Synthetic data** The use of synthetic data to improve learning in NLP is ubiquitous (Alberti et al., 2019; Lewis et al., 2019; Wu et al., 2016; Leonardya et al., 2019). Salvatore et al. (2019) focus on textual entailment and probes models with synthetic examples. In semantic parsing Wang et al. (2015); Iyer et al. (2017); Weir et al. (2020) use templates to augment the training data for text-to-SQL tasks and Geva et al. (2020) do so to improve numerical reasoning, as do Eisenschlos et al. (2020) on tabular data. They also create minimal contrastive examples (Kaushik et al., 2020; Gardner et al., 2020) by automatically swapping entities in the statements by plausible alternatives that exists elsewhere in the table.

## 3 System

Our system is a two stage process that first decides whether a statement is neutral, and then decides if non-neutral statements are entailed or refuted. Both stages are implement using a binary TAPAS

Dataset	Statements	Tables	Entailed	Refuted	Neutral
Crowdsourced Train	4,506	981	2,818 (62.54%)	1,688 (37.46%)	
Auto-generated Train	179,345	1,980	92,136 (51.37%)	87,209 (48.63%)	
Stage 1 train	9,012	1,915	4506 (50%)		4506 (50%)
Dev	556	52	250 (44.96%)	213 (38.31%)	93 (16.73%)
Test	653	52	274 (41.96%)	248 (37.98%)	131 (20.06%)

Table 1: SEMTABFACT (Wang et al., 2021) statistics. The training data for the first stage was created from the crowdsourced training data using artificial neutral statements created by deleting columns with evidence or swapping statements randomly. For the second stage we use the crowdsourced training data.

classifier. TAPAS (Herzig et al., 2020; Eisenschlos et al., 2020) is a variation of BERT (Devlin et al., 2019), extended with special token embeddings that give the model a notion of the row and column a token is located in and what is its numeric rank with respect to the other cells in the same column.

### 3.1 Pre-training

The original TAPAS model (Herzig et al., 2020) was pre-trained with a Mask-LM objective (Devlin et al., 2019) on tables extracted from Wikipedia. It was later found (Eisenschlos et al., 2020) that its reasoning capabilities can be improved by further training on artificial counter-factual entailment data. This led to substantial improvements on the TABFACT dataset (Chen et al., 2020), a binary table entailment task similar to SEMTABFACT. On that dataset the test set accuracy for a BERT-based model improved from 69.6 to 78.6. In this work, we use models fine-tuned on TABFACT as the foundation for both stages. We also experimented with using models fine-tuned on INFOTABS (Gupta et al., 2020) and SQA (Iyyer et al., 2017) as the initial models but did not find that to achieve better accuracy. The overall pre-training strategy is described in Figure 1, where we also show how we use these checkpoints to use the two classification models described below.

### 3.2 Neutral Identification Stage

As discussed, the first stage of the system identifies if a statement is neutral. Training a system for this task is challenging as the SEMTABFACT training data does not contain neutral statements. We therefore created artificial neutral statements from two sources. Following the recommendation of the shared-task organizers, we created neutral statement by randomly pairing statements from the training set with new tables. Additionally, we created

neutral statements by identifying columns that contained evidence for deciding whether a statement is entailed and then randomly removing one of these columns. Our assumption is that it should not be possible to decide whether the statement is entailed when an evidence column has been removed. We do not remove the first column of a table since that often contains the name of the row entries. In order to detect the columns containing the evidence, we trained an ensemble of 5 TAPAS QA models on the automatically generated SEMTABFACT training set. Note that the auto-generated data is generated from templates and in contrast to the crowdsourced training data does have evidence cell annotations. The models are trained to predict the binary entailment decision as well as the evidence cells at the same time, and are initialized using a TAPAS model fine-tuned on SQA. The model is trained to predict the binary entailment decision as well as the evidence cells at the same time. Our models take as input  $[CLS]s_1\dots s_n[SEP]t_1\dots t_m$  where  $s_1, \dots, s_n$  represents the tokenized statement and  $t_1, \dots, t_m$  the tokenized table. For each token  $t$  of the table the model outputs a score for the token to be an evidence for the statement  $S$ ,  $s(t \in S) \in \mathbb{R}$ . Additionally, it outputs the scores of the entailment decision using the  $[CLS]$  tokens  $s([CLS]) \in \mathbb{R}$ .

We use the same hyper-parameters as SQA (as discussed in Herzig et al. (2020)). We then run these models over the crowdsourced training data and for all examples where the majority of the models correctly predicts the entailment label, we extract all columns for which a majority of the ensemble predicted at least one evidence cell. Evaluation on the SEMTABFACT development set showed that the precision of this column selection process is 0.87 (87% of the extracted columns contain a reference cell). For each column, we then create a new artificial neutral example by removing the

Stage 1	Stage 2	Dev				Test			
		f1 2-way		f1 3-way		f1 2-way		f1 3-way

Table 2: Stage 1 and 2 ablation at 20,000 steps. majority, TABFACT (drop) and TABFACT (random) use majority voting (always predicting non-neutral), only the artificial data created by removing columns and only the random neutral statements respectively. All other models use both kinds of artificial statements.

respective column from the table. This procedure yields 651 unique new instances from the 4506 training examples. However, similarly to the first approach of pairing random statements and tables, the process is not perfect. It may happen that refuted statements continue to be refuted after removing some of the evidence, but in practice we find it beneficial to generate examples in this fashion.

The final training data is then created by taking the original crowdsourced training examples as positive examples and randomly sampling an equally-sized set of negative examples, where half of the negatives are random combinations of a statement with a table and the other half are drawn with replacement from the 651 artificial examples.

### 3.3 Entailment Stage

Training the entailment stage is rather straightforward, we train the model on the crowdsourced training data using the same hyper-parameters as Eisenschlos et al. (2020).

### 3.4 Calibration and Ensemble

As our training data for stage 1 is balanced but the development data is skewed we find it to improve accuracy if we trigger for examples with a logit larger than 4.0 (rather than 0.0). Empirically we also find the threshold of 4.0 to work better for the second stage. This could be explained by the fact that the development set has a different label distribution than the training set.

We train 5 models per stage and use them as an ensemble. The ensemble score is defined as the median of all the model scores. Using the median

worked better than the mean and voting in preliminary experiments.

## 4 Experimental Setup

In this section we explain the SEMTABFACT task and dataset and give additional details about the experimental setup we used.

The SEMTABFACT dataset consists of statements and tables from the scientific literature. It is much smaller than similar datasets such as TABFACT (Chen et al., 2020) and INFOTABS (Gupta et al., 2020). It is note-worthy that the training set only contains entailed and refuted statements while the dev and test set also contain neutral (unknown) statements. The statements were written by crowd workers, which presented with 7 different types of statements were instructed to write one statement of each type. The types of statements were using aggregation, superlatives, counting, comparatives, unique counting and the usage of the caption or common-sense knowledge.

The main metric of the task is the micro f1-score computed over the statements belonging to a table. The 3-way score takes all statements into account while the 2-way score is restricted to refuted and entailed statements.

## 5 Results

Table 2 compares our system to multiple baselines. Unless stated otherwise all baselines have been trained with the same neutral data generation as discussed above and for 20,000 steps. All numbers are based on 5 independent model runs. For all setups we report the median of the individual runs as

well as the results for a system based on the median logit of the 5 models. We report error margins for the medians as half the inter-quartile range.

Looking at the first stage of the system in Table 2, we see that the system based on TABFACT is the best choice for the initialization, out-performing a simple BERT model as well as models trained with only the mask-lm and intermediate pre-training on both dev and test ensemble accuracy. However, the model trained on the intermediate data gives higher median dev and test accuracy (e.g. 72.12 vs 70.76).

With respect to the data generation we observe that any kind of neutral data generation out-performs the majority baseline. Combining the column removal and random statements yields the best results. The drop in the 2-way metrics going from the majority Stage 1 model to a learned model is expected as that metric ignores all neutral statements in the eval set.

On the second stage of our system (Table 2), we see that a TAPAS model based on TABFACT outperforms the other baselines by a bigger margin than for Stage 1. For example, a model based on only MASKLM pre-training achieves 57.01 test f1 score while the TABFACT-based model achieves 68.03. We also found that for this stage there is a more pronounced difference between BERT and MASKLM (54.15 vs 57.01) and MASKLM and intermediate pre-training (57.01 vs 66.43).

Table 5 in the appendix shows the results for different number of steps and thresholds showing that results can be slightly tweaked by tuning them.

## 6 Analysis

Table 3 shows that the recall and precision on the *neutral* class are 37.6 and 71.4, respectively. Inspecting some instances of false positives, we find that the system is quite easily fooled; for example classifying the statement “*The lowest Factor 8 is 0.027*” as non-neutral for a table that has 5 columns labeled as Factor 1 to 5. False negatives are sometimes caused by failing to map words with typos (“paramters” vs “parameters”) or abbreviations (“measurement errors” vs “ME”). Adding harder examples of neutral statements to the training set could potentially further improve the identification. We also see that the recall on the refuted class (74.3) is lower than the recall of the entailed class (85.2) while their precision values are similar.

In Table 4 we construct mutually excluded groups of the validation set. Each set is identified

Reference \ Prediction	Non-neutral	Neutral	Recall
	Non-neutral	449	14
Neutral	58	35	37.6
Precision	88.6	71.4	

Reference \ Prediction	Refuted	Entailed	Recall
	Refuted	153	53
Entailed	36	207	85.2
Precision	81.0	79.6	

Table 3: Confusion matrix for Stage 1 and Stage 2 on the development set.

	Size	Acc	Baseline	ER
Overall	100.0	71.0	45.0	29.0
Superlatives	15.8	73.9	50.0	4.1
Aggregations	13.8	61.0	46.8	5.4
Comparatives	12.2	58.8	47.1	5.0
Negations	3.1	82.4	41.2	0.5
Multiple of the above	5.9	72.7	63.6	1.6
Other	49.1	75.1	43.6	12.2

Table 4: Accuracy and total error rate (ER) for different question groups derived from the same word heuristics defined in Eisenschlos et al. (2020). The baseline is simple class majority and the error rate in each group is taken with respect to the full set. Comparatives show the biggest margin for future improvements comparing with the overall system accuracy.

by specific keywords appearing in the statement, for example *Comparatives* must contain “higher”, “better”, “than”, etc. The full list is defined in the appendix of Eisenschlos et al. (2020). We observe that comparatives and aggregations have the largest total error rates, meaning that the biggest gains in overall accuracy can be made by improving those reasoning skills. Between these two, Comparatives have the lowest in-group accuracy. Table 6 and Table 7 in the appendix show the some analysis for Stage 1 and Stage 2, respectively. The trend for Stage 2 is similar to the overall trend whereas Stage 1 accuracy is relatively stable across the different groups except for comparatives where the accuracy drops from 87% overall to 81%.

Another class of examples with relatively low accuracy are statements around unique counting. We find that statements containing the word *different* have an accuracy of 51.3 (vs. 71% overall) and account for 3.4 percentage points of the total error rate. Examples include “*There are six different classes*” and “*They have ten different parameters*”.

## 7 Conclusion

We presented our contribution to the SEMTABFACT task (Wang et al., 2021) on table entailment. Our system consists of two stages that classify statements into non-neutral or neutral and refuted or entailed. Our model achieves 68.03 average micro f1-score on the test set. We showed that our procedure for creating artificial neutral statements improves the system over a majority baseline but results in a relatively low recall of 37.6. Other methods for creating harder neutral statements might further improve this value. In line with Eisenschlos et al. (2020), we find that pre-training on intermediate data improves the system accuracy over a system purely pre-trained with a MASKLM objective. While these initial results look promising, we find that the model struggles with statements that involve complex operations such as comparisons and unique counting.

## Abstract

In this paper, we present our text augmentation based approach for the Table Statement Support Subtask (Phase A) of SemEval-2021 Task 9. We experiment with different text augmentation techniques such as back translation and synonym swapping using Word2Vec and WordNet. We show that text augmentation techniques lead to 2.5% improvement in F1 on the test set. Further, we investigate the impact of domain adaptation and joint learning on fact verification in tabular data by utilizing the SemTabFacts and TabFact datasets. We observe that joint learning improves the F1 scores on the SemTabFacts and TabFact test sets by 3.31% and 0.77%, respectively.

## 1 Introduction

Recognizing Textual Entailment (RTE) (Dagan et al., 2005) is one of the core NLP problems for understanding the semantic relations between words and sentences, which is useful for other tasks including Question Answering (Abacha and Demner-Fushman, 2019), Text Summarization (Lloret et al., 2008), and Text Classification (Yin et al., 2019). For the RTE task, datasets of various sizes (Dagan et al., 2005; Bowman et al., 2015) and from different domains (Romanov and Shivade, 2018) have been introduced. However, these works and datasets are solely focused on textual data without considering structured data such as tables.

Recently, question answering (Iyyer et al., 2017) and textual entailment datasets (Wenhu Chen and Wang, 2020; Wang et al., 2021) for tabular data have been introduced. SemEval-2021 Task 9 addresses the problem of statement verification

<sup>1</sup>The grammatical error exists in the given dataset.

*Distance statistics between buildings of ancient buildings and modern buildings to the main water channel (unit: meter).*

Figure 1: Sample table, description, and statements from SemTabFacts.

(Phase A) and evidence finding (Phase B) using tables from scientific articles (Wang et al., 2021). The shared task also introduced a new dataset, namely the SemTabFacts dataset, an example from which is provided in Figure 1. The goal of Phase A (Table Statement Verification) of the shared task is to determine whether a statement is entailed, refuted, or unknown given a table and its description (if available). For example, given the table and its description in Figure 1, the first two statements

are entailed, whereas the third statement is refuted. This example demonstrates that there are various challenges such as understanding numerical operations and comparisons as well as textual entailment.

Transformers architecture (Vaswani et al., 2017) enabled the pretraining of large language models, which achieve significant improvement in numerous NLP tasks (Wang et al., 2018, 2019). Recent works have also focused on pretraining language models for tabular data by introducing new embedding layers and objective functions, as well as large-scale augmented data to better represent numerical values and rankings (Herzig et al., 2020; Eisenschlos et al., 2020).

Data augmentation is a way to enrich training data to improve the supervised training scheme and is widely used in computer vision (Perez and Wang, 2017) and speech recognition (Park et al., 2019). Different text augmentation techniques such as back translation, synonym replacement, and text editing have been investigated for various tasks including text classification (Wei and Zou, 2019) and natural language inference (Min et al., 2020).

In this study, we aim at investigating the impact of text augmentation on the statement verification task from tables. We implement various text augmentation techniques based on WordNet (Miller, 1998), Word2Vec (Mikolov et al., 2013), and Back Translation (Yu et al., 2018) to enrich the statement variety in the SemTabFacts dataset. We finetune a recently introduced pretrained transformer architecture, the TAPAS model (Eisenschlos et al., 2020), for our approach. In addition, we investigate the domain adaptation and joint learning capabilities of two tabular fact verification datasets: SemTabFacts and TabFact. Promising results are achieved on the SemTabFacts test dataset.

## 2 Datasets

We use two different table-based fact verification datasets for the experiments: SemTabFacts (Wang et al., 2021) and TabFact (Wenhu Chen and Wang, 2020). We compare SemTabFacts and TabFact in terms of the average size of the tables, average word length of the statements, and the number of examples for each class in Table 1. We only report the statistics for the training sets, since the development and test sets have similar distributions with the training sets in both datasets. There is almost an order of magnitude difference between the datasets in terms of the number of tables and

	SemTabFacts	TabFact
# Tables	981	13,182
# Statements	4,506	92,283
# Entailed	2,818	50,820
# Refuted	1,688	41,463
Avg. Row Size	9.0±8.0	13.5±8.6
Avg. Column Size	5.3±2.9	6.4±1.7
Avg. Statement Length (Words)	11.5±7.1	13.2±4.5

Table 1: Comparative statistics of SemTabFacts and TabFact.

statements. Furthermore, we observe that the average table size and average statement length in terms of words are greater in TabFact than SemTabFacts.

**SemTabFacts** (Wang et al., 2021): This dataset consists of tables from articles published in Elsevier, which are available on ScienceDirect. After filtering complicated examples, five entailed and five refuted statements about these tables are generated by high-quality crowd-sourcing. These statements are further verified by additional crowd-source workers, especially for filtering out ungrammatical sentences. To increase the quality level, Wang et al. (2021) further verified the statements in the development and test sets. The SemTabFacts dataset also contains automatically generated statements and unknown classes in the development and test sets for the fact verification and evidence finding tasks. In this study, we target two-way (Entailed / Refuted) classification without automatically generated statements for the fact verification task.

SemTabFacts releases tables and statements in XML format. We convert these tables into CSV format to properly use in our models. Due to cells with multirow and multicolumn features in XML, we could not accurately convert all tables into CSV, which might affect our models’ overall performance. We manually checked the XML to CSV conversion of 50 tables. We identified three errors related to multirow and multicolumn features, and one error that causes a missing column.

**TabFact** (Wenhu Chen and Wang, 2020): This dataset crawls tables from Wikipedia articles following previous works on table question answering (Pasupat and Liang, 2015; Zhong et al., 2017).

Designed input parameters during experimental set-up.

Experimental bottle ID	Material type	Material amount, g
A	Inoculum	200.2
B	Inoculum	200.4
1A	Inoculum + Olive cake	200.4
1B	Inoculum + Olive cake	199.7

Augmentation Methods	Sentence
Original	199.7 is the lowest Inoculum compare to all others.
WordNet	199.7 is the small Inoculum compare to all others.
Word2Vec	199.7 is the lowest Inoculum comparisons to all others.
Back Translation	199.7, compared to others is the most low inoculum.

Figure 2: Generated sentences by different text augmentation methods for the same statement. The table for the original statement is given above with some modifications.

Complicated tables including multirows, multi-columns, and latex symbols, and large tables with more than 50 rows or 10 columns were filtered out. Amazon Mechanical Turk was used to generate simple and complex statements about tables. The Mechanical Turk workers also filtered out poor statements that have grammatical errors or vague claims. Finally, annotator agreement scores were computed by having the same set of statements labeled by another set of Mechanical Turk workers.

### 3 Methods

#### 3.1 TAPAS

Deep transformers models such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) have achieved significant improvement in different NLP tasks as seen in the GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019) benchmarks. However, it is not straightforward to benefit from these models for structured data formats such as tables or graphs. TAPAS (Herzig et al., 2020) introduces different objectives such as cell selection and aggregation prediction, and new additional embeddings such as column/row id and rank id over BERT’s architecture, which are more suitable for complex numerical operations and comparisons in tables. The TAPAS model has been designed by focusing on the task of question answering over tables (Herzig et al., 2020). However, TAPAS fails to handle complex compositional structures like multiple aggregations and large tables due to the maximum length limit of the tokenizer.

To overcome the problems in (Herzig et al., 2020), recently, Eisenschlos et al. (2020) introduced new mechanisms such as table pruning to

make TAPAS work with large tables without memory errors. Furthermore, two augmentation methods for statements were presented (Eisenschlos et al., 2020). The first one is based on creating counterfactual statements by replacing entity mentions with other entities on entailed examples to populate negative samples. The second one is based on a synthetic data generation method to populate statements with complex numerical operations.

In this study, we use a TAPAS model from HuggingFace’s Transformers library (Wolf et al., 2019). This model is pretrained on Masked Language Model and additional intermediate pretraining steps as discussed in (Eisenschlos et al., 2020). In addition, it is finetuned on the TabFact dataset (Wenhu Chen and Wang, 2020). We further finetuned this model on SemTabFacts (Wang et al., 2021) with additional augmentation steps by utilizing WordNet, Word2Vec, and back translation.

#### 3.2 Text Augmentation

##### 3.2.1 WordNet

WordNet (Miller, 1998) is a lexical database that groups words into adverbs, adjectives, nouns, and verbs, and shows the relations between them such as hyponymy, antonymy, and synonymy. In this work, we focus on swap-based WordNet augmentation that changes words by their WordNet synonyms. The implementation is done by the TextAttack (Morris et al., 2020) library. As shown in Figure 2, the word *lowest* is changed to *small* by synonym swapping.

##### 3.2.2 Word2Vec

Word2Vec (Mikolov et al., 2013) is a technique to find dense word embeddings by shallow networks.

Training Set	Dev	Test
SemTabFacts	0.7661	0.7044
SemTabFacts+WN	0.7791	<b>0.7294</b>
SemTabFacts+W2V	0.7486	0.7201
SemTabFacts+BT	0.7725	0.6941
SemTabFacts+WN+W2V	0.7648	0.7147
SemTabFacts+WN+BT	<b>0.7869</b>	0.7217
SemTabFacts+W2V+BT	0.7614	0.7202
SemTabFacts+W2V+WN+BT	0.7484	0.7101

Table 2: F1 scores of different augmentation techniques on SemTabFacts. WN, W2V, and BT represent WordNet, Word2Vec, and Back Translation, respectively.

It helps to represent syntactic and semantic features of words by a dense vector. Due to the low dimensional space, similar words and synonyms have closer word embeddings. We make use of this feature of Word2Vec to replace words with their Word2Vec synonyms by TextAttack library. For example, this augmentation technique changes the word *compare* to *comparisons* as shown in Figure 2. While WordNet augmentation preserves the part of speech tags of the words, Word2Vec augmentation may distort the part of speech tags and may produce ungrammatical sentences.

### 3.2.3 Back Translation

The back translation technique paraphrases a given sentence from a source language by translating it into another target language and then translates it back into the source language. It was first introduced as a data augmentation mechanism for the reading comprehension task (Yu et al., 2018), where significant improvement was observed by back translation augmentation. Recent machine translation systems (Sennrich et al., 2016) are robust to back translation mechanism and tend to produce the same sentence. To overcome this issue, we used two different versions of the same system. First, we translated the statements in English to Turkish by Google Translate<sup>2</sup>. Then, we translated the Turkish statements into English by the GOOGLETRANSLATE function in Google Sheets. The back translation method paraphrases the sentence and unlike the WordNet and Word2Vec approaches, it may change word order in addition to the words, as illustrated in Figure 2.

## 4 Experimentation and Results

We conduct two different experimental setups to compare our results. In both experiments, we finetune all layers of a pretrained TAPAS model and its classifier head. First, we finetune the TAPAS model on the SemTabFacts dataset with all combinations of different augmentation techniques. Second, instead of using augmentation techniques, we finetune the TAPAS model on TabFact only and then on SemTabFacts and TabFact jointly and compare the results on the test sets of TabFact and SemTabFacts. In all these experiments, we use the AdamW (Loshchilov and Hutter, 2018) optimizer with a  $5e-5$  learning rate and 0.01 weight decay. We set batch size as 8 with 2 accumulation steps, and the number of steps used for linear warm-up is 100 in SemTabFacts training and 2000 in TabFact and joint training. We finetune this model over 10 epochs and decide the best model based on the development set. We use the official evaluation metric, which is the macro-average of F1 scores over the tables.

In the augmentation steps, we include new augmented statements for each statement and augmentation method to the training data of SemTabFacts. The original versions of the development and test sets are used without any augmentation. We observe that different augmentation techniques in SemTabFacts can improve F1 scores on the test set as shown in Table 2. The best model for the development set of SemTabFacts is the model with WordNet and back translation augmentations. Besides, all augmentation techniques, except back translation, improve the test F1 score over the base model without augmentation. Finally, we observe that WordNet augmentation increases the test F1 score by 2.5% over the base model without augmentation.

In Table 3, we investigate the domain adaptation and joint learning capabilities of SemTabFacts and

TabFact. We have finetuned three separate models, with SemTabFacts training data, TabFact training data, and SemTabFacts and TabFact training data. We evaluate these finetuned models on the development and test sets of the datasets. The original versions of the training, development, and test sets are used in these experiments without any additional augmentation. The model trained with TabFact and SemTabFacts data achieved the highest F1 scores on the test sets of both datasets. The joint model improves the F1 score by 3.31% and 0.77% on the SemTabFacts and TabFact test sets, respectively. Further, we observe that we can achieve similar scores on the SemTabFacts test set when the model is trained on the SemTabFacts training data or on the TabFact training data.

We further analyzed the errors in terms of table sizes (number of rows x number of columns) and length of the statements. However, our results indicate that there is no significant difference in F1 scores for different table sizes and different lengths of statements. Our models have similar performance for small and large tables as well as for short and long statements.

## 5 Conclusion

In this work, we described our models for the Table Statement Support Subtask (Phase A) of SemEval-2021 Task 9. Our base model relies on the recently introduced pretrained transformer architecture for tabular data, TAPAS. We proposed three different augmentation techniques which are based on WordNet, Word2Vec, and Back Translation. We showed that all combinations of these augmentation techniques except Back Translation perform better on the test set than methods without augmentation. Furthermore, we investigated the domain adaptation and joint learning capabilities of SemTabFacts and TabFact. We showed that our best model in terms of development and test F1 for SemTabFacts occurs when we trained TAPAS jointly on the SemTabFacts and TabFact datasets. Additionally, we illustrated that the joint model achieves better results on the TabFact test set than the model trained only on the TabFact training dataset. As future work, we plan to focus on better preprocessing the SemTabFacts dataset and more diverse augmentation techniques by integrating perplexity scores of augmented statements.

## Abstract

Recent progress in deep learning has primarily been fueled by the availability of large amounts of annotated data that is obtained from highly expensive manual annotating processes. To tackle this issue of availability of annotated data, a lot of research has been done on unsupervised domain adaptation that tries to generate systems for an unlabelled target domain data, given labelled source domain data. However, the availability of annotated or labelled source domain dataset can't always be guaranteed because of data-privacy issues. This is especially the case with medical data, as it may contain sensitive information of the patients. Source-free domain adaptation (SFDA) aims to resolve this issue by using models trained on the source data instead of using the original annotated source data. In this work, we try to build SFDA systems for semantic processing by specifically focusing on the negation detection subtask of the SemEval 2021 Task 10. We propose two approaches - *ProtoAUG* and *Adapt-ProtoAUG* that use the idea of self-entropy to choose reliable and high confidence samples, which are then used for data augmentation and subsequent training of the models. Our methods report an improvement of up to 7% in F1 score over the baseline for the Negation Detection subtask.

## 1 Introduction

The availability of large scale datasets has been the main driving factor behind the success of supervised deep learning in the recent times. However, the process of data annotation is very expensive and time consuming, being one of the major challenges in extending deep learning techniques for new tasks.

One possible way to solve this problem is to *train* a machine learning model using an annotated

\* Authors contributed equally to the work. Names in alphabetical order.

source dataset to assist the annotation process over some unlabelled target dataset. However, there may be differences in the source and target domain distributions, which may lead to inaccuracies. Thus the challenge is to update the weights of the source classifier to generalize it well on the target domain. This aligns with the well studied problem of *Unsupervised Domain Adaptation* (UDA) (Kouw and Loog, 2019; Wang and Deng, 2018; Ramponi and Plank, 2020)

A common denominator across many popular UDA methods is their dependence on large amounts of labelled source domain data (Ganin and Lempitsky, 2015; Saito et al., 2018). However, many a times it is not possible to release the source domain dataset because of privacy concerns. This problem becomes particularly relevant when working with clinical Natural Language Processing (NLP) datasets because they contain highly sensitive information which cannot be freely distributed. To tackle these data sharing constraints, the framework of *Source-Free Domain Adaptation* (SFDA) is gaining interest (Laparra et al., 2020). In SFDA, instead of sharing the source domain data, only a model that has been trained on the source domain data is shared. This model is then used for solving the original task for the unlabelled target domain.

SemEval 2021 Task 10 (Laparra et al., 2021) asks participants to develop SFDA models for two subtasks. The first subtask involves **Negation Detection**, where we are required to determine whether or not a clinical entity (*diseases, symptoms, etc.*) mentioned in a sentence is negated in the given context. The second subtask is of **Time Expression Recognition**, where the objective is to detect and label all time expressions mentioned in a given document. In this work we have focused on the negation subtask. For solving this subtask our strategy is to make use of high-confidence prototypes from the *target* domain to reinforce the *target*-

*specific* features of the source model. We propose a simple augmentation technique that makes use of these *high-confidence* prototypes to generate labelled artificial datapoints. These augmented samples are then used to perform supervised fine-tuning of our source model. Using our methods, we were able to obtain upto a 7% improvement in F1 score over the baseline. The code for models and experiments is made available via GitHub.<sup>1</sup>

## 2 Background

In source free domain adaptation (SFDA) problem for semantic analysis, the goal is to create accurate systems for un-annotated target domain data. For these tasks, we are provided with un-annotated target domain data, and a model trained on the annotated source domain data for a similar task.

The shared task is further divided into 2 sub-tasks – Negation detection and Time expression recognition. In this work we focus only on the first subtask.

**Negation Detection:** The task is to classify clinical event mentions for whether they are negated by their context. This is essentially a “span-in-context” classification problem, where both the entity to be classified and its surrounding context are to be considered. For example, the sentence - “*Has no <e>diarrhea </e>and no new lumps or masses*” has the entity *diarrhea* which is negated by its context, and the model’s task is to correctly identify this entity as negated.

**Pretrained Models:** For negation detection, a given pre-trained classification model has been fine-tuned on the 10,259 instances in the SHARP Seed dataset(Rea et al., 2012) of de-identified clinical notes from Mayo Clinic of which 902 instances are negated.

**Practice Data:** The development data for the negation task is a subset of the i2b2 2010 Challenge (Uzuner et al., 2011) on concepts, assertions, and relations in clinical text. The practice dataset is further divided into *train* and *dev* splits. The *train* split contains 2886 unlabeled sentences while the *dev* split is composed of 5545 labeled sentences.

**Test Data:** A part of the MIMIC III corpus v1.4 (Johnson et al., 2016), is used as the test set for the negation detection subtask. The processed test data contains around 600K instances.

## 2.1 Prior Work

The limitations in creating large scale annotated datasets have led to a large amount of work on unsupervised domain adaptation in the recent years (Ganin and Lempitsky, 2015; Ganin et al., 2016; Tzeng et al., 2017; Saito et al., 2018). However, most of this work assumes free availability of source domain data. In source free domain adaptation (SFDA) problems, when no annotated source data is available, and only a pretrained model is provided, the domain adaptation problem becomes rather difficult, and this remains a largely unexplored area in the NLP community. However, there have been some recent works in the computer vision domain that attempt to solve this problem. Hou and Zheng (2020) propose a model to transfer the style of source images to that of the target images by exploiting the information stored in the batch normalization layers of the pre-trained model. In another work, (Kim et al., 2020) observed that the target domain data points with lower entropy are generally classified correctly and are reliable enough to generate pseudo labels for the entire target dataset.

The two sub-tracks for the current SemEval task are well studied problems in the supervised setting and a lot of work has been done on developing models for both the negation detection in clinical settings (Chapman et al., 2001; Cotik et al., 2016) and the time expression recognition task (Laparra et al., 2018). However, in this work, we attempt to approach the negation detection task from the perspective of SFDA, and not on improving these techniques in general.

## 3 System Overview

In this paper we offer a novel perspective on the problem of domain adaptation for the negation detection task in clinical NLP. The proposed approaches attempt to utilize some of the aspects of both self-learning and semi-supervised learning, as explained next.

**Class Prototypes:** If there was any access to the labeled target data then the most intuitive approach would have been the fine-tuning. But for unlabeled case, in order to fine-tune the pre-trained network  $S$ , it would become necessary to generate a labeled set of data from the given unlabeled target domain data. One way to approach this would be through a concept from self-learning, i.e., by finding the most reliable samples from the target data over which the

model  $S$  is sufficiently confident and using these predictions as the corresponding ground truth. In order to find reliable target samples, self-entropy  $H$  can be used to quantify the prediction uncertainty:

$$H(x) = - \sum_{k=1}^K p_k^S(x) \log(p_k^S(x)) \quad (1)$$

Here,  $S$  refers to the network (pre-trained classifier),  $K$  are total number of classes, and  $p_k^S(x)$  is the probability of the instance  $x$  belonging to the class  $k$ .

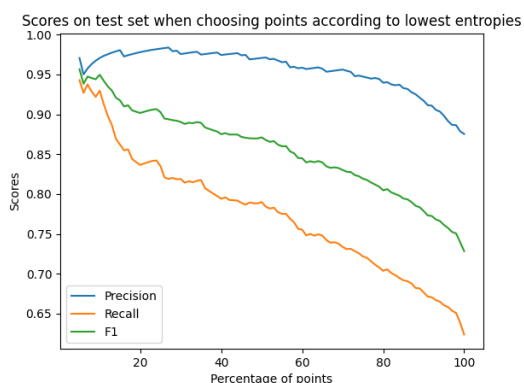

Figure 1: For any point P on the x-axis, the y-axis shows the performance scores on the data points having their self-entropies in the lowest P percentile.

The samples with smaller self-entropy indicate that the classifier is more confident over them, and these are referred to as *Prototypes*. The relationship between the self-entropy value and certainty in the prediction can be clearly observed in figure 1. Due to very high confidence of the model and accuracy over these prototypes, we can safely consider their predicted labels as their actual true labels. Here, one crucial hyperparameter to consider is the self-entropy threshold below which the residing target samples will be identified as prototypes. The key issue faced while determining the value of this hyperparameter is the disparities and highly imbalanced data distribution between the classes. Especially, in the negation task, the presence of the negated sentences in the practice data itself is in a very small proportion than that of non-negated sentences making negated a minority and non-negated a majority class. Analysis of the practice data (figure 2) further showed that the lowest self-entropy achieved by the negated class is far higher than that of non-negated class. For now, the self-entropy threshold value is defined by the 50th percentile (median) self-entropy value of the

minority class i.e. negated class. The rationale for this is provided in the Analysis section (section 5).

Unfortunately, the fine-tuning of the pre-trained network  $S$  with the prototypes identified from the target samples, didn't enable the trained network to generalise its performance over unseen target data as it made it highly likely to overfit on the prototypes without any early intervention. With this approach, we were able to get improvement of about 1% in F1 score over the baseline but that too with the highly unstable and unreproducible training results. Only using the reliable samples became a major issue as the trained model seemed to be unaware of the samples over which the model was less confident before.

**Augmentation:** To address the issue of lack of generalisation of the model towards the unseen and not-so-reliable target data, we propose the use of **augmentation**, inspired by the Mean Teacher model proposed by Tarvainen and Valpola (2018). The basic idea is to regularize the network by introducing noise to the prototypes in a way that can keep the label same and thereby creating new data points with the known labels. Mean Teacher model uses similar strategy for the labeled data points, instead here we apply that to the identified prototypes from the target data. This way, the pre-trained network can be subjected to a further constructive training by introducing a set of new labelled samples, which could help with the generalisation for the trained model.

Another use of the augmentation here is to address the issue of highly skewed and imbalanced distribution of data between the classes. Here, the augmentation is utilized not just to generate new samples to regularize the network but also to make the data distribution balanced across the classes by adding new samples in accordance with the preferred proportions.

Although there could be many possible ways to augment the samples so that their labels can be maintained, for this specific task, since we have a highlighted concept term in each sentence, we have used the augmentation by replacing that concept term. The new sentences are generated from their parent prototype sentences by replacing the concept term with a concept term from any randomly selected sentence of the same class in the data set. Here we have assumed that most of the concept terms will represent medical condition and thus nouns. Even when the grammar and the sentence

structure is preserved, the result of the augmentation might still not be perfect due to the possible ambiguity in the concept term selection or incorrect grammar in the original sentence itself. For example, consider the sentence “...<e> cortisol </e> is currently pending.”. Here it is not clear if the entity “cortisol” is negated or non-negated. However, it should be noted that such ambiguities are relatively less frequent which in turn implies that the augmentation will suffice its purpose for the majority of the time.

**ProtoAUG and Adapt-ProtoAUG:** Combining the concepts discussed above, here we propose our two approaches *ProtoAUG* and *Adapt-ProtoAUG*, both of which share the same set of concepts of class prototypes and augmentation as explained before. For both *ProtoAUG* and *Adapt-ProtoAUG*, the common underlying procedure is as follows: first the prototypes are identified from the target domain data and then the augmentation follows with the intent of regularizing the network and to create a more balanced distribution of samples across the classes. Now both the prototypes and their augmented samples with their respective labels are used with cross entropy loss to update the weights of the feature extractor module  $F$  of the pre-trained network  $S$ , with classifier module  $C$  of the pre-trained network being frozen.

The fundamental difference between *ProtoAUG* and *Adapt-ProtoAUG* is about the adaptive nature of *Adapt-ProtoAUG* in recognizing the prototypes from the original target domain dataset after every epoch, which *ProtoAUG* does only at the beginning of the training. *Adapt-ProtoAUG* makes incremental changes to the percentile score (initially 50) for the self-entropy threshold. The intuition behind using this strategy is that as the training proceeds, model will become more confident on the training samples and the entropy values for all the samples will significantly decrease. A possible drawback of using a fixed percentile criteria for the threshold at every epoch would likely exclude some reliable samples even when they achieve objectively quite lower values of self-entropy. To avoid such scenarios, apart from repeating the same process of prototype identification followed by augmentation after every epoch, we also propose to increase the percentile score for determining the self-entropy threshold in an uniform manner throughout the training with some fixed upper bound (70). This is also explained further in the Analysis (section 5).

## 4 Experimental Setup

**Model:** The pre-trained model used in subtask-1 is a RoBERTa (Liu et al., 2019) based sequence classification model<sup>2</sup> provided by organizers after training on source domain data inaccessible to us. It has two modules - a feature extractor and a classifier that operates over the output [CLS] token from the feature extractor.

**Data:** In the practice phase, *train* split of the practice dataset was used to further train the pre-trained model whereas the *dev* split was used as a validation set for the hyper-parameter tuning. In the evaluation phase, due to our computational constraints, we were only able to utilize a randomly selected subset of 25k samples from around 600k sentences of the test dataset, for retraining of the pre-trained model. For evaluation the organisers use an annotated subset of the test dataset. During the evaluation phase this subset was kept hidden from the participants.

**Hyper-parameters setting:** For *ProtoAug*, self-entropy percentile threshold is set to 50% whereas as for *Adapt-ProtoAUG* it is uniformly increased after every epoch from being 50% at the first to being 70% at the final epoch. Using augmentation, the final number of samples per class is set to be  $x$  times the number of prototypes belonging to the majority (non-negated) class. In our experiments, we choose  $x$  to be 4. For both the approaches, the model training is performed for 10 epochs. During the test phase, we reuse the hyper-parameters obtained from the practice phase. Further details about hyper-parameter selection can be found in Appendix A.

## 5 Results

Table 1 shows results on the development data for the two approaches - *ProtoAUG* and *Adapt-ProtoAUG*. For reference, results obtained from the pre-trained model are shown as the baseline.

Model	F1 score	Precision	Recall
Baseline	0.834	0.850	0.818
ProtoAUG	0.877	0.948	0.816
Adapt-ProtoAUG	<b>0.888</b>	<b>0.959</b>	<b>0.827</b>

Table 1: Results obtained on dev data of practice phase

<sup>2</sup>Model is available on [https://huggingface.co/tmills/roberta\\_sfda\\_sharpseed](https://huggingface.co/tmills/roberta_sfda_sharpseed)

Table 2 shows results of our two proposed approaches with the baseline model on the test set. In evaluation phase, the observed improvement in F1-score was of roughly 7% from the original baseline.

Model	F1 score	Precision	Recall
Baseline	0.66	0.917	0.516
ProtoAUG	0.706	<b>0.939</b>	0.566
Adapt-ProtoAUG	<b>0.729</b>	0.876	<b>0.624</b>

Table 2: Results obtained on test data of evaluation phase

**Analysis:** To ascertain the relationship between self-entropy and a prediction’s reliability, we analyse the baseline performance scores for the data points within the varying self-entropy percentile threshold as shown in figure 1. For the baseline, we observe a direct correlation between a lower self-entropy and a higher prediction score on the respective data points. This further supports the use of low self-entropy data points as class prototypes in our proposed approaches.

As shown in figure 2, the lowest self-entropy achieved by minority (negated; label 1) class is far higher than that of majority (non-negated; label -1) class. This may be attributed to the skewed nature of the target dataset and potentially the source dataset as well.

Another interesting observation from figure 2 is that most of the majority class samples have a self-entropy lower than the lowest self-entropy achieved by the minority class. Thus, for selecting the threshold for prototype selection, we apply the percentile-based criteria only on the self-entropy values of the minority class.

For prototype selection, instead of using an absolute threshold value, we have chosen a percentile-based entropy threshold as it adapts relatively well across different domains. This follows from the fact that confidence of the model may vary from domain to domain due to which a threshold chosen for one domain might not be a good criteria for another domain.

For Adapt-ProtoAUG, as the upper bound for the self-entropy threshold is increased beyond 70, we observed a gradual decline in the model’s performance for the dev set. This may be due to the 85% precision of the baseline. Precision here refers to the proportion of correctly classified negated

samples to the model’s total number of negated predictions. So, it could be the case that as the threshold reaches near or get past the precision score, the probability of identifying a wrongly labelled sample as a prototype will rapidly increase. Compared to ProtoAUG, as the percentile threshold was increased from 50 to 70, we observed an overall increment of recall for both the dev and test dataset. Furthermore, introducing augmentation in the framework drastically increased the stability and reproducibility of the training process.

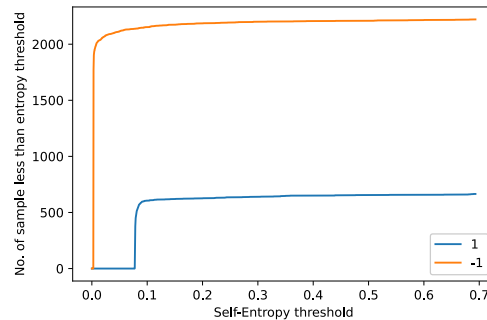

Figure 2: Cumulative number of sample vs entropy threshold curve

Appendix B provides some insights from t-SNE analysis, visually justifying the performance improvement. It analyses the predictions of the baseline model and Adapt-ProtoAUG over a fixed two-dimensional feature-space, comparing the similarities of their respective predictions with the original ground-truth labels. We observe that Adapt-ProtoAUG can capture the label distribution better than the baselines by performing well on various non-trivial data-points.

## 6 Conclusion

In this work, we carefully explored the problem of source-free domain adaptation for the Negation Detection subtask. We studied the importance of the confidence that a model places on its prediction and analyzed its formulation in terms of the samples’ self-entropy scores. Further, using those insights, we proposed two simple and intuitive approaches, namely ProtoAUG and Adapt-ProtoAUG for the Negation Detection Subtask and got an improvement of 7% on the test set with respect to the baseline model.

## A Training Hyper-parameters

We train our models with a batch size of 32 using SGD optimizer with initial  $lr = 0.0005$  which decays after every iteration by multiplying it with  $(1 + 10 * itr / max\_iter)^{-0.75}$  (where  $itr$  is current iteration and  $max\_iter$  is maximum iteration of training),  $weight\_decay = 0.0005$  and  $momentum = 0.9$ .

## B t-SNE Analysis

We performed low dimensional analysis of the models using tsne. In the following figures, we took the 768 dimensional output of the baseline roberta model for the test dataset, and projected it in two dimensions using tsne.

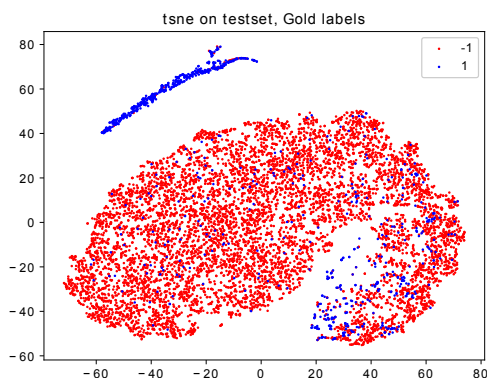

Figure 3: Ground truth labels. Blue points correspond to negation = 1.

- Figure 3 shows the the 2-dimensional tsne plots with the original ground truth labels. The blue points are the true positives and reds are the true negative points. We broadly observe two clusters - a smaller one with majority of points being true positives and a larger cluster with a majority of points being negatives. We also observe some blue points scattered in the red cluster and vice-versa.
- Figure 4 shows the predictions of the baseline model on the target domain. We see that the baseline classifier segregates the test data into almost perfect clusters, and thus misclassifies the scattered points.
- Figure 5 shows the prediction results of adapt-protoaug. In this case the F1 score improved from the baseline score by around 7%. Looking at the figure, we clearly see an improvement

Figure 4: The predictions of the baseline model on the test set of the target domain.

Figure 5: Visualisation of the predictions of an improved model

with respect to the baseline model, as we are now able to correctly capture some of the points that randomly fall within in the opposite cluster.

# PTST-UoM at SemEval-2021 Task 10: Parsimonious Transfer for Sequence Tagging

## Abstract

This paper describes PTST, a source-free unsupervised domain adaptation technique for sequence tagging, and its application to the SemEval-2021 Task 10 on time expression recognition. PTST is an extension of the cross-lingual parsimonious parser transfer framework (Kurniawan et al., 2021), which uses high-probability predictions of the source model as a supervision signal in self-training. We extend the framework to a sequence prediction setting, and demonstrate its applicability to unsupervised domain adaptation. PTST achieves  $F_1$  score of 79.6% on the official test set, with the precision of 90.1%, the highest out of 14 submissions.<sup>1</sup>

## 1 Introduction

SemEval-2021 Task 10 presents source-free unsupervised domain adaptation (SFUDA) for semantic processing.<sup>2</sup> The goal of *unsupervised domain adaptation* is to transfer a model from a source domain to another, different domain — called target domain — using only unlabelled data in the target domain. *Source-free* unsupervised domain adaptation additionally assumes no access to source domain data: only the source model pre-trained on the source domain data is available. This situation may occur when the source domain data contains protected information that cannot be shared, or even if it can, requires signing a complex data use agreement. While there are numerous works on SFUDA outside NLP (Hou and Zheng, 2020; Kim et al., 2020; Liang et al., 2020; Yang et al., 2020), SFUDA research for NLP is severely lacking in spite of its importance in, for example, clinical

NLP (Laparra et al., 2020). There are two tasks involved in SemEval-2021 Task 10: negation detection and time expression recognition. We participate only in the latter.

Our approach is an extension of the parsimonious parser transfer framework (PPT; Kurniawan et al. (2021)). PPT allows cross-lingual transfer of dependency parsers in a source-free manner, requiring only unlabelled data in the target side. It leverages the output distribution of the source model to build a chart containing high probability trees for each sentence in the target data. We extend this work by (1) formulating PPT for chain structures and evaluating it on a semantic sequence tagging task; and (2) demonstrating its effectiveness in a domain adaptation setting. We call our method **Parsimonious Transfer for Sequence Tagging** (PTST).

We find PTST effective for improving the precision of the system in the target domain. It ranks 7th out of 14 submissions in the official leaderboard in terms of  $F_1$  score, but 1st in precision, with a gap of 3 points from the second best. Drawing on the model calibration literature, we provide a way to combat the problem of model overconfidence which is key to make PTST outperform a simple transfer of a source model to the target domain. However, we also find that PTST struggles in improving recall. In conclusion, our results suggest that PTST can be used for SFUDA, but further work is required to improve the precision-recall trade-off in the target domain.

## 2 Background

In the SemEval-2021 Task 10 time expression recognition task, the input is a single sentence, and the output is a sequence of tags indicating the time entity type of a word (if any). There are 32 time entities in total (e.g., Year, Hour-of-Day), and

A woman was killed Thursday evening

Figure 1: An example input sentence and its output sequence of tags for the time expression recognition task.

the tags are coded in BIO format. Fig. 1 shows an example input sentence and its output. The task organisers provided a pre-trained source model for the task. This source model is RoBERTa-base (Liu et al., 2019) that is pre-trained on more than 25K time expressions in English clinical notes from Mayo Clinic in SemEval-2018 Task 6. The model is distributed online via HuggingFace Models,<sup>3</sup> which can be obtained with HuggingFace Transformers library.<sup>4</sup> The organisers also released trial data for the practice phase containing 99 annotated English articles from the news domain. The official test data released by the organisers in the evaluation phase contains 47 articles that are in a different domain from the source and development data.

The time expression recognition task is formalised as a sequence tagging task. The literature on sequence tagging in NLP is massive (Jiang et al., 2020; He and Choi, 2020; Rahimi et al., 2019; He et al., 2019; Xie et al., 2018; Clark et al., 2018, *inter alia*). One closely related task is named-entity recognition (NER) whose goal is to detect mentions of named entities such as a Person or Organisation in an input sentence. Lample et al. (2016) introduced a now widely adopted neural architecture for this task, where input word embeddings are encoded with a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) before they are passed through per-word softmax layers. In recent times, it is common to replace the LSTM with a Transformer (Vaswani et al., 2017). With the advancements of large pre-trained language models, the standard is to use a model such as BERT (Devlin et al., 2019) as the encoder and fine-tune the model on labelled data. The source model of the time expression recognition task provided by the organisers was also trained in this manner.

In the context of unsupervised domain adaptation, a popular approach is domain adversarial training. Introduced by Ganin et al. (2016), it leverages multi-task learning in which the model is optimised

not only on the main task objective but also a domain prediction objective. The learning signal for the latter is passed through a gradient reversal layer, ensuring that the learnt parameters are predictive for the main task, but general across domains. With pre-trained language models, Han and Eisenstein (2019) proposed to continue pre-training on the unlabelled target domain data, prior to finally fine-tuning on the labelled source domain data. Unfortunately, these approaches require access to the source domain data.

There is relatively little work on SFUDA in NLP, however, some works on source-free cross-lingual transfer exist. Wu et al. (2020) employ teacher-student learning for source-free cross-lingual NER. A teacher model trained on the source side predicts soft labels on the unlabelled target side data, and a student model is trained on those soft labels. Their method outperforms a simple direct transfer method where the source model is directly applied on the target side. More recently, a method for source-free cross-lingual transfer of dependency parsers was introduced by Kurniawan et al. (2021). The key idea is to build a chart of high probability trees based on arc marginal probabilities for each unlabelled sentence on the target side, and treat all those trees as a weak supervision signal for training. Their method outperforms direct transfer as well as a variety of recent cross-lingual transfer methods that are not source-free. That said, the effectiveness of their method on (a) semantic (sequence labelling) tasks and (b) in a domain adaptation setting is unexplored, which is what we aim to address in this work.

### 3 System Description

We first describe our sequence tagging model (Section 3.1), before we present parsimonious transfer for sequence tagging (PTST) in Section 3.2.

#### 3.1 Model

Our model is a linear-chain conditional random field (CRF) over tag sequences. It assigns a score  $s(\mathbf{x}, \mathbf{y})$  to a pair of input sentence  $\mathbf{x}$  and output tag sequence  $\mathbf{y}$ , which can be expressed as

$$s(\mathbf{x}, \mathbf{y}) = \sum_j \pi(\mathbf{x}, j, y_j) + \phi(y_j, y_{j+1}) \quad (1)$$

where  $\pi(\mathbf{x}, j, t)$  is the *emission* score of word  $x_j$  having tag  $t$  and  $\phi(t, t')$  is the *transition* score of having tag  $t$  followed by tag  $t'$ . The probability of

<sup>3</sup><https://huggingface.co/clulab/roberta-timex-semeval>

<sup>4</sup><https://github.com/huggingface/transformers>

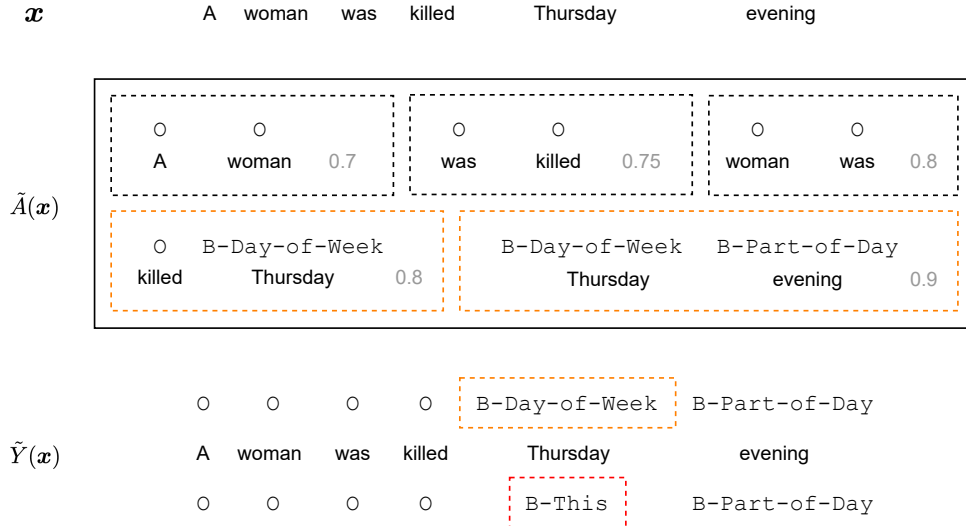

Figure 2: Illustration of our method. Given an unlabelled sentence  $\mathbf{x}$  from the target domain, we build the set of high probability tag pairs  $\tilde{A}(\mathbf{x})$  using the source model, which may contain correct tag pairs that do not occur in the predicted tag sequence (in orange). From these tag pairs, we build the chart  $\tilde{Y}(\mathbf{x})$  containing tag sequences that can be assembled from tag pairs in  $\tilde{A}(\mathbf{x})$ . The single predicted tag sequence from the source model (bottom) is also included in the chart, but it may contain an incorrect tag (in red) as it is noisy.

$\mathbf{y}$  given  $\mathbf{x}$  is then

$$P(\mathbf{y} | \mathbf{x}) \propto \exp s(\mathbf{x}, \mathbf{y}). \quad (2)$$

The emission score function  $\pi$  is parameterised by a neural network whose parameters are initialised with the source model. Specifically, the emission score function is the RoBERTa model provided by the task organisers. The transition score function  $\phi$  is a  $T \times T$  parameter matrix that is learned during training, where  $T$  is the number of tags. Note that with dynamic programming, we can efficiently compute quantities such as the marginal probabilities of tag pairs  $P((j, y_j, y_{j+1}) | \mathbf{x})$  or the partition function  $Z(\mathbf{x}) = \sum_{\mathbf{y} \in \mathcal{Y}(\mathbf{x})} \exp s(\mathbf{x}, \mathbf{y})$  where  $\mathcal{Y}(\mathbf{x})$  is the set of all possible tag sequences for  $\mathbf{x}$ .

### 3.2 Unsupervised Adaptation

To perform unsupervised adaptation on the unlabelled target domain data, we extend PPT, our past work for source-free cross-lingual parsing (Kurniawan et al., 2021), to chain structures. Given a set of unlabelled sentences  $D$  in the target domain, we build a chart of high probability tag sequences  $\tilde{Y}(\mathbf{x})$  by leveraging the output distribution in the source model. The model then treats all sequences with sufficiently high predicted probability as possible tag sequences for  $\mathbf{x}$  for training. Concretely, it minimises the loss:

$$\ell(\theta) = - \sum_{\mathbf{x} \in D} \log \sum_{\mathbf{y} \in \tilde{Y}(\mathbf{x})} P_{\theta}(\mathbf{y} | \mathbf{x}) \quad (3)$$

where  $\theta$  denotes the target model parameters. The set  $\tilde{Y}(\mathbf{x})$  is defined formally as

$$\tilde{Y}(\mathbf{x}) = \{\mathbf{y} | \mathbf{y} \in \mathcal{Y}(\mathbf{x}) \wedge A(\mathbf{y}) \subseteq \tilde{A}(\mathbf{x})\} \quad (4)$$

where  $\mathcal{Y}(\mathbf{x})$  is the set of all possible tag sequences for  $\mathbf{x}$ ,  $A(\mathbf{y}) = \{(j, y_j, y_{j+1}) | 1 \leq j < |\mathbf{y}|\}$  is the set of consecutive tag pairs in tag sequence  $\mathbf{y}$ , and  $\tilde{A}(\mathbf{x}) = \bigcup_j \tilde{A}(\mathbf{x}, j)$  where  $\tilde{A}(\mathbf{x}, j)$  is the set of high probability consecutive tag pairs  $(j, t_j, t_{j+1})$  for words  $x_j$  and  $x_{j+1}$  (see Fig. 2 for illustration). Analogous to PPT, this set is constructed by adding tag pairs  $(t_j, t_{j+1})$  in order of decreasing marginal probability until their cumulative probability exceeds a threshold  $\sigma$ . The predicted tag sequence from the source model is also included in  $\tilde{Y}(\mathbf{x})$  so the chart is never empty.

Note that the method above is very similar to self-training where the predictions from the source model are used as supervision signal for training. In contrast to self-training, however, we build a chart of high probability predictions for each sample instead of just a single best prediction. We expect these predictions to be more useful than a single best prediction because it is more likely for the correct tag sequence to be in the chart than equal to the single best prediction. Even when this is not the case, we expect the partially correct tag sequences occur frequently enough in the chart so the model is still able to learn what the correct tag sequence is.

Table 1: TIMEX leaderboard on the test data.

In our preliminary experiments, we find that it is crucial to introduce temperature scaling to the emission scoring function in order to achieve good performance. Thus, for our main result, we define a new emission scoring function  $\pi'$  as

$$\pi'(\mathbf{x}, j, y_j) = \pi(\mathbf{x}, j, y_j) / \tau \quad (5)$$

where  $\tau$  is the temperature scale hyperparameter. We discuss and provide an analysis of this temperature scaling in Section 5.

## 4 Experimental Setup

We use the pre-trained source model and data provided for SemEval-2021 Task 10. We only use the model and data for the time expression recognition task (TIMEX hereinafter) as we only participate in that task. We use the practice data as the development set to tune the hyperparameters of our model with random search.<sup>5</sup> We set the threshold  $\sigma = 0.95$  following the setup of Kurniawan et al. (2021). We do not use any data sets other than those provided by the task organisers for TIMEX.

We train PTST on the unlabelled test data for 5 epochs. As described in Section 3.1, we initialise the neural network for the emission scoring with the source RoBERTa model provided by the task organisers. We enforce the BIO constraints by initialising the transition matrix  $\phi$  with  $-\infty$  for entries corresponding to illegal transitions, and zero otherwise.<sup>6</sup> We use the linear CRF implementation provided in the Torch-Struct library (Rush, 2020). To avoid out-of-memory error, we discard

<sup>5</sup>Best learning rate and  $\tau$  are  $9 \times 10^{-6}$  and 2.56 respectively.

<sup>6</sup>The constraints require an inside tag be always preceded by an inside or beginning tag of the same entity.

sentences longer than 30 tokens. Additionally, we find that it is useful to freeze the embedding and the first few layers of the RoBERTa encoder. Thus, in our main result, we freeze the embedding layer and the first 6 (out of 12) layers of the encoder. An analysis is provided in Section 5.

## 5 Results and Discussion

Table 1 shows the TIMEX leaderboard on the official test data in the evaluation phase.<sup>7</sup> Our model PTST is ranked 7th out of 14 submissions in terms of  $F_1$  score, below the baseline model submission by the task organisers which ranks 4th. This baseline model is the pre-trained source model fine-tuned on the labelled development data. Despite the relatively low  $F_1$  score, PTST achieves 90.1 % precision, which is the highest among all submissions, and markedly above the second highest precision of 87.3 % achieved by the second best performing model. Looking at recall, our model has the second lowest score of 71.3 %, which is fairly below the third lowest one of 73.2 %. This result suggests that our model is sacrificing recall in favour of precision, which may be a desirable property for downstream tasks where making the right prediction is more critical.

**Model overconfidence** As mentioned in Section 3.2, in our preliminary experiments, we find that the source model is extremely confident about its predictions, making the marginal probability distribution of tag pairs at any position  $j$  very sharp. This sharpness results in  $\hat{Y}(\mathbf{x})$  containing mostly just a single tag sequence, which is the predicted sequence from the source model, rendering the whole approach no different from simple self-training. To remedy this problem, we introduce temperature scaling in the emission score, which has been shown to be a simple but effective trick in model calibration (Geman and Geman, 1984; Guo et al., 2017). We define the new emission scoring function as shown in Eq. (5). Table 2 shows how the performance of PTST changes when  $\tau$  is varied. We see that as  $\tau$  increases, precision does too, but recall decreases, although in a relatively slower rate so the  $F_1$  score tends to increase as well. Also reported in Table 2 is the median number of tag sequences and the fraction of gold tag sequences

Table 2: Model performance on the development data as  $\tau$  changes. SRC is the pre-trained source model directly applied on the development data.  $F_1$ , precision (P), and recall (R) scores are averages ( $\pm$  std) over 3 runs.  $n$  is the median number of high probability tag sequences in the chart  $\tilde{Y}(\mathbf{x})$ .  $p$  is the fraction of gold tag sequences contained in the chart.

	$F_1$	P	R
SRC	77.1	77.5	76.8
No freezing	$77.8 \pm 0.5$	$81.2 \pm 0.2$	$74.7 \pm 1.0$
Freeze emb	$77.7 \pm 0.2$	$81.0 \pm 0.4$	$74.7 \pm 0.6$
Freeze emb + 6 layers	$78.2 \pm 0.2$	$80.3 \pm 0.3$	$76.2 \pm 0.0$
Freeze emb + 12 (all) layers	$77.2 \pm 0.0$	$77.7 \pm 0.0$	$76.7 \pm 0.0$

Table 3: Model performance on the development data when the RoBERTa embedding and encoder layers are frozen during training. SRC is the pre-trained source model directly applied on the development data. Scores are averages ( $\pm$  std) over 3 runs.

contained in the chart. The two quantities grow as  $\tau$  does, which indicates that increasing  $\tau$  indeed allows the chart to contain more tag sequences, and thus increasing the coverage of correct tag sequences in the chart. However, when  $\tau$  is too large ( $\tau = 3.0$ ), the model breaks down, presumably because  $\tilde{Y}(\mathbf{x})$  contains too many noisy tag sequences to be useful.

The decline in recall might be explained by the nature of the task, where in a single sentence most of the words are not time entities. When  $\tau$  grows, the number of high probability tag sequences in  $\tilde{Y}(\mathbf{x})$  does too. In the majority of these tag sequences, a word in  $\mathbf{x}$  is likely to be tagged as a non-entity because time entities are naturally rare. Since tag sequences are treated uniformly (i.e. no tag sequence weighs more than the others), this provides a strong signal for the model that the word is a non-entity. Therefore, the model’s capability of recognising entities is reduced. Conversely, a similar argument may explain the rise in precision. When the model predicts a word as an entity, it is likely that in the majority of tag sequences in  $\tilde{Y}(\mathbf{x})$ , the word is tagged as the same entity, providing a strong signal that the word is indeed that entity. In other words, if the model predicts an entity, the model is very confident about it. When confidence is high, it is more likely that the prediction is correct, thus resulting in higher precision.

**Freezing layers** We also find that it is helpful to freeze the embedding layer and the first few layers of the RoBERTa model’s encoder during training, presumably because they encode low-level linguistic information that is invariant across domains. Table 3 reports how the model performance changes with varying numbers of layers frozen ( $\tau$  is fixed to 2.5). We observe that freezing the embedding and first several encoder layers gives a small boost to performance, with best performance reached with 6 frozen layers (the setting adopted in the model reported in the main results).

**Error analysis** To better understand the errors of PTST, we present the confusion matrix of the model on the test data in Fig. 3. We see that the majority of the errors arise from the model not recognising actual time entities, consistent with the relatively low recall. The model has serious difficulties in recognising `Season-Of-Year`, for example, in fragments like:

*The increase in food aid beneficiaries is partly attributed to **Meher** harvest loss [...]* (1)

*The increase, which follows a **seasonal** trend, is seen in all regions except Tigray.* (2)

The model also seems to struggle with recognising `Between` and `This`. Example sentence fragments where the model wrongly predicts a

Figure 3: Confusion matrix on the test data.

non-entity are:

*In Gambella region, **between** 1 and 12 April, 3,346 South Sudanese refugees arrived [...]* (3)

where the model fails to recognise `Between`, and *[...] to prevent a potential national outbreak of AWD during **this** rainy season* (4)

where the model fails to recognise `This`. Although the model has good precision, we still see that it misclassifies non-entities and `Calendar-Interval` as `Period` relatively often. For example, in the fragment

*[...] the malnutrition situation is expected to aggravate in the coming **months*** (5)

the word *months* is a `Calendar-Interval` but the model predicts it as `Period`. Another example, the model predicts the word *period* in the sentence fragment

*During the reporting **period**, an estimated 1,000 south Sudanese arrived [...]* (6)

as `Period`, while the word is actually not a time entity.

## 6 Conclusions

We present PTST, our submission to the time expression recognition task of SemEval-2021 Task 10. We describe our sequence tagging model as a CRF over chain structures, parameterised by a neural network. Our domain adaptation approach leverages the output distribution of the source model to build a chart of high probability tag sequences for every sentence in the unlabelled target domain data.

PTST ranks 7th in terms of  $F_1$  score in the official leaderboard, but achieves the highest precision out of 14 submissions. We provide analyses on the importance of temperature scaling to mitigate model overconfidence and the patterns of errors.

## Abstract

Source-free domain adaptation is an emerging line of work in deep learning research since it is closely related to the real-world environment. We study the domain adaption in the sequence labeling problem where the model trained on the source domain data is given. We propose two methods: Self-Adapter and Selective Classifier Training. Self-Adapter is a training method that uses sentence-level pseudo-labels filtered by the self-entropy threshold to provide supervision to the whole model. Selective Classifier Training uses token-level pseudo-labels and supervises only the classification layer of the model. The proposed methods are evaluated on data provided by SemEval-2021 task 10 and Self-Adapter achieves 2<sup>nd</sup> rank performance.

## 1 Introduction

Domain adaptation (DA) is the task of applying an algorithm trained on a source domain data to a different target domain data with limited/undefined labels. DA has gotten significant attention as an alternative of fine-tuning approach (Ganin and Lempitsky, 2015; Saito et al., 2018; Tzeng et al., 2017), especially in situations rich supervision is not possible (Morero et al., 2018). DA is an important way of overcoming the data shortage of deep learning since it enables the utilization of knowledge from other labeled data.

Source-free DA is then proposed to cope with such data sharing in the general setting of DA, the data distribution in the source domain and the target domain are related but different (Storkey and Sugiyama, 2007), and annotated samples from the source domain are available during the training process. However, many of the data resources are not allowed to be shared in real-life environments as there are increasing concerns for privacy issues. For example, Twitter has a regulation that prevents

sharing tweet text. The policy is even more rigorous in the financial/clinical domain under the privacy protection issue.

Unlike conventional DA, one can not get access to the source domain data in source-free DA but is provided a model trained on the source domain data. About source-free DA in computer vision, several approaches have been proposed; (Sahoo et al., 2020) assumes the target domain data is a transformation from the source domain data along natural axes such as brightness and contrast; (Kundu et al., 2020) proposes universal DA that is trained via two-stage learning of procurement and deployment; (Kim et al., 2020) progressively updates the target model with pseudo-labels which are selected under self-entropy criterion.

As for natural language processing (NLP), the application of source-free DA is slightly more complicated since sentences are usually considered as having discrete representations. In this context, SemEval-2021 task 10 has proposed a challenge that is related to source-free domain adaptation for semantic processing.

In this paper, we propose **Self-Adapter** for the *time expression recognition* sub-task in SemEval-2021 task 10. Following (Kim et al., 2020), we employ pseudo-labels from the target domain to further supervise the model trained on the source domain data, while the entropy-based evaluation of reliable pseudo-labels is adopted in consideration of the discrete text data. In addition, we adopt *Sloughing* trick to prevent over-fitting.

To demonstrate the efficacy of the Self-Adapter, we evaluate the proposed method on the dataset by (Laparra et al., 2018). We also compare the proposed method with several variations and another method we come up with, named **Selective Classifier Training (SCT)**. In the end, the Self-Adapter has achieved 2<sup>nd</sup> rank in the official evaluation period getting 0.811  $F_1$  which is 1.7 percentage

points higher than the RoBERTa-based sequence tagging model pre-trained only on source data.

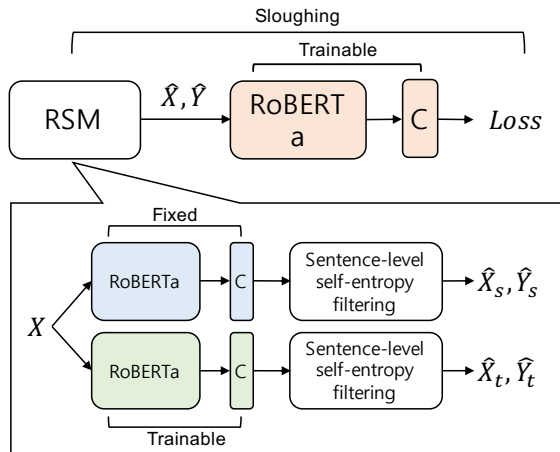

Figure 1: Training pipeline of Self-Adapter. At the beginning of every stage of training, RSM is initialized with ‘reliable’ samples generated by both fixed and trainable models. A trainable model is supervised using samples - *source-oriented pseudo-labels* and *target-oriented pseudo-labels* - stored in RSM.

## 2 Systems Description

Our proposed methods have three operations in common: (1) generating pseudo-labels, (2) filtering out pairs of reliable samples and pseudo-labels based on models’ self-confidence, and (3) doing supervised learning using the pseudo-labels. We concentrate on sorting out ‘reliable’ pseudo-labels since training with incorrect labels harms the performance of the model.

Self-entropy is usually treated as an indicator of self-confidence (Zou et al., 2018; Saporta et al., 2020). We adopt normalized self-entropy as the evaluation metric for pseudo-labels:

$$H(x_t) = -\frac{1}{\log N_c} \sum l(x_t) \log(l(x_t)) \quad (1)$$

where  $x_t$  denotes each token that makes up a sentence  $X \in \mathbf{X}$ .  $l(x_t)$  denotes the predicted probability of the predicted label by the classifier, and  $N_c$  refers to the total number of labels.

Specifically, we propose two adaptation methods to efficiently fit the model trained on a source domain to a target domain: Self-Adapter and SCT.

### 2.1 Method 1: Self-Adapter

We propose Self-Adapter which is a self-learning method under the supervision of reliable sample

memory (RSM). RSM is a set of data with pseudo-labels that consists of two parts, *source-oriented pseudo-labels* and *target-oriented pseudo-labels*, and each of them represents the knowledge learned from the source domain and new features to learn from the target domain. We further apply a trick called ‘*Sloughing*’ which helps prevent over-fitting. The overall workflow of Self-Adapter is shown in Figure 1.

#### 2.1.1 Reliable Sample Memory

RSM is the pairs of input sentences and the corresponding pseudo-labels obtained from a Siamese-like network structure. Two RoBERTa-based (Liu et al., 2019) classifiers are initialized with a RoBERTa-based sequence tagging model fine-tuned only on source train data, which is given as a baseline model in the task. One of the branch maintains fixed weight parameters while another is fine-tuned during training.

Both branches of the network take a target domain sentence  $X$  as an input and output a set of probabilities for labels each token should be assigned to. We utilize the self-entropy as the evaluation metric for the self-confidence of each token. If the self-confidence of each token is smaller than the predefined threshold, the pair of input sentences with the pseudo-labels generated by the model is kept as a part of RSM.

The fixed part of the network consistently outputs the same pairs  $(\hat{X}_s, \hat{Y}_s)$  which are called *source-oriented pseudo-labels*. The trainable part of the network outputs different pairs  $(\hat{X}_t, \hat{Y}_t)$  called *target-oriented pseudo-labels* after each update and both are stored in the RSM. All sentence-label pairs in RSM, both *source-oriented pseudo-labels* and *target-oriented pseudo-labels*, are used to train the trainable part of the network in a supervised manner. We call the cycle in which RSM are updated as a stage and each stage is composed of several epochs.

#### 2.1.2 Sloughing trick

After sufficient update of RSM, we generate pseudo-labels with RSM and do another self-entropy filtering to gain new reliable samples. Subsequently, we re-initialize the trainable part of the network with the parameter of the baseline and train it under the supervision of the new reliable samples. We call this procedure *Sloughing*. Since many of the reliable samples in each RSM update overlaps, over-fitting tends to happen over time.

The *Sloughing* then efficiently prevents over-fitting by newly initializing a model which is not fitted to test data yet.

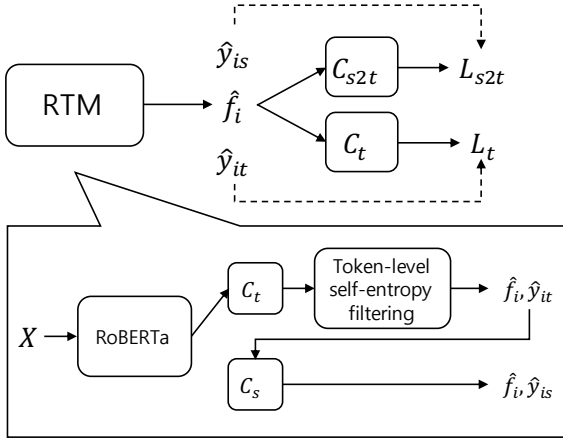

Figure 2: Training pipeline of Selective Classifier Training. RTM is updated at the start of each step of training. In multi-branch network whose two branches  $C_{s2t}$  and  $C_t$  share a fixed RoBERTa-based feature extractor, loss of  $C_{s2t}$  branch is calculated by supervision with *source-oriented token-wise pseudo-labels* and loss of  $C_t$  branch is calculated by supervision with *target-oriented token-wise pseudo-labels*.

## 2.2 Method 2: Selective Classifier Training

Selective Classifier Training is a training method that consists of a RoBERTa-based feature extractor and multi-branch classifiers. The feature extractor and classifiers are initialized with the RoBERTa-based sequence tagging model fine-tuned only on source train data, given as baseline model in the development phase. In SCT, only the classifiers are updated under the supervision of Reliable Token Memory (RTM).

### 2.2.1 Reliable Token Memory

RTM is the pairs of tokens and their pseudo-labels obtained from a network with two separate branches. Both the branches share the fixed feature extractor which is the same with the feature extractor of the SCT training pipeline. Two classifiers, a trainable classifier  $C_t$  and a fixed classifier  $C_s$ , make predictions on contextual embedding passed from the feature extractor.

To update RTM, we first get contextual embeddings for all tokens in target domain sentences by putting in all sentences as input of shared feature extractor and we get prediction on each token embeddings. Token embeddings  $\hat{f}_i$  whose normalized self-entropy predicted by  $C_t$  are lower

than the threshold  $\theta$  are called *reliable token-wise samples*. The pseudo-labels of reliable token-wise samples predicted by  $C_s$  are called *source-oriented token-wise pseudo-labels*. The pseudo-labels of reliable token-wise samples predicted by  $C_t$  are called *target-oriented token-wise pseudo-labels*. The pairs of *reliable token-wise samples* and their *source-oriented token-wise pseudo-labels*, and the pairs of *reliable token-wise samples* and their *target-oriented token-wise pseudo-labels* consists RTM.

### 2.2.2 Multi-branch network

With RTM, we train a multi-branch network in which each branch shares a fixed feature extractor. They divide into two classifiers  $C_{s2t}$  and  $C_t$ . Loss of  $C_{s2t}$  branch is calculated by supervision with *source-oriented token-wise pseudo-labels* and loss of  $C_t$  branch is calculated by supervision with *target-oriented token-wise pseudo-labels*. RTM updates at the start of each step of training.

The loss function is formulated as

$$L_{total} = (1 - \alpha)L_{s2t} + \alpha L_t \quad (2)$$

where  $L_{s2t}$  and  $L_t$  indicates loss function of  $C_{s2t}$  branch and  $C_t$  respectively.  $\alpha$  is a weight between two branches. We gradually increase  $\alpha$  from 0 to 1 to deal with high instability in the early stages of learning, in the same way as (Kim et al., 2020). In the test phase, we use the classification probability of the  $C_t$  branch.

## 3 Experiments

We evaluate our two models: Self-Adapter, SCT and their variations. The baseline on the development data is a RoBERTa-based sequence tagging model pre-trained on only the source data: de-identified clinical notes from the Mayo Clinic, called Source-Trained. Also, there is another baseline Dev-Tuned on the test data which is the source pre-trained model (i.e., Source-Trained) fine-tuned on the labeled development data. The development data is the annotated news portion of the SemEval-2018 Task 6 data. Test data is a set of annotated documents extracted from food security warning systems. development data consists of 1580 sentences and test data consists of 3911 sentences. The total number of labels is 65, where label 0 indicates non-time entity, and label 1-64 indicates different types of time entities.

Method	$F_1$	<i>Precision</i>	<i>Recall</i>
SCT	0.784	0.814	0.756
SA	0.808	0.819	0.797
SA+ <i>Sloughing</i> *	<b>0.812</b>	0.822	0.801
SA-filtering	0.771	0.774	0.768
Source-Trained	0.771	0.768	0.775

Table 1:  $F_1$ , *Precision*, *Recall* on development data. The model submitted to the competition is marked with \*. SA indicates Self-Adapter and SA+*Sloughing* is a system where *Sloughing* is applied on a model trained with Self-Adapter. SA-filtering is a system whose training pipeline is the same as Self-Adapter except that confidence filtering is not done. Source-Trained is a RoBERTa-based sequence tagging model pre-trained on only the source data: de-identified clinical notes from the Mayo Clinic, given as baseline model in the development phase of the competition.

### 3.1 Experimental setup

For all of our models, we set normalized self-entropy threshold  $\theta = 0.1$  except when applying *Sloughing* trick, on which  $\theta = 0.01$ . We train Self-Adapter for 3 stages. Each iteration consists of 4 epochs with batch size 1 (sentence-level) and the learning rate is fixed as  $5e-5$ . In Self-Adapter, pseudo-labels are updated at every stage. In Self-Adapter combined with *Sloughing*, we apply *Sloughing* for 3 times, 4 epochs training with batch size 1 (sentence-level) is done every time. The learning rate is fixed as  $5e-5$ . In SCT, pseudo-labels are updated every epoch. We train 2 epochs with batch size 4 (token-level) and the learning rate is scheduled with inverse decay scheduler same as (Kim et al., 2020), with initial learning rate  $5e-5$ . We use Adam optimizer in all models.

### 3.2 Experimental results and analysis

Table 1 and Table 2 shows the performance of the proposed methods on development and test data respectively. Each method is evaluated with *Precision*, *Recall*, and  $F_1$ . *Precision* is the ratio of correctly predicted positive observations to the total predicted positive observations. *Recall* is the ratio of correctly predicted positive observations to all observations in the actual class.  $F_1$  is the weighted average of *Precision* and *Recall*. Our major concern is  $F_1$ , which is the most preferred indicator of accuracy in text classification tasks.

On both data, Self-Adapter combined with *Sloughing* performs the best in  $F_1$  and Self-Adapter performs the second-best. SCT does not provide

Method	$F_1$	<i>Precision</i>	<i>Recall</i>
SA	0.81	0.874	0.754
SA+ <i>Sloughing</i> *	<b>0.811</b>	0.873	0.757
Source-Trained	0.794	0.849	0.746
Dev-Tuned	0.804	0.827	0.782

Table 2:  $F_1$ , *Precision*, *Recall* on the test data. The model submitted to the competition is marked with \*. SA indicates Self-Adapter and SA+*Sloughing* is a system where *Sloughing* is applied on a model trained with Self-Adapter. Source-Trained is a RoBERTa-based sequence tagging model pre-trained on only the source data: de-identified clinical notes from the Mayo Clinic and Dev-Tuned is a the source pre-trained model (i.e., Source-Trained) fine-tuned on the labeled development data.

significant improvement of  $F_1$  compared to Self-Adapter. Self-Adapter without confidence filtering performs almost the same as Source-Trained on every evaluation metric.

#### 3.2.1 Impact of confidence filtering

Our confidence filtering proves to be effective in dealing with the uncertainty of pseudo-labels. Self-Adapter, whose core is confidence filtering, increases 3.7, 1.6 percentage points of  $F_1$  on development data and test data for each. The system whose training pipeline is the same as Self-Adapter except that confidence filtering is not done performs almost the same as the Source-Trained.

#### 3.2.2 Necessity of training feature extractor

Well-trained BERT embeddings contain both syntactic (Hewitt and Manning, 2019) and semantic (Coenen et al., 2019) information of words. However, this is only when the model is fine-tuned with data from the domain same as the target domain. It is well known that embedding models trained on different domains poorly capture the domain-specific vocabularies and word semantics due to domain shift. (Sarma et al., 2018)

Since RoBERTa is a BERT-based language model, the same issue arises on RoBERTa used in this task. Thus if the feature extractor used for embedding words is fixed during training, the embeddings obtained do not provide sufficient information to the classifier, resulting in a limitation to improving performance. This is also shown through experimental results in which Self-Adapter outperforms SCT.

### 3.2.3 Inefficiency of *Sloughing*

In Self-Adapter, the model learns from almost all sentences in development data and test data. Only 333 sentences out of 1580 and 917 sentences out of 3911 were filtered in development data and test data for each despite the high threshold we set ( $\theta = 0.1$ ). It affects the magnitude of the effect of the *Sloughing* in our method. *Sloughing* improves performance on both development and test data, but not enough to be taken as meaningful. 0.04 percentage points of  $F_1$  on development data and 0.1 percentage points of  $F_1$  on test data increase by application of *Sloughing*.

Somewhat discouraging effect of *Sloughing* is due to the setting of our task, in which training is done with almost all samples in test data, despite confidence filtering. We expect *Sloughing* to be more effective in the setting where the bigger proportion of samples are filtered and thus the ability for generalization on unseen data is more important. However, verification of these hypotheses will be carried out as a follow-up study.

## 4 Conclusion

In this paper, we propose novel training methods Self-Adapter and Selective Classifier Training that improve model performance on the target domain only by leveraging the RoBERTa-based model pre-trained on source data. Both models rely on self-learning with highly credible pseudo-labels that are filtered based on self-entropy, differ only in the range of trainable parts. Also, we propose *Sloughing* trick to prevent over-confidence of the model by softening the network output. Our work is highly applicable in the real world since we have achieved remarkable improvement in performance using only a few test data which is not annotated at all, without any manual supervision.

## Abstract

This paper describes our systems for negation detection and time expression recognition in SemEval 2021 Task 10, Source-Free Domain Adaptation for Semantic Processing. We show that self-training, active learning and data augmentation techniques can improve the generalization ability of the model on the unlabeled target domain data without accessing source domain data. We also perform detailed ablation studies and error analyses for our time expression recognition systems to identify the source of the performance improvement and give constructive feedback on the temporal normalization annotation guidelines.

## 1 Introduction

Unsupervised Domain Adaptation (UDA) is a task that generalizes knowledge acquired from a model trained on labeled data in one domain (source domain) to unlabeled data in a different domain (target domain). Conventional UDA algorithms usually require access to both source-domain and target-domain data (Ganin et al., 2016; Glorot et al., 2011; Chen et al., 2012; Louizos et al., 2016). However, sharing source-domain data is often not practical for clinical texts due to their highly sensitive personal information and complex data use agreement procedures (Laparra et al., 2020). To overcome this difficulty, Laparra et al. (2020) propose a new task of source free domain adaptation (SFDA) where only models trained on source-domain data are shared, which allows the possibility of using the information from the source-domain while reducing private information leakage. The biggest challenge of this task is to transfer task-related information embedded in the trained models.

Our team participated in both subtasks of SemEval 2021 Task 10 (Laparra et al., 2021), Source Free Domain Adaptation for Semantic Processing: negation detection and time expression recognition.

For both tasks, participants were given a RoBERTa model (Liu et al., 2019) fine-tuned on the source-domain, and asked to make predictions in the target-domain.

The goal of the negation detection task is to predict whether an event in a sentence is negated by its context. This is a binary sentence classification task. For example, given the event *diarrhea* and the sentence *Has no diarrhea and no new lumps or masses*, the goal is to predict that *diarrhea* is negated by its context.

The goal of time expression recognition sub-task (Laparra et al., 2018) is to recognize time expressions in the target domain. This is a named entity recognition (NER) task. The number of entity types (inside–outside–beginning format) is 65. Entity types in this task are formally defined time entity types from the Semantically Compositional Annotation of Time Expressions (SCATE) (Bethard and Parker, 2016) annotation schema. For example, in *2021-02-19*, *2021* will be labeled as Year, *02* will be labeled as Month-Of-Year and *19* will be labeled as Day-Of-Month.

We investigate self-training, active learning, and data augmentation techniques on negation detection and time expression recognition under the SFDA setting. Our contributions are:

1. We demonstrate that simple self-training over a small portion of the target domain data can effectively improve the performance of the negation detection model.
2. We demonstrate that active learning with data augmentation can significantly improve time expression recognition performance when selected examples are accurately annotated.
3. We perform ablation studies for the time expression recognition systems to analyze where the performance improvement comes from.
4. We analyze our annotation errors for the time recognition task and give constructive feed-

back on the annotation guideline and schema.

## 2 System Description

The source-domain models for both subtasks are RoBERTa-base models with linear classification output layers, implemented via the Huggingface Transformers library (Wolf et al., 2020), using RobertaForSequenceClassification for negation, and RobertaForTokenClassification for time.

The input to the models is a sequence tokenized by Byte-Pair Encoding (BPE). Following the conventions of the RoBERTa model input format, two special tokens  $\langle s \rangle$  and  $\langle /s \rangle$  are inserted at the beginning and end of the sequence, respectively. In the negation detection task, targeted events are denoted with two special tokens  $\langle e \rangle$  and  $\langle /e \rangle$  that are inserted before and after the event. For example, the sentence *Has no diarrhea and no new lumps or masses* with event *diarrhea* will be converted to  $\langle s \rangle$ *Has no*  $\langle e \rangle$ *diarrhea*  $\langle /e \rangle$  *and no new lumps or masses.*  $\langle /s \rangle$ . The model output for negation detection is whether the target event is negated and the model output for time expression detection is the labels for each input tokens.

### 2.1 Negation Detection System

We employ a simple self-training (Yarowsky, 1995) approach that fine-tunes the model with its own predictions on the unlabeled dataset. We start with the pre-trained source-domain model,  $M$ . Then, for each self-training iteration:

1. We initialize an empty training set,  $L$ .
2. We use  $M$  to label the target domain data.
3. If an instance is labeled with a probability above a threshold  $\tau$ , we add it to  $L$  with the predicted label as its pseudo label.
4. We fine-tune  $M$  on  $L$ .

When the source-domain model predictions are the same for two consecutive iterations or the number of iterations of self-training is greater than the predefined maximum number, self-training stops. Note that the training set  $L$  is reinitialized at each iteration, and the model is iteratively fine-tuned.

### 2.2 Time Expression Detection System

Our approach combines active-learning (Cohn et al., 1996) and data-augmentation (Simard et al., 2003). We start with the pre-trained source-domain model,  $M_0$ , a copy of the pre-trained source-domain model,  $M$ , and initialize an empty training set  $L$ . Then, for each iteration:

1. We select the  $k$  instances where  $M$  is most uncertain, manually annotate them, and add them to  $L$ . (Details in section 2.2.1.)
  2. We augment each manually annotated instance with  $n$  new examples and add them to  $L$ . (Details in section 2.2.2.)
  3. We re-initialize  $M$  to  $M_0$  and fine-tune on  $L$ .
- We repeat this process  $i$  times. Note that the training set  $L$  is built cumulatively, and  $M$  is reinitialized on each iteration.

#### 2.2.1 Active Learning

We use active learning methods to manually label the most uncertain examples of the model in the target domain. We believe that it is not practical to manually label the entire target domain dataset during the test phase. This requires sufficient expertise and time from annotators (we show later that it is very difficult to understand annotation guidelines in a short time). Otherwise, low-quality annotations will hurt the performance of the model. In each iteration, we select the top  $k$  target domain sentences with the highest uncertainty scores to manually annotate. We define the uncertainty score of an example as the sum of the model’s prediction’s entropy for each token within the sentence. Manual annotation follows the SCATE annotation guidelines released by the organizers.

The annotators were the first two authors of this paper, a Linguistic PhD student and a Information PhD student. During the annotation process, we first individually annotated examples and then resolved annotation differences through discussion. Our first exposure to the SCATE annotation schema was approximately 10 days before the start of the test phase, when we began reading the guidelines and posting questions on the Google forum. We used gold annotations from the development set (on the news domain) to simulate the annotation process during the practice phase. We believe this is similar to most real-world SFDA situations, where the person applying the model on the target domain is unfamiliar with the annotation guidelines and has limited time to learn them.

#### 2.2.2 Data Augmentation

Inspired by Miao et al. (2020), we applied data augmentation to increase the size of our training set beyond what can be achieved by manual annotation, and to improve the generalization of the model. For each time entity that we manually annotated, we automatically generated new training examples by

Task	Type	Domain	#	# of labeled	Open to participants
Negation	Train	-	-	all	✗
Negation	Dev	Clinical	8431 sentences	5545 sentences	✓
Negation	Test	Clinical	622703 sentences	9580 sentences	✓
Time	Train	-	-	all	✗
Time	Dev	news	99 documents	all	✓
Time	Test	food security	48 documents	17 documents	✓

Table 1: Data summary for negation detection and time expression recognition tasks

substituting original time entities with entities of the same type randomly sampled from a predefined entity candidates pool. We generate up to  $n$  new sequences (the size of the pool may be less than  $n$  for some entities). For example, if we manually annotate the three time entities from *2021-02-19* (*2021*: Year, *02*: Month-Of-Year, *19*: Day-Of-Month) in a sentence, after data augmentation, it can generate up to  $n \times 3$  additional sequences with different years, months and days (e.g., *2020-10-05*). The entity candidates pool is created based on the time entities in the development set and the annotation guideline. We filtered out entities that do not appear in the unlabeled test set data during the testing phase. See appendix A.1 for the final pool.

### 3 Data

All data used is in English. Both subtasks had training, development and test data, each representing different domains. As participants, we did not have access to the training set. The training sets are used by organizers to fine-tune the pre-trained RoBERTa-base models to obtain the source-domain models. We used the source-domain models and development sets to develop source-free domain adaptation systems during the practice phase, and tested our systems during test phase. We summarize the data in table 1.

## 4 Experiments

The organizers provided two baseline models for each task: the source-domain model, and the source-domain model fine-tuned on the development set. The official evaluation metric is the F1 score. Precision and recall scores are also reported.

### 4.1 Negation Detection

In the testing phase, we first fine-tuned the source-domain model on the labeled development set. Although the domains of the development set and

Strategy	F1	Precision	Recall
<i>Test Phase</i>			
SD	0.660	0.917	0.516
SD + FT	0.730	0.908	0.611
SD + FT + ST	<b>0.767</b>	0.880	0.680

Table 2: The performance of the negation detection systems during test phase. SD is the source-domain model. FT is fine-tuning on the development set. ST is self-training on test set.

the test set are different, they are both clinically relevant data, so we believed that fine-tuning the model on the development set could improve its performance on the test set. Because of time and hardware constraints, we randomly sampled 3000 instances from the 622,703 test set instances as unlabeled data for self-training. We used the same hyperparameters for fine-tuning the source-domain model on the development set and self-training the fine-tuned model on the randomly sampled test data. All the hyperparameters are shown in table 4 in appendix A.2. Our submission ranked 2<sup>nd</sup>. Table 2 shows that our system outperformed both baseline models provided by the organizers.

### 4.2 Time Expression Recognition

We did not fine-tune the source-domain model on the development set during the test phase. The development set is from the newswire domain, while the test set is from the food security domain. We thought that there might be a large difference between these two domains. Fine-tuning on a different domain may hurt the performance of the model on the test set. As with the code provided by the organizer, we used the sentencizer from Spacy (Honnibal et al., 2020) to split the input documents into sentences and used them as inputs to the model. All the hyperparameters are shown in table 5 in

#	Strategy	F	P	R
<i>Test Phase</i>				
1	SD (baseline)	0.794	0.849	0.746
2	SD + FT (baseline)	<b>0.804</b>	0.827	0.782
3	SD + AL (32*5) + DA (5) + Manual Annotations	0.795	0.783	0.807
<i>Post-Evaluation</i>				
4	SD + AL (32*5) + DA (5) + Manual Annotations (fixed seasonal(1y))	0.837	0.824	0.850
5	SD + AL (32*5) + DA (5) + Gold Annotations	0.955	0.945	0.965
6	SD + FT + AL (32*5) + DA (5) + Gold Annotations	<b>0.959</b>	0.949	0.969
7	SD + AL (32*5) + Gold Annotations	0.890	0.893	0.887
8	SD + AL (16*5) + DA + Gold Annotations	0.929	0.918	0.941
9	SD + AL (8*5) + DA + Gold Annotations	0.900	0.880	0.920
10	SD + AL (4*5) + DA + Gold Annotations	0.877	0.860	0.894
11	SD + AL (4*5) + Gold Annotations	0.851	0.846	0.855

Table 3: The performance of the time expression recognition systems during the test and post-evaluation phases. SD is the source-domain model. FT is fine-tuning on the development set. AL ( $k*i$ ) is active learning with  $k$  samples and  $i$  iterations. DA ( $n$ ) is data augmentation with  $n$  generated examples.

appendix A.2. Our submitted system ranked 6<sup>th</sup>. Table 3 shows that our submitted system’s performance (row 3) is no better than the best baseline model (row 2) provided by the organizers.

To investigate the reasons for the lower-than-expected test performance, we used the gold annotations in the test set for our post-evaluation runs (row 5-11 in table 3). Note that performance for these rows will be artificially inflated, since up to 160 of the 926 test sentences were included in the system’s training data. Nonetheless, we see that by using the gold annotations instead of our manual annotations (row 5 vs row 3 in table 3), the performance of our system improved by 0.160 F1 score. This seems to suggest that our system can improve its generalization ability if we can accurately label the target domain data.

We further analyze where the performance improvement comes from in section 5 and provide a detailed analysis of our annotation errors and give feedback on annotation guidelines in section 6.

## 5 Time Expressions Ablation Study

**Effect of Fine-Tuning on Dev Data** From the baseline models’ performances (row 1 vs row 2 in table 3), we can see that the test performance of the model fine-tuned on the development set is slightly better than the pure source-domain model (+.010 F1 score). To verify if this is also true for our active learning system, we add the fine-tuning strategy to

our system (row 6 in table 3) and run the system on the labeled portion of the test set. The results (row 5 vs row 6 in 3) indicate that fine-tuning on the additional domain continues to help a bit (+.004 F1 score) even when followed by active learning.

**Effect of Data Augmentation** We also investigate the contribution of our data augmentation strategy, removing it from our system and running on the labeled test set. The result shows that data augmentation brings a +.065 F1 score improvement to our system (row 7 vs row 5 in table 3). This indicates that data augmentation was a major source of performance improvements.

**Effect of Size of Annotation Data** In real-world use cases, we often want to keep the size of annotated data as small as possible, since annotation is time consuming and error-prone. To understand how our system performs with less manual annotated examples, we reduce the number of sentences to be annotated at each active learning iteration to 16, 8 and 4 resulting in rows 8, 9 and 10 in table 3. The results show that with only 20 correctly annotated sentences but incorporating data augmentation (row 10), our system outperform the best baseline model (row 2) by .073 F1. If we remove data augmentation from this model (row 11) its performance declines, but still outperforms the best baseline model by .047 F1.

## 6 Time Expressions Annotation Analysis

Though gold annotations led to large performance improvements, the annotation for this task is challenging for untrained people. Through reading the SCATE annotation guidelines and posing questions on the share task google group, our team annotated 160 sentences of which 48 sentences were in the labeled portion of the test set. We annotated 13008 tokens in total (including padding tokens) and our overall accuracy on the gold 48 sentences is 0.991 for all categories and 0.785 excluding the category O. We report detailed performance for each of the entity types in table 6 in appendix A.3.

We found several annotation patterns where our team consistently disagreed with the gold annotations. Our errors can be broadly attributed to two reasons: misinterpretation/underspecification of annotation guidelines, and ambiguity of the phrases.

**Errors from misinterpretations/underspecification of annotation schema** : We annotated the token *seasonal(ly)* (e.g., *seasonal progress*, *seasonal rainfall*) as Calendar-Interval instead of Season-Of-Year as we thought Season-Of-Year is applied to seasons that are explicitly specified (such as summer). We considered *seasonal* similar to *weekly*, both referring to an interval unspecified. However, Season-Of-Year could be applied to very broad categories such as dry seasons and rainfall seasons including seasons that are not specified. Also, *seasonal* unlike *weekly/monthly/yearly* only refers to one season of a year instead of every season of a year. Due to the ubiquity of this token in the dataset, this error affects our overall performance. Correcting the annotation of this particular token leads to +.042 F1 score improvement (row 4 vs row 3 in table 3). Another erroneous pattern is that we double-annotated the phrase such as *from ... to ...* and *between ... to ...*. Specifically, we annotated both adpositions instead of choosing the first adposition only. Finally, we also annotated more modifiers than the gold annotations. For instance, we annotated *marketing* in *marketing year* and *long* in *long dry Jiaal Season* as ‘Modifier’ instead of the category ‘O’. It turns out that the category of modifier in the gold annotation is a closed category, and only a specific set of tokens are considered modifiers.

**Errors from ambiguity within phrases** Some phrases allow multiple interpretations that lead to different ways of annotations. For instance, con-

fusion between ‘Period’ and ‘Calendar Interval’ occurred frequently (e.g., we annotated *weeks* in *recent weeks* as ‘Period’ rather than ‘Calendar-Interval’). Although “/” between seasons is commonly annotated as ‘I-Season-Of-Year’ in the gold annotations, we found different roles it might play in specific contexts. For example, if “/” is used between two terms that refer to the same season, then it should be annotated as ‘I-Season-Of-Year’; if it is used between two non-adjacent seasons, it should be annotated as ‘Union’; and if it is used between two adjacent seasons, then it could be annotated as ‘Between’ or ‘Union’. Thus, the correct annotation requires a surprising amount of external knowledge about Ethiopian season terms. In fact, there are still cases that remained uncertain: For example, *Xaran* refers to seasonal rains from April through September and *Xagaa* refers to the second dry season (July to September) and when the two tokens joined by “/” it is difficult to interpret the meaning of “/”. We also found the conjunction *and* causes ambiguity. For example, *and* in *rains in May and August* could be considered as an operator over months (i.e., rains in Union(May, August)) or an operator over rains (i.e., Union(rains in May, rains in August)). The former understanding requires annotating *and* whereas the latter does not despite the fact that the two interpretations are essentially semantically equivalent. Lastly, we also found the particle *the* is difficult to annotate. For instance, *the* in *the month* depending on the context may be annotated as *this* or *last* and sometimes the context may not be clear enough to tell the differences.

Our annotation analysis leads to several suggestions for the annotation schema and the documentation. Our errors in the first category indicate some potential helpful updates can be made such as including more examples in categories (e.g., ‘Season-Of-Year’), explicit documentation of whether the certain category is closed or open as well as the specific manner to deal with multi-word phrases or even circumpositions. The second category of errors, however, might involve the refinement of the annotation schema. For example, maybe ‘Between’ and ‘Union’ can be unified together, and ‘Period’ can be merged into ‘Calendar Interval’ or confined to an explicit set of circumstances.

## 7 Conclusion

Our overall rank (by F1 score) for negation detection task was 2<sup>nd</sup> and for time expression recogni-

tion was 6<sup>th</sup>.

Our results suggest that simple self-training can be used in sentence-level SFDA tasks to improve a trained model’s performance on a new domain. As for token-level tasks, our analysis shows that both active learning and data augmentation can bring significant performance improvements, but the premise is that the data in active learning can be correctly annotated. Our analysis and feedback could also be used to improve the SCATE annotation guidelines/schema in future work.

## Abstract

Research in Natural Language Processing is making rapid advances, resulting in the publication of a large number of research papers. Finding relevant research papers and their contribution to the domain is a challenging problem. In this paper, we address this challenge via the SemEval 2021 Task 11: NLPContributionGraph, by developing a system for a research paper contributions-focused knowledge graph over Natural Language Processing literature. The task is divided into three sub-tasks: extracting contribution sentences that show important contributions in the research article, extracting phrases from the contribution sentences, and predicting the information units in the research article together with triplet formation from the phrases. The proposed system is agnostic to the subject domain and can be applied for building a knowledge graph for any area. We found that transformer-based language models can significantly improve existing techniques and utilized the SciBERT-based model. Our first sub-task uses Bidirectional LSTM (BiLSTM) stacked on top of SciBERT model layers, while the second sub-task uses Conditional Random Field (CRF) on top of SciBERT with BiLSTM. The third sub-task uses a combined SciBERT based neural approach with heuristics for information unit prediction and triplet formation from the phrases. Our system achieved F1 score of 0.38, 0.63 and 0.76 in end-to-end pipeline testing, phrase extraction testing and triplet extraction testing respectively.

## 1 Introduction

Given the advancements in Natural Language Processing (NLP), a large number of research papers are published every year. However, given the field's dynamic nature, keeping track of all the papers is a non-trivial task. This motivated the formulation

of an Open Research Knowledge Graph (Jaradeh et al., 2019), a knowledge graph of research contributions and the relation between them. Task 11 of SemEval 2021 (D'Souza et al., 2021) formalizes the building of a contributions-focused knowledge graph of NLP literature. The task is divided into three sub-tasks:

- **Sub-task A** Extracting sentences that posit contributions in a research paper.
- **Sub-task B** Extracting relevant phrases that include scientific terms and relational cues from the extracted sentences of the sub-task A.
- **Sub-task C** Triplet (subject phrase, predicate phrase, object phrase) formation from the extracted phrases of the sub-task B and classification of the triplet in one of the information units (IU). There are twelve information units (Research problem, Approach, Results, Model, Code, Dataset, Experimental setup, Hyperparameters, Baselines, Tasks, Experiments, and Ablation analysis), each focusing on different sections in a research paper. These information units can represent all the findings given in a research paper. Out of twelve, first three information units are present in each article.

Recently, transformer-based approaches have been popular for NLP applications (Liu and Lapata, 2019; Yao et al., 2019). For the sub-task A, we propose a sentence level classifier, leveraging SciBERT (Beltagy et al., 2019) and Bidirectional Long Short-Term Memory (BiLSTM) (Hochreiter and Schmidhuber, 1997). SciBERT model has been trained on 1.14M scientific papers from Semantic Scholar corpus, which has 18% papers from the computer science domain. Our system for sub-task B also uses SciBERT based model using CRF

\* Authors equally contributed to this work.

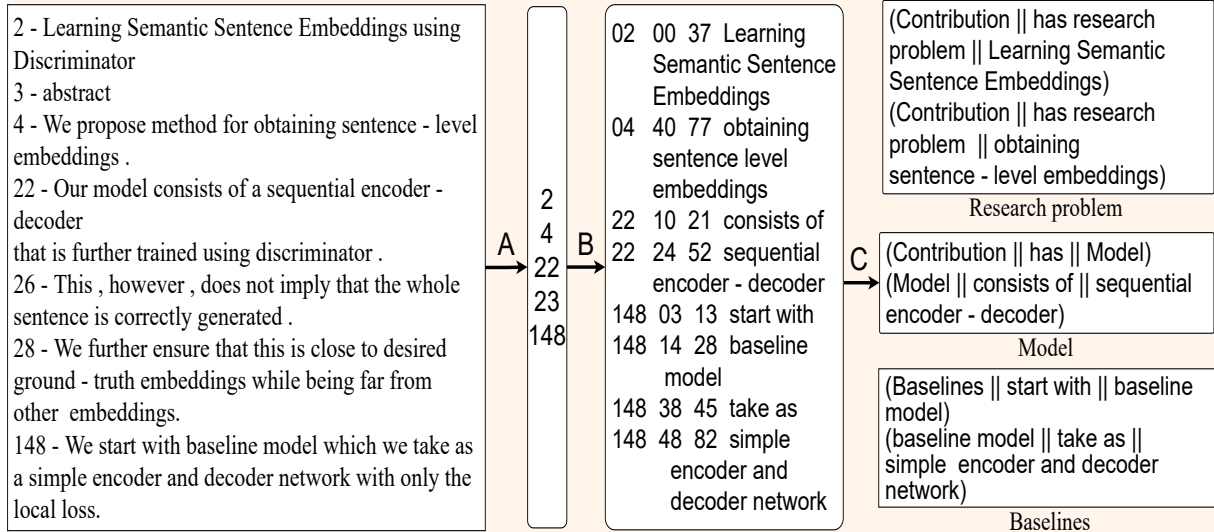

Figure 1: Dataset Example

(Lafferty et al., 2001) on top of BiLSTM layers using BILUO (B=start token of phrase, I=interior tokens of phrase, L=last token of phrase, U=single token phrase and O=Non-phrase tokens) labelling scheme for tokens. For sub-task C, we build a combination of neural and heuristic-based approach. The IU prediction for sub-task C is at document level where two information units use heuristic approach while others use a multi-label classifier based on BiLSTM stacked on top of SciBERT. For triplet formation in sub-task C, we use a separate SciBERT+BiLSTM classifier along with heuristics. These triplets are classified into one of the already predicted information units, i.e., the output unit having the maximum score among the predicted IU. However, some of the IU, such as Baselines, Ablation analysis, Code and Research problem triplets, perform well using heuristic, so we use heuristic instead of a neural approach for these IU. Our proposed system was ranked third in the overall end-to-end pipeline (A+B+C) testing and achieved F1 score of 0.38. Our proposed model was ranked fourth in phrase extraction ( $A_{GT}+B+C$ ) and triplet extraction testing ( $A_{GT}+B_{GT}+C$ ) with a F1 score of 0.63 and 0.76 respectively where  $A_{GT}$  and  $B_{GT}$  represent ground-truth for sub-task A and B respectively. Phrase extraction testing uses ground-truth labels for sub-task A, while triplet extraction testing uses ground-truth for both sub-task A and B. We found that the heuristic-based model for two IU (Research problem and Code) in sub-task C can achieve high performance and achieved F1 score of 0.98 and 1.00, respectively. Our system imple-

mentation code is made available via GitHub<sup>1</sup>.

## 2 Background

### 2.1 Problem Definition

Consider a document  $D = \{s_1, s_2, \dots, s_i, \dots, s_N\}$  having  $N$  sentences  $s_i$ . Sub-task A finds  $M$  contribution sentences denoted by  $S = \{s_1, s_2, \dots, s_M\}$  from  $D$ . Sub-task B selects phrases  $P = \{p_1, p_2, \dots, p_i, \dots, p_L\}$  where  $p_i$  is a phrase selected from a sentence  $s \in S$  and  $L$  is total number of phrases in  $D$ . Sub-task C is forming triplets of extracted phrases for IU denoted by  $U = \{u_1, \dots, u_i, \dots, u_X\}$  where  $u_i$  is one of the twelve IU and  $X$  is number of IU in document  $D$  ranging between three to twelve. For each  $u_i \in U$ , there is a triplet set called  $T^i = \{(su_1^i, pr_1^i, ob_1^i), (su_2^i, pr_2^i, ob_2^i), \dots, (su_j^i, pr_j^i, ob_j^i), \dots, (su_O^i, pr_O^i, ob_O^i)\}$  where  $(su_j^i, pr_j^i, ob_j^i)$  is a triplet representing subject, predicate (relation) and object respectively and  $O$  is total number of triplets in  $u_i$  IU in document  $D$ . An example dataset is given in Figure 1 for reference. Here, on moving from left to right is research paper, contribution sentences, phrases and IU along with triplets given in a research paper respectively.

### 2.2 Related Work

Knowledge graphs (Rebele et al., 2016; Hertling and Paulheim, 2018; Lehmann et al., 2015; Carlson et al., 2010) have shown to be helpful in several areas such as search, knowledge extraction, inter

<sup>1</sup><https://github.com/sshailabh/SemEval-2021-Task-11>

alia. However, only a handful are based on research articles (Xu et al., 2020). Typically, most knowledge graphs are created with rule-based approaches, hence, limiting their performance and generalization. However, some recent approach such as Sang et al. (2018); Wang et al. (2020b) uses neural approach in biomedical literature. To the best of our knowledge, there is no available contributions-focused knowledge graph over NLP literature using the neural approach.

**Sub-task A:** The sub-task of extracting contribution sentences can also be posed as an extractive summarization problem (Nallapati et al., 2016; Narayan et al., 2018; Liu, 2019; Cheng and Lapata, 2016; Zhou et al., 2018; Dong et al., 2018; Wang et al., 2020a). BERTSUM (Liu and Lapata, 2019) and MATCHSUM (Zhong et al., 2020) are the recent methods leveraging language models and uses ROUGE-1, ROUGE-2 and ROUGE-L scores (Lin, 2004) on DailyMail data-set (Hermann et al., 2015). However, this extractive summarization technique may not be applicable in our case due to a number of reasons. Firstly, extractive summarization alone will not give all the contribution sentences because some sentences may not be relevant to the summarization task. Secondly, extractive summarization models are not tested on large documents such as research articles due to the limitation of the input token length for transformer-based language models. Some long document transformer-based methods are proposed (e.g., Beltagy et al., 2020), and can consider documents up to a length of 4096 tokens, however, in our case, documents have on an average  $\sim 10,000$  tokens. Some of the extractive summarization methods (Liu and Lapata, 2019; Miller, 2019) take the number of contribution sentences as a hyper-parameter, but in our case, this is a trainable parameter in our model.

**Sub-task B:** Sub-task B closely resembles the phrase extraction problem and several neural methods (Zhu et al. (2020); Wang et al. (2016); Zhang et al. (2016), inter alia) and non-neural based methods (using n-grams and noun-phrases with certain Part-of-speech (POS) patterns (Hulth, 2003)) have been proposed. Gollapalli et al. (2017) have shown that CRF has the potential to improve the existing phrase extraction model. Alzaidy et al. (2019) jointly leverages CRF and BiLSTM to capture hidden semantics for phrase extraction. Zhu et al. (2020) extended the work of Alzaidy et al. (2019) with the idea of self-training and used word em-

beddings, POS embeddings, and dependency embeddings with a BILUO labelling scheme in the output. Our proposed model took inspiration from Zhu et al. (2020) and propose a SciBERT based model using CRF on top of BiLSTM layers using BILUO labelling scheme on tokens. Our model captures better semantics than the word embeddings based approach in Zhu et al. (2020) because of SciBERT, which is trained on the scientific corpus. Moreover, our model uses the WordPiece tokenizer and hence, robust to Out-of-Vocabulary (OOV) tokens. Sahrawat et al. (2020) used contextual embeddings to the BiLSTM and CRF model using BIO (B=start token of phrase, I=continuation tokens of phrase and O=Non-phrase tokens) labelling scheme. Ratnov and Roth (2009) discussed that the BILUO scheme is superior to the BIO scheme; hence we adopt the BILUO scheme for sub-task B. Recently, Lai et al. (2020) combined sequence labelling with joint learning inspired from self-distillation to boost model performance on unsupervised datasets. However, their model used BIO labelling scheme and gave a comparable or marginal improvement in a supervised setting.

**Sub-task C:** The sub-task C can be divided into two parts - information units (IU) prediction and triplet formation. The information unit prediction and triplet formation have been approached in the literature mainly using rule-based methods. Rusu et al. (2007) suggests using syntactic parsers for generating parse trees, followed by triplet extraction using parser dependent techniques. Jivani et al. (2011) proposed an algorithm that exhibits the relationship between subject and object in a sentence using Stanford parser. This rule-based algorithm can form multiple triplets from a sentence as compared to Rusu et al. (2007). Stanford OpenIE Relation triplet formation (Angeli et al., 2015) uses a classifier, which learns to extract self-contained clauses from longer sentences to form the final triplets using heuristics. Hamoudi (2016) and Jaiswal and George (2015) are also rule-based methods for triplet formation using Stanford dependency parser and constituency parser, respectively. KG-Bert (Yao et al., 2019) uses the BERT language model and utilize entity and relation descriptions of a triplet to compute its scoring function.

### 3 System Overview

The proposed system is shown in Figure 2 depicting the entire pipeline and its respective model.

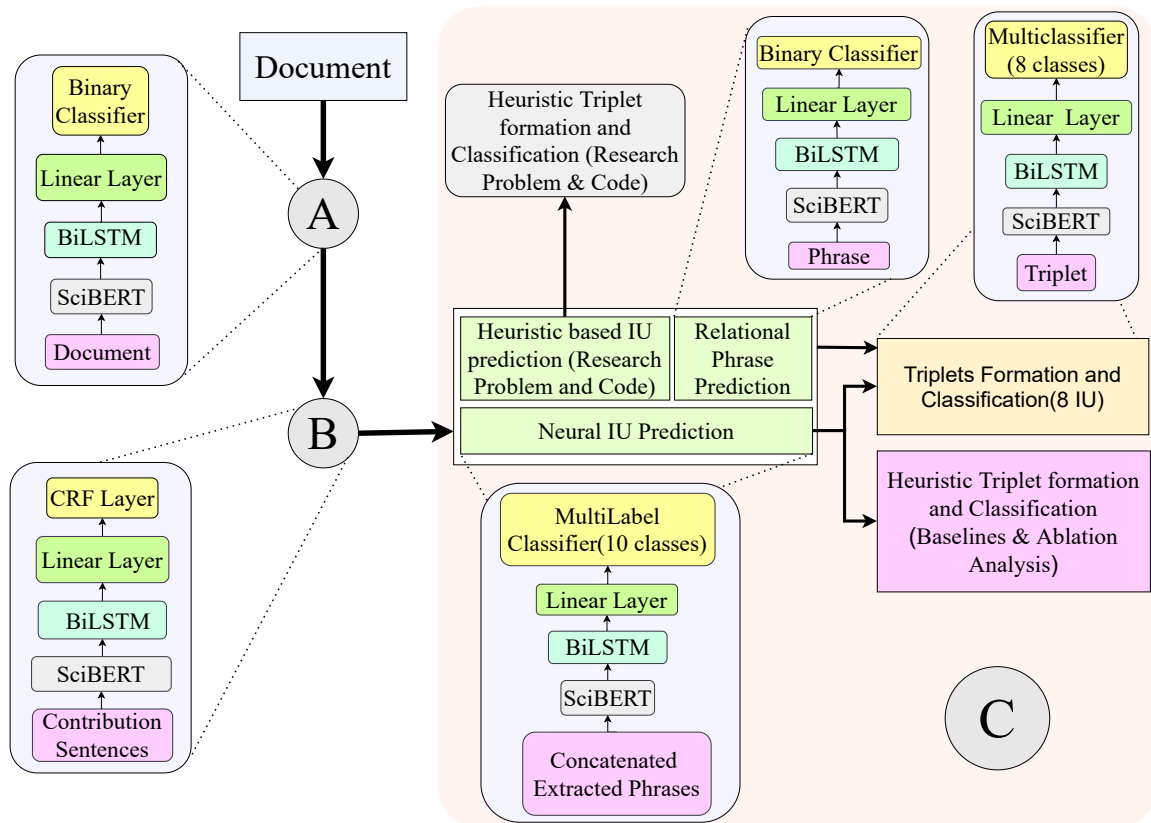

Figure 2: Overall system architecture for end-to-end pipeline showing all the sub-tasks and their respective model.

### 3.1 Sub-Task A

**Initial Experimentation:** We experimented with SciBERT, a language model trained on research papers to build a binary classifier. The classifier encodes the sentence using feature representation corresponding to [‘CLS’] token from the last layer of the pre-trained SciBERT model to predict a binary label. Since the fine-tuning dataset is small, linear layers were not able to capture contextual information well. We experimented by adding a Convolution Neural Network (Zhang and Wallace, 2015) layer on the top of SciBERT. The CNN architecture use three kernels of size two, three and four. The model boosted the performance; however, the model cannot classify long sentences due to their ambiguous nature and lack of CNN’s capacity to capture long semantic dependency among tokens.

**Proposed Approach:** We propose the SciBERT+BiLSTM model (a sentence-level binary classifier where BiLSTM is stacked on top of the SciBERT model). This helps to encode hidden semantics and long-distance dependency. Consider the training dataset as  $Tr = \{D_1, D_2, \dots, D_i, \dots, D_Z\}$  comprising of  $Z$  documents. Each  $D_i$  can be represented as  $D_i = \{s_{i1}, s_{i2}, \dots, s_{ij}, \dots, s_{iN}\}$  where  $N$

is the number of sentences in the document and  $s_{ij}$  is the  $j^{th}$  sentence of document  $D_i$ . Each sentence is assigned a ground-truth label where label “1” represents a contribution sentence and label “0” a non-contribution sentence. The sentences are processed using a SciBERT model followed by stacked BiLSTM layers whose output is further processed through linear layers with ReLU (Nair and Hinton, 2010) non-linearity. We add dropout layers to avoid overfitting. The last linear layer consists of two units corresponding to label “0” and label “1”. The final output label is the label whose corresponding unit has a higher score in the last linear layer. Our loss function is weighted binary cross-entropy loss, where weights are in according to the number of samples in each class.

### 3.2 Sub-Task B

**Initial Experimentation:** We built our initial method, the BiLSTM+CRF model, on the lines of Zhu et al. (2020). The model uses a BiLSTM layer along with CRF for sequence to sequence (BILUO) labelling in order to mark the phrases in a sentence. We introduced SciBERT (by replacing BiLSTM layers) to fine-tune and better generalise with an increase in performance. We tested the significance

of CRF by replacing it with a softmax layer, which gave poor performance since it is unable to learn the constraints in the BILUO scheme.

**Proposed Approach:** We further improved the SciBERT+CRF model to improve semantic information. Our proposed model stack BiLSTM layers on top of SciBERT, followed by CRF (see Figure 2). The word-level representation  $\{x_1, x_2, \dots, x_N\}$  from the input sentence passes through the SciBERT tokenizer. We used the representation of the first sub-token for every word as the input to the SciBERT. The tokenized input is passed into the SciBERT layer, followed by the BiLSTM layer. The final feature output is mapped to a hidden linear layer to get the score matrix  $Z$ , which is passed into the CRF layer for label prediction  $y$ . The CRF layer is the same as described in Lample et al. (2016).

The output produced by the SciBERT + BiLSTM + Hidden Layer corresponds to a scoring matrix  $Z^{(n \times l)}$  where  $n$  denotes the number of words in the input sentence, and  $l$  is the number of labels ( $l=5$ ). The score of an output sequence  $y$  using CRF is given by:

$$Scr(s, y) = \sum_{i=0}^n (Z_{i, y_i} + T_{y_{i-1}, y_i}) \quad (1)$$

where  $Z_{i,j}$  denotes the score of word  $w_i$  with the  $j$ th label,  $T_{y_{i-1}, y_i}$  is the transition score from the label  $y_{i-1}$  to  $y_i$ ,  $y = \{y_1, y_2, \dots, y_n\}$  is the sequence of true labels and  $Scr(s, y)$  corresponds to output score for sentence  $s$  and true labels  $y$ . A softmax over all possible label sequences yields a probability for true labels  $y$ :

$$P(y|s) = \frac{\exp(Scr(s, y))}{\sum_{y' \in Y(s)} \exp(Scr(s, y'))} \quad (2)$$

where  $Y(s)$  corresponds to all the possible label sequences for sentence  $s$ . Now during training, our task is to maximize the log-probability of the correct label sequence  $y$ . Model loss is defined as follows:

$$L(\Theta) = -(1/M) \sum_{i=1}^M \log(P(y_i|s_i)) + \frac{\lambda}{2} \|\Theta\|^2 \quad (3)$$

where  $s_i$  is the input sentence,  $y_i$  is the corresponding true label sequence,  $\Theta$  denotes the model parameters,  $\lambda$  is the regularization hyperparameter and  $M$  is the train set size. Output label prediction is made by:

$$y^* = \operatorname{argmax}_{y' \in Y(s)} P(y'|s) \quad (4)$$

Here  $y^*$  represents the final output label sequence,  $s$  is the input sentence,  $Y(s)$  is the set of possible label sequences and  $P(y'|s)$  denotes the probability of getting  $y'$  label sequence from sentence  $s$ . The phrases are extracted using BILUO scheme based on the prediction outputs.

### 3.3 Sub-Task C

**Initial Experimentation:** We used a combination of neural and rule-based approach for sub-task C. An IU triplet has three phrases - subject, predicate and object. Research problem and Code IU triplets have fixed subject and predicate in triplets. We employed a heuristic to scan the phrases of the first thirty lines of each document and select only those sentence's phrases that have only a single phrase extracted out. These phrases form object in Research problem IU triplets. A regex expression is used to extract all the sentences in the article that contain any URLs for Code IU triplet's object. However, only those URL sentences are selected which have token such as "our" or "code" or "our code".

Our initial approach was to form the triplets for all other IU and classify them into one of the ten remaining information units using SciBERT + BiLSTM multi-class classifier (BiLSTM layers stacked on top of SciBERT). The heuristic for triplet formation is based on orthographic visualization of the document - firstly, the phrases are arranged in the exact order as they appear in the original sentence. Then, every three consecutive pair of phrases present within the same sentence are considered as one triple. This approach gave us decent results since most of the research paper is written in the active voice; hence the subject phrase should occur first, then its corresponding predicate and last should be the object phrase. The SciBERT + BiLSTM multi-class classifier takes concatenated triplets as the input and their corresponding information unit as the ground truth. The loss is a cross-entropy loss, with the final softmax layer having ten classes corresponding to 10 information units. One of the drawbacks of the model is that the IU prediction depends on triplet formation's correctness. Further, a single triplet does not have enough context to be correctly classified into the correct information unit. We visualized triplet formation for feature extraction and found that some IU triplet's, such as Baselines and Ablation analysis, can be better formed using heuristics. Our proposed approach

is a better triplet formation model and eliminates these limitations.

**Proposed Approach:** Our proposed approach has some information unit such as Research problem and Code, whose model for prediction and triplet formation is entirely heuristic-based and the same as initial experimentation. Our proposed method for the rest of ten IU is divided into two parts -

**IU Prediction** - We propose a SciBERT+BiLSTM multi-label classifier (BiLSTM layers stacked on top of SciBERT) (refer to Figure 2) whose input is the concatenated phrases and predicts the IU of the document. The concatenation is in the order of the occurrence of phrases in the document. Moreover, these concatenated extracted phrases represent the whole document since it includes all relevant keywords of the research article necessary for information unit prediction. Hence, our proposed model encodes information at the document level, which makes it superior to the initial experimentation method.

**Triplet Formation and Classification** - In general, a phrase is either a relational phrase or a scientific term (Figure 1). A specific trend observed in ground truth triplets is that a triplet’s predicate is unique for a triplet. This contrasts with the subject and object phrase, which can be used multiple times in other triplets. Hence, a one-to-one relation between predicate phrase and triplet exists. We identify all predicate phrases from the extracted phrases of sub-task B; then, a corresponding triplet will be formed for each predicate phrase. We train a SciBERT+BiLSTM based binary classifier (BiLSTM layers stacked on top of SciBERT model) to identify the phrases which act as predicates (relational phrases). The model is fine-tuned on our dataset and uses the weighted binary cross-entropy loss. In labelling, “1” denote as predicate while “0” denote as non-predicate. To form triplets, we use a simple heuristic to arrange the phrases in the exact order as they appear in the original sentence. For every phrase predicted as a predicate, we take its previous phrase as the subject and its next phrase as the triplet object.

Now, a multi-class classifier for triplet classification for 8 IU (corresponding to all IU except Research problem, Code, Baselines and Ablation analysis) (refer to Figure 2) is built, which is similar to the one described in the initial experimentation. Since we have already predicted the information units, during inference, the triplet can be assigned

only to one of the already predicted information units, i.e., the output unit having the maximum score among the predicted IU.

We used rule-based heuristics for triplet formation of Baselines and Ablation analysis IU. The target sentences, whose phrases belong to baselines IU, are identified by selecting all the headings (i.e. lines having no punctuation) with words such as “baseline”, “comp” using a regex expression. Then, we took all the sentences between selected headings and their consecutive headings as the target sentences. The phrases associated with extracted sentences are used for triplet formation via the rule of three consecutive phrases present within the sentence. The same method is followed for Ablation analysis IU triplets with only change that the relevant headings are found using the regex expression that identifies if that heading contains the word such as “ablation”, “analysis”.

## 4 Experimental Setup

### 4.1 Data

The dataset annotation scheme is as per [D’Souza and Auer \(2020\)](#). The pre-processed dataset con-

Token Length	% of sentences less than token length
50	94.57
100	99.74
150	99.93
200	99.96

Table 1: Token length statistics on train set

sists of 287 annotated NLP research documents in the English language with ground truth for each sub-task. Train, dev and test set have 237, 50 and 155 documents, respectively. We have chosen 100 as the maximum token length in a sentence with WordPiece tokenizer since 99.7% sentences in the train set have less than or equal to 100 tokens. The Table 1 shows token length and percentage(%) of sentences less than that length. In the sub-task C, if there is no suitable predicate available in the extracted phrases, then the triplet’s predicate is chosen from the predefined set of predicates, i.e. “has”, “on”, “by”, “for”, “has value”, “has description”, “based on”, “called”. Table 2 shows the dataset statistics related to sub-task A and B. The dataset statistics for sub-task C is given in Table 3. Tasks information unit has no triplets in train set while

Statistics	Train	Dev

Ablation analysis	1407	155

Table 3: Number of triplets in each Information Unit on train and dev set.

Code and Dataset information units have very few triplets in dev set.

## 4.2 Hyperparameters

We have used the dev set to tune our hyperparameters. In every neural model, we are fine-tuning SciBERT.<sup>2</sup> We tried different batch sizes and learning rates for fine-tuning (Dodge et al., 2020). We found the best results using the AdamW optimizer in the neural models.

**Sub-task A** : We used batch size = 32, learning rate = 1e-05, epoch = 2, two layers of BiLSTM with hidden dimension of 400 and three linear layers (size = 800, 400, 100) with dropout = 0.1. Over-sampling of minority class (contribution sentences) counters the skewness in data.

**Sub-task B** : We used batch size = 1, learning rate = 2e-05, epoch = 4, single layer of BiLSTM with

<sup>2</sup><https://github.com/huggingface/transformers>

hidden dimension = 200 and linear layer with CRF. **Sub-task C** : We used batch size = 4, max-tokens = 512, learning rate = 2e-05, epoch = 16, threshold on sigmoid output = 0.5, two layers of BiLSTM with hidden dimension of 400 and three linear layers (size = 800,400,100) with dropout = 0.2 for multi-label classification of information units (ten out of twelve). We have used batch size = 32, max tokens = 25, learning rate = 2e-05, epoch = 4, two BiLSTM layers with hidden dimension = 400 and three linear layers (size = 800, 400, 100) with dropout = 0.1 for relational phrase prediction model. We have used batch size = 16, max tokens = 50, learning rate = 2e-05, epoch = 2, two BiLSTM layers with hidden dimension = 400 and three linear layers (size = 800, 400, 100) with dropout = 0.2 for triplet classification (eight out of twelve info-units).

## 4.3 Evaluation Metrics

In this task, organizers used Precision, Recall and F1 score metrics. In sub-task A, the predicted and ground-truth contribution sentences of the document calculate the metrics score. The sub-task B output has predicted phrase, contribution sentence number, starting and ending character number of the predicted phrase (Figure 1). These outputs are the basis for sub-task B metric calculations. The sub-task C has two groups of metrics. First is the Information Units prediction of a document (regardless of triplets). The second group calculates using both Information Units and triplets (the predicted triplet is correct only if it exactly matches the ground truth triplet and the ground-truth IU; otherwise, it is incorrect). The final score is the average of all the four F1 scores on the dataset. The participating team rankings are according to this score.

## 5 Results

Table 4 shows all the participating teams average F1 score. In end-to-end pipeline testing, the input is the documents. In phrase extraction testing ( $A_{GT}+B+C$ ), the input is the document and ground-truth for sub-task A. Here,  $A_{GT}$  represents the true label of sub-task A, and the F1 score for sub-task A is 1.00. In the triplet extraction phase ( $A_{GT}+B_{GT}+C$ ), the input is the document and ground truth labels (F1 score = 1.00) for both sub-tasks A and B to the system. Our team “Know-Graph@IITK” achieved an F1 score of 0.3783 and ranked third in end-to-end pipeline testing.

Team Name	A+B+C	A <sub>GT</sub> +B+C	A <sub>GT</sub> +B <sub>GT</sub> +C
BioNLP@UIUC	0.3828	<b>0.7612</b>	<b>0.8594</b>
ecnuica	0.3335	0.7113	0.8145
ITNLP	<b>0.4703</b>	0.6863	0.7931
<b>KnowGraph@IITK</b>	<b>0.3783</b>	<b>0.6318</b>	<b>0.7600</b>
INNOVATORS	0.3205	0.5252	0.5971
DuluthGrad	0.2838	0.4921	0.7579
YNU-HPCC	-	0.4562	0.6541
DFKI-SLT	0.2651	-	0.7137
NLP_IITGN	-	0.3522	-

Table 4: Average F1 score on test set of participating teams in end-to-end pipeline testing(A+B+C), phrase extraction testing(A<sub>GT</sub>+B+C) and triplet extraction testing(A<sub>GT</sub>+B<sub>GT</sub>+C).

In phrase extraction and triplet extraction testing phases, our system ranked fourth with an F1 score of 0.6318 and 0.76, respectively. Our heuristic-based triplet extraction for Code and Research problem information unit achieved excellent performance with an F1 score of 1.00 and 0.9756, respectively, on the test set.

### 5.1 Ablation and Error Analysis

Methods	Dev F1 score
Sub-task A	
SciBERT + CNN	0.440
SciBERT + BiLSTM	<b>0.451</b>
Sub-Task B	
BiLSTM + CRF	0.361
SciBERT + CRF	0.444
SciBERT + BiLSTM + CRF	<b>0.480</b>

Table 5: F1 score of several methods of sub-task A and sub-task B on development set.

We built several models using SciBERT, LSTM and CNN for each sub-task to understand each method’s significance (Table 5). We found that language models are knowledge-rich and boost the existing models. On top of language models, BiLSTM based model performs better than the CNN-based model due to long semantic dependency in sequential models. In sub-task B, BiLSTM+CRF based model performed inferior to the same model built on top of SciBERT. In triplet formation in sub-task C, our rule-based approach of Research problem and Code information unit yield excellent results (highest on the leaderboard). A significant improvement in the F1 score for Baseline and Ablation Analysis IU suggests that the rule-based approach can boost neural models since specific

patterns are present for these information units’ triplets. In sub-task A, the dataset is highly skewed between minority and majority classes (1:10), making the training of a neural model difficult. On visualization of sub-task B outputs, we found some ambiguous phrases that our model fails to predict correctly. Extracting both scientific and relation cue phrases with high precision and recall in a single model is difficult. Sometimes, our model predicts scientific phrases correctly but fails to predict relation cue phrase in the same sentence.

In sub-task C, some IU triplet’s such as Model, Hyperparameters, Results were present in large number comparatively and while Tasks and Dataset IU triplets are scarce in number. This skewness resulted in biasing of our multi-label classification model for IU prediction. In triplet formation, our predicate approach fails when the predicate is not present in the sentence and selected from the organizer’s closed set of predicates. The proposed system also fails in the case of branching between the triplets, i.e. multiple triplets share the same subject phrase. Our triplet formation is unable to predict Approach, Dataset and Tasks triple. On visualizing, we found that Model triplets are predicted instead of Approach triplets. Further, the triplets lack enough features to be classified into an information unit using a neural-based method. Our system performance on sub-task C is poor in the end-to-end pipeline and phrase extraction testing because we submitted our initial experimentation model.

## 6 Conclusion

In this paper, we have presented our system for NLPContributionGraph task of SemEval 2021. We found that neural models combined with heuristics

can build a knowledge graph by dividing it into small tasks. The heuristic-based model can outperform the neural approach in the triplet formation of some Information Units. In future work, neural models can use sparse transformers to encode long documents without increasing much memory. The pre-defined predicate incorporation could also be a future direction of work for our system.

## Acknowledgments

We thank Shubham Kumar Nigam for his guidance and SemEval-2021 organizers for running the competition. We are also very grateful to the Pytorch developers.

# YNU-HPCC at SemEval-2021 Task 11: Using a BERT Model to Extract Contributions from NLP Scholarly Articles

Xinge Ma, Jin Wang and Xuejie Zhang  
School of Information Science and Engineering  
Yunnan University  
Kunming, China

Contact: maxinge@mail.ynu.edu.cn, {wangjin, xjzhang}@ynu.edu.cn

## Abstract

This paper describes the system we built as the YNU-HPCC team in the SemEval-2021 Task 11: *NLPContributionGraph*. This task involves first identifying sentences in the given natural language processing (NLP) scholarly articles that reflect research contributions through binary classification; then identifying the core scientific terms and their relation phrases from these contribution sentences by sequence labeling; and finally, these scientific terms and relation phrases are categorized, identified, and organized into subject-predicate-object triples to form a knowledge graph with the help of multiclass classification and multi-label classification. We developed a system for this task using a pre-trained language representation model called BERT that stands for Bidirectional Encoder Representations from Transformers, and achieved good results. The average  $F_1$ -score for Evaluation Phase 2, Part 1 was 0.4562 and ranked 7th, and the average  $F_1$ -score for Evaluation Phase 2, Part 2 was 0.6541, and also ranked 7th.

## 1 Introduction

As the number of research publications increases, there is a growing need for digital libraries to equip researchers with alternative knowledge representations. In addition, because scientific literature is growing at a rapid rate and researchers today are faced with a publication deluge, it is difficult to keep up with the research progress even within ones own narrow discipline. The open research knowledge graph (ORKG) (Jaradeh et al., 2019) is posited as a solution to the problem of keeping track of research progress without the cognitive overload imposed by reading dozens of full papers. To this end, the aim of this task is to build a comprehensive knowledge graph that represents the research contributions of scholarly publications

per paper and also shows where the contributions are interconnected across papers (D’Souza and Auer, 2020).

The task was defined on a dataset containing natural language processing (NLP) scholarly articles with their contributions structured to be integrable within a knowledge graph infrastructure, such as the ORKG. The structured contribution annotations were provided as follows: (1) contribution sentences: a set of sentences about the contribution in the article; (2) scientific terms and relations: a set of scientific terms and relational cue phrases extracted from the contribution sentences; and (3) triples: semantic statements that pair scientific terms with a relation, modeled toward the subject-predicate-object statements for building knowledge graph. The triples were organized under three (mandatory) or more of the twelve total information units (i.e., *ResearchProblem*, *Approach*, *Model*, *Code*, *Dataset*, *ExperimentalSetup*, *Hyperparameters*, *Baselines*, *Results*, *Tasks*, *Experiments*, and *AblationAnalysis*). An illustration of this process is shown in Figure 1.

The difficulty of this task lies in text classification (Joulin et al., 2017) and sequence labeling (Ma and Hovy, 2016). Text classification refers to determining which of the two or more labels a one-dimensional linear sequence belongs to. Similarly, sequence labeling is used to tag each element in a one-dimensional linear sequence with a label from a set of labels. Before the popularity of deep learning, the common solutions to the sequence-labeling problem were all based on either the hidden Markov model (Zhou and Su, 2001) or conditional random field (CRF) (Ye and Ling, 2018), with CRF being the mainstream method. With the development of deep learning, convolutional neural networks (CNN) (Kim, 2014) and recurrent neural networks (RNN) (Cho et al., 2014) have achieved great success in text classification and se-

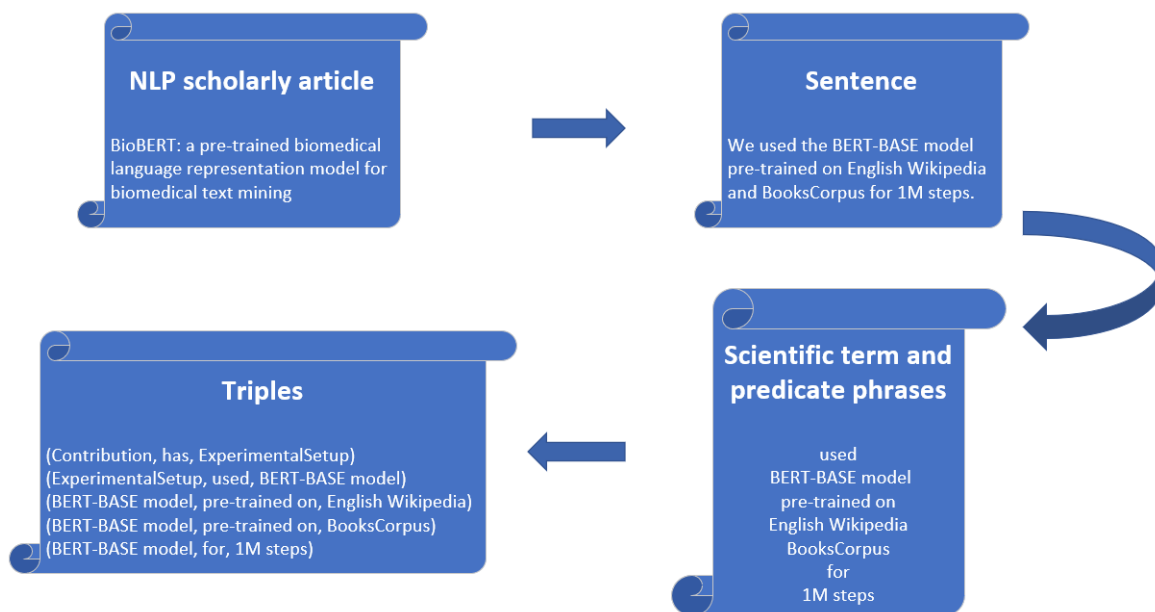

Figure 1: Example of contribution extraction of NLP scholarly articles

quence labeling. Since then, long short-term memory (LSTM) (Wang and Jiang, 2016), Bi-LSTM (Bi-directional long short-term memory), and other models (Yuan et al., 2020) have performed better than CNN and RNN in text classification and sequence labeling. However, since the introduction of bidirectional encoder representations from transformers (BERT) (Devlin et al., 2018), the accuracy and training efficiency in both text classification and sequence labeling have reached new heights.

The SemEval-2021 shared Task 11 (D’Souza et al., 2021) consists of three subtasks:

- Subtask 1: identifying contribution sentences;
- Subtask 2: identifying scientific terms and predicate phrases;
- Subtask 3: categorizing, identifying and organizing scientific terms and predicate phrases into subject-predicate-object triples.

In this study, after analysis, we converted the above three subtasks into four downstream tasks in the field of NLP: binary classification for solving Subtask 1, sequence labeling for solving Subtask 2, multiclass classification and multi-label classification for solving Subtask 3. Then, we used a pre-trained language model, BERT, to generate word embeddings and integrated them into the corresponding models for the different tasks. After

completion of the task, our results were satisfactory. Our submission ranked 7th in both Part 1 and Part 2 of Evaluation Phase 2. The implementation for our system is made available via Github<sup>1</sup>.

The remainder of this paper is organized as follows. Section 2 describes the details of the BERT model used in our system. Section 3 presents the experimental results. Finally, the conclusions are presented in Section 4.

## 2 System Description

We used a pre-trained BERT model to accomplish the task, which was defined in terms of three dataset annotation elements, where the extraction of each data element relied on the extraction of the previous data element.

### 2.1 Subtask 1: Sentence Classification

The first part of this task was to extract sentences that reflected the research contribution in the given NLP scholarly articles. We termed this sentence classification (Dao et al., 2020), where we predicted whether a sentence in an article was a contribution sentence. To this end, our approach was to pass each sentence in an article through the pre-trained BERT model to generate 768-dimensional word embeddings for each word in the sentence. The next thing we were going to do was to take the word embeddings of the first token of each sentence

<sup>1</sup><https://github.com/maxinge8698/SemEval2021-Task11>

(i.e. '[CLS]') to do sentence classification because it integrated the semantic information of the whole sentence. Then this word embeddings acquired from the previous step was connected with a fully connected layer that converted the 768-dimensional input into 2-dimensional numerical values. These values were then input into *softmax* to calculate the probability of a sentence being a contribution sentence. Finally, the probability outcomes were input into *argmax*, where, in our experimental setup, an output of 1 indicated a contribution sentence and 0 indicated the contrary. The overall architecture of the system is shown in Figure 2.

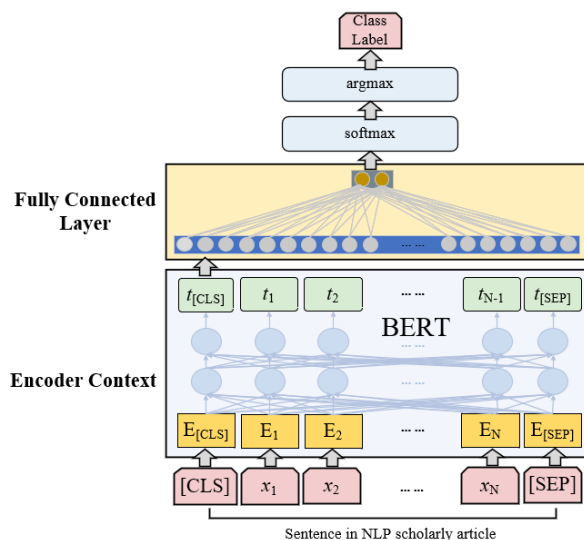

Figure 2: System of binary classification for sentence classification task

## 2.2 Subtask 2: Span Identification

Span identification (Singh et al., 2020) was a binary sequence tagging task where we classified each token in a contribution sentence to indicate whether it was part of a scientific term or predicate phrase fragment. We passed the contribution sentence identified from Subtask 1 into a pre-trained BERT model and obtained embeddings for each token in the sequence. Next, the word embeddings for each token were passed through a fully connected layer, and thereafter through *softmax* and *argmax*, where they were mapped to a class label respectively except the tokens of '[CLS]' and '[SEP]', indicating whether the token was part of a scientific term or predicate phrase fragment. The model architecture is illustrated in Figure 3. Note that the fully connected layer, *softmax*, and *argmax* were shared across all tokens.

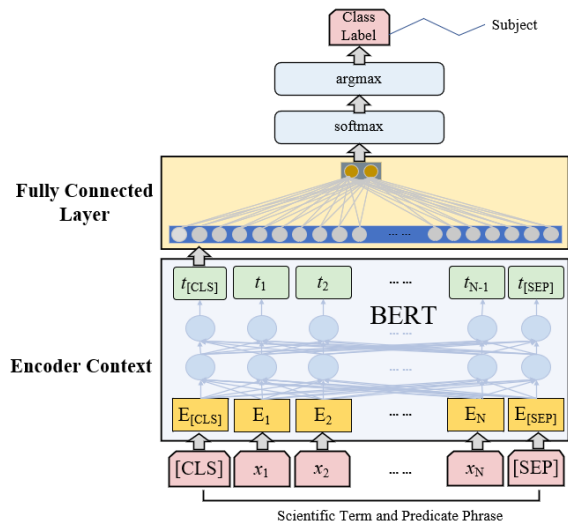

Figure 3: System of sequence labeling for span identification task

## 2.3 Subtask 3: Triple Extraction

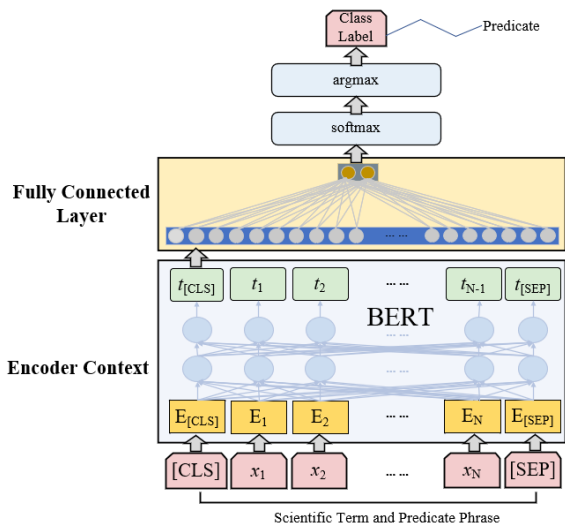

This subtask was the most cardinal and complex step in the entire task. This could be considered a relation extraction task (Lin et al., 2016), which was completed by dividing into parts information units classification and triple formation. First, it was necessary to classify all scientific term and predicate phrases in a contribution sentence extracted from Subtask 2 to determine which category of the 12 information units the extracted phrases belonged to. This was a multiclass-sequence classification problem, where we identified the unit information belonging to the scientific term and predicate phrase fragments in a given contribution sentence by concatenating all phrases into a single string to feed our model. The system architecture of this part was similar to the sentence classification system, except that there were 12 class labels and 12 output dimensions instead of 2 each (refer to Figure 4a). The next step was to identify the subject, predicate, and object in the scientific term and predicate phrases included in a contribution sentence obtained from Subtask 2 by using multi-label classification. More specifically, each scientific term and predicate phrase could be labeled with one or more of the three tags of subject, predicate and object, which could be solved by transforming the multi-label classification problem into three binary classification problems similar to the sentence classification system whereas using each phrase as input instead of each sentence. First, a binary classification system was used to

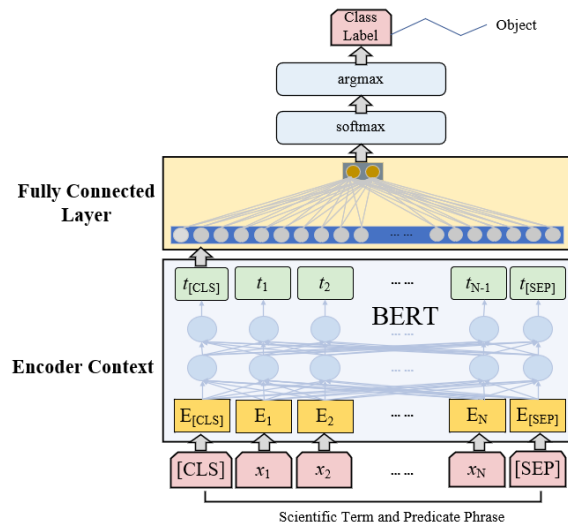

(a) Multiclass classification system for classifying information unit

(b) Multi-label classification system for identifying subjects

(c) Multi-label classification system for identifying predicates

(d) Multi-label classification system for identifying objects

Figure 4: System of multiclass classification and multi-label classification for triple extraction task

identify the subject in each scientific term and predicate phrase (refer to Figure 4b). Then, a second binary classification system was used to identify the predicate (refer to Figure 4c), and a third binary classification system was used to identify the object (refer to Figure 4d). A brief overview of this system is presented in Figure 4. At the end of the classification, for all phrases in a contribution sentence, that the corresponding label conformed to the subject-predicate-object order was found as triples iteratively from the beginning position.

### 3 Experimental Results

**Datasets.** The *NLPContributionGraph* shared task comprises a dataset of NLP scholarly articles with annotated contributions. The annotations were provided in terms of three data elements: (1) contribution sentences, (2) scientific term and predicate phrases from the sentences, and (3) (subject, predicate, object) triple statements. All the triples together formed the contribution-centered knowledge graph of the articles. The dataset released by the organizers contained 237 annotated articles as training data and 155 annotated articles as testing data for the final evaluation phases. For the training data, the annotations of each scholarly article were provided in a directory. The directory contained the full article in plain text, which was pre-processed for tokenization and sentence splitting. The annotations were provided in the following three files: (1) **sentence.txt**, specifying the annotated contribution sentence numbers from the plain text file; (2) **entities.txt**, specifying the sentence number, tab-separated from the start and end token numbers of the annotated phrase in the sentence; and (3) a directory **triples/** containing files with triples of scientific term and phrase pairs and a relation cue phrase, and the files were named to indicate the information unit that the triple data represented. For the article under the directory “training-data/natural\_language\_inference/0” as illustrated in Table 1, the sentence.txt file gave the line index of the articles contribution sentences (starting at 1). As illustrated in Table 2, the entities.txt file presented the line index which was identical to sentence.txt file, beginning position (starting at 0), end position, and corresponding text content of the scientific term and predicate phrases for each of the contribution sentences of the article. As illustrated in Table 3, the triples folder contained files named as one of the 12 information units covered in the

article, and each information unit file provided (subject, predicate, object) triples that were comprised of the scientific term and predicate phrases.

**Evaluation Metrics.** An *NLPContributionGraph* submission would be considered complete with predictions made for all three tasks (sentences, phrases, triples). The evaluation metrics that were applied are

- Sentences: *precision*, *recall* and  $F_1$ -score;
- Phrases: *precision*, *recall* and  $F_1$ -score;
- Triples: *precision*, *recall* and  $F_1$ -score overall and for each information unit.

The calculation of these three evaluation metrics is as follows:

$$precision = \frac{true\ positives}{true\ positives + false\ positives} \quad (1)$$

$$recall = \frac{true\ positives}{true\ positives + false\ negatives} \quad (2)$$

$$F_1 = 2 \cdot \frac{precision \cdot recall}{precision + recall} \quad (3)$$

For the final evaluation stage of the task, the evaluation metrics is as follows:

$$F_1 = avg(F_1(Sentences), F_1(Phrases), F_1(InformationUnits), F_1(Triples)) \quad (4)$$

**Implementation Details.** The articles were split into sentences to feed into the language model, which resulted in 55,201 sentences in the training data (44,160 sentences served as the training set and 11,041 as the development set) with a maximum length of 398 words, and 33,800 sentences in testing data that originated from the evaluation phase, with a maximum length of 385 words. We used the Tensorflow framework provided by the Huggingface<sup>2</sup> library for the pre-trained BERT models and `bert-base-uncased` for binary classification, sequence labeling, multiclass classification, and multi-label classification included in this task. In addition, we fine-tuned the model using the Adam optimizer (Loshchilov and Hutter, 2018), by using a loss function of categorical cross-entropy with a learning rate of  $2 \times 10^{-5}$  and a batch size of 8 for three epochs. The activation function used by the fully connected layer was *softmax*.

**Result and Discussion.** To allow a thorough evaluation of the systems, *NLPContributionGraph* was organized into three evaluation phases:

- **Evaluation Phase 1: End-to-end pipeline testing phase.** The participant systems were expected to output contribution sentences, their corresponding scientific terms, and predicate phrases as well as triples.
- **Evaluation Phase 2, Part 1: Phrases extraction testing.** The participant systems were given gold-annotated contribution sentences and were expected to provide purely scientific terms and predicate phrases as well as triples as extraction output.
- **Evaluation Phase 2, Part 2: Triples extraction testing.** The participant systems were given gold phrases and were expected to provide triples as the only output.

We used the Scikit-Learn<sup>3</sup> library to divide the training data into training and development sets in a 8:2 ratio. We trained our models on the training set and evaluated the prediction with the golden scores of the good performance of our approaches. For these three subtasks, the  $F_1$ -score, *Precision*, and *Recall* of our system on the development set are shown in Table 4.

<sup>3</sup><https://scikit-learn.org>

Our system achieved an average  $F_1$ -score of 0.4562 in Evaluation Phase 2, Part 1 and ranked 7th among the participating systems, and an average  $F_1$ -score of 0.6541 in Evaluation Phase 2, Part 2 and also ranked 7th among all participants. The results showed that our proposed system was effective in extracting contributions from an NLP scholarly article. The main reason was that the BERT model is a multi-layer bidirectional transformer encoder, which can be integrated into various NLP downstream tasks and achieves the best results.

Subtask	$F_1$ -score	<i>Precision</i>	<i>Recall</i>
Subtask1	0.6423	0.6554	0.6932
Subtask2	0.4768	0.5326	0.4356
Subtask3	0.4385	0.4109	0.6151

Table 4: Score of the pre-trained BERT model for the three subtasks on the development set

## 4 Conclusions

In this paper, we presented the system we submitted to the SemEval-2021 Task 11, which leveraged a pre-trained BERT model to extract contributions from an NLP scholarly article using binary classification, sequence labeling, multiclass classification, and multi-label classification. The experimental results showed that the proposed models achieved a good performance in the final evaluation phases.

Furthermore, in the three subtasks, there appeared to be significant room for improvement compared to the top-ranked participant systems. Therefore, in future research, we will attempt to generalize models with better capabilities to obtain better results.

## Abstract

This paper describes the winning system in the End-to-end Pipeline phase for the NLP-ContributionGraph task. The system is composed of three BERT-based models and the three models are used to extract sentences, phrases and triples respectively. Experiments show that sampling and adversarial training can greatly boost the system. In End-to-end Pipeline phase, our system got an average F1 of 0.4703, significantly higher than the second-placed system which got an average F1 of 0.3828.

## 1 Introduction

The Knowledge Graph (KG) describes the concepts, entities and their relationships in the objective world in a structured form, expresses Internet information in a form closer to the human cognitive world. Information extraction is the first step of the KG construction. Information extraction is a technology that extracts structured information such as entities and relationships from semi-structured or unstructured data automatically. Similarly, as the rate of research publications increases, it is critical to construct Knowledge Graphs to represent scholarly knowledge efficiently. The target of the NLPContributionGraph task (D'Souza et al., 2021) is to find a systematic set of patterns of subject-predicate-object statements for the semantic structuring of scholarly contributions that are generically applicable for NLP research articles, then apply the discovered patterns in the creation of a larger annotated dataset for ingesting the dataset into the Open Research Knowledge Graph infrastructure to assist users manually manage their article contributions. Our task consists of three sub-tasks: Sentences Extraction (SE), Phrases Extraction (PE) and Triples Extraction (TE).

The dataset used in the NLPContributionGraph task contains hundreds of Natural Language Pro-

cessing (NLP) scholarly articles annotated for their contributions. Each article is written in English and contains three types of annotation information: 1) contribution sentences; 2) scientific term and predicate phrases from the sentences; and 3) subject-predicate-object triple statements from the phrases toward KG building.

Our code is available at <https://github.com/itnlp606/nlpcb-graph>.

## 2 Related Work

In recent years, pretrained language models (Peters et al., 2018; Devlin et al., 2019; Sun et al., 2019; Lan et al., 2020) have achieved impressive performance in various NLP tasks including information extraction. BERT (Devlin et al., 2019) uses Bidirectional Transformers (Vaswani et al., 2017) to pretrain the model on the Masked Language Model (MLM) task and the Next Sentence Prediction (NSP) task and advances the state-of-the-art for eleven NLP tasks. The system presented in this paper is based on fine-tuning BERT. This section will introduce two strategies to boost the BERT model.

### 2.1 Sampling

In classification tasks, we often encounter uneven distribution of positive and negative samples. Under such distribution, the model may not be able to make accurate predictions. The trained model naturally tends to predict the majority set, and the minority set may be considered as noise. Compared with the majority set, the minority set is more likely to be misclassified. Modifying loss function (Lin et al., 2017; Li et al., 2019) and sampling methods (Chawla et al., 2002; Liu et al., 2009) are valid approaches to solve this problem, and the later was adopted in our system. Oversampling achieves sample balance by increasing the number of minority samples in classification.

The most direct method is to simply copy the minority samples to form multiple records. The disadvantage of this method is that if the sample features are few, the model is easy to overfit. SMOTE (Chawla et al., 2002) interpolates between samples of the minority class to generate additional samples. Under-sampling achieves sample balance by reducing the number of samples of the majority class in classification. The most direct method is to randomly remove some samples of the majority class. EasyEnsemble (Liu et al., 2009) divides the majority samples into several parts randomly, so the data of each part is equal to the number of minority samples. Then, multiple models are trained on different parts of data, and the output of each model will be integrated. BalanceCascade (Liu et al., 2009) combines a subset of the majority class with the minority class to train the model, then discards the samples that are correctly classified in the next round, so that the subsequent base learner can pay more attention to those samples that are incorrectly classified. Our model uses under-sampling for sentences extraction and triples extraction. For different tasks, diverse sampling strategies have been adopted.

## 2.2 Adversarial training

As machine learning model is vulnerable to some small worst-case perturbations, adversarial training (Goodfellow et al., 2014) aims to make the AI systems safer by improving the robustness of the model. In Computer Vision tasks, adversarial training usually hurts the generalization of the model. However, Miyato et al. (2017) adopted adversarial training in text classifying by applying perturbations to the word embeddings, which can improve both generalization and robustness of the NLP models.

Considerable efforts have been made to find better adversarial perturbations. The Fast Gradient Sign Method (FGSM) (Goodfellow et al., 2014) generates adversarial examples by formulation:

$$\hat{\mathbf{x}} = \mathbf{x} + \mathbf{r}_{adv}$$

$$\mathbf{r}_{adv} = \epsilon \text{sign}(\nabla_{\mathbf{x}} J(\boldsymbol{\theta}, \mathbf{x}, y))$$

where  $\mathbf{x}$  are the embeddings of the input text,  $\mathbf{r}_{adv}$  are the adversarial perturbations,  $\boldsymbol{\theta}$  are model parameters,  $\hat{\mathbf{x}}$  are embeddings of adversarial examples that are used to update the model. The Fast Gradient Method (FGM) (Miyato et al., 2017) is another generation of FGSM in which the pertur-

bations are normalized by gradients:

$$\mathbf{r}_{adv} = -\epsilon \frac{\mathbf{g}}{\|\mathbf{g}\|_2}$$

where  $\mathbf{g} = \nabla_{\mathbf{x}} \log p(y | \mathbf{x}; \hat{\boldsymbol{\theta}})$ .

Madry et al. (2018) used a min-max formulation as follows to cast both attacks and defenses into a common theoretical framework,

$$\min_{\theta} \left\{ \mathbb{E}_{(x,y) \sim \mathcal{D}} \left[ \max_{r \in \mathcal{S}} L(\theta, x + r, y) \right] \right\}$$

in this formulation, the inner maximization problem describes attack which aims to find the most adversarial data leading to a high loss, the outer minimization problem describes defense which aims to find the most robust model. They also proposed Projected Gradient Descent (PGD) that uses an iterative algorithm to generate the most adversarial data.

The Friendly Adversarial Training (FAT) (Jingfeng et al., 2020) adopted by our team is an early-stopped version of PGD, its adversarial data was generated by a min-min formulation as following:

$$\tilde{x}_i = \arg \min_{\tilde{x} \in B(x_i)} \ell(f(\tilde{x}), y_i)$$

$$\text{s.t. } \ell(f(\tilde{x}), y_i) - \min_{y \in \mathcal{Y}} \ell(f(\tilde{x}), y) \geq \rho$$

different from PGD, FAT generates friendly adversarial data rather than the most adversarial data,  $\rho > 0$  is a margin that indicates the confidence of adversarial data being misclassified. FAT is more computationally efficient than PGD, and model trained with FAT can reach higher accuracy.

Figure 1: System Overview

## 3 System Description

For three sub-tasks in NLPContributionGraph, we designed four modules to implement these tasks. These modules use fine-tuning BERT with FAT as

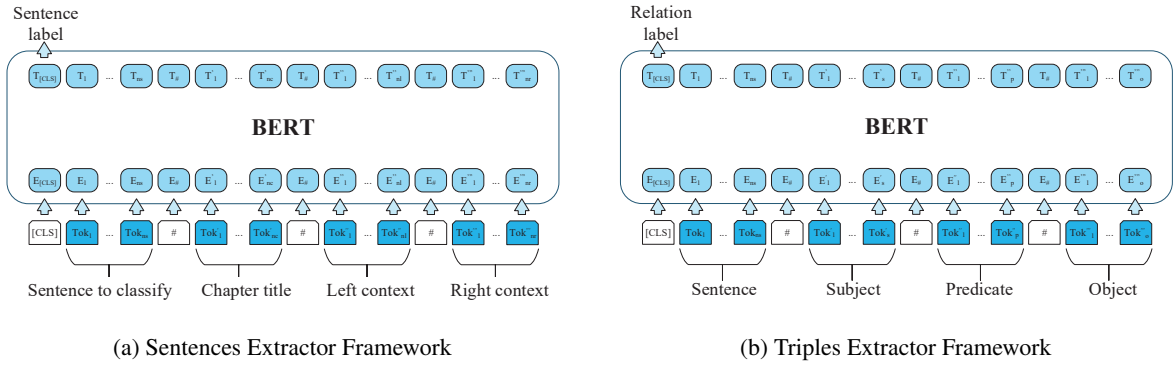

Figure 2: Both of the Sentences Extractor and the Triples Extractor are build by the BERT-based classification model.

the base model and adopt different boosting methods to improve overall results. The full framework of the system is shown in Figure 1. The three extractors can extract contribution information by classification. The Triples Generator can convert discrete phrases into triples. These modules will be explained further in following sections.

### 3.1 Sentences Extractor

The system uses the Sentence Extractor to solve the SE task. The extractor can extract the sentences that have the contribution information such as research problem, code, etc. As shown in Figure 2a, the Sentences Extractor uses the sentence context and paragraph heading as additional features and uses BERT as a binary classifier to determine whether the sentence contains the contribution information. In an annotated paper, most sentences do not contain the contribution information. Therefore, we adopted an under-sampling strategy. In the training process, the ratio of positive samples and negative samples is fixed to an integer for each batch to ensure that the model will not overfit on negative samples. The ratio is a hyperparameter that needs to be tuned in the training process.

### 3.2 Phrases Extractor

The Phrases Extractor can extract contribution phrases from the sentences to solve the PE task. For this task, the BERT-based sequence labeling model is effective. The phrases predicted by the trained model will sometimes be incomplete, resulting in high recall and low precision. Fortunately, ensembling learning can solve this problem well. In the competition, we trained ten different models by ten-fold cross-validation. After training, the

trained models will make their own predictions, and the module will count the number of votes for each phrase. Only phrases with more than a certain number of votes will be seen as a valid output.

### 3.3 Triples Generator

After the Phrases Extractor completes the prediction, we can obtain discrete phrases. The role of the Triples Generator is to convert these phrases into triples through permutation and combination. This section will introduce two methods to finish this task.

**Language Model Approach** Language models are usually used to evaluate the probability of a sentence. The triples to be extracted are composed of subject, predicate and object, which are components of a sentence. This approach uses a language model to evaluate the probability of triples. The input of the module is all permutations of contribution phrases, and the permutation that has the highest probability will be the output of the module, which are candidate triples.

**Combination Approach** Due to the lack of data, the prediction made by language model is not accurate. In the annotated data, the order of about ninety percent of the triples is sequential. In order to deal with the insufficient representation ability of the language model, we directly use the combination of all serial phrases as the output of this module. In the competition, we adopted Combination Approach as the Triples Generator.

### 3.4 Triples Extractor

The Triples Extractor can classify all candidate triples based on the BERT model. As shown in Figure 2b, sentences and triples are separated by

hash marks, and inputted into BERT for classification. Unfortunately, the trained model will easily overfit on negative samples due to the large number of combinations. Therefore, we need to adopt the under-sampling strategy to boost the base BERT. For complex combinations, the module combines two strategies to select negative samples:

**Random Replacement (RR)** For each of the three phrases in the positive sample, we will randomly select one and replace it with another phrase.

**Random Selection (RS)** Randomly select three phrases that are not positive samples.

The module combines the two sampling methods above to generate negative samples. For each batch, it fixes the ratio of positive and negative samples to generalize better.

## 4 Experimental Setup

In this section, we did some ablation analysis on the validation set for the boosting methods proposed in this paper, and gave some analysis through the experimental results.

### 4.1 Adversarial Training

We tested the performance of different adversarial training approaches. Table 1 shows that FAT achieved the best results in all three tasks. Especially in the SE task, adversarial training can greatly improve the model’s performance. During the experiment, we also found that if adversarial training is not applied, training will converge in an average of five epochs. If the system uses adversarial training, the training will last for about twenty epochs and will continuously improve the performance on the validation set. The perturbations added by the adversarial training make the model generalize better. In addition, ensembling is not applied in the PE task, so the F1 score of this task is low. This issue would not affect the experimental results.

Task	Natural	FGM	FAT
SE	0.4112	0.5527	<b>0.5615</b>
PE	0.2011	0.2128	<b>0.2231</b>
TE	0.4641	0.4740	<b>0.5176</b>

Table 1: F1 scores of Natural training (no adversarial training), FGM and FAT.

### 4.2 Sentences Features

We randomly selected five domains of papers to test the effect of different features on the SE task. These domains are Question Answering (QA), Relation Extraction (RE), Sentence Classification (SC<sub>1</sub>), Sentence Compression (SC<sub>2</sub>) and Text Generation (TG).

Table 2 shows that adding either context or title can significantly improve the accuracy of classification and the best results can be achieved by concatenating both of them.

Domain	Natural	Title	Context	T&C
QA	0.4068	0.5294	0.6471	<b>0.6977</b>
RE	0.4516	0.5128	0.5781	<b>0.5827</b>
SC <sub>1</sub>	0.3636	0.5417	0.7391	<b>0.7826</b>
SC <sub>2</sub>	0.5600	0.5714	0.5926	<b>0.6667</b>
TG	0.4681	0.5424	0.5385	<b>0.5763</b>

Table 2: F1 scores while adding different features. T&C means adding both Title and Context.

### 4.3 Triples Extractor Sampler

In the TE task, RR and RS are applied as the sampling methods. Without the under-sampling strategy, the model is difficult to converge. Table 3 shows the performance of different sampling methods on papers in various domains. Among them, the combination of RR and RS strategies achieved the best results. The diversity of the sampling strategies improves the generalization.

Domain	RR	RS	RR&RS
QA	0.3621	0.3592	<b>0.4267</b>
RE	0.3782	0.4033	<b>0.4163</b>
SC <sub>1</sub>	0.3359	0.3505	<b>0.3692</b>
SC <sub>2</sub>	0.4585	0.4623	<b>0.4777</b>
TG	0.4900	0.5351	<b>0.5748</b>

Table 3: Macro-F1 scores with different triple sampling methods

### 4.4 Evaluation Results

In End-to-end Pipeline phase, our system got F1 scores of 0.5619, 0.4522 and 0.1379 in tasks SE, PE, TE, respectively. Our system has achieved good results on tasks SE and PE, but task TE can still be improved. Since our system only considers sequential triples, some triples will be missed, which can be a defect of our system.

## 5 Conclusion

BERT is a powerful model that has considerable applications in numerous fields of NLP. Using BERT in the NLPContributionGraph task allows researchers to read papers more efficiently. The methods of adversarial training and sampling proposed in this paper can greatly boost the performance of BERT on this task and can also offer some thoughts for future work on knowledge extraction of papers.

# Duluth at SemEval-2021 Task 11: Applying DeBERTa to Contributing Sentence Selection and Dependency Parsing for Entity Extraction

Anna Martin & Ted Pedersen

Department of Computer Science

University of Minnesota

Duluth, MN 55812, USA

{mart5877, tpederse}@d.umn.edu

## Abstract

This paper describes the Duluth system that participated in SemEval-2021 Task 11, NLP Contribution Graph. It details the extraction of contribution sentences and scientific entities and their relations from scholarly articles in the domain of Natural Language Processing. Our solution uses deBERTa for multi-class sentence classification to extract the contributing sentences and their type, and dependency parsing to extract phrases from each sentence and format into subject-predicate-object triples. Our system ranked fifth of seven for Phase 1: end-to-end pipeline, sixth of eight for Phase 2 Part 1: phrases and triples, and fifth of eight for Phase 2 Part 2: triples extraction.

## 1 Introduction

The rapid rate at which scientific literature grows makes it difficult to keep up with new research even in one’s own field. Automated solutions are challenging since text formatted and written for human consumption does not lend itself to machine processing.

(Jaradeh et al., 2019) have proposed a knowledge graph based system for collecting and structuring articles in a machine-readable format. This requires the annotation of many scholarly articles, a task that is time consuming to do by hand. The purpose of this SemEval task (D’Souza et al., 2021) is to enable the construction of a scholarly contributions graph over English language NLP articles by automating the task of annotating scientific papers.

This annotation processes consists of:

1. selecting sentences that describe the contribution of the article and outputting them to a sentences.txt file,
2. extracting scientific entities and relations from the selected sentences and outputting them to an entities.txt file,

3. and structuring the entities and relations into triples of the form subject-predicate-object. These triples are sorted into one of twelve information units, which are labels that describe the type of contribution being made by the sentence outlined in the triples file.

Following is an example of the annotation process using a sentence taken from the training data with the human-labeled entities in braces:

We [apply] [dropout] of [0.4] [to layers], [0.3] [to RNN layers], [0.4] [to input embedding layers], [0.05] [to embedding layers], and [weight dropout] of [0.5] [to the RNN hidden-to-hidden matrix].

This task requires the 1) identification of this sentence as a contribution sentence belonging to the information unit HYPERPARAMETERS, 2) the extraction of the entities in braces, and 3) the formatting of those entities into triples. This example and various others will be used throughout this paper to help contextualize our system description.

SemEval-2021 Task 11 was organized into three phases, called Phase 1: end-to-end pipeline, Phase 2 Part 1: phrases and triples, and Phase 2 Part 2: triples extraction. Phase 1 tested the entire system, scoring for sentence extraction, phrases extraction, and triples extraction. The gold sentences.txt files were released for use in Phase 2 Part 1, in order to test phrases and triples extraction given perfect sentence selection. The gold entities.txt files were released for use in Phase 2 Part 2, in order to test triples extraction given perfect phrases selection.

There are four datasets mentioned in this paper. Gold data refers to the sentences.txt, entities.txt, and triples folders released by the organizers after each phase of the task. Test data refers to the data used to test the system during evaluation phases. Training data refers to the entire training dataset provided by the organizers. The trial dataset is the

segment of the training dataset that we used to test the Duluth system during validation, before the first evaluation phase began. For more information on how this dataset was created, see Appendix B.

Our approach<sup>1</sup> employs a variety of techniques to address each component of the task. The selection of contribution sentences was done by fine-tuning the base deBERTa model (He et al., 2021) on the training data, as fine-tuned BERT (Devlin et al., 2019) models have been found to perform well on multi-class text classification tasks (Liu and Wang-perawong, 2019). The fine-tuned model is used to classify each sentence as either non-contributing, or one of the twelve information units.

The selected contribution sentences were then tagged to indicate likely scientific entities using a Maximum Entropy Markov Model (MEMM) (Bird et al., 2009) that was trained on the noun phrases selected as entities in the training data.

A dependency parse (Manning et al., 2014) was then found for each sentence. The dependency parse and entity tags were then leveraged to select contributing phrase spans and triples by using the entity tags to determine whether a subject or object noun phrase ought to be considered, and using the dependencies to extract Subject–Predicate–Object patterns from sentence.

## 2 Previous Work

Two previous SemEval tasks were also concerned with the extraction of relations and key phrases from scientific publications: SemEval 2017 Task 10: (ScienceIE - Extracting Keyphrases and Relations from Scientific Publications) (Augenstein et al., 2017), and SemEval 2018 Task 7: (Semantic Relation Extraction and Classification in Scientific Papers) (Gábor et al., 2018).

Many of the approaches in these tasks use neural models to extract entities and their relations. The AI2 system (Ammar et al., 2017) at SemEval-2017 Task 10, which ranked first and second for task scenarios one and three respectively, approached this by building separate entity and relation models, each of which contain layers of LSTMs. The ETH-DS3Lab system (Rotsztein et al., 2018) at SemEval-2018 Task 7, which ranked first in three of four subtasks, built an entity and relation classifier using a combination of RNNs and CNNs.

Other approaches used supervised machine

---

<sup>1</sup>Code is available at <https://github.com/amartin94/DuluthSemEval2021Task11>.

learning algorithms while leveraging grammatical features. The LIPN system (Hernandez et al., 2017) approached SemEval-2017 Task 10 by first filtering possible keyphrases by labeling phrases with their POS sequence. Candidate keyphrases are filtered by comparing the POS tags of the phrase with POS sequences developed from the training data. They then trained a CRF model using the candidate phrases labeled with IOB tags. They were able to improve recall for keyphrase extraction by filtering candidate sentences before using a CRF.

## 3 Selection of Contribution Sentences

We approached the selection of a contribution sentence as a multi-class sentence classification problem with 13 classes, where each of the twelve information units is a class, and class 0 represents non-contributing sentences. Although the subtask of sentence extraction could be performed using a binary classifier to label sentences as either contributing or non-contributing, we decided to sort the sentences further into their information units. The alternative would require classifying phrases or triples further down the pipeline; the benefit to classifying the contributions during the sentence extraction step is that the whole context of each sentence is taken into account.

The main challenge with this approach was in the unbalanced nature of the data; 90.11% of the sentences used to train the classification model for Phase 1: end-to-end pipeline were non-contributing sentences, and the standard deviation of the frequencies of contributing classes was 8.59%. These frequencies can be seen in Appendix D.

Logistic regression and decision tree classifiers (Pedregosa et al., 2011) were not able to identify the underrepresented classes such as TASKS and DATASET, and were heavily skewed towards the dominant class of non-contributing sentences. During initial experiments using the trial dataset described in Appendix B, decision tree classifier earned a macro-F1 score of 0.1736 and the logistic regression classifier earned a macro-F1 score of 0.1738. The base deBERTa model performed better than both decision tree and logistic regression classifiers on the trial dataset, resulting in a macro-F1 score of 0.3079.

### 3.1 Phase 1: Classifying Sentences using DeBERTa

For Phase 1: end-to-end pipeline testing, we fine-tuned the base deBERTa model on sentences from the training dataset to create a thirteen-class sentence classification model, using HuggingFace transformers’ deBERTa for Sequence Classification model (Wolf et al., 2020). Hyperparameter settings can be found in Appendix E.

The provided training dataset includes sentences files that contain a list of the indexes of contributing sentences for each scholarly article. It also contains files for each information unit provided in json format; each of these files include the full sentences belonging to its specified information unit. We labeled the contributing sentences with their information units by looking up each sentence in the information unit json files. Sentences from the articles in the training dataset that were not included in the sentences files were labeled as non contributing.

### 3.2 Phase 2: Classifying Given Sentences

During evaluation Phase 2 the gold contribution sentences for the test data were given to all participants by the task organizers in sentences files containing the indexes of contributing sentences. Given this, we altered the sentence classification step by fine tuning deBERTa only on contribution sentences from the training data. This resulted in a twelve-class classifier that labeled the test data sentences according to their predicted information unit. The reason why a classification step was still required here is that the triples extraction task further down the pipeline require the sentences to be classified according to their information unit. Without the information unit json files, the information unit labels must be predicted.

Observing that the sentence indexes in the given sentences files appeared to be sorted by information unit, we adjusted the output from the sentence classifier so that chunks of consecutive sentence indexes would all receive the same label. This was performed by searching the classifier output for spans of consecutive sentences where the classifier vacillated between two commonly confused information units, such as EXPERIMENTAL SETUP and HYPERPARAMETERS. For each of these spans, the information unit that was more frequent within the span would be assigned to every sentence.

## 4 Entity and Relation Extraction

The Duluth system for Phase 1: end-to-end pipeline combined statistical and rule-based approaches for extracting scientific entities and their predicates from the contribution sentences. We used a dependency parser to extract noun phrases and their predicates, and trained an maximum-entropy Markov model (MEMM) on the training data entities files to predict whether each noun phrase contains a scientific entity.

### 4.1 MEMM Entity Extraction

For Phase 1, in order to tag likely scientific entities in the test data, we trained a MEMM on the provided training data. The features we used include:

- current word type,
- current part-of-speech tag,
- current word shape,
- current IOB tag (I or B if present in the scientific entities list, O if not), and
- the above features for the previous word.

We generated the scientific phrases list from the training data entities files, by extracting the noun phrases from the phrase spans and inputting them into a file to be looked up by the MEMM entity extractor.

For Phase 2 Part 1: phrases and triples, the model was altered to only perform IO tagging. This change was made to address the fact that sometimes individual words appear in different positions in different phrases. For example, the noun “loss” appears in 41 different phrases in the scientific phrases list, sometimes in the beginning of a phrase as in “loss function”, and sometimes in the end of a phrase as in “cross entropy loss”.

We used these features to train NLTK’s Maxent-Classifier method (Bird et al., 2009) with maximum iterations set to 40. The model achieved a testing accuracy of 0.995. We used the Viterbi algorithm to derive the most likely IO tags for every word in each sentence.

The model was able to identify some scientific entities in the test data that aren’t present in the scientific entities list derived from the training data. However, a complicating factor is that not all entities that must be found can be considered to be exclusively scientific entities. For example, terms like *ReLU*, and *SCIBERT* are clearly specific to

Figure 1: This is a dependency parse of example sentence from corenlp.run/, which shows the information provided to the phrase extraction system by the dependency parser. The dependencies are traced by the Duluth system in order to extract subject-predicate-object phrases from each sentence.

natural language processing and machine learning, but words such as *image*, *action*, *humans*, and other common nouns were also present in the entities training data. Since there is a wide range of specificity in the terms that must be extracted as entities, filtering the sentences through the MEMM entity tagger ultimately worsened the system’s performance in Phase 2 Part 1: phrases and triples from a total F1 score of .4634 to .4299. This is because it filtered out sentences which were contribution sentences but whose subject phrases did not contain nouns tagged as scientific entities by the classifier.

## 4.2 Dependency Parsing

We used Stanford Core NLP’s dependency parser (Manning et al., 2014; Chen and Manning, 2014) to generate a dependency parse for each contribution sentence. We used the dependency parse of each sentence to extract the root verb phrase from each sentence, its noun subject phrase, and dependent object phrases. In Phase 1, if neither the subject of the sentence nor the words dependent on it within its noun phrase were tagged as scientific entities, then the sentence would be ignored. Any object noun phrases not containing a scientific entity were also ignored. The intention was to create an outline of each contribution sentence that included only the relevant noun phrases and the relation between them.

Figure 1 illustrates the dependency parse of our running example. The system would extract the verb phrase “is employed” as the relation by finding the ROOT of the sentence (“employed”), finding the adjacent dependency (“is”), and concatenating the two into the phrase “is employed”. Next, it would extract the dependent nsubj “Dropout” as the subject entity by searching for nsubj types dependent on “employed”. Lastly, the system would extract the noun phrase which is dependent on the verb phrase “is employed” as the object entity. This would be accomplished by finding the noun

dependent on “employed”, which is “layer”, and building the noun phrase “word embedding layer” from the words dependent on “layer”. The phrases “Dropout” and “word embedding layer” would be labeled as scientific phrases, which means that this subject-predicate-object phrase would be kept.

In Phase 2, we altered our system so that it would not throw away any sentences, since it was provided with the gold contribution sentences made available by the task organizers. Rather, if the subject was a pronoun and the subject phrase did not contain a scientific entity, then the subject phrase would be removed. If there was a previously selected noun phrase from the same information unit, that phrase would replace the removed subject phrase. Otherwise, the name of the information unit would be used instead. The intention was to handle cases where a pronoun referring to an entity from the previous sentence was the subject of the verb phrase.

## 5 Triples Extraction

During evaluation Phase 1: end-to-end pipeline, almost all of the task of extracting Subject–Predicate–Object triples into information units files was already performed by previous steps. The entity extractor described in section 4 extracts phrase spans three at a time, following the subject-predicate-object format needed to organize phrase spans into triples. The sentence extractor described in section 3 classifies sentences into their information units, so the class label for the sentence that the triple is extracted from can be used to determine the information unit that the triple belongs to.

For Phase 1: end-to-end pipeline and Phase 2 Part 1: phrases and triples, the system formed triples based on the subject, predicate, and object phrases determined by the entity selection process described in section 4.

For example, if the sentence “Dropout, with a rate of 0.5, is employed on the word embedding layer” is classified by the sentence extractor as

belonging to the information unit EXPERIMENTAL SETUP, and the phrases “Dropout”, “is employed”, and “word embedding layer” were selected as a subject-predicate-object pattern, then triples would be formatted in the experimental-setup.txt triples file like so:

(Contribution  has  Experimental Setup)
(Experimental Setup  has  Dropout)
(Dropout  is employed   word embedding layer)

## 5.1 Triples Formatting

While most of the information units’ triples were formatted in the training data following the pattern in section 5, the information units Code and Research Problem were formatted following these patterns, respectively:

(Contribution  Code  url)
(Contribution  has research problem  phrase)

The triples files for information units Code and Research Problem were handled separately from the others in order to reflect these differences.

## 5.2 Phase 2 Part 2: Adapting to the Released Entities Files

The main problem with the method for building triples described in section 5 is that it does not address the fact that triples often build on each other and overlap. Triples build on each other in two ways: the first item of a triple may be the last item in the previous triple; and the first item of a triple may be the first item in a previous triple.

The Duluth system solution for Phase 2 Part 2: triples extraction attempts to imitate these patterns by following these rules: while items in the entities file alternate between noun phrases and predicates, then triples are formed where the middle item for each triple is a predicate phrase and the phrases on either side of it are the noun phrases in the entities file on either side of the predicate in the entities file. This creates the first pattern identified above. However, if two consecutive noun phrases are found in the entities file, then the second noun phrase is paired with the previous subject-predicate pair, rather than the previous noun phrase. If there is no previous subject-predicate pair, then the second

Table 1: F1 scores for each information unit based on evaluation on test data. Macro-F1 score = .2949. Weighted-F1 score = .8866.

noun phrase is paired with the name of the information unit and the predicate *has*. This creates the second pattern identified above.

## 6 Sentence Selection Results

The official competition F1 score on the gold standard test data for selection of contribution sentences in Phase 1: end-to-end pipeline was 0.38095. This score evaluates the results as a binary classification problem, where sentences are either contributing or non-contributing. Because our sentence selector performs multi-class classification, labeling each sentence as either non-contributing or belonging to one of twelve information units, we provide a confusion matrix in Table 2 that shows the detailed results by information unit, as well as a break down of individual F1 scores for each information unit in Table 1. The official competition F1 score for information units in Phase 1 was 0.6441.

### 6.1 Confusion Matrix Analysis

The high frequency of false positives and false negatives for the non-contribution class (None in Table 2) is likely due to its high frequency, as 90.11% of the sentences from the training dataset belong to this class. This shows that using a BERT model without any filtering or sampling techniques is not sufficient to accurately handle the unbalanced nature of this dataset. We will focus our discussion here on the most frequently confused information units.

30.19% (109 of 361) of sentences describing

Tasks	0	0	0	0	0	0	0	0	0	0	0	0	0

Table 2: Confusion matrix for thirteen-class sentence classification. The quantities in bold face correspond with the boldfaced quantities in section 6.1.

EXPERIMENTAL SETUP were falsely labeled as belonging to the information unit HYPERPARAMETERS by our classifier, and 19.28% (**27** of 140) of sentences describing HYPERPARAMETERS were falsely labeled as EXPERIMENTAL SETUP. This makes sense, as sentences describing experimental setup may include discussion of hyperparameters.

Sentences belonging to the information unit ABLATION ANALYSIS were incorrectly labeled as RESULTS 17.28% (**28** of 162) of the time (the classification of RESULTS was more successful, only being incorrectly classified as ABLATION ANALYSIS 2.24% (**14** of 625) of the time). This confusion makes sense, as ablation analysis may often be discussed alongside analysis of results. Furthermore, the information unit RESULTS appears almost 3.65 times as often as the information unit ABLATION ANALYSIS, another example of how the uneven distribution of information units impacts the accuracy of our classifier.

Similarly, sentences describing EXPERIMENTS were incorrectly labeled as belonging to RESULTS 25.97% (**87** of 335) of the time, and RESULTS appears in the training data 3.16 times as often as EXPERIMENTS. This resulted in experiments sentences never being positively identified by our system in Phase 1. Lastly, our system was not able to positively identify sentences belonging to the information unit APPROACH, either classifying them as non-contributing, or as belonging to the information unit MODEL.

## 6.2 Implications for Future Work

Because the frequently confused sentences often have many features in common, in future work we will investigate a document-level classification approach, to explore whether there is information in the paper as a whole that can point towards one information unit over another. For example, the information units APPROACH and MODEL never appear together in the same article in the training data, because they describing the model used is equivalent to describing the approach taken. One might be able to determine whether a paper is likely to discuss a model rather than a general approach by looking at features of the whole document.

One type of feature that might be leveraged for better results is section headers. For example, sentence 5 in Table 3 is found in a section with the header “Our Approach”, which indicates the gold label of APPROACH. Often, the contribution sentences describing results are under a section header with the word “Results” in it, as is the case for sentence 3 in Table 3. Similarly, sentence 2 in Table 3 is found in a section labeled “Experimental Setup”. However, the correct information unit is not always consistent with the section header. Sentence 1 in Table 3 is labeled with the information unit HYPERPARAMETERS, though it is found in a subsection called “Set-Up” under the section “Experiment Results”. Sentence 4 in Table 3 is found in a section called Experimental Results, but has the gold label ABLATION ANALYSIS.

	Predicted	True	Sentence
1	Experimental Setup	Hyperparameters	The initial learning rate is 0.0004 and the batch size is 32 .
2	Hyperparameters	Experimental Setup	Word2vec is used to produce the word embeddings .
3	Ablation Analysis	Results	Furthermore , using pseudo entity annotations boosted the accuracy by 0.3 % .
4	Results	Ablation Analysis	The best performance is achieved by Faceness , with a recall below 20 % .
5	Model	Approach	Crucially , the BiLSTM is trained with the rest of the parser in order to learn a good feature representation for the parsing problem .

Table 3: Examples of mislabeled sentences

Error	Common Words (frequency)	Top POS (probability)
B-miss	our (124), all (17), to (14), each (14)	PRP\$ (.2255)
E-miss	model (20), to (17), using (13), method (8)	NN (.2411)
B-extra	best (3), use (2), set (2), the (2)	NN (.4235)
E-extra	. (24), on (8) in (7), than (7), by (6)	IN (.2784)

Table 4: For each error type, this table shows the most frequent words either missed by predicted phrase spans, or added (extra) by predicted phrase spans. Column 3 contains the most frequent POS tag for each error type (e.g. 22.55% of all words missed from the beginning of a span were possessive pronouns).

## 7 Entity and Relation Extraction Results

The gold test data had 13,028 total phrase spans, of which our system identified 4,277. 39.72% of these predicted phrase spans were exact matches with gold phrase spans. 29.97% of predicted phrase spans were complete false positives, not overlapping with any gold phrase spans. 30.30% of predicted phrase spans were not perfect matches, but did overlap with gold phrase spans. The majority of partial matches were missing a word, reflecting the fact that the average span length for the gold data was 12.37 characters but the average span length for the predicted data was 10.49 characters. 42.44% of partial matches were missing characters in the beginning of the phrase span, 52.11% were missing characters in the end of the phrase span, 6.56% had extra characters in the beginning of the phrase span, and 14.97% had extra characters in the end of the phrase span.

### 7.1 Partial Phrase Matches

In this section we first look at the characteristics of the partial matches to discover the cause of these errors. Because the Duluth system selected phrase spans using grammatical features, we look at the parts of speech of the words that were either missed by the Duluth system or erroneously added to phrase spans. Then, we look at the grammatical characteristics of the gold phrase spans that were entirely missed by the Duluth system.

The most common errors and their frequencies are shown in Table 4. The part-of-speech that was most likely to be missing from the end of a span (E-miss) in the Duluth system output was NN. Our system misses these noun phrases because the Duluth system outlines sentences starting with the verb labeled as ROOT by Stanford Core NLP’s dependency parser, and identifying the nsubj of that root and its dependencies as an entity <sup>2</sup>.

However, there are some cases where the word identified as the ROOT is not the verb that the subject of the sentence is directly dependent on. In these cases, the sentence subject goes undetected by our system. For sentence 1 in Table 5, if the verb *improves* were properly identified as the ROOT, the sentence might be outlined like so: Built on top of the model in but excluding ELMo, *base reinforced model* (ENTITY) *improves* (RELATION) the *average F1 score* (ENTITY). However, *Built* is identified by the dependency parser as the ROOT, so the Duluth system fails to extract the noun phrase *our base reinforced model*, which is the nsubj phrase dependent on *improves*. Notice also in this example the omission of the possessive pronoun *our* in the system outline; this illustrates the most common part-of-speech missing from the beginning of

<sup>2</sup>ROOT refers to the root of the dependency parse tree. The nsubj of a parse is the nominal subject dependent on the root.

1	Built on top of the model in but excluding ELMo, our base reinforced model improves the average F1 score around 2 points [...]	
1	System: base, built on, top	Gold: our base reinforced model, improves, the average F2 score, around, 2 points
2	Finally, the baseline model, EDA, is largely outperformed by all other examined methods.	
2	System: baseline model, outperformed by, other examined methods	Gold: EDA, largely outperformed, by, all other examined methods
3	We also compare with TagSpace ( Weston et al. , 2014 ) , which is a tag prediction model similar to ours [...]	
3	System: We, compare with, TagSpace	Gold: compare with, TagSpace (Weston et al., 2014), tag prediction model

Table 5: Example sentences with phrase spans improperly extracted by the Duluth system. The phrase spans are shown separated by commas.

a phrase span, as 24.11% of words missing from the beginning of phrase spans have POS tag PRP\$.

27.84% of words that were erroneously appended to the end of phrase spans by the Duluth system were prepositions (IN). This is because the Duluth system includes prepositions in verb phrases, while the gold data contains some phrase spans where the preposition is separated from the verb, and others where the preposition is included in the same phrase span as the verb. Sentence 2 in Table 5 shows the Duluth system incorrectly including the preposition *by* with the verb *outperformed*, while sentence 3 in 5 shows our system correctly including the preposition *with* with the verb *compare*.

Phrase (Frequency)	of (502), with (295), on (274), for (260), in (190), to (129), from (87), using (85), by (80), as (66), than (60), at (52), is (46), between (44), results (39), over (36), achieves (36), based on (32), outperforms (31), training (26)
--------------------	---

Table 6: Most frequently missed phrases.

Phrase spans that improperly capture additional words can have a ripple effect when the additional word is supposed to belong to a different phrase span, like the additional word *by* in the phrase span *outperformed by*. Because *by* is included in a phrase span already, it does not exist in its own phrase span as it does in the gold data, which means that the phrase span *by* is completely omitted by the Duluth system.

This error is quite common; 97% of the phrase spans in the gold data consisting of a single preposition were not identified by the Duluth system, due to the fact that these words tend to get absorbed by other phrases. This continues to have a detrimental effect further down the pipeline, as whether the prepositions are alone or chunked with other phrases affects the formation of triples.

## 7.2 Missed Phrases

To determine the possible causes of missing phrase spans, we looked at the error rates by part-of-speech. Since 77.31% of the total phrase spans in the gold standard data were missed by our system, we are only considering POS patterns that were missed over 77.31% of the time. We are also only looking at POS patterns that occurred at least 100 times in the gold data.

Phrase spans made up of a single preposition were frequently not identified by the Duluth system. This is apparent in Table 6; the top 5 phrases most commonly ignored by the Duluth system are all prepositions. Table 7 shows the phrase types (phrases described by the POS tag for each word) that are least likely to be captured in their entirety by the Duluth System. In addition to prepositions, infinitive verbs (TO VB) are also frequently omitted by the Duluth system. This is because the Duluth system bases the outline of the sentence off of the ROOT, which is almost always a finite verb. For this reason, infinitives are frequently ignored.

Our grammar-based approach might be improved on by changing the rule that outlines the sentences based on the ROOT verb of the sentence, in order to focus more on noun phrases that are more likely to be scientific entities. This would

POS Pattern	Missed/Total	Example
IN	.9735	for
TO	.9416	to
CD	.9364	99.60
TO VB	.9098	to compute
RB	.9040	jointly
VBG	.8837	using
NN NNS	.8750	feature maps

Table 7: These are the POS patterns that are most likely to be ignored by the Duluth system, and the conditional probability that they will be omitted.

require developing a method for tagging likely scientific entities that improves on our MEMM entity tagger. However, entities extraction might be better addressed with a neural approach since our grammatical approach (without semantics) does not capture the nuances in the training data.

## 8 Triples Extraction Results

The official F1 score on the gold standard test data for triples extraction from Phase 2 Part 2 was 0.2762, and the F1 score for information units was 0.7556. The Duluth system scored the lowest at extracting triples for the information units DATASET, TASKS, EXPERIMENTS, receiving F1 scores of 0.0, 0.0, and 0.0597 respectively. The extracted triples are input into files named for the information unit they belong to.

Triples extracted from a sentence classified as RESEARCH PROBLEM are output into a file named research-problem.txt. The gold data does not contain any tasks.txt files, so all tasks.txt files generated by our system were false positives. The gold data contained two dataset.txt files, both of which were missed by our system. These scores are consistent with the initial results from sentence classification, as seen in Table 1. Because our system deals with information unit classification during the sentences extraction step rather than the triples extraction step, we focus our discussion here on errors related to our triples extraction methodology.

Our triples extraction system relies heavily on part-of-speech tagging to determine whether an entity belongs to the edge of a triple or the middle (for example, noun-phrases are more likely to be subjects or objects, and verb-phrases are more likely to be predicates). In order to determine the efficacy of this approach, we look at the words that were improperly positioned in our system triples.

One pattern that emerged is that many words were wrongly positioned in the Duluth system data. Some phrases and their POS tags that only exist in the middle position in the gold data that are found in the edges of triples in the system data include “achieves” (VBZ), “propose” (VB), “performs” (VBZ), and “uses” (VBZ). Other phrases that only exist in the edges of triples in the gold data that are found in the middle position in the system data include “outperformed” (VBG), “worse” (JJR), “outperforming” (VBG), and “randomly initialized” (RB VBN).

This observation is consistent with the POS distributions found for the gold triples not identified by the system and the system triples that were wrongly identified; 70 of the 792 phrases belonging to the edge of the gold triples missed by the Duluth system have the POS pattern RB VBN, while 46 of the 730 phrases that were wrongly positioned in the middle of triples by the Duluth system also have the pattern RB VBN. Similarly, 324 of the 1,656 phrases belonging to the middle of gold triples missed by the Duluth system have the POS tag VBZ, while 712 of the 4,242 phrases that were wrongly positioned at the edge of triples by the Duluth system have the same POS tag of VBZ. This shows that the Duluth system sometimes shifts the phrases to the left or right of where they ought to be in the triple pattern.

## 9 Future Work

One weakness of this system is that the selection of contributing sentences only uses sentence-level information; the classifier misses useful contextual information such as headers and the predicted class of preceding and following sentences. Future work may be able to address this problem by fine-tuning BERT to classify sequences of sentences rather than isolated sentences (Cohan et al., 2019). Generally, a document-level approach could be beneficial in terms of capturing important context.

Another issue is that the end of the system does not have the ability to provide feedback to earlier parts of the pipeline; the only agency it has in terms of contributing sentence selection is the ability to discard a sentence provided by the sentence classifier. Future work could incorporate a neural entity classification model into the entity and triple extraction subsystem, which could be used to validate or invalidate the classification made at the sentence level (Rotsztein et al., 2018).

## A Ethical Considerations

The use of knowledge graphs to process, organize, and display information comes with some ethical implications, due to the fact that such a system acts as an intermediary between human readers and academic research. Overall such a system, if integrated into academia, may benefit authors of scholarly work by making their articles easier to find. It may also benefit readers, by making the process of literature exploration more efficient. However, unintentional harm may arise if there is bias in the training used to annotate the articles. Since the Open Research Knowledge Graph is structured so that contributions are interconnected in the graph across papers, there may be a risk that different kinds of contributions are more easily found than others.

Another concern is whether such an infrastructure could affect how people design and report their research, and if that effect is harmful. If researchers know that their work will be read by a machine and then integrated into the knowledge graph according to its most likely contributions, they could be consciously or unconsciously motivated to favor some methods and terms over others, in an attempt to optimize the likelihood that their work is seen. There is also the potential for bias to become embedded in the machine reader, that could influence what kinds of researchers have work that is easily discoverable in the knowledge graph.

## B Task Data

Prior to Phase 1, most of the data used to train the models was extracted from the original training dataset, and most of the provided trial dataset was used for evaluation. Six of the eight articles in the trial data that contained the information unit TASKS were moved to the training dataset so that it would contain enough examples to learn the patterns associated with this information unit. These folders were folder 7 from machine-translation, folders 3, 4, and 8 from named-entity-recognition, folder 8 from question-answering, and folder 2 from text-classification. For all evaluation phases, the models were retrained on the combined training and trial datasets.

## C System Architecture

The system architecture is organized into three sections: preprocessing, training, and testing. The preprocessing section is responsible for :

1. extracting noun and noun phrases from the training data entities.txt files,
2. extracting each sentence from the training data and labeling them with their information unit (or 0 for non-contributing sentences), and
3. extracting sentences from the evaluation phase data and labeling each one with its file path and sentence index.

The training pipeline is responsible for fine-tuning the deBERTa model using the sentences extracted from the training data, and training the MEMM using the extracted sentences and the list of nouns extracted from the training entities files.

The testing pipeline is responsible for taking the sentences extracted from the evaluation phase data and labeling each sentence with their predicted information unit, entity tags, and dependency parse. The data is passed between each step of the pipeline in a dictionary, which is added to at each step.

## Abstract

In this work, we describe our system submission to the SemEval 2021 Task 11: NLP Contribution Graph Challenge. We attempt all the three sub-tasks in the challenge and report our results. Subtask 1 aims to identify the contributing sentences in a given publication. Subtask 2 follows from Subtask 1 to extract the scientific term and predicate phrases from the identified contributing sentences. The final Subtask 3 entails extracting *triples* (subject, predicate, object) from the phrases and categorizing them under one or more defined information units. With the NLPContributionGraph Shared Task, the organizers formalized the building of a scholarly contributions-focused graph over NLP scholarly articles as an automated task. Our approaches include a BERT-based classification model for identifying the contributing sentences in a research publication, a rule-based dependency parsing for phrase extraction, followed by a CNN-based model for information units classification and a set of rules for triples extraction. The quantitative results show that we obtain the 5<sup>th</sup>, 5<sup>th</sup>, and 7<sup>th</sup> rank respectively in three evaluation phases. We make our codes available at <https://github.com/HardikArora17/SemEval-2021-INNOVATORS>

## 1 Introduction

Thousands of papers are published by the scientific community every day. It is now increasingly becoming difficult to browse the huge pool of papers to identify relevant work and thereby keep up with the latest research findings. Scientific literature is growing at an exponential rate and researchers today face the problem to identify the latest state-of-the-art contributions. Keeping track of recent advancements is becoming a tedious exercise, if not practically impossible. The Open Research

Knowledge Graph (ORKG) (Jaradeh et al., 2019) is posited as a solution to keeping track of research progress minus the cognitive overload that reading dozens of full papers imposes. It aims to build a comprehensive knowledge graph that publishes scholarly publications' research contributions per paper, where the contributions are interconnected via the graph even across documents.

As described in D'Souza et al. (2021), with the ORKG comparisons feature, researchers are no longer faced with the daunting cognitive ingestion obstacle from manually scouring through dozens of papers of unstructured content in their field. This process traditionally would take several days or months; using the ORKG contributions comparison tabulated view, the task is reduced to just a few minutes. Assuming the individual paper contributions are structured in the ORKG, they can then deconstruct the graph, tap into the aspects they are interested in, and can enhance it for their purposes. Further, they can select multiple such paper graphs and click a button to generate their tabulated comparison. This presents an opportunity to enhance content ingestion enabled via their fine-grained machine interpretability by transforming scholarly articles into knowledge-based information flows by representing and expressing information through semantically rich, interlinked knowledge graphs (Auer et al., 2018).

In this paper, we present our approach for the three sub-tasks in the NLP Contribution Graph Challenge. Our contribution are as follows:

1. Fine tuning BERT for contributing sentences (a set of sentences about the contribution in the article).
2. A rule-based approach for extracting scientific and phrases (a set of scientific terms and relational cue phrases extracted from the contributing sentences; for each paper ) using
