Table 3. Experiment 2 – Event Arguments Identification (End-to-End system) - 10-fold Cross-Validation Results (Average)

From the table 3 we observe that, the final event and event arguments identification results are decreased by 11%. In the NE identification it is observed that the NE types Yield_Other, Yield_Percent and Reaction_Product are not identified properly by the system, the recall of these types is lower, which affects the same in Event extraction.

5 Conclusion

ChemXtract works on extracting names of chemical compounds and event that identify the specific involvement of the chemical compounds in a chemical reaction. We have used Neural Conditional Random Fields (NCRFs) to identify and extract chemical compounds. The patent documents were preprocessed using NLP tools for obtaining syntactic information, Part-of-Speech and Noun/Verb phrases. The relationships between the chemical compounds are based on the chemical reaction events. Again the same Neural Conditional Random Fields (NCRFs) is used to identify the relationships and the relation arguments. The results obtained are encouraging and comparable with the state of the art.

Mind the User! Measures to More Accurately Evaluate the Practical Value of Active Learning Strategies

Julia Romberg
Department of Social Sciences
Heinrich Heine University Düsseldorf, Germany
julia.romberg@hhu.de

Abstract

One solution to limited annotation budgets is *active learning* (AL), a collaborative process of human and machine to strategically select a small but informative set of examples. While current measures optimize AL from a pure machine learning perspective, we argue that for a successful transfer into practice, additional criteria must target the second pillar of AL, the human annotator. In *text classification*, e.g., where practitioners regularly encounter datasets with an increased number of imbalanced classes, measures like F_1 fall short when finding all classes or identifying rare cases is required. We therefore introduce four measures that reflect class-related demands that users place on data acquisition. In a comprehensive comparison of uncertainty-based, diversity-based, and hybrid query strategies on six different datasets, we find that strong F_1 performance is not necessarily associated with full class coverage. Uncertainty sampling outperforms diversity sampling in selecting minority classes and covering classes more efficiently, while diversity sampling excels in selecting less monotonous batches. Our empirical findings emphasize that a holistic view is essential when evaluating AL approaches to ensure their usefulness in practice – the actual, but often overlooked, goal of development. To this end, standard measures for assessing the performance of text classification need to be complemented by such that more appropriately reflect user needs.

1 Introduction

A well-known problem in supervised machine learning (ML) is scenarios where there are limited resources (e.g., budget or time) to annotate data. One approach to solving this problem is *active learning* (AL; Cohn et al. 1996), a collaborative process between human and machine. Through targeted query strategies, AL aims to find a minimal subset of examples whose labels provide the most information for fitting a model.

In *text classification*, many applications have been found to benefit from AL, such as sentiment analysis, intent or topic detection (e.g., Li et al., 2012; Zhang and Zhang, 2019; Tong and Koller, 2001). In addition to these task-specific studies, increased efforts have been made to systematically evaluate the performance of AL strategies across different use cases (e.g., Settles, 2011; Siddhant and Lipton, 2018; Ein-Dor et al., 2020).

Yet many academic studies ignore crucial real-world factors, leading to flawed assessments of practical utility. Literature has pointed out several limitations, including: the difficulty of making a-priori forecasts about the practical value of strategies (Lowell et al., 2019); the fact that actively acquired datasets are often only effective coupled with the respective model (Lowell et al., 2019; Tomanek and Morik, 2011); the need for out-of-distribution generalization (Longpre et al., 2022); taking into account class imbalance that is regularly encountered in real-world text classification (Ein-Dor et al., 2020); and the consideration of extreme multi-label scenarios (Wertz et al., 2022).

While these works seek to optimize AL from a ML perspective, it has been largely neglected that users themselves can present significant challenges that may impact the success of AL. For instance, it has been found that the effectiveness of AL depends on the expertise of the annotators (Baldridge and Palmer, 2009). Furthermore, examples selected by acquisition functions tend to be more ambiguous in terms of class assignment, leading to an increase in annotation uncertainty (Settles, 2011) and annotation time (Hachey et al., 2005). Such details can affect and even challenge the entire AL process.

We therefore argue that a successful transition from research to practice requires a more holistic evaluation that targets both pillars of AL, the

Proceedings of Recent Advances in Natural Language Processing, pages 996–1006
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_107

machine learner and the human annotator. In this work, we focus primarily on the requirements that the human annotator places on a successful AL process. More precisely, we introduce evaluation measures that already take this perspective into account during the development phase of AL approaches, further referred to as "user-centric"[1].

Considering the frequent scenario of multi-class text classification with imbalanced classes (Ein-Dor et al., 2020; Wertz et al., 2022), we contribute through four novel measures that capture class-related demands in AL. We compare different query strategies coupled with BERT across six datasets and analyze the results from both a standard ML and a more user-centric perspective. Our findings indicate that the proposed measures can provide important insights into strengths and weaknesses of AL that complement existing approaches.

2 Related Work

In evaluating the performance of AL, predictive accuracy has generally been the main focus (Kottke et al., 2017). Prior work has relied on task-specific measures, such as accuracy and F_1. Less commonly, AL-specific measures like deficiency (Yanık and Sezgin, 2015) were used. In addition, several measures have addressed desirable characteristics of query strategies, such as uncertainty of the acquired examples (Yuan et al., 2020; Wang et al., 2022), diversity of the acquired examples (Zhdanov, 2019; Yuan et al., 2020), and representativeness w.r.t the full dataset (Zhu et al., 2008; Ein-Dor et al., 2020). The majority of these measures focus on the input or feature space, but representativeness has also been measured in the output label space (Prabhu et al., 2019; Chaudhary et al., 2021). Another focus besides predictive accuracy has been on the computational effort (Schröder et al., 2022).

With a strong emphasis on ML performance, the current measures tend to overlook the human component in the real-world application of AL. Although user studies have proven helpful in uncovering user-centric pitfalls that can get in the way of practicality (Settles, 2011; Peshterliev et al., 2019), they are expensive and time-consuming, which is why they are often avoided in research. To overcome this hurdle, Calma and Sick (2017) suggested to simulate user factors from real-world applications when evaluating AL in an experimental setup (i.e., benchmarking on an already labeled dataset). They addressed error-proneness in AL and presented a theoretical framework for simulating annotation uncertainty of the user.

Our work follows this lead by incorporating user factors into the laboratory evaluation of AL to provide a simple alternative to costly user studies. However, we focus on the requirements that users place on AL applications in order for them to be considered beneficial in practice. In particular, we address the need for achieving high or full class coverage in a timely manner and covering minority classes. Furthermore, as a solution approach to the annotation uncertainty problem modeled by Calma and Sick (2017), we hypothesize how examples should be acquired to reduce annotation errors and introduce a corresponding measure.

3 Methodology

In this section, we first give a more formal introduction to AL. Then, we motivate and define the four user-centric measures that are central to this work.

3.1 Active Learning

We make use of the pool-based AL scenario (Lewis and Gale, 1994), which assumes that there is a large pool of unlabeled data $\mathcal{U}$ and a small set of labeled data $\mathcal{L}$ at the beginning. We decided to acquire examples in mini-batches, as a practical method.

AL proceeds according to the following scheme: Using some query strategy, a batch $\mathcal{B}$ of examples is selected (and consequently removed) from $\mathcal{U}$. These examples are then labeled by an oracle (e.g., a human annotator) and added to $\mathcal{L}$. Finally, a model is fit to $\mathcal{L}$. This process is repeated until a predefined stop criterion (e.g., a given annotation budget) is met. In the initial run, a default set of labeled examples is used to start the AL process.

3.2 Measures from User-Centric Perspective

In the following, we introduce four measures that reflect demands users may place on AL in practice. The definitions refer to single-label classification.

We draw motivation for the measures from two sources. On the one hand, we refer to the scientific literature, as specified below. On the other hand, we relate directly to the needs of practical users that have been communicated to us in our transdis-

[1] In the following, we will use the terms human annotator and user interchangeably. This terminology is adopted because in certain application scenarios, the human role goes beyond simply annotating data, as AL can simultaneously serve as an analytical tool, e.g., for computational social science.

ciplinary work over several years (among others documented in Romberg and Escher, 2020).

Minority-aware Batch Distribution When "dealing with imbalanced datasets in practice, the rare classes are often the ones that are particularly interesting." as Wertz et al. (2022) state. This is especially true for real-world use cases where AL is used not only for effective dataset creation, but also for efficient dataset analysis (Bonikowski et al., 2022; Yang et al., 2022). In the topic classification of citizens' contributions, e.g., human evaluators are often aware of the common issues in advance (Romberg and Escher, 2022). Thus, from the user's point of view, preference should be given to unexpected classes, which usually corresponds to minority classes. We measure this demand by

$$M(\mathcal{B}) = \frac{1}{n_{\mathcal{B}}} \sum_{c \in C} (1 - \frac{n_{\mathcal{U}_c}}{n_{\mathcal{U}}}) \cdot n_{\mathcal{B}_c} \quad (1)$$

where $n_{\mathcal{B}}$ is the batch size, $n_{\mathcal{U}}$ is the number of examples in $\mathcal{U}$, $n_{\mathcal{U}_c}$ is the number of examples in $\mathcal{U}$ that belong to class c, and $n_{\mathcal{B}_c}$ denotes the number of examples in $\mathcal{B}$ that belong to class c. To give more emphasis to rare classes, we weight all classes by their counter probability of occurring in the initial pool of unlabeled data. $M(\mathcal{B}) \in [0, 1]$, and a higher value indicates more awareness.

Class Coverage It is also of interest to consider how many classes AL can find (Schröder et al., 2021; Wertz et al., 2022). Achieving a high or even full class coverage is desirable for several reasons.

Knowing how query strategies handle the set of classes can be critical to building trust in human-machine collaboration. Indeed, a concern of our practice partners was missing some classes. If there was any potential for incomplete class coverage, this could even be a reason to completely avoid using machine text classification in their use case.

Such needs can relate to task requirements to which the human analyst is also subject. Thus, in these situations, it is not enough to, e.g., simply educate users about the strengths and weaknesses of ML algorithms; ML must meet these requirements.

What is more, with respect to the previously described utilization of AL for data analysis, a timely overview of the collection is an often desired feature, which is given by a fast class coverage.

And overall, having as complete a representation as possible of the classes relevant to the task at hand is generally an important prerequisite for creating reliable datasets.

We measure the class coverage of the examples in $\mathcal{L}$ as

$$K(\mathcal{L}) = \frac{|C_{\mathcal{L}}|}{|C|} \quad (2)$$

where $C_{\mathcal{L}}$ is the set of classes included in $\mathcal{L}$, and C is the total set of classes in the collection.

As a further indicator, we define the full class coverage I_K of an AL experiment as the number of iterations it takes to cover all classes in C.

Variation-aware Batch Distribution The performance of human annotators can be affected by various factors, including declining concentration or fatigue (Calma et al., 2016). One reason for the (more rapid) onset of these factors can be batches that offer little alternation in terms of the classes to be annotated. To reduce error-proneness in annotation caused by monotonous batches, we propose batches to fulfill two conditions: they should represent the available classes (measured by the ratio of acquired to the total number of classes available), and the acquired examples should be uniformly distributed among classes to offer variety (measured via entropy):

$$V(\mathcal{B}) = \frac{|C_{\mathcal{B}}|}{|C_{\mathcal{B}} \cup C_{\mathcal{U}}|} \cdot \sum_{c \in C_{\mathcal{B}}} - \left(\frac{\frac{n_{\mathcal{B}c}}{n_{\mathcal{B}}} \cdot \log_2(\frac{n_{\mathcal{B}c}}{n_{\mathcal{B}}})}{\log_2(|C_{\mathcal{B}}|)} \right) \quad (3)$$

where $C_{\mathcal{B}}$ is the set of classes included in the batch and $C_{\mathcal{U}}$ is the set of classes in the unlabeled pool. $V(\mathcal{B}) \in [0, 1]$, with larger values indicating a more varied set of examples with reference to the classes.

4 Evaluation Design

We provide an overview of the study design next by going into detail about the dataset selection, the chosen classification model, the selection of query strategies, and the experimental setup.

4.1 Datasets

We aim at a broad comparison across different datasets to empirically demonstrate the strengths and weaknesses of different query strategies with respect to the introduced user-centric measures. In doing so, we consider six datasets for different multi-class tasks and from diverse domains. An overview is given in Table 1.

DBPedia (Zhang et al., 2015) is a large-scale ontology dataset of Wikipedia articles (title and

Dataset	Task	Domain	$\lvert C\rvert$	Train	Val	Test
DBPedia	T	Wikipedia	14	15,000	2,000	4,000
20NG	T	News	20	2,507	354	721
ATIS	I	Flight reservations	17	3,802	537	1,093
TREC-50	Q	Diverse	46	4,163	589	1,196
BILLS	T	Congressional bills	20	15,000	2,000	4,000
CDB	T	Public participation	29	1,372	194	395

Table 1: Details of the six datasets. The task types are topic (T), intent (I), and question (Q) classification. $\lvert C\rvert$ denotes the number of classes.

abstract) and their topics. 20 Newsgroups[2] (20NG) contains messages collected from diverse newsgroups. Airline Travel Information Systems (ATIS; Siddhant and Lipton, 2018) is a dataset of transcribed audio recordings for classifying the intent of costumer utterances. TREC (Li and Roth, 2002) provides answer types for a collection of English-language questions.

These four English-language datasets regularly serve for benchmarking AL. While previous work has mostly relied on TREC-6, which organizes the questions into six main categories, we use the finer answer types of TREC-50 to give more weight to the multi-class setting that motivates this work.

The remaining two datasets come from real-world applications of topic classification in the computational social sciences. The Congressional Bills Corpus (BILLS; Purpura et al., 2008) provides information on bills introduced in the U.S. Congress between 1947 and 2008. One of its purposes is to examine what attention the congress has paid to various issues by thematically analyzing the bill's titles. The Cycling Dialogues Bonn (CDB; Romberg and Escher, 2022) is a German dataset of citizen contributions to a public participation process on cycling infrastructure.

While ATIS, TREC-50, BILLS, and CDB reflect the common class imbalance of real-world data, DBPedia and 20NG have been artificially counterbalanced at creation. To simulate a plausible scenario, we adjust the distribution of the two datasets through sub-sampling. Since we lack knowledge about the original data sources' actual distributions, we assume a distribution according to Zipf's law: the most frequent class should occur about twice as often as the second most frequent class, three times as often as the third most frequent class, and so on.

We follow Ein-Dor et al. (2020) by limiting the size of large datasets to $21K$ (DBPedia and BILLS) and apply a $70\%/10\%/20\%$ split for training, validation and testing. There were predefined splits available for some of the datasets (train/test splits for TREC-50 and 20NG; a train/val/test split for DBPedia), which we rejected for the following reasons: For TREC these are neither consistent in their distribution (Lowell et al., 2019), nor does the test split for TREC-50 contain all of the original 47 classes. For 20NG and DBPedia, we modified the structure of the datasets to a greater extent by adapting them to Zipf's distribution. We therefore decided to define new splits selected according to a stratified random sample. Classes with less than 5 examples were removed.

Detailed insights into the resulting dataset splits and the code for the experiments are available at https://github.com/juliaromberg/ranlp-2023.

4.2 Classification Model

Several studies have shown the potential of AL coupled with pre-trained language models (PTMs) (e.g., Ein-Dor et al. 2020; Yuan et al. 2020; Longpre et al. 2022; Zhang et al. 2022). We adhere to these findings and apply the BERT base model (Devlin et al., 2019), as has been done in much of the related work. For English datasets, we use uncased BERT[3] (pre-trained on English data), and for the German dataset, we rely on cased GBERT[4].

4.3 Query Strategies

We compare a variety of strategies that have stood out in previous work for their strong results and cost-effectiveness when used with PTMs in imbalanced settings. As a baseline, we use *Random Sampling* (Random).

Traditional uncertainty-based acquisition functions select examples according to the confidence of model prediction. They are efficient and have proven to keep up with more advanced AL strategies when used with PTMs (Zhang and Zhang, 2019; Margatina et al., 2021, 2022). We consider *Least Confidence* (LC; Lewis and Gale, 1994), which has proven effective for imbalanced datasets (Ein-Dor et al., 2020; Schröder et al., 2022), and *Breaking Ties* (BT; Luo et al., 2005), which was recommended as a baseline for uncertainty sampling with transformers by Schröder et al. (2022). LC selects those examples for annotation where the model's probability output is lowest for the most likely class, i.e., cases in which the model is least

[2] http://qwone.com/ jason/20Newsgroups/

[3] https://huggingface.co/bert-base-uncased

[4] https://huggingface.co/deepset/gbert-base

confident. BT aims to improve classification confidence by selecting examples where the difference in probability outputs between the two most likely classes is the smallest.

Diversity-based query strategies aim to select examples that best represent the full dataset. We include *Core-Sets* (Sener and Savarese, 2018), which have been found to select batches of high diversity and representativeness in addition to a promising boost of model performance in imbalanced settings (Ein-Dor et al., 2020). Core-sets are subsets of examples that represent the dataset in a learned feature space (for PTMs: CLS) in the sense that a model trained on a Core-set is competitive to a model trained on the entire dataset. We rely on the lightweight and fast algorithm for building the Core-sets by Bachem et al. (2018).

As a proxy for functions with a hybrid objective, we choose *Contrastive Active Learning* (CAL; Margatina et al., 2021) which has the potential to outperform alternatives such as BADGE (Ash et al., 2020) and ALPS (Yuan et al., 2020) in terms of computational efficiency and accuracy (Margatina et al., 2021). CAL combines the characteristics of uncertainty- and diversity-based strategies by seeking so-called contrastive examples. These are examples that, despite high similarity in the feature space (i.e., among the k nearest neighbors), exhibit maximum mean Kullback-Leibler divergence between their predictive likelihoods.

4.4 Experimental Setup

In each AL iteration, training runs for 30 epochs on a batch size of 12 and the best model, in terms of validation loss, is retained. To avoid overfitting to the data from previous iterations, BERT is fine-tuned from scratch at each iteration (Hu et al., 2019). We use the AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of $2e-5$, beta coefficients of 0.9 and 0.999, and an epsilon of $1e-8$, and set the maximum sequence length to 100 for all datasets.

For each of the six datasets, the unlabeled pool $\mathcal{U}$ is formed by the respective training splits and 50 examples are randomly sampled from the pool to build the set of initially labeled data $\mathcal{L}$. Then, 20 iterations of AL are performed, in each of which a new batch of 50 unlabeled examples is selected from $\mathcal{U}$ according to the respective query strategy. The model performance is evaluated at the end of each iteration using a hold-out test set.

We run the AL simulation five times with different sets of initially labeled data for each combination (datasets × query strategies). To allow for a fair comparison, these seeds remain the same for each dataset across the different query strategies.

In accordance with our experimental setup, $3,156$ experiments (6 datasets $\times$ (5 query strategies $\times$ 5 initial seeds $\times$ (1 initial model $+$ 20 iterations) $+$ 1 full supervision model)) were conducted. The experiments were run on a single Nvidia Tesla P100-PCIE-16GB GPU and with 2.2 GHz Intel Xeon CPU processor.

We refer the reader to Appendix A for further details on hyperparameter selection, reproducibility of the experiments and computational costs.

5 Results

In this section, we report the experimental results. We start by shedding light on the performance of the different query strategies as is common in the literature via a standard measure for classification tasks, in our case the F_1 score. Using the newly introduced user-centric measures, we then shift our focus to analyzing additional indicators that can help select an appropriate query strategy for practical use.

5.1 F_1 Performance

Figure 1 illustrates how the F_1 score evolves over the iterations of AL in the experiments. It can be seen that full supervision performance can be achieved on all datasets within the chosen annotation budget of 20 iterations, except for BILLS.

Our analysis across all datasets shows a clear pattern of superior performance for uncertainty-based sampling compared to the other strategies. In particular, BT performs consistently strong. While hybrid CAL is in the middle of the rankings, it is evident that the diversity-based strategy mostly underperforms.

Based on these findings, from a ML-perspective that is commonly shared among many studies in the field, it seems an obvious conclusion to recommend BT as the strategy for practical application in imbalanced multi-class settings. In the following, we will examine whether this assumption can be supported from a user-centric perspective.

5.2 User-Centric Measures

Table 2 lists the results of the four user-centric measures for the datasets and query strategies, averaged

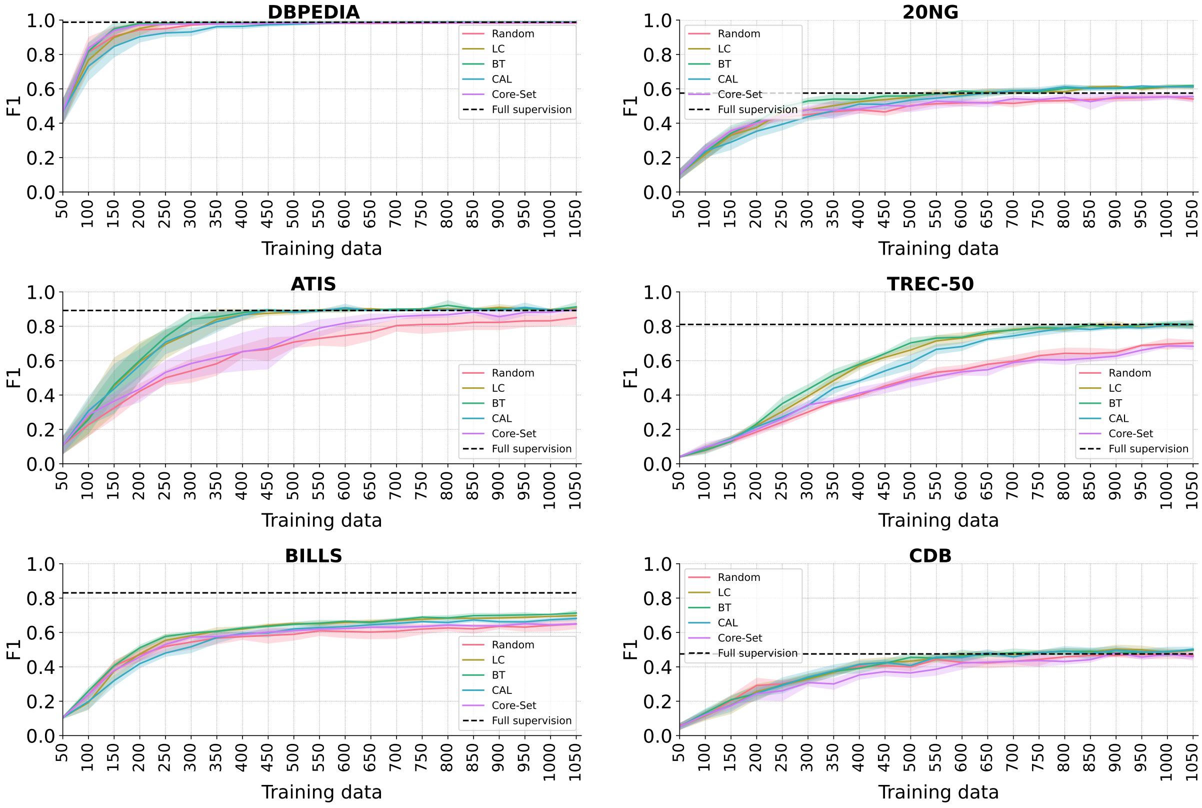

Figure 1: F_1 scores, averaged over the five seeds and with the shaded area illustrating the standard deviation. As a reference for the maximum achievable F_1 score for each dataset, the performance of the BERT models trained on the complete training data is indicated (full supervision).

over the iterations of AL for a better overview.

Which strategies favor minority classes? First, we evaluate whether, among the strategies considered, there are such that promote a higher representation of rare classes in the batches. We apply the minority-aware batch distribution measure $M(\mathcal{B})$ for this purpose.

All advanced strategies are found to consider rare classes more than random sampling. In particular, uncertainty-based strategies promote a higher minority representation on average. A detailed look shows that this trend is consistent among datasets, but there are major differences in how pivotal the choice of query strategy is. For BILLS and CDB, this makes a negligible difference. In contrast, the effect is much more dramatic on ATIS, where the scores range from 0.44 to 0.84.

Which strategies favor class coverage? Next, we examine whether there are any query strategies that prioritize quick and extensive class coverage by applying the class coverage measure $K(\mathcal{L})$.

The results show that uncertainty-based and hybrid query strategies stand out positively. BT achieves the highest average class coverage and turns out to be a good choice for a rapid growth in the coverage curve (as a detailed look at progress between iterations confirms).

Are the strategies capable of finding all classes? As argued in Section 3.2, a realistic requirement of the practice may be that all classes that a dataset comprises are found in the AL process. We measure the full coverage with I_K.

Contrary to our expectation, three strategies failed to find all classes within the budget of 20 annotation cycles on the datasets ATIS and TREC-50. In addition to random sampling and Core-Sets, in TREC-50 this surprisingly also affects the previously excelling strategy BT. The failure is systematic in each case, as we can observe it for several random seeds.

To gain better insight into the extent of the failure, we ran additional experiments beyond the AL budget of 20 iterations until full class coverage was achieved for the affected cases. On TREC-50, Core-Sets and BT both required up to 28 iterations on average. However, the deviations between the different seeds are much more extreme with BT: In

Table 2: Detailed results for $M(\mathcal{B})$, $K(\mathcal{L})$, I_K, and $V(\mathcal{B})$ on the six datasets of evaluation. The scores are averaged over the seeds and iterations of AL, and standard deviation is stated. The best scores are marked in bold. Cases in which a strategy failed to reach full coverage within the given budget are marked with an asterix.

the worst case, BT asked for manual labeling of over three quarters of the pool $\mathcal{U}$, which sums up to 60 iterations of AL.

We further discovered that in case of incomplete class coverage, it was the minority classes that were not found. This is why we repeated the experiments for TREC-50 and ATIS with an increased required minimum class support of 20 to spot check how performance changes. As for Random and Core-Sets, this modification allowed all experiments to achieve full class coverage within the given annotation budget. However, for BT, the undesired effects persisted on TREC-50. Moreover, failure even extended to the other two strategies associated with uncertainty, namely LC and CAL.

Overall, in the average comparison between all strategies, the hybrid CAL stands out, requiring on average only 6 iterations to successfully detect all classes.

How variant are the batches in terms of classes? Last, we apply $V(\mathcal{B})$ in order to account for variance in batches with the goal of reducing monotonous patterns.

Here, it is the diversity-based query strategy Core-Sets that on average produces batches that best fulfill the condition. Individually, though, the results are very mixed for the different acquisition functions and datasets. For example, BT performs best on three of the datasets, rendering this query strategy a strong contender.

6 Discussion

We considered several measures that take into account aspects that may determine the practicality of active learning strategies with respect to specific application scenarios. For the datasets under consideration, it can be seen that the F_1 score, the rapidity of class coverage, and the minority-awareness in the batches advocate for the use of uncertainty-based acquisition functions, in particular BT, in practical scenarios with multiple and imbalanced classes. However, Core-Sets offer the opportunity to add more variety to the monotonous task of annotation by filling batches with rather different classes and in a more balanced way. This may potentially help prevent annotation fatigue and thus human annotation errors that negatively impact AL. In addition, such variation could be a plus in terms of usability.

What is more, we found weaknesses in reaching full class coverage for all strategies. For random sampling and Core-Sets, we hypothesize that this is caused by extremely rare classes. However, for uncertainty sampling, the problem became even more apparent when excluding those classes. This is of particular interest since full supervision F_1 can be well achieved within the annotation budget (see Figure 1).

Although the F_1 score and some user-centric measures recommend BT as a favorite, the lack of reliability in achieving full class coverage, which we have empirically determined, may become a decisive criterion for practical applicability. Not only can it have a significant impact on human trust in AL. This finding affects AL in general, as the reliability of models strongly depends on the quality of the datasets.

7 Conclusion

With our results, we were able to illustrate that different query strategies stand out in different aspects that might be desirable or even necessary from the user's perspective in the practical application of AL. So what implications can be drawn for AL research beyond this study? The main reason why research on AL exists is its development and improvement for real-world use. In this, AL is a collaberative interaction between human and machine. However, this particular feature of AL seems to have gradually faded from the community's awareness, with the main focus being on optimizing the established performance measure for the particular machine learning task, e.g. classification. It is true that these established measures have important informational value about the methods. But there are additional requirements that arise specifically from the human factor inherent in the nature of AL, which likewise impact the practical value of AL. These should therefore be taken into account.

Therefore, we argue that future studies on AL should report a wider range of measures in their experimental evaluation. With this broader foundation, practitioners will be able to make a more informed decision when selecting an AL strategy based on academic findings in order to comply with their specific needs for a given application. For example, in applications where the annotation step is simultaneously used to analyze the dataset at hand, features such as a quick overview of all classes or, in particular, minority classes can be desired, as we have discussed in more detail in Section 3.2. Surely, the measures we have suggested are by no means exhaustive. Therefore, this work should also serve as a motivation to cover other aspects of the human component of AL in future research.

Ultimately, selecting an appropriate AL strategy for some practical use case is a matter of balancing different needs. The suggested measures make an important contribution to this, as they enable more reflective decisions, especially in combination with common performance measures like the F_1 score.

To sum up, AL has the potential to support ML in scenarios where the annotation budget is limited. We have argued that in order to assist the transfer of such methods from research to practice, both the machine learner and the human annotator must be taken into account. Considering the frequent use case of multi-class text classification with imbalanced classes, we introduced four measures that evaluate the acquired examples w.r.t. class-related requirements from the user's point of view. These measures are based on scientific literature and practical experience. Our results show that as complete a picture as possible should be considered to avoid failures in practical application.

The next step will be to conduct a user study to validate the usefulness of the metrics presented here. In future work, we will also investigate in more detail which influencing factors prevent a fast finding of all classes. This necessitates a study that investigates, among other aspects, the effect of data distribution on the class coverage of the different strategies in order to draw general conclusions.

Appendix

A Implementation Details

Hyperparameters The choice of batch size, number of training epochs, and maximum sequence length is a tradeoff between model performance, runtime, and GPU restrictions. We empirically determined that setting the batch size to 12 yielded good results. As for the number of 30 training epochs, we found that model prediction benefits from this increased number especially when there are only a few labeled examples, but also as the AL process progresses. Future work may consider whether the number of epochs can be curtailed as $\mathcal{L}$ grows larger. In consideration with the runtime due to the chosen number of epochs and the total number of experiments, as well as with regard to GPU constraints, we decided on an overall maximum sequence length of 100. For TREC-50 and ATIS, the longest encountered sequence comprises only 41 respectively 52 tokens, so we set the maximum sequence length correspondingly lower in these cases.

Reproducibility Experiments were performed with the same five random seeds, randomly selected from the range $[1, 9999]$, to make them reproducible.

Computational Costs Table 3 provides the average duration of each AL experiment. The decisive factor for the runtime is model fine-tuning.

Full Supervision Models These (c.f. Figure 1 in the main body) were fit on the full training data of the respective dataset with AdamW, $lr = 2e-5$, $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 1e-8$. We trained for five epochs in case of large datasets (DBPedia, BILLS) and for 30 epochs in case of small datasets (20NG, ATIS, TREC-50, CDB), and selected the best model by validation loss. To obtain reliable results, we repeated each experiment five times with different random seeds.

	Random	LC	BT	CAL	Core-Set

Abstract

Code-mixing (CM) is a frequently observed phenomenon on social media platforms in multilingual societies such as India. While the increase in code-mixed content on these platforms provides good amount of data for studying various aspects of code-mixing, the lack of automated text analysis tools makes such studies difficult. To overcome the same, tools such as language identifiers, Parts-of-Speech (POS) taggers and Named Entity Recognition (NER) for analysing code-mixed data have been developed. One such important tool is Event Detection, an important information retrieval task which can be used to identify critical facts occurring in the vast streams of unstructured text data available. While event detection from text is a hard problem on its own, social media data adds to it with its informal nature, and code-mixed (Kannada-English) data further complicates the problem due to its word-level mixing, lack of structure and incomplete information. In this work, we have tried to address this problem. We have proposed guidelines for the annotation of events in Kannada-English CM data and provided some baselines for the same with careful feature selection.

1 Introduction

With the rising popularity of social media platforms such as Twitter, Facebook and Reddit, the volume of texts on these platforms has also grown significantly. Twitter alone has over 500 million test posts (tweets) per day[1]. India, a country with over 300 million multilingual speakers, has over 23 million users on Twitter as of January 2022[2], and code-switching can be observed heavily on this social media platform (Rijhwani et al., 2017).

Code-switching or code-mixing[3] occurs when ”lexical items and/or grammatical features from two languages appear in one sentence”(Muysken, 2000). Multilingual society speakers often tend to switch back and forth between languages when speaking or writing, mostly in informal settings. It is of great interest to linguists because of its relationship with emotional expression (Rudra et al., 2016) and identity. However, research efforts are often hindered by the lack of automated NLP tools to analyse massive amounts of code-mixed data (Rudra et al., 2016).

Below is an example of a code-mixed Kannada-English tweet that has also been translated into English. Named entities have been tagged along with the language tags (*Ka*-Kannada, *En*-English, *NE*-Named Entity, *Univ*-Universal).

> **Ka-En:** Sinchu/*Person/NE* last/*Other/En* month/*Other/En* Kerala/*Location/NE* visit/*Other/En* madidlu/*Other/Ka* #beautiful/*Other/En* :D/*Other/Univ*
>
> **Translation:** *Sinchu visited Kerala last month #beautiful :D*

Event detection in Natural Language Processing (NLP) and Information Retrieval (IR) refers to the process of identifying and extracting relevant information about events from text data. An event can be defined as something that happens at a particular time and place, involving one or more participants and having certain properties or attributes. The emphasis is on detecting the presence of events. This information can be useful for various applications, including news analysis by accurate selection of news messages(Cimiano and

[1] https://www.internetlivestats.com/twitter-statistics/

[2] https://www.statista.com/statistics/242606/number-of-active-twitter-users-in-selected-countries/

[3] The terms ”code-mixing” and ”code-switching” are used interchangeably by many researchers, and we also use these terms interchangeably

Proceedings of Recent Advances in Natural Language Processing, pages 1007–1014

https://doi.org/10.26615/978-954-452-092-2_108

Staab, 2004), enhanced risk analytics (Capet et al., 2008), improve traffic monitoring systems (Kamijo et al., 2000), forecasting civil unrest (Ramakrishnan et al., 2014), social media monitoring, event detection, trend analysis, and knowledge graph construction (Ye et al., 2022). Furthermore, by detecting the occurrence of events as early as possible, the performance of risk analysis systems (Capet et al., 2008), traffic monitoring systems (Kamijo et al., 2000) can be improved and forecast civil unrest (Ramakrishnan et al., 2014).

The structure of the paper is as follows. In Section 2, we review the related work. In Section 3, we discuss the annotation methodology and the challenges involved while dealing with ambiguous tokens. In Section 4, we describe the steps involved in corpus creation and data statistics. In Section 5, we describe the baseline systems that have been used. In Section 6, we have discussed the feature selection. In Section 7, we have talked about the experimental setup of our work. In Section 8, we present the results of the experiments conducted. Finally, in section 9, we conclude the paper and discuss the future prospects.

2 Background and Related Work

The study of events dates back quite a long time, and pre-linguistic definitions of events sought to describe and recognise events as ”change in aspects of the perceived sense.” Before we start with event detection, we should be first clear on what constitutes an event in a sentence. The guidelines for annotation of events have been published in English in 2006 (Saurí et al., 2006), while guidelines for event annotation in monolingual Kannada data was recently published by Prabhu et al., 2020. Automated event mention detection in an open domain setting is a keystone for various information extraction tasks. This task was first brought to light during SemEval-2007, where the shared task *Task 15: TempEval Temporal Relation Identification* (Verhagen et al., 2007) was added as a new task with a focus on identification of temporal constructions. One of the six proposed tasks was concerned with the detection of events mention extent in the text. In early works, most of the methods (Allan et al., 1998, Yang et al., 1998) proposed for event extraction have focused on news articles, which is the only best source of information for current events. More recently, Iqbal et al., 2019 proposed NLP techniques, handwritten rules and WordNet for event extraction from emails. They have used methods like event trigger identification and morphological analysis for event extraction from the email and achieved an accuracy of 72%. With the ability of social media tools to virally popularize news items and their acceptance across the masses, numerous media agencies have been relying on Twitter, Facebook feed pages to disseminate their news highlights. Twitter feeds for Hindi [4][5] and Kannada [6][7] are few examples of social media forums continuously posting the news items. Among the posts made by these feeds, only a small fraction of tweets contain events. Allan et al., 1998 developed the first open-domain event extraction tool (TWICAL) for Twitter data. There have been attempts at event detection from social media streams (Hossny and Mitchell, 2018), but we will not be working on those as part of this work.

We have recently seen an interest related to Kannada-English code mixed data. Sowmya Lakshmi and Shambhavi (2017) have proposed an automatic word-level Language Identification (LID) system for sentences from social media posts. Appidi et al. (2020) reported a work on annotating CM Kannada-English data collected from Twitter and creating POS tags for this corpus. S and Shrivastava (2022) presented an automatic NER of Kannada-English CM data. We are using the dataset created in the above works related to NER and POS tags in our event extraction task.

3 Annotation Methodology

In this section, we shall discuss the method that we have used to annotate our corpus. We label each tokens with the inside-outside-beginning (IOB) format (Ramshaw and Marcus, 1999), where B refers to the beginning of an event, I refers to the token that is part of the event but not the first token and O refers to all other tokens. We propose these principles, which are inspired by TimeML, and are organised by the Part-of-Speech (POS) of the event nugget. Nouns, finite verbs, non-finite verb constructions such as infinitives, and adjectival and adverbial participle constructions are examples of these components of speech. As most of the code-mixed Kannada-English sentences follow the structure of Kannada grammar while swapping language

[4] https://twitter.com/aajtak?lang=en

[5] https://twitter.com/bbchindi?lang=en

[6] https://twitter.com/NewsFirstKan

[7] https://twitter.com/OneindiaKannada

for keys words such as common nouns, we will follow the guidelines that we have proposed for Kannada monolingual event annotation in our paper - Detection and Annotation of Events in Kannada (2020) (Prabhu et al., 2020). For English grammar based sentences, we have the TimeML annotation guidelines (Saurí et al., 2006).

For Kannada grammar based sentences, we have the annotation guidelines from Prabhu et al., 2020. Some examples are given below.

Noun-Nominal events refer to abstract nouns that relate to a temporal phenomenon and inherently convey a notion of finiteness, such as chunavane (election), pasavu (famine), etc.

> **Ka-En:** Karnataka *chunavane* sheeghra agutte antha namme home minister announce madidru
>
> **Transation:** Our home minister announced that Karnataka *election* will be soon

Finite verb- Categorized as events because they denote actions that bring about a change in the state of the world. They possess tense and aspect information, which inherently conveys a notion of temporality.

> **Ka-En:** Prashant avna resignation letter annu *kalisidaane*
>
> **Translation:** Prashant *sent* his resignation letter

Adjectival participle construction, non-finite verb- In Kannada, this involves converting the verb into an adjective to describe the noun involved in the main verb through its previous actions. These constructions exhibit semantics of sequentiality in relation to the main verb and convey a sense of finiteness in the action. The adjectival participle is also inflected with tense, aspect, and modality, indicating its event-like nature.

> **Ka-En:** avnu *oduva* shoes annu wear madida
>
> **Translation:** He wore his *running* shoes

Adverbial participle construction, non-finite verb- Similarly, in Kannada these are used to represent verbs performed by or associated with a noun in the dative or accusative case. Unlike adjectival constructions, there is no direct sequentiality associated with the main verb and the adverbial participle.

> **Ka-En:** *malkondiruva* deer annu Rakesh shoot maadida
>
> **Translation:** Rakesh shot the *sleeping* deer

Infinitives, non-finite verb- In Kannada, these are identified by the characteristic inflective ending of 'lu'. These infinitive forms of the verb are also considered as events in linguistic annotation.

> **Ka-En:** Samiksha eega computer alli *oodalu* hoguttale
>
> **Translation:** Samiksha will now *go read* on computer

Subjunctives, non-finite verb- An uncommon verb form that expresses desires or imagined situations. It is used to indicate events that are uncertain or not guaranteed to happen. As a result, subjunctive verbs are also labeled as events in linguistic annotation. Subjunctives can undergo morphological inflections for tense, aspect, and modality, allowing for the expression of different temporal and modal nuances within the desired or imagined events.

> **Ka-En:** ninage olle aarogya irali anta *bayasutteene*
>
> **Translation:** *I wish* you good health

As stated, we will be using the Inside-Outside-Beginning (IOB) format, so the total number of tags becomes 3 - B, I, and O. An example of the same is given below-

> **Ka-En:** avanu/O Mysore/O alliro/O international/O school/O ge/O hoogi/B science/O odustaane/B
>
> **Translation:** He *goes* to the international school in Mysore and *teaches* science

3.1 Dealing with Ambiguous Tokens

The following are some of the challenges while working with social media data-

- Users tend to use colloquial words/slang on social media and have their own preference of native words. For example, *baralilla* is a Kannada word and it can be written as *brlilla*, *barlilla*, etc.

- Misspelled words are very common on social media. For example, a word like *tonight*

Quantity	Value
Total number of tokens	21,342
Avg. tweet length	9.61
Total tweets	2250

Table 1: Corpus statistics

Event type	Count of occurances
Singe word events	1,955
Multi-word events	1,057

Table 2: Event types statistics

could be written as *tonight, tonite, tonihgt, ton8, etc.,* which posed a significant challenge while building spelling agnostic models.

In case a word has different means in the two languages we are working with and the words refers to an action/event in one language while it does not in the other language, we tag the token with whatever seems appropriate based on the context of the sentence. The annotators shall make such context based decisions for any other ambiguity that they might come across as some words can have multiples meanings, in the same language or across languages.

4 Corpus and Statistics

4.1 Dataset

As we intend to use Part-of-Speech (POS) tags in our work, we have used a subset of the annotated dataset created by Appidi et al., 2020 for POS tagging of Kannada-English code-mixed data. The corpus was created from Twitter[8].

We annotated 2,250 of these code-mixed Kannada-English tweets. For language identification part, we used the tool that was developed by Bhat et al., 2015 but it needed manual checks as social media data differs from the standard language.

The corpus has a total of 21,342 tokens which were tagged for the 7 tags mentioned in the Section 3. The corpus statistics and the event types statistics can be seen in Table 1 and Table 2 respectively.

4.2 Inter Annotator Agreement

Annotation of the dataset for event tags in the tweets was carried out by 2 human annotators having linguistic background and proficiency in both Kannada and English based on the methodology in Section 3. In order to validate the quality of annotation, we calculated the inter annotator agreement (IAA) between the 2 annotation sets of 2,250 code-mixed tweets having 21,342 tokens using Cohen's Kappa (Cohen, 1960) which came up to 0.89 which is fairly high given the challenges we have with the task at hand, discussed in Section 3.1, and the complexity of the annotation guidelines.

Disagreements about the tags were resolved through discussions between the annotators to reach a mutual agreement.

5 Supervised Approaches for Event Detection

Supervised machine learning is a category of machine learning where a model is trained on labeled training data, where each data point has both input features and corresponding output labels. The goal of supervised learning is for the model to learn the mapping between input features and output labels so that it can make accurate predictions on unseen data.

As we have a limited amount of data for our task of event detection (2,250 sentences), we will only explore probabilistic models. They have been described in the following sub-sections.

5.1 Hidden Markov Model

Hidden Markov Models (HMMs), that was first introduced by Baum and Petrie, 1966, have been used for event detection in NLP, particularly in scenarios where the focus is on sequential data (Zhou and Su, 2002, Kupiec, 1992, Jiampojamarn et al., 2007). HMMs are probabilistic models that involve hidden states and observable outputs, making them suitable for modeling the sequential nature of the text. HMMs are finite stochastic automata consisting of two stochastic processes. The first process is a Markov chain with transition probabilities and hidden states. The second process generates observable emissions based on a state-dependent probability distribution. In our context, the emission probability refers to the likelihood of a token being assigned a B, I, or O tag.

It's important to note that HMMs make the simplifying assumption of the Markov property, which assumes that the current hidden state depends only on the previous state. While this assumption may not always hold in complex NLP tasks, HMMs can still be effective for event detection in certain

[8] http://twitter.com/

scenarios. Overall, HMMs provide a framework for modeling sequential data and can be utilized for event detection in NLP when the focus is on capturing the sequential nature of events in text.

5.2 Conditional Random Fields

Conditional Random Fields (CRFs) are probabilistic models used for sequence labeling tasks, such as named entity recognition and event detection in Natural Language Processing. CRFs are trained using optimization techniques such as maximum likelihood estimation (MLE) to estimate the model parameters. The parameters are learned to maximize the log-likelihood of the training data.

CRF is effective for event detection and sequence labeling tasks because it captures dependencies between adjacent labels, considering the contextual information from neighboring words. It enables global optimization by finding the most likely label sequence that maximizes the joint probability, leading to more coherent and accurate predictions. CRF's ability to model the structure of the sequence enhances its performance in identifying event segments within text.

6 Feature Selection

In "A Semantico-Syntactic Approach to Event-Mention Detection and Extraction In Hindi", by Goud et al., they have used specific features for HMMs and some additional features for CRF. We shall use those features along with an additional feature - language identifier (LID) which will either be Kannada (Ka), English (En), Named Entity (NE) or a Universal (Univ) token.

The list of features picked for the HMM are:

1. Word Identity (WI) : This would be the annotated event tag of the token.
2. Part-of-Speech (POS) : This would be the relevant POS tag of the token.
3. Beginning Of Sentence (BOS) : This would be a binary to mark if a token is the first token of a sentence.
4. Capitalization (C) : This is to identify if the token is capitalisized as capitalisation signifies nouns most of the time if not emphasis.
5. Language Identifier (LID) : This is binary feature that is important for code-mixed data as we need to know which language it belongs to - Kannada or English.

The list of features picked for CRF are the following:

1. Word Identity (WI) : This would be the annotated event tag of the token.
2. Part-of-Speech (POS) : This would be the relevant POS tag of the token.
3. Bi-gram features : Adjacent 2 token feature.
4. Tri-gram features : Adjacent 3 token feature.
5. Beginning Of Sentence (BOS) : This would be a binary to mark if a token is the first token of a sentence.
6. Previous word's POS : This feature would help in context understanding of the present token.
7. Previous word's WI : If the previous token's tag was B, then the present token would either be a I or an O tag. This helps in contextual understanding for a CRF.
8. Next word's POS : Similar to previous token's POS tag, next token's POS tag helps understand the present token better.
9. Next word's WI : Similar to previous token's event tag, next token's event tag helps understand the present token better.
10. Language Identifier (LID) : This is binary feature that is important for code-mixed data as we need to know which language it belongs to - Kannada or English.

7 Experimental Setup

In this section, we conducted a series of experiments to assess the impact of different features and model parameters. Our goal was to understand the effect of individual features that we discussed in Section 6 and explore the influence of various model settings that we discussed in the Section 5.

To achieve this, we performed experiments using different combinations of features and systems with rigorous hyper-paparemeter tuning, for both HMM and CRF using GridSearch. We experimented with using a subset of features together and all features simultaneously.

To evaluate the performance of our classification models, we employed 5-fold cross-validation. This approach helped us validate the models by partitioning the data into five subsets, training the models on four subsets, and evaluating their performance on the remaining subset. We repeated this process five times, each time using a different subset for evaluation.

For the implementation of the algorithms, we utilized the data handling libraries in Python for HMM and CRF++[9] tool for CRF, which are efficient and user-friendly tools for our tasks.

In terms of data splitting, we allocated 60% of the data for training, 10% for validation, and 30% for testing. This division allowed us to train our models on a substantial portion of the data, validate their performance on a separate subset, and finally assess their generalization ability on a dedicated testing set.

By conducting these experiments, we aimed to gain insights into the impact of different features and model parameters, enabling us to make informed decisions about the best configuration for our classification models. We use precision, recall and F1-score as our evaluation metrics.

8 Results and Analysis

Table 3 captures the performance of our models for our dataset. Our best model is the CRF (window size 3) which achieved a weighted average F1-score of 0.53 compared to 0.39 for HMM. The performance of the HMM is in line with expectations. This limitation can be attributed to their ineffectiveness in capturing contextual details and their reliance on a restricted set of features during training, resulting in sparse information availability.

As CRFs are trained to develop a local model at the sentence level for event identification, as we observe improvements in the accuracy of the CRF's local model, it indicates that the engineered features effectively capture all the available information within the sentence's local structure.

Even then, the results are nowhere near perfect but the purpose of the models was just to provide an exploratory baseline for the dataset created with the annotation guidelines.

We should also note that the grammatical structure of the sentences are not standard, making prediction harder. This gets more difficult with Kannada-English code-mixed data as mixing happens at word-level, mostly for Kannada language prepositions and named entities or English language nouns.

Model	Precision	Recall	F-1 score
HMM	0.38	0.42	0.39
CRF	0.46	0.63	0.53

Table 3: Evaluation of HMM and CRF models for Event Detection

9 Conclusion

In conclusion, our work on Event Detection for code-mixed Kannada-English social media data has yielded the following:

1. **Annotation Guidelines:** We have provided guidelines for annotating code-mixed Kanglish social media data for event detection.

2. **Annotated Corpus:** We have created a new annotated corpus specifically for code-mixed Kannada-English Event Detection. To the best of our knowledge, this is the first corpus of its kind, providing valuable resources for future research in this domain.

3. **Research Problem:** We have identified and addressed the challenge of event detection in code-mixed Kannada-English data as a research problem. Code-mixed data presents unique linguistic complexities, and our work contributes to advancing event detection and other information extraction techniques in this particular context.

4. **Machine Learning Models:** We conducted experiments using probabilistic machine learning models on our annotated corpus. Specifically, we employed Hidden Markov Model and Conditional Random Fields (CRF) models which could be employed as baseline models for further exploration.

As part of future work, we plan to explore downstream tasks like question answering, which makes use of Event Detection for code-mixed data. The size of the corpus can be increased to include more data from varied topics.

10 Acknowledgements

We would like to thank our annotators for their hard work and dedication. We would also like to

Three Approaches to Client Email Topic Classification

Branislava Šandrih Todorović, Katarina Josipović
NLB DigIT / Serbia
{branislava.sandrih.todorovic, katarina.kovacevic}@nlbdigit.rs
Jurij Kodre
NLB d.d. / Slovenia
jurij.kodre@nlb.si

Abstract

This paper describes a use case that was implemented and is currently running in production at the Nova Ljubljanska Banka, that involves classifying incoming client emails in the Slovenian language according to their topics and priorities. Since the proposed approach relies only on the Named Entity Recogniser (NER) of personal names as a language-dependent resource (for the purpose of anonymisation), that is the only prerequisite for applying the approach to any other language.

1 Introduction

Together with Nova Ljubljanska Banka's (NLB) Centre of Excellence, Belgrade IT company **NLB DigIT** has a mission to incorporate smart, data-driven IT solutions to various aspects of everyday work in different Bank's business sectors. One such case is the classification of client emails sent to the Bank's Contact Centre (*Kontakt Centar* in Slovenian, dubbed KC) with respect to their topic (e.g. accounts/loans/cards, etc.) and priority (high, low, medium).

In this paper we present the whole procedure, from having only the plain Outlook files to the models assigning topics and priorities to emails in real time. Section 2 mentions some of the previously published scientific articles that inspired this research. We propose and discuss three different approaches for the modelling of emails in Section 3. Afterwards, we explain the process of preparing the dataset in Section 4: selection of optimal classification schemes and manual annotation, followed by certain cleaning steps and anonymisation of personal information. Having the prepared dataset, we trained and exhaustively evaluated different NLP models for the case of topic classification. We explain the training process in more detail in Section 5, where we also show evaluation results first on a validation and then on a separate test set. Finally, we close with some final remarks, ideas for further improvement and conclusions in Section 6.

2 Related Work

The problem of email classification has been an active area of research for several decades, with numerous studies focusing on developing effective algorithms to accurately categorise incoming emails based on their content. Researchers still experiment with different techniques and approaches in order to improve the existing SPAM and Phishing email classifiers. Iqbal and Khan (2022) achieved the 98.06% accuracy using the binary Support Vector Machine (SVM) classifier for the case of SPAM, whilst Shuaib et al. (2018) developed the optimal SPAM classifier using Rotation Forest algorithm, achieving the accuracy of 94.2%. Ali et al. (2021) experimented with feature engineering and RNN/CNN architectures, concluding that RNN provides the highest 94.9% accuracy. The binary SVM classifier also proved to be the best Phishing email detector for Sundararaj and Kul (2021), with 87.85% accuracy. SVM proved to be the optimal classifier in all our experiments, which we clarify in the coming sections.

3 Methodology

In this section we will describe three different approaches that we hypothesised to be appropriate for the multi-class email topic classification:

3.1 BERT "all-in-one" approach

BERT (Devlin et al., 2019) is a pre-trained deep learning model developed by Google for natural language processing applications such as question answering and language inference. The model works by training on a massive dataset of text,

Proceedings of Recent Advances in Natural Language Processing, pages 1015–1022
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_109

learning the relationships between words and their meanings. Once pre-trained, BERT model can be fine-tuned on a specific task using a smaller dataset. This step allows the model to adapt to the specific task and improve its performance.

The BERT "all-in-one" approach refers to training each of the models on all samples at once by fine-tuning an off-the-shelf BERT language model for the Slovenian language. Having the same general pre-processing pipeline for all cases of email classification (described in Subsection 4), we propose to fine-tune the SloBERTa (Ulčar and Robnik-Šikonja, 2021) model for the Slovenian language on the whole dataset. The first step is to ensure that only Slovenian emails are present in the dataset, using an off-the-shelf language detection tool. After performing a pre-defined text processing procedure, two different models are to be trained separately: TOPICSLOBERTA (for the topic classification) and PRIORSLOBERTA (for the priority classification). The same would hold for any other BERT model.

There are certain drawbacks with this method. First, the performance of the final model depends on the underlying BERT model. If the BERT model itself is trained on data that comes from a domain that very much differs from the lexica of client emails, one cannot expect too much from the classification outcome. Fine-tuning of BERT models demands all class labels to be well covered in the means of number of representative samples, and to be well balanced, which represents one potential issue with client emails. Additionally, despite there not being any official lower boundary in the means of number of instances on which a BERT model should be fine-tuned, it is well known that for the case of deep neural network models holds the "more the merrier" rule, which could also be one of the performance limitations in our case. Finally, from the technical point of view, fine-tuning of this model demands strong computing resources, which could also represent one of the reasons against using this approach.

3.2 Waterfall-1 approach

Topics of the client emails to the KC are not uniformly distributed: clients commonly ask questions about their accounts, cards, mobile banking application, and less frequently they refer to KC regarding loans. This results in class imbalance. Similarly, the more classes there are in the multi-classification setup, the harder the problem is. This especially holds if the topics are related, which strongly holds in this case.

One peculiar case is with emails in which clients report phishing attempts. These emails contain completely different vocabulary from the regular account- or card-based queries. Hence, we propose the WATERFALL-1 approach, displayed in Figure 1, whose fundamental idea is to separately train a classifier for the dominant classes (dubbed as "major") in the dataset from a classifier trained on less frequent classes (dubbed as "minor"). The whole procedure is illustrated in the process of inference. First, as in the previous method, only emails written in the Slovenian language should be taken into consideration, ensured by the LANG-DETECT component. Since emails that report phishing attempts can be easily differentiated from other categories (due to the different vocabulary) the next step in the procedure is retrieving prediction from the KCPHI, binary classifier that identifies such emails. If such an email is detected, the inference ends there. If this was not the case, the model checks whether an email belongs to any of the major categories, predicted by the KCMAJOR. This classifier is still multi-class, but theoretically, since it would be trained on a smaller number of balanced classes, it should be more reliable. If any of the major classes is predicted, the inference ends there. This classifier has (number of major classes + 1) outputs, where this additional class represents emails from other, non-major categories. If this additional class is predicted, then the inference is pushed to the bottom of the approach, where the KCMINOR MODEL tries to determine which of the minor class labels it should assign to the input email. This classifier also outputs the *Other/Can't decide* category which covers samples that were not classified in any of the major or minor categories.

It is also important to note that putting KCMAJOR classifier above the KCMINOR statistically gives higher probabilities to the more frequent classes. We also propose to include the *SPAM* category in the KCMINOR step. Despite all email servers having spam filters nowadays, some junk still arrives to the inbox. This case is not that common, but since it is still possible, we propose to add it to the bottom classifier as an additional SPAM-detector. One potential drawback of this approach, however, is that spam emails can be in any language, and this procedure would immediately dis-

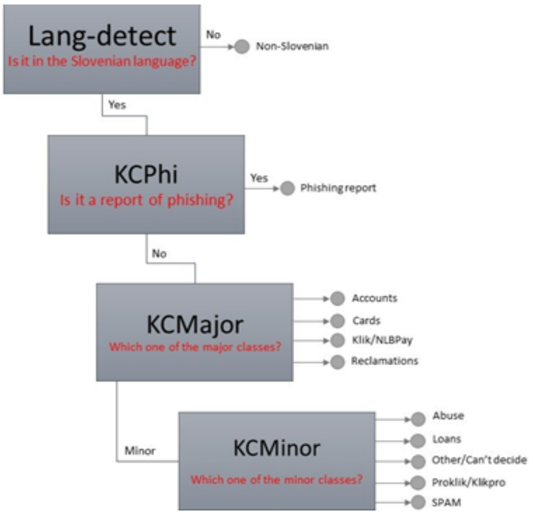

Figure 1: WATERFALL-1 approach

card them as foreign ones. If in practice these emails would get forwarded to KC staff that deal with non-Slovenian emails, they would potentially be the ones receiving junk mail from time to time.

3.3 Waterfall-2 approach

Another perspective to put at multi-class classification task is to divide it into smaller wholes, giving priority to the classes that are of higher importance to be dealt with. As opposed to the WATERFALL-1 approach, in the WATERFALL-2 MODEL (shown in Figure 2), SPAM filter is configured up as a zero-layer. This should fix the WATERFALL-1's SPAM-related potential issue. However, this would demand having a descent amount of SPAM emails to train a satisfactorily performing binary classifier. Afterwards, as in the WATERFALL-1, language detection is performed. Next, KCPHI classifier checks whether an email reports phishing. If this is not the case, KCABUSE classifier checks whether the email reports abuse of an account, card, or mobile banking application. This classifier is put high in the inference process since these emails have the highest priority. Similarly, if abuse is not detected, KCRECLAMATIONS checks whether a client communicates a reclamation. Next steps are the same as in the WATERFALL-1 approach, having KCMAJOR followed by the KCMINOR multi-class classifiers. Yet, the number of classes for both classifiers is smaller than in the WATERFALL-1, since three categories (spam, abuse, reclamations) were given higher priorities by being escalated to the top.

This approach breaks the large classification problem into smaller bits, and consequently, instead of training one large multi-classifier on imbalanced data, it trains several binary or multi-class classifiers on less training samples, but better balanced. Despite this approach being theoretically the most promising, the strongest drawback is a need for many data samples: the more training data for each of the components separately, the better. For the sake of being as reliable as possible, each classifier needs to see many positive instances, but also many negative ones.

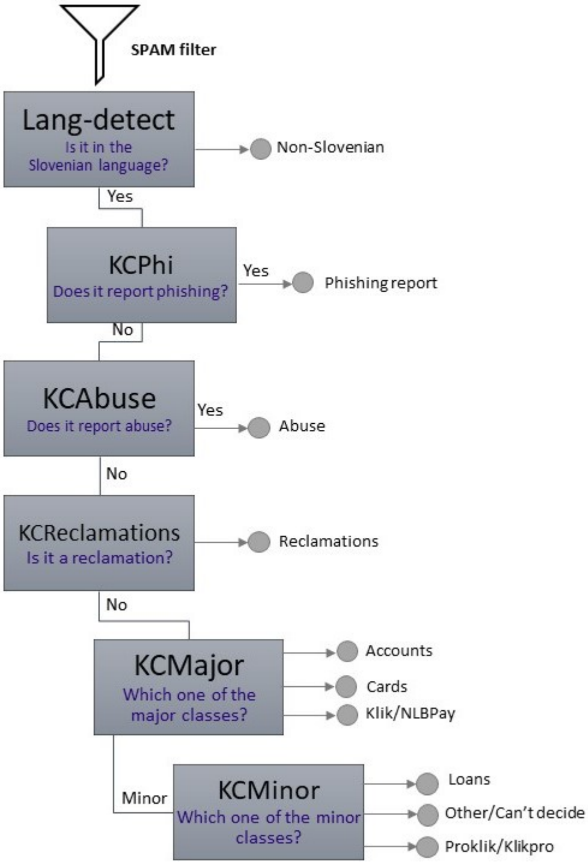

Figure 2: WATERFALL-2 approach

As an example, let's observe a zero-layer binary SPAM classifier trained on training samples annotated as SPAM. Since there is already a SPAM filter in any email server, we would not expect too many of such emails in the training set. If we want a balanced sub-sample, if there are n emails annotated as SPAM in the original dataset, we would sample exactly (or nearly) n negative samples from the remaining set of class labels. Regardless of the distribution of the sampled negative data (did we sample the same number of samples for each of the remaining classes or we followed the natural distribution of classes), the classifier potentially would not be able to see enough negative samples to be

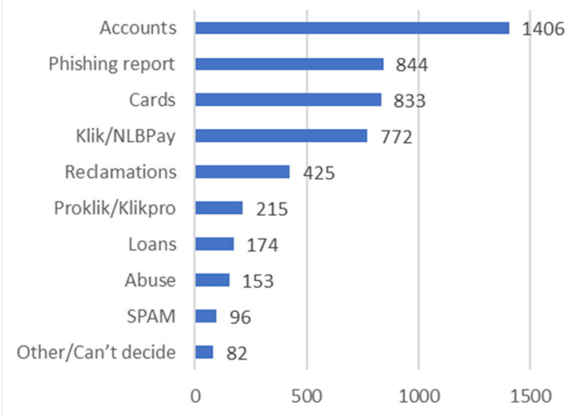

Figure 3: Final topic distribution

able to generalise well enough. As a result, the prediction would result in many false positives, because of the lack of negative instances seen during the training phase.

4 Dataset

It was first necessary to define the annotation schema and the data cleaning process. After taking into account the internal schema KC used over time when archiving finished email correspondences with clients into a database, and agreeing that the priority should directly follow from the topic, we settled on the 10 topics shown in Table 1: high priority Reclamations (1), Phishing Report (3), and Abuse (6); low priority SPAM (2), Other/Can't decide (5); medium priority Cards (4), Accounts (7), Klik/NLBPay (8), Loans (9), Proklik/Klikpro (10).[1] After manual annotation following the guidelines, the final dataset had the topic distribution shown in Figure 3.

Before using textual data for any machine-learning-related task, certain pre-processing steps should be performed. What has turned out to be a very beneficial in practice is to reduce the vocabulary of the text collection as much as possible, as long it does not affect the semantics of the content. Let us observe an email given in Table 2. Values X, Y, W and Z are displayed instead of personal names.

Only segments that were not struck out (subject and middle of the body) contain the client's query, while the rest is either some generic content (generated by the NLB's mail server or by the user's mobile email application). Similarly, personal information such as addresses, full names, mobile phone numbers, PIN, and account numbers represent sensitive information, yet do not in any way influence classification predictions.

On the email body concatenated to its subject, pre-processing procedure consists of the following stages: 1) removal of generic content; 2) tokenisation/the first anonymisation (masking personal names)/ lemmatisation; 3) the second anonymisation (masking email addresses, URLs) and final clean.

After step 1 there is no more generic content (e.g., *Sent from my iPhone*). In the 2^{nd} step, whenever possible, words are replaced by their lemmas. Simultaneously, personal names are replaced with a predefined token "Janez", and only words comprising of alphanumeric characters are kept. This was done using the CONLL-U format outputted by the classla Python library,[2]. For every sentence segmented from the input text provided to the classla's processor, a verticalised list of tokens is given. In each row, there are 10 columns. For our needs, we used the third column that contains lemma of the original token, and the last column that contains information about a recognised named entity, if that was the case. During this second step of the cleaning procedure, we kept only the non-punctuation tokens, simultaneously replacing every token with its lemma. Special case is when a token is recognized as a personal named entity, what we treat by replacing the original name with the common Slovenian name "Janez."

Finally, after the 3^{rd} step, all sequences of numbers were masked with the word "num", and using the scrubadub Python library[3] remaining sensitive information was also masked by corresponding tokens predefined by the library's configuration. The reduced vocabulary of the final, processed dataset of emails was 13,943.

5 Model training and evaluation

In this section we will describe the conducted experiments on the dataset of prepared emails, using the approaches proposed in Section 3.

5.1 BERT "all-in-one" approach

Idea was to fine-tune the existing BERT language model for Slovenian on the whole dataset of emails and teach it how to classify them. We first wanted

[1] To maintain client privacy and the bank's confidentiality, both the dataset and the code are not accessible to the public.

Table 2: Example email

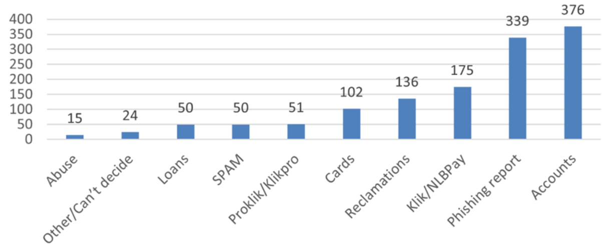

Figure 4: Sample topic distribution

to approximate the time needed for the fine-tuning on the whole dataset, hence we initially experimented only on a subset of annotated emails, whose distribution is shown in Figure 4.

With the learning rate of 1e-6, 10 epochs and batch size equal to 16, SLOBERTA was fine-tuned for the 10-class classification yielding TOPICSLOBERTA (around 6 hours on a local CPU machine). Simultaneously, topics were replaced with their priorities, resulting in 74 emails with low priority, 754 with medium and 490 with high priority and yielding PRIORSLOBERTA (around 4 hours). However, after experimenting with different parameters and adding more training samples from the other email batch, we realised that model's performance does slightly improve with the increase in the number of instances, so our conclusion was that we needed more training instances.

However, the results were not encouraging, since the model performed successfully mostly only for the major classes, *Accounts* and *Phishing report*. Nevertheless, we continued to assess the other two proposed approaches, what we describe in detail in the next subsections.

5.2 Waterfall-1 approach

Core concept of the both WATERFALL techniques is to train separate classifiers and assembly them into one step-structure. Since we wanted lightweight classifiers with fast inference, and we knew that we should not have high grand expectations from the transformers-based BERT language model, we decided to continue experimentation with the more

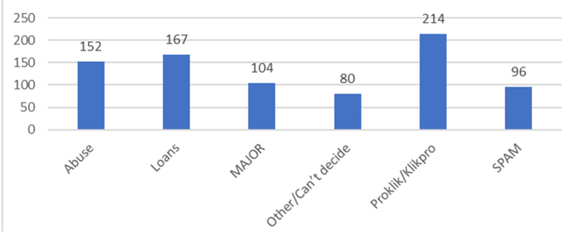

Figure 5: KC-DATASET-MINOR

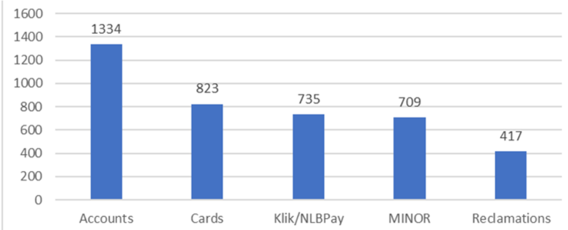

Figure 6: KC-DATASET-MAJOR

traditional machine learning models. In order to represent emails as vectors, we used the TF-IDF vectorisation technique. Among different classifiers with optimal parameters found by applying grid search technique, we trained a linear SVM (with C=10) on the first-annotation-round dataset and obtained more encouraging results. We concluded that for our type of dataset (in the means of length of instances and the overall size), traditional machine learning models are a better fit.

As described in Section 3, in the WATERFALL-1 approach we proposed to divide the final model into three sub-models, first phishing-report-classifier, and then one for the major and the other for the minor classes. Since the WATERFALL models require samples of all other classes present, unified into a single negative class, for the minor-classifier we uniformly sampled other classes and joined the samples into class *MAJOR*. This dataset dubbed as KC-DATASET-MINOR is shown in Figure 5.

The *Phishing report* category was separated for the WATERFALL models (comprised of 836 emails), since it represents a separate component in the inference process. Uniform sampling the same number of negative instances from the other classes yielded the KC-DATASET-PHI.

After adding minor-class representatives, sampled uniformly as in the previous step, we ended up with the KC-DATASET-MAJOR depicted in Figure 6.

The *Phishing report* category, and sampling uniformly the same number of instances of other classes for the purpose of having a balanced dataset for the KCPHI model we obtained the KC-DATASET-PHI.

After having the dataset prepared, we trained the SVM algorithm on these three datasets (8:2 ratio for the train/validation split). The resulting models were dubbed KCMINOR-SVM, KCMAJOR-SVM and KCPHI-SVM for the major, minor, and phishing components, respectively. The best parameters for the both KCMINOR-SVM and KCMAJOR-SVM were C=1000, gamma=0.001 with the RBF kernel, and for the KCPHI-SVM the optimal was linear SVM with C=1. The results on the validation test of all the three model components separately are shown in Table 3.

Class	P	R	F_1	Nr.
Abuse	.94	.86	.9	36
Other/Can't decide	.85	.65	.73	17
Loans	.93	.9	.91	41
SPAM	.84	.84	.84	19
Proklik/Klikpro	.74	.93	.82	30
MAJOR	.55	.55	.55	20
Cards	.91	.81	.86	171
Reclamations	.51	.53	.52	77
Klik/NLBPay	.86	.82	.84	144
MINOR	.79	.7	.74	149
Accounts	.75	.87	.81	263
Not	.90	.94	.92	164
Phishing report	.94	.89	.92	171

Table 3: WATERFALL-1 components on validation set

5.3 Waterfall-2 approach

The main idea of the novel WATERFALL-2 approach is to break the 10-class classification task into smaller tasks, as proposed in Figure 2. For the binary classifiers (the first four components) number of negative samples equal to number of positive samples, while in the case of the multi-class classifiers, number of negative samples for the *Non-Major* and *Non-Minor* represent the mean number of other class labels in the component, sampled from the natural distribution of the negative class labels. Each of these sub-datasets was divided into training and validation sets (9:1). Then we performed grid search for various classifiers on each of the sub-datasets, and finally trained and exported optimal models. We report our findings in Table 4 (LR represents Logistic Regression, while RF stands for Random Forest).

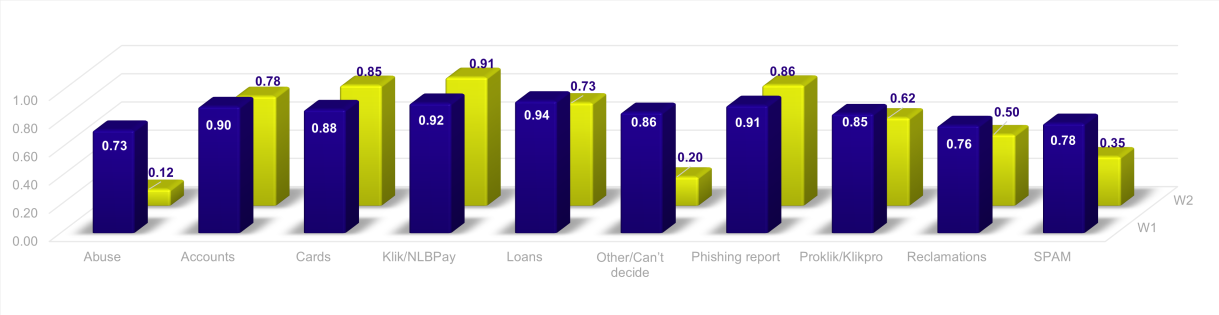

Figure 7: WATERFALL-1 vs. WATERFALL-2

	Nr.	A	F_1	Cls
SPAM	96	.9	.9	LR
Phishing	844	.91	.92	SVM
Abuse	153	.85	.86	RF
Reclamations	425	.78	.78	RF
Accounts	1406	.83	.84	LR
Cards	833		.81	
Klik/NLBPay	772		.85	
Non-Major	1003		.83	
Loans	174	.81	.79	SVM
Other/Can't decide	82		.5	
Proklik/Klikpro	215		.91	
Non-Minor	157		.7	

Table 4: WATERFALL-2 components on validation set

5.4 Discussion

So far we have shown evaluation metrics only on separate components of the both approaches. After joining all components into two models, Figure 7 shows their F_1 scores on the whole 5,000-sample dataset. Worse performance of the WATERFALL-2 could be interpreted as follows. Let us observe the SPAM component: there were 96 emails of that class in the dataset, and the same number of negative instances. The model has seen all cases of SPAM from our dataset during the training and recognises them perfectly. However, the model has seen only ninety-six examples that are not SPAM and mistakes frequently other classes for SPAM. In summary, it marked 456 emails as SPAM (therefore, the rate of false positives was extremely high) which is unacceptable for the final model.

The conclusion is that these smaller models work better separately, but assembled they are worse on our dataset. Each model has seen only a few samples from the negative pool. We could say that the BERT model-all-at-once approach and the WATERFALL-2 approach represent opposite ends of the spectrum, whereas the WATERFALL-1 approach strikes a balance in between. Therefore, for the first production model, we decided to use the WATERFALL-1 approach.

We finally report WATERFALL-1 performance on a separate, independent test set of emails in Table 5, comprising of 304 emails.

Class	P	R	F_1	Nr.
Accounts	.86	.8	.83	106
Cards	.76	.9	.82	27
Klik/NLBPay	.67	.75	.71	27
Loans	1	.9	.95	16
Non-Slovenian	.84	1	.91	3
Other/Can't decide	.71	.33	.46	16
Phishing report	.73	.95	.83	22
Proklik/Klikpro	.89	1	.95	20
Reclamations	.45	.45	.45	26
SPAM	1	.81	.9	41

Table 5: WATERFALL-1 on a test set

6 Conclusions and Future Work

One way to further enhance the model would be to log the topic labels predicted by the model and see how many assigned topics were corrected by the person who received the email. This way the dataset would naturally grow, and we would get the feedback about number of cases the KC accepted the model's predictions, and in situations when that was not the case, what were the common mistakes and the reasons behind them.

With the enlarged dataset, it would be possible not only to improve existing WATERFALL-1 model, but also to give another try to the other two approaches, since their bottlenecks in practice were lack of training samples.

Exploring Abstractive Text Summarisation for Podcasts: A Comparative Study of BART and T5 Models

Parth Saxena **Mahmoud El-Haj**
School of Computing and Communications
Lancaster University
Lancaster, United Kingdom
parth.s.1909@gmail.com m.el-haj@lancaster.ac.uk

Abstract

Podcasts have become increasingly popular in recent years, resulting in a massive amount of audio content being produced every day. Efficient summarisation of podcast episodes can enable better content management and discovery for users. In this paper, we explore the use of abstractive text summarisation methods to generate high-quality summaries of podcast episodes. We use pre-trained models, BART and T5, to fine-tune on a dataset of Spotify's 100K podcast. We evaluate our models using automated metrics and human evaluation, and find that the BART model fine-tuned on the podcast dataset achieved a higher ROUGE-1 and ROUGE-L score compared to other models, while the T5 model performed better in terms of semantic meaning. The human evaluation indicates that both models produced high-quality summaries that were well received by participants. Our study demonstrates the effectiveness of abstractive summarisation methods for podcast episodes and offers insights for improving the summarisation of audio content.

1 Introduction

Podcasts are a rapidly growing and popular medium for consuming knowledge and entertainment through spoken audio files that can be streamed or downloaded. With the podcast industry reaching new heights, there is a need for innovative and computationally effective methods for processing, analysing, and summarising podcast content. This need is further highlighted by the fact that Spotify[1] acquired Anchor and Gimlet Media, two leading podcast companies, for $340 million in 2018 and has since invested approximately $500 million in this industry, demonstrating the growth and importance of podcasting (Sullivan, 2019).

The abundance of data generated in various forms worldwide necessitates the need for methods to compress and understand this data, enabling the discovery of content available globally. One of these methods is automatic text summarisation, a technique used to shorten lengthy input texts to small coherent texts that convey the original meaning, reducing reading time and facilitating faster processing of research information. The field of Natural Language Processing (NLP) has witnessed significant progress in the development and research of text summarisation, resulting in an active research area in both Information Retrieval (IR) and NLP. The successful integration of transformer architecture and attention mechanisms has also contributed significantly to the advancement of text summarisation techniques.

The podcast domain presents unique challenges in text summarisation due to its conversational nature and informal language use, which could cause difficulties in extracting salient information. Furthermore, podcast episodes can be lengthy, making it a daunting task for listeners to find and identify those of interest. Summarising podcast transcripts into short, readable text can alleviate these issues, allowing podcast listeners to make more informed decisions on which episodes to listen to and enabling easier retrieval of information (Tulley, 2011).

The two fundamental approaches in text summarisation are extractive and abstractive summarisation. Extractive summarisation involves selecting the most relevant sentences from the input text to form a summary, while abstractive summarisation involves generating new sentences to capture the content of the input. Although both approaches can be used to summarise podcast transcripts, abstractive text summarisation is more challenging and requires the use of sophisticated techniques (El-Haj, 2012).

This paper focuses on generating automated summaries of podcast episodes using abstractive text summarisation to provide users with a concise summary of the podcast's content. The paper aims to

https://doi.org/10.26615/978-954-452-092-2_110

explore how state-of-the-art NLP (SOTA) models can generate summaries that convey the essence of the podcast and investigate the effectiveness of these summaries for podcast listeners. To achieve these objectives, the paper presents a systematic review of the background research on summarisation, the podcast domain, and related work in this field. It also analyses a dataset of podcast transcripts to develop a conceptual framework for the methods and techniques applied in this study. Finally, the paper examines the results and findings of the study, including the state-of-the-art evaluation metrics adopted for this study, and presents a conclusion that discusses the study's limitations, potential future work, and reflection on the study.

2 Background

Recent years have seen significant advancements in the field of automatic text summarisation, with the development of new techniques and models for generating summaries. Two main approaches are commonly used in text summarisation: extractive and abstractive summarisation. Extractive summarisation involves selecting the most relevant sentences from the source text, while abstractive summarisation generates a summary by rephrasing the text into new sentences. While extractive summarisation can be simpler and more efficient, abstractive summarisation has the potential to produce more informative and coherent summaries (Zmandar et al., 2021; El-Haj et al., 2010).

In recent years, the use of deep learning models, such as transformers, has led to significant improvements in the quality of abstractive text summarisation. Models such as BART, T5, and GPT-3 have achieved state-of-the-art performance on summarisation tasks, demonstrating the potential of these models for generating high-quality summaries. These models are pre-trained on large amounts of text data and can be fine-tuned on task-specific datasets to generate summaries that capture the essential content of the source text (Lewis et al., 2019; Xue et al., 2021; Brown et al., 2020)

The task of summarising podcasts has gained attention in recent years, with several studies proposing approaches for automated podcast summarisation. Laban et al. (2022) proposed an interactive summarisation approach for news podcasts, which allows users to engage with the summarisation process by providing feedback. This approach uses extractive summarisation to select important sentences from the podcast transcript and then generates a summary from these sentences. The system then allows users to rate the summary and provide feedback, which is used to refine the summary for future users.

Vartakavi et al. (2021) proposed an extractive summarisation approach for podcast episodes, where the summary is generated by selecting the most important sentences from the podcast transcript. They used a graph-based ranking algorithm to score each sentence based on its importance, and then selected the top sentences to form the summary. The system was evaluated on a dataset of 100 podcast episodes and achieved a ROUGE-2 score of 0.26.

Risne and Siitova (2019) introduced both extractive and abstractive summarisation approaches for news and podcast data using transfer learning. They fine-tuned BERT and GPT-2 models on a dataset of news articles and podcast transcripts to perform extractive and abstractive summarisation, respectively. The authors reported that the abstractive model outperformed the extractive model in terms of ROUGE scores on both news and podcast data.

Vartakavi and Garg (2020) presented an extractive summarisation approach for podcast episodes that uses sentence embeddings to score the importance of each sentence. The system selects the top sentences based on their scores to generate the summary. The authors evaluated their system on a dataset of 400 podcast episodes and achieved a ROUGE-2 score of 0.30.

Karlbom (2021) proposed an abstractive summarisation approach for podcast episodes, which uses a transformer-based model to generate summaries. The system was trained on a dataset of podcast transcripts and evaluated on a separate test set. The author reported that the system was able to generate coherent and informative summaries of the podcast episodes.

In summary, podcast summarisation has gained attention in recent years, with both extractive and abstractive approaches proposed for the task. Extractive approaches are simpler to implement but often produce less informative summaries, while abstractive approaches require more complex models but can produce more informative summaries.

3 Dataset

The podcast domain is notably distinct from other domains such as news in terms of its style and structure. To conduct this study, a dataset was obtained from Spotify, which has created the most extensive corpus of transcribed data and audio files in this emerging domain. The corpus is comprised of over 100,000 podcast episodes, amounting to almost 60,000 hours of speech. The transcriptions were generated using Google Cloud Platform's Speech-to-text API (GCP-API), revealing a unique and noisy set of data that has yet to be fully explored in the field of NLP. Additional information about the dataset can be found in (Clifton et al., 2020a). Podcasts are structured in different ways such as scripted and unscripted monologues, interviews, conversations, debate, and includes clips of non-speech audio material. This dataset includes a diverse range of topics, subject matter, speaking styles, and formats, comprising both audio files and transcripts of podcast episodes in Portuguese and English. However, the study solely focuses on summarizing English-language podcasts. Future work could incorporate audio files and transcripts in Portuguese. Additionally, the dataset features metadata, such as descriptions provided by the creators, which can serve as labeled data or reference summaries for summarization.taset covers a wide range of topics, speaking styles, and formats, and includes both audio files and transcripts of podcast episodes in Portuguese, although this study focuses solely on summarising English-language podcast episodes. Furthermore, the dataset provides metadata, including descriptions provided by creators, which are used as labelled data for the summarisation task.

3.1 Analysis of Dataset

The podcast dataset used in this study was obtained from Spotify, which holds one of the largest and most extensive collections of podcasts, including more than 5 million podcast titles[2]. The podcast dataset used in this paper consists of 105,360 podcast episodes that have been transcribed using the Google Cloud Platform's Speech-to-Text API[3]. The resulting dataset comprises a big corpus of approximately 60,000 hours of spoken audio and over 600 million tokens (Clifton et al., 2020b). The transcripts in the dataset have an average length of just under 6000 words, varying from a small number of extremely short episodes to as long as 45,000 words. The majority of the transcripts, approximately two-thirds of them, fall within the range of 1,000 to around 10,000 words. There is also a small percentage, about 1% or 1000 episodes, consisting of very short trailers used to promote the creator's content.

The average episode duration in the dataset is around 33.8 minutes (Figure 1), and the average number of transcribed words in an episode is 5,700. This shows that the documents in the dataset are considerably longer than typical summarisation data. Each show, on average, contains five episodes (Figure 2), with a median of two episodes per show. The dataset covers a wide range of topics and subject matter, including Comedy, Sports, Health & Fitness, Society & Culture, Business, and Education, among others. The dataset is significantly large and varied, making it an ideal resource for the development and evaluation of summarisation techniques in the podcast domain.

This dataset is publicly available and can be accessed through the Spotify API or by contacting Spotify's data research team.

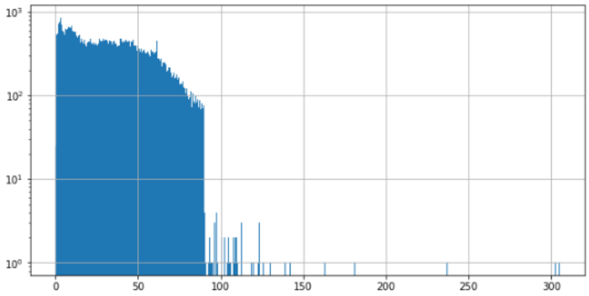

Figure 1: Average duration of episodes.

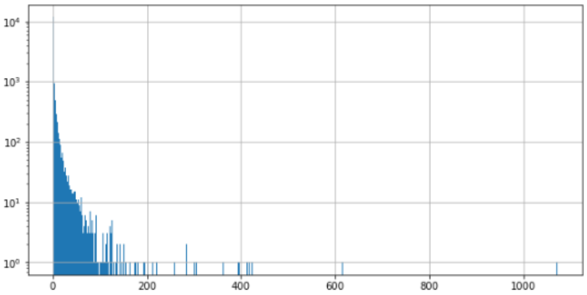

Figure 2: Number of episodes per show.

3.2 Challenges with the Dataset

The podcast dataset used in this study presents several challenges due to its nature and characteristics. Firstly, the transcripts of the audio files are automatically transcribed from the GCP-API, which

[2] Spotify Newsroom February 2023 https://newsroom.spotify.com

[3] https://cloud.google.com/text-to-speech

makes them prone to speech recognition errors.As a result, the dataset is inherently noisy, which can make it more challenging to extract meaningful information despite the post-editing process. In the context of summarisation, having multiple reference summaries for a single source document is beneficial for the models. However, in this particular dataset, we encounter a limitation where only a single summary is available for each episode, provided by the creator. This restriction places a heavy reliance on the creator's provided summary as the sole reference for generating abstractive summaries. Consequently, this limitation may result in a lack of diversity and alternative perspectives in the generated summaries.

Secondly, as podcasts are conversational in nature, they have disfluencies and redundancies in the spoken text. These conversational elements can make it more difficult to accurately interpret the data, especially when compared to data from other domains.

Thirdly, the podcast documents are significantly longer than typical summarisation data, which presents a challenge for SOTA models due to the limitation on the number of tokens. This can make it more difficult to generate high-quality summaries that capture the essence of the episode while remaining concise.

Finally, the descriptions provided by the creators vary widely in quality and often contain sponsorship details that are not intended to act as summaries of the episode. These descriptions were used as labelled data for the summarisation task, highlighting the need for users to be able to read summaries that give an overview of the episode.

These challenges underline the need for sophisticated approaches and techniques to accurately summarise podcast episodes, and this study aims to address these challenges by exploring the use of abstractive text summarisation techniques on this unique dataset.

4 Design and Methodology

The primary objective of this study is to develop an abstractive summarisation system that generates a concise and informative summary of podcast episodes, enabling users to make an informed decision about which podcast to listen to. The ideal summary should accurately convey the essence and most important attributes of the episode, including topical content, participants, and genre, and it should be easily readable on a smartphone with less than 200 words (Liu and Wang, 2022). To achieve this, we aim to fine-tune state-of-the-art transformer-based models (e.g. T5 and Bart) on podcast data. To achieve this we use podcast transcripts rather than audio files to fine-tune the models. Audio data has not been selected for this project due to several reasons. One of the main considerations is the significant variability in audio quality across different podcast episodes. The audio content ranges from professionally produced podcasts with high-quality audio to amateur podcasts that exhibit a wide variety of audio quality. Additionally, the dataset includes episodes self-published through a phone application, further introducing variations in the quality and equipment used by the creators. Given these factors, opting for transcript data ensures a more consistent and standardised input for the summarisation task. Our research pipeline follows a sequential approach that involves several processes to ensure effective summarisation. The process includes text pre-processing, model fine-tuning, and summary generation. This study evaluates the quality of the generated summaries using state-of-the-art evaluation metrics and investigates user attitudes towards the produced summaries. The ultimate goal is to improve the accessibility of podcast content by providing a concise summary that saves users' time and effort in selecting podcasts to listen to.

4.1 Data Pre-processing

The quality of reference summaries is vital for training accurate and reliable models for summarisation. However, episode descriptions provided by podcast creators varied in quality and often contained noisy information, such as sponsorships and promotional content. To improve the accuracy of training data, we filtered out low-quality descriptions dominated by emojis, URLs, advertisements, and promotions.

In addition to filtering, we employed the TextRank algorithm, to identify the most relevant sentences in a text (Mihalcea and Tarau, 2004). Our method was employed on both the descriptions and transcripts of podcast episodes. We aimed to pinpoint crucial keywords and to assess the quality of each episode's description by calculating precision, recall, and F1 scores. To differentiate between low and high-quality descriptions, we set a filter based on precision scores. In particular, episodes that achieved precision scores greater than 0.88 were labeled as high-quality, whereas those with lower scores were deemed low-quality. Although this cut-off point could be adjusted with further testing, we selected a higher value due to computational resource constraints.

Utilizing the TextRank algorithm, we enhanced the accuracy and relevance of our reference summaries. This resulted in more reliable and applicable summaries for model training. Although this processing step of filtering and applying TextRank reduced the number of dependable episodes for training, it guaranteed the preservation of accuracy and reliability in our summarizer. Moreover, it enabled the effective use of transfer learning.

Implementing these measures allowed us to generate a top-quality dataset of reference summaries to train our summarization model. This empowered us to create precise and succinct summaries for podcast episodes.

4.2 Summarisation Approach

The abstractive approach to text summarisation involves the use of neural methods to generate a condensed representation of documents. A number of approaches have been developed in recent years, which are surveyed in (Lin and Ng, 2019).

For this study, we utilised two state-of-the-art transformer-based models: BART and T5. The BART model (Lewis et al., 2019) is a pre-trained sequence-to-sequence (seq2seq) model that uses a denoising autoencoder to generate summaries. The architecture is based on the transformer model, which has proven highly effective for machine translation tasks (Vaswani et al., 2017). In particular, the BART model is fine-tuned on news summarisation data such as CNN/DailyMail or XSum (Lewis et al., 2019) before being fine-tuned on our podcast dataset. We used the BART-LARGE variant, which contains 12 layers of transformer blocks in both the encoder and decoder. To learn more about the BART model and how to access it using HuggingFace[4]

The T5 model (Xue et al., 2021) is also a transformer-based encoder-decoder model that has been pre-trained on a variety of unsupervised and supervised tasks. One of its key features is the ability to convert NLP problems into a text-to-text format, which makes it highly versatile. For our study, we fine-tuned the T5-BASE model, which has a total of 220 million parameters. To learn more about the T5 model and how to access it using HuggingFace[5]

Both models were fine-tuned on our cleaned and filtered dataset using the episode descriptions provided by podcast creators as training summaries and ground truth summaries. Hyperparameters for the models were chosen based on their effectiveness in prior research, as well as on our specific goals for this project.

The key hyperparameters for both models were as follows: It's worth noting that some of the hyperparameter values used for BART and T5 are default values that are known to work well for their respective architectures.

1. $Maximum\ length$: As the aim of the project was to generate summaries that could be easily read on a smartphone screen, we set a maximum length of 150 characters (Liu and Wang, 2022).

2. $Early\ stopping$: Enabling early stopping helped to prevent overfitting during training.

3. $Length\ penalty$: We used a length penalty of 2 for the BART model and 1 for the T5 model to discourage the models from generating excessively long summaries.

4. $No\ repeat\ n - gram\ size$: To avoid generating repetitive content in the summaries, we set the n-gram size to 3, which ensures that a trigram cannot be generated more than once in the summary.

5. $Num\ beams$: We used a value of 2 for the T5 model and 4 for the BART model. This hyperparameter keeps track of the number of steps taken while the model generates a sequence. Larger values typically generate better summaries, but at the cost of slower processing speeds.

6. $Learning\ rate$: We set the learning rate to 1e-4 for the T5 model and 3e-5 for the BART model to allow the models to converge without overfitting.

7. $Optimiser$: We used the Adam optimiser for the T5 model and the Ranger optimiser for the BART model to compare the performance of different optimisers with different learning rates.

[4] For BART: https://rb.gy/ehvcj

[5] For T5: https://rb.gy/xa3d5

8. *Epochs*: 2 (T5) and 3 (BART): Our models were trained for a total of 3 epochs, but because they were pre-trained, we didn't need to fine-tune them for an extended period of time. This is because we were able to take advantage of transfer learning. The number of epochs was chosen based on early stopping, which was enabled to prevent overfitting. Early stopping was set to 5 epochs, but the models converged in fewer epochs. Therefore, we chose to stop at 2 epochs for T5 and 3 epochs for BART, which provided good results without overfitting the models.

Other hyperparameter values were set to default because the creator descriptions varied greatly in quality so optimising hyperparameters was not worthwhile. Apart from validation, the fine-tuned models were tested with the official TREC 2020 (Clifton et al., 2020a) test set which consists of 1,027 podcast episodes.

We selected hyperparameters based on best practices and previous research. For instance, we set a maximum length for the summaries to ensure they would be easy to read on a smartphone screen. We also used a length penalty to discourage excessively long summaries, and a limit on the n-gram size to prevent repetitive content. We selected the number of beams based on the trade-off between summary quality and processing speed. Additionally, we used standard optimizers and learning rates to help the models converge without overfitting. Finally, we chose the number of epochs based on early stopping as explained by Bai et al. (2021), which we enabled to prevent overfitting. These hyperparameters were tested on a dataset of podcast episodes and validated using standard evaluation metrics.

5 Evaluation

In this section, we present the results of our evaluation, which was conducted on the test set consisting of 1,027 podcast episodes. In addition to the automated metrics, we conducted a human evaluation to gain a better understanding of how people interpret the generated summaries, especially since the creator-provided descriptions were of poor quality.

For automated metrics, we used ROUGE (Lin, 2004) and BERTScore (Zhang et al., 2020). ROUGE score automatically determines the quality of a summary by comparing it to reference summaries. It does this by counting the number of overlapping units, such as word sequences, n-grams, and word pairs between the sets of summaries (Lin, 2004). However, since the aim of abstractive text summarisation is to generate new sentences in the final summary, this metric may not be appropriate. Therefore, we also used BERTScore to better understand the semantic meaning of the summaries. BERTScore computes a similarity score for each token in the candidate sentence with each token in the reference sentence using contextual word embedding. This metric has been shown to correlate well with human judgement (Zhang et al., 2020). Two variants of BERTScore were used: one that utilises IDF weightings and another that does not.

BERTScore		
Model	**F1 Score(%)**	
IDF Weighting	**Yes**	**No**
BART Fine-tuned	80.25	**82.21**
T5 Fine-tuned	**80.43**	82.17
T5 Base	76.74	79.06

Table 1: F1 Measure of BERT Score.

The F1 measure of BERTScore and the F1 measure of ROUGE-1, ROUGE-2, and ROUGE-L are summarised in Table 1 and Table 2, respectively. These results were used to compare the models as well as the pre-trained model.

Model	**R1-F**	**R2-F**	**RL-F**
BART FT	**19.16**	**4.43**	**17.06**
T5 FT	16.88	3.27	14.76
T5 Base	16.55	1.60	14.45

Table 2: F1 Measure of ROUGE Scores.
FT: Fine-Tuned.

5.1 Human Evaluation

In order to evaluate how humans judge summaries, we conducted a qualitative evaluation. A total of 50 participants were recruited as volunteers for the study, with ages ranging from 18 to 50 years old. A questionnaire was distributed to the participants as part of the study. To gather more information about the participants and their views on the importance of podcast episode summaries, there were some questions regarding their demographics at the beginning of the study such as occupation and asked participants about their podcast listening habits. Participants were also asked whether they believe a summary of a podcast episode is important and how an accurate summary would be beneficial to them. For this study, it took participants on average 15-20 minutes to complete the questionnaire. Participants were not compensated for their time as their participation was completely voluntary.

A questionnaire was distributed to compare the summaries generated by models and determine their quality. For comparison, participants were required to rank summaries generated by the fine-tuned models and the pre-trained models. They were provided with some information about the episode, such as a link to the episode and necessary metadata. This information was sufficient to determine the episode's context and comprehend the summary. The next set of questions were aimed at determining the quality of the generated summaries based on the Excellent, Good, Fair and Bad scale as shown in Table 5 in the Appendix. The details of each scale were given to the participants, and moreover, participants were asked to describe the reason for their choice of selection. This provided more details into the human evaluation of the project. Figure 3 shows an excerpt from the questionnaire that illustrates the type of questions posed to participants.

5.2 Analysis of Results

The results in Table 2 indicate that the BART model fine-tuned on the podcast dataset achieved a higher ROUGE-1 and ROUGE-L score compared to other models. Similarly, the T5 fine-tuned model outperformed its baseline, as evidenced by its higher ROUGE-1 and ROUGE-L scores. While the BART model fine-tuned on the podcast dataset showed higher ROUGE scores, the difference between the two fine-tuned models was minimal when analysing BERTScores in Table 1. When calculating the semantic meaning of generated summaries with IDF weighting set to true, the T5 fine-tuned model performed better than both the BART model by 0.18 percentage points and the T5 Base by 3.69 percentage points, indicating a strong correlation between the meaning of the generated summaries and the descriptions provided by the creators.

The results of the human evaluation revealed that both the BART and T5 fine-tuned models produced high-quality summaries that were well received by participants. The majority of participants rated the summaries generated by both models as Good or Excellent. This suggests that the summaries were coherent, accurate and provided a meaningful overview of the content of the podcast episode.

The results of the human evaluation (Table 3) indicate that there was minimal difference between the performance of the BART and T5 models, both fine-tuned on the podcast dataset, and that their results were highly comparable. The BART model produced summaries that achieved an Excellent rating of 39.29% and a Good rating of 35.7%, with only 3.57% rated as Bad. These results indicate that the generated summaries were of high quality and were well received by the participants. The T5 fine-tuned model can be similarly described as it obtained a majority of Good ratings, with 44.6% of participants rating it as such.

In contrast, the baseline T5 model (T5 Base) had a high percentage of Bad ratings at 64.3%, indicating that it struggled to capture the meaning and context of the podcast episodes. This highlights the importance of fine-tuning on domain-specific data for generating high-quality summaries.

Participants were also asked to rank the summaries generated by the models for an episode. The evaluation results (Table 4) show that 60.22% of participants ranked the summaries generated by the fine-tuned BART model as first, while 50.55% ranked the fine-tuned T5 as second, and the T5 baseline model was ranked as third by 73.45% of the participants. These findings suggest that both fine-tuned models, particularly BART, generated summaries that were of high quality compared to the baseline. Participants praised the fine-tuned models' summaries for being ”very concise and accurate”, for ”grabbing the reader's attention” and ”containing accurate descriptions of the content that were easy to read.” On the other hand, participants described the baseline model's summary as too long and poorly formatted. Table 6 provides example of summaries generated by the models and the metadata of an episode.

Overall, the evaluation results demonstrate the effectiveness of both the BART and T5 models for summarising podcast episodes. The BART model performed well in terms of ROUGE scores, while the T5 model excelled in capturing the semantic meaning of the summaries. The human evaluation confirmed that the generated summaries were of high quality and provided a meaningful overview of the podcast episode. The success of these models could have significant practical applications, such as assisting listeners in choosing which episodes to listen to or summarising podcasts for users with limited time.

Model	E	G	F	B
BART FT	**39.3%**	35.7%	21.4%	3.57%
T5 FT	25.0%	**44.6%**	**25.0%**	5.4%
T5 Base	8.9%	7.1%	19.7%	**64.3%**

Table 3: The mean percentage of the quality of the generated summaries.

Model	1	2	3
BART FT	**60.22%**	29.64%	10.15%
T5 FT	35.07%	**50.55%**	14.38%
T5 Base	13.60%	12.96%	**73.45%**

Table 4: The table displays the mean percentage of the ranking, which compares three models based on a scale of 1 (best) to 3 (worst).

6 Conclusion

In conclusion, this paper presents a study on the summarisation of podcast episodes using abstractive methods. We explored the use of the BART and T5 models, fine-tuned on a dataset of podcast episode descriptions, and evaluated their performance using automated metrics and human judgement. Our results showed that the fine-tuned models outperformed their pre-trained counterparts and achieved high scores in both ROUGE and BERTScore metrics. Moreover, the human evaluation indicated that the generated summaries were of high quality and well-received by participants. Overall, our findings demonstrate the potential of using abstractive summarisation for podcasts, providing listeners with a quick and accurate summary of episodes.With the help of abstractive text summarisation, podcast creators can implement this technology to automatically generate descriptions for their episodes, which was a manual process in the podcasting industry, helping them save time and allowing the users to read high-quality descriptions for their favourite podcasts. In light of these findings, it is clear that the podcast domain could greatly benefit from the use of NLP technology in generating accurate and concise summaries of audio content. This could help users better manage and discover relevant content, while also making podcast episodes more accessible to individuals with hearing impairments or language barriers in the future. Future work could explore the use of additional features or fine-tuning methods to further improve the performance of the summarisation models on podcast data. Another aspect that can be explored is finding methods to tackle disfluencies in spoken text.Overall, this project has provided valuable insights into the application of NLP in the podcast domain and the potential for improving the accessibility and usability of podcast content.

Episode Name - Interview with Kevin Kiner - Composer for The Clone Wars & Star Wars Rebels (The Last Missions)

For more information, please refer - Episode Link

It was like, you know, I had to go back to my dorm in the late 70s and I realized that I wasn't going to be a doctor or anything like that. You know, when we were doing Star Wars Rebels, you know, I started looking at what George Lucas wanted me to do with his music. Yeah, yeah. It's kind of cool to have him on board because he's so knowledgeable about music and how to make it work for us as artists. And I think that'

We talk about how we got to the end of the Clone Wars series. We also have a guest on the show, Kevin Kiner. He is one of the most talented musicians in the show. They're joined by Dave Filoni who has worked with George Lucas and Kenny Loggins for many years.

Kevin Kiner is the composer for the final season of Star Wars: The Clone Wars. He has received multiple Emmy and Annie nominations as well as 12 BMI Awards. His work includes. Making a murderer narcos Mexico and CSI, Miami and you will especially recognize his music from the Clone Wars and Star Wars Rebels.

Please briefly explain why you selected the summary as your most preferred choice (e.g. readability, accuracy, conciseness, etc.)

Figure 3: One of the questions from qualitative evaluation. This questions asks participants to rank the summaries generated by the models, from 1 (best) to 3 (worst).

Exploring the Landscape of Natural Language Processing Research

Tim Schopf, Karim Arabi, and Florian Matthes
Technical University of Munich, Department of Computer Science, Germany
{tim.schopf,karim.arabi,matthes}@tum.de

Abstract

As an efficient approach to understand, generate, and process natural language texts, research in natural language processing (NLP) has exhibited a rapid spread and wide adoption in recent years. Given the increasing research work in this area, several NLP-related approaches have been surveyed in the research community. However, a comprehensive study that categorizes established topics, identifies trends, and outlines areas for future research remains absent. Contributing to closing this gap, we have systematically classified and analyzed research papers in the ACL Anthology. As a result, we present a structured overview of the research landscape, provide a taxonomy of fields of study in NLP, analyze recent developments in NLP, summarize our findings, and highlight directions for future work. [1]

1 Introduction

Natural language is a fundamental aspect of human communication and inherent to human utterances and information sharing. Accordingly, most human-generated digital data are composed in natural language. Given the ever-increasing amount and importance of digital data, it is not surprising that computational linguists have started developing ideas on enabling machines to understand, generate, and process natural language since the 1950s (Hutchins, 1999).

More recently, the introduction of the transformer model (Vaswani et al., 2017) and pretrained language models (Radford and Narasimhan, 2018; Devlin et al., 2019) have sparked increasing interest in natural language processing (NLP). Submissions on various NLP topics and applications are being published in a growing number of journals and conferences, such as TACL, ACL, and EMNLP, as well as in several smaller workshops that focus on specific areas. Thereby, the ACL Anthology[2] as a repository for publications from many major NLP journals, conferences, and workshops emerges as an important tool for researchers. As of January 2023, it provides access to over 80,000 articles published since 1952. Figure 1 shows the distribution of publications in the ACL Anthology over the 50-year observation period.

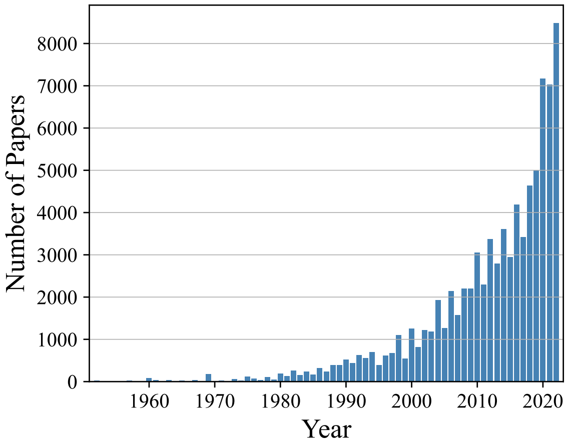

Figure 1: Distribution of the number of papers per year in the ACL Anthology from 1952 to 2022.

Accompanying the increase in publications, there has also been a growth in the number of different fields of study (FoS) that have been researched within the NLP domain. FoS are academic disciplines and concepts that usually consist of (but are not limited to) tasks or techniques (Shen et al., 2018). Given the rapid developments in NLP research, obtaining an overview of the domain and maintaining it is difficult. As such, collecting insights, consolidating existing results, and presenting a structured overview of the field is important. However, to the best of our knowledge, no stud-

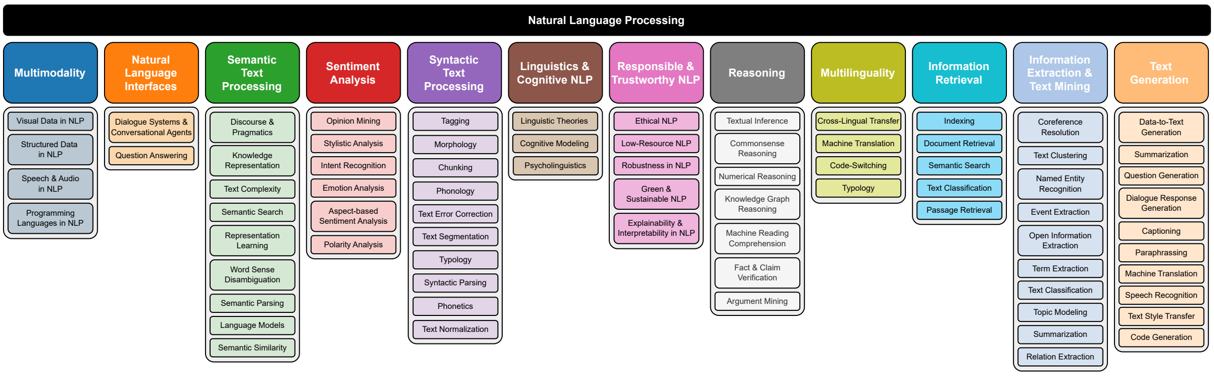

Figure 2: Taxonomy of fields of study in NLP.

ies exist yet that offer an overview of the entire landscape of NLP research. To bridge this gap, we performed a comprehensive study to analyze all research performed in this area by classifying established topics, identifying trends, and outlining areas for future research. Our three main contributions are as follows:

- We provide an extensive taxonomy of FoS in NLP research shown in Figure 2.
- We systematically classify research papers included in the ACL Anthology and report findings on the development of FoS in NLP.
- We identify trends in NLP research and highlight directions for future work.

Our study highlights the development and current state of NLP research. Although we cannot fully cover all relevant work on this topic, we aim to provide a representative overview that can serve as a starting point for both NLP scholars and practitioners. In addition, our analysis can assist the research community in bridging existing gaps and exploring various FoS in NLP.

2 Related Work

Related literature that considers various different FoS in NLP is relatively scarce. Most studies focus only on a particular FoS or sub-field of NLP research.

For example, related studies focus on knowledge graphs in NLP (Schneider et al., 2022), explainability in NLP (Danilevsky et al., 2020), ethics and biases in NLP (Šuster et al., 2017; Blodgett et al., 2020), question answering (Liu et al., 2022b), or knowledge representations in language models (Safavi and Koutra, 2021).

Studies that analyze NLP research based on the entire ACL Anthology focus on citation analyses (Mohammad, 2020a; Rungta et al., 2022) or visualizations of venues, authors, and n-grams and keywords extracted from publications (Mohammad, 2020b; Parmar et al., 2020).

Anderson et al. (2012) apply topic modeling to identify different epochs in the ACL's history.

Various books categorize different FoS in NLP, focusing on detailed explanations for each of these categories (Allen, 1995; Manning and Schütze, 1999; Jurafsky and Martin, 2009; Eisenstein, 2019; Tunstall et al., 2022).

3 Research Questions

The goal of our study is an extensive analysis of research performed in NLP by classifying established topics, identifying trends, and outlining areas for future research. These objectives are reflected in our research questions (RQs) presented as follows:

RQ1: *What are the different FoS investigated in NLP research?*

Although most FoS in NLP are well-known and defined, there currently exists no commonly used taxonomy or categorization scheme that attempts to collect and structure these FoS in a consistent and understandable format. Therefore, getting an overview of the entire field of NLP research is difficult, especially for students and early career researchers. While there are lists of NLP topics in conferences and textbooks, they tend to vary considerably and are often either too broad or too specialized. To classify and analyze developments in NLP, we need a taxonomy that encompasses a wide range of different FoS in NLP. Although this taxonomy may not include all possible NLP concepts, it needs to cover a wide range of the most popular FoS, whereby missing FoS may be considered as subtopics of the included FoS. This taxonomy serves as an overarching classification scheme in which NLP publications can be classified according to at least one of the included FoS, even if they do not directly address one of the FoS, but only subtopics thereof.

RQ2: *How to classify research publications according to the identified FoS in NLP?*

Classifying publications according to the identified FoS in NLP is very tedious and time-consuming. Especially with a large number of FoS and publications, a manual approach is very costly. Therefore, we need an approach that can automatically classify publications according to the different FoS in NLP.

RQ3: *What are the characteristics and developments over time of the research literature in NLP?*

To understand past developments in NLP research, we examine the evolution of popular FoS over time. This will allow a better understanding of current developments and help contextualize them.

RQ4: *What are the current trends and directions of future work in NLP research?*

Analyzing the classified research publications allows us to identify current research trends and gaps and predict possible future developments in NLP research.

4 Classification & Analysis

In this section, we report the approaches and results of the data classification and analysis. It is structured according to the formulated RQs.

4.1 Taxonomy of FoS in NLP research (RQ1)

To develop the taxonomy of FoS in NLP shown in Figure 2, we first examined the submission topics of recent years as listed on the websites of major NLP conferences such as ACL, EMNLP, COLING, or IJCNLP. In addition, we reviewed the topics of workshops included in the ACL Anthology to derive further FoS. In order to include smaller topics that are not necessarily mentioned on conference or workshop websites, we manually reviewed all papers from the recently published EMNLP 2022 Proceedings, extracted their FoS, and annotated all 828 papers accordingly. This provided us with an initial set of FoS, which we used to create the first version of the NLP taxonomy. Based on our initial taxonomy, we conducted semi-structured expert interviews with NLP researchers to evaluate and adjust the taxonomy. In the interviews, we placed particular emphasis on the evaluation of the mapping of lower-level FoS to their higher-level FoS, and the correctness and completeness of FoS in the NLP domain. In total, we conducted more than 20 one-on-one interviews with different domain experts. After conducting the interviews, we noticed that experts demonstrated a high degree of agreement on certain aspects of evaluation, while opinions were highly divergent on other aspects. While we easily implemented changes resulting based on high expert agreement, we acted as the final authority in deciding whether to implement a particular change for aspects with low expert agreement. For example, one of the aspects with the highest agreement was that certain lower-level FoS must be assigned not only to one but also to multiple higher-level FoS. Based on the interview results, we subsequently adjusted the annotations of the 828 EMNLP 2022 papers and developed the final NLP-taxonomy, as shown in Figure 2.

4.2 Field of Study Classification (RQ2)

We trained a weakly supervised classifier to classify ACL Anthology papers according to the NLP

Dataset →	*Validation*			*Test*		
Model ↓	**P**	**R**	**F_1**	**P**	**R**	**F_1**
BERT	**96.57**±**0.14**	95.43±0.16	96.00±0.03	89.77±0.20	93.58±0.07	91.64±0.10
RoBERTa	95.77±0.19	95.19±0.16	95.48±0.17	87.46±2.75	93.29±0.10	90.27±1.42
SciBERT	96.44±0.17	95.65±0.14	96.05±0.10	90.18±3.17	**94.05**±**0.06**	92.06±1.65
SPECTER 2.0	96.44±0.11	95.69±0.14	**96.06**±**0.08**	**92.46**±**2.58**	93.99±0.22	**93.21**±**1.39**
SciNCL	96.39±0.11	**95.71**±**0.09**	96.05±0.04	89.97±1.85	93.74±0.18	91.81±0.93

Table 1: Evaluation results for classifying papers according to the NLP taxonomy on three runs over different random train/validation splits. Since the distribution of classes is very unbalanced, we report micro scores.

Table 2: Overview of the most popular FoS in NLP literature. Representative papers consist of either highly cited studies or comprehensive surveys on the respective FoS.

taxonomy. To obtain a training dataset, we first defined keywords for each FoS included in the final taxonomy to perform a database search for relevant articles. Based on the keywords, we created search strings to query the Scopus and arXiv databases. The search string was applied to titles and author keywords, if available. While we limited the Scopus search results to the NLP domain with additional restrictive keywords such as ”NLP”, ”natural language processing”, or ”computational linguistics”, we limited the search in arXiv to the cs.CL domain. We subsequently merged duplicate articles to create a multi-label dataset and removed articles included in the EMNLP 2022 proceedings, as this dataset is used as test set. Finally, we applied a fuzzy string matching heuristic and added missing classes based on the previously defined FoS keywords that appear twice or more in the article titles or abstracts. The final training dataset consists of 178,521 articles annotated on average with 3.65 different FoS. On average, each class includes 7936.50 articles, while the most frequent class is represented by 63728 articles and the least frequent class by 141 articles. We split this unevenly distributed dataset into three different random 90/10 training/validation sets and used the human-annotated EMNLP 2022 articles as the test dataset.

For multi-label classification, BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), SciBERT (Beltagy et al., 2019), SPECTER 2.0 (Cohan et al., 2020; Singh et al., 2022), and SciNCL (Ostendorff et al., 2022) models were fine-tuned in their base versions on the three different training datasets and evaluated on their respective validation and test datasets. We trained all models for three epochs, using a batch size of 8, a learning rate of $5e-5$, and the AdamW optimizer (Loshchilov and Hutter, 2019).

The evaluation results are shown in Table 1. SPECTER 2.0 shows significant performance on both validation and test data. Therefore, we selected SPECTER 2.0 as our final classification model, which we subsequently trained with the same parameters on the combined training, validation, and test data. Using the final model, we classified all papers included in the ACL Anthology from 1952 to 2022. To obtain our final dataset for analysis, we removed the articles that were not truly research articles, such as prefaces; articles that were not written in English; and articles where the classifier was uncertain and simply predicted every class possible. This final classified dataset includes a total of 74,279 research papers. Table 2 shows the final classification results with respect to the number of publications for each of the most popular FoS.

4.3 Characteristics and Developments of the Research Landscape (RQ3)

Considering the literature on NLP, we start our analysis with the number of studies as an indicator of research interest. The distribution of publications over the 50-year observation period is

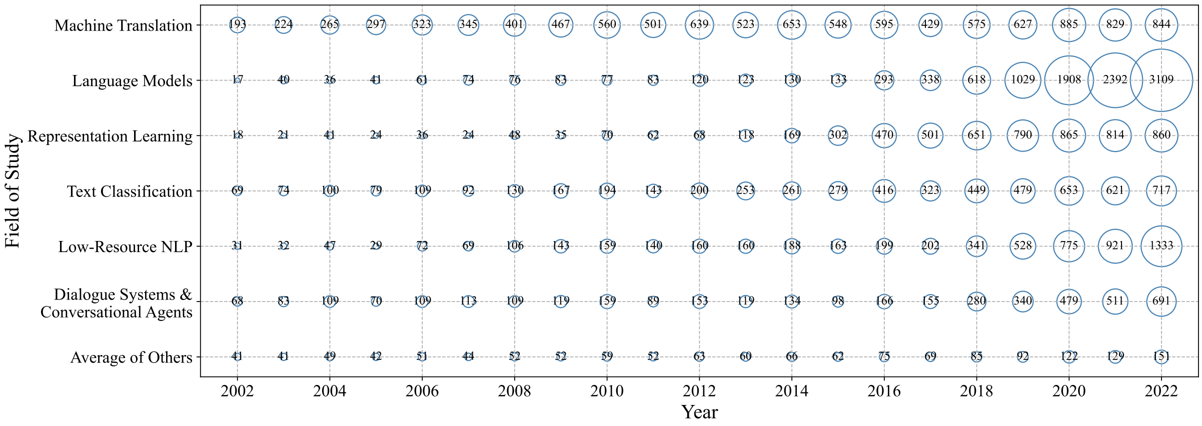

Figure 3: Distribution of number of papers by most popular FoS from 2002 to 2022.

shown in Figure 1. While the first publications appeared in 1952, the number of annual publications grew slowly until 2000. Accordingly, between 2000 and 2017, the number of publications roughly quadrupled, whereas in the subsequent five years it has doubled again. We therefore observe a near-exponential growth in the number of NLP studies, indicating increasing attention from the research community.

Examining Table 2 and Figure 3, the most popular FoS in the NLP literature and their recent development over time are revealed. While the majority of studies in NLP are related to machine translation or language models, the developments of both FoS are different. Machine translation is a thoroughly researched field that has been established for a long time and has experienced a modest growth rate over the last 20 years. Language models have also been researched for a long time. However, the number of publications on this topic has only experienced significant growth since 2018. Similar differences can be observed when looking at the other popular FoS. Representation learning and text classification, while generally widely researched, are partially stagnant in their growth. In contrast, dialogue systems & conversational agents and particularly low-resource NLP continue to exhibit high growth rates in the number of studies. Based on the development of the average number of studies on the remaining FoS in Figure 3, we observe a slightly positive growth overall. However, the majority of FoS are significantly less researched than the most popular FoS. We conclude that the distribution of research across FoS is extremely unbalanced and that the development of NLP research is largely shaped by advances in a few highly popular FoS.

4.4 Research Trends and Directions for Future Work (RQ4)

Figure 4 shows the growth-share matrix of FoS in NLP research inspired by Henderson (1970). We use it to examine current research trends and possible future research directions by analyzing the growth rates and total number of papers related to the various FoS in NLP between 2018 and 2022. The upper right section of the matrix consists of FoS that exhibit a high growth rate and simultaneously a large number of papers overall. Given the growing popularity of FoS in this section, we categorize them as *trending stars*. The lower right section contains FoS that are very popular but exhibit a low growth rate. Usually, these are FoS that are essential for NLP research but already relatively mature. Hence, we categorize them as *foundational FoS*. The upper left section of the matrix contains FoS that exhibit a high growth rate but only very few papers overall. Since the progress of these FoS is rather promising, but the small number of overall papers renders it difficult to predict their further developments, we categorize them as *rising question marks*. The FoS in the lower left of the matrix are categorized as *niche FoS* owing to their low total number of papers and their low growth rates.

Figure 4 shows that language models are currently receiving the most attention, which is also consistent with the observations from Table 2 and Figure 3. Based on the latest developments in this area, this trend is likely to continue and accelerate in the near future. Text classification, machine translation, and representation learning rank among the most popular FoS, but only show marginal growth. In the long term, they may be replaced by faster-growing fields as the most popular FoS.

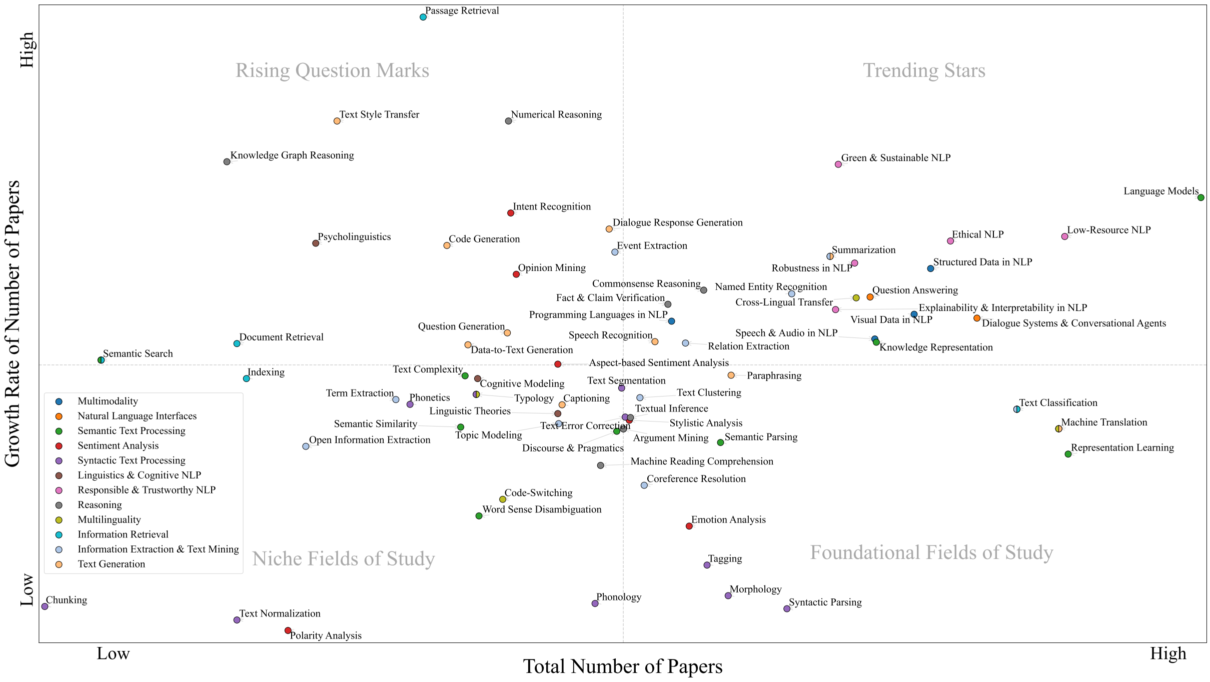

Figure 4: Growth-share matrix of FoS in NLP. The growth rates and total number of works for each FoS are calculated from the start of 2018 to the end of 2022. To obtain a more uniform distribution of the data, we apply the Yeo-Johnson transformation (Yeo and Johnson, 2000).

In general, FoS related to syntactic text processing exhibit negligible growth and low popularity overall. Conversely, FoS concerned with responsible & trustworthy NLP, such as green & sustainable NLP, low-resource NLP, and ethical NLP tend to exhibit a high growth rate and also high popularity overall. This trend can also be observed in the case of structured data in NLP, visual data in NLP, and speech & audio in NLP, all of which are concerned with multimodality. In addition, natural language interfaces involving dialogue systems & conversational agents and question answering are becoming increasingly important in the research community. We conclude that in addition to language models, responsible & trustworthy NLP, multimodality, and natural language interfaces are likely to characterize the NLP research landscape in the near future.

Further notable developments can be observed in the area of reasoning, specifically with respect to knowledge graph reasoning and numerical reasoning and in various FoS related to text generation. Although these FoS are currently still relatively small, they apparently attract more and more interest from the research community and show a clear positive tendency toward growth.

5 Discussion

The observations of our comprehensive study reveal several insights that we can situate to related work. Since the first publications in 1952, researchers have paid increasing attention to the field of NLP, particularly after the introduction of Word2Vec (Mikolov et al., 2013) and accelerated by BERT (Devlin et al., 2019). This observed growth in research interest is in line with the study of Mohammad (2020b). Historically, machine translation was one of the first research fields in NLP (Jones, 1994), which continues to be popular and steadily growing nowadays. However, recent advances in language model training have sparked increasing research efforts in this field, as shown in Figure 3 and Figure 4. Since scaling up language models significantly enhance performance on downstream tasks (Brown et al., 2020; Kaplan et al., 2020; Wei et al., 2022a; Hoffmann et al., 2022), researchers continue to introduce increasingly larger language models (Han et al., 2021). However, training and using these large language models involves significant challenges, including computational costs (Narayanan et al., 2021), environmental issues (Strubell et al., 2019), and ethical considerations (Perez et al., 2022). As a result, a recent increase in research efforts has been noted to render language models and NLP more responsible & trustworthy in general, as shown in Figure 4. Additionally, recent advances aim to train large-scale multimodal language models capable of understanding and generating natural language text and performing all types of downstream tasks while interacting with humans through natural language input prompts (OpenAI, 2023). From our observations in Figure 4, we again find support for this trend in NLP literature for multimodality, text generation, and natural language interfaces.

Although language models have achieved remarkable success on various NLP tasks, their inability to reason is often seen as a limitation that cannot be overcome by increasing the model size alone (Rae et al., 2022; Wei et al., 2022b; Wang et al., 2023). Although reasoning capabilities are a crucial prerequisite for the reliability of language models, this field is still relatively less researched and receives negligible attention. While Figure 4 exhibits high growth rates for knowledge graph reasoning and numerical reasoning in particular, research related to reasoning is still rather underrepresented compared to the more popular FoS.

6 Conclusion

Recent years have witnessed an increasing prominence of NLP research. To summarize recent developments and provide an overview of this research area, we defined a taxonomy of FoS in NLP and analyzed recent research developments.

Our findings show that a large number of FoS have been studied, including trending fields such as multimodality, responsible & trustworthy NLP, and natural language interfaces. While recent developments are largely a result of recent advances in language models, we have noted a lack of research pertaining to teaching these language models to reason and thereby afford more reliable predictions.

7 Limitations

Constructing the taxonomy highly depends on the personal decisions of the authors, which can bias the final result. The taxonomy may not cover all possible FoS and offers potential for discussions, as domain experts have inherently different opinions. As a countermeasure, we aligned the opinions of multiple domain experts and designed the taxonomy at a higher level, allowing non-included FoS to be considered as possible subtopics of existing ones.

For this study, we limited our analysis to papers published in the ACL Anthology, which typically feature research presented at major international conferences and are written in English. However, research communities that publish their work in regional venues exist, often in languages other than English. In addition, NLP research is also presented at other prominent global conferences such as AAAI, NeurIPS, ICLR, or ICML. Therefore, the findings we report in this study pertain specifically to NLP research presented at major international conferences and journals in English.

Furthermore, the accuracy of the classification results poses another threat to the validity of our study. Data extraction bias and classification model errors may negatively affect the results. To mitigate this risk, the authors regularly discussed the used classification schemes and conducted a thorough evaluation of the performance of the classification model.

Efficient Domain Adaptation of Sentence Embeddings Using Adapters

Tim Schopf, Dennis N. Schneider, and Florian Matthes
Technical University of Munich, Department of Computer Science, Germany
{tim.schopf,dennis.schneider,matthes}@tum.de

Abstract

Sentence embeddings enable us to capture the semantic similarity of short texts. Most sentence embedding models are trained for general semantic textual similarity tasks. Therefore, to use sentence embeddings in a particular domain, the model must be adapted to it in order to achieve good results. Usually, this is done by fine-tuning the entire sentence embedding model for the domain of interest. While this approach yields state-of-the-art results, all of the model's weights are updated during fine-tuning, making this method resource-intensive. Therefore, instead of fine-tuning entire sentence embedding models for each target domain individually, we propose to train lightweight adapters. These domain-specific adapters do not require fine-tuning all underlying sentence embedding model parameters. Instead, we only train a small number of additional parameters while keeping the weights of the underlying sentence embedding model fixed. Training domain-specific adapters allows always using the same base model and only exchanging the domain-specific adapters to adapt sentence embeddings to a specific domain. We show that using adapters for parameter-efficient domain adaptation of sentence embeddings yields competitive performance within 1% of a domain-adapted, entirely fine-tuned sentence embedding model while only training approximately 3.6% of the parameters.

1 Introduction

Learning sentence embeddings is an essential task in natural language processing (NLP) and has already been extensively investigated in the literature (Kiros et al., 2015; Hill et al., 2016; Conneau et al., 2017; Logeswaran and Lee, 2018; Cer et al., 2018; Reimers and Gurevych, 2019; Gao et al., 2021; Wu et al., 2022; Schopf et al., 2023d,a). Sentence embeddings are especially useful in information retrieval (Lewis et al., 2020; Schopf et al., 2022; Schneider et al., 2022) or unsupervised text classification settings (Schopf et al., 2021, 2023b,c). Lately, the most popular approach for sentence embedding learning is to fine-tune pretrained language models with a contrastive learning objective (Liu et al., 2021; Zhang et al., 2022; Chuang et al., 2022; Nishikawa et al., 2022; Cao et al., 2022; Jiang et al., 2022). While this approach provides state-of-the-art results, all of the model's weights are updated during fine-tuning, making this method resource-intensive. This is a problem, particularly when domain-specific models are needed. Then, a specialized model must be trained for each domain of interest, resulting in resource-intensive training.

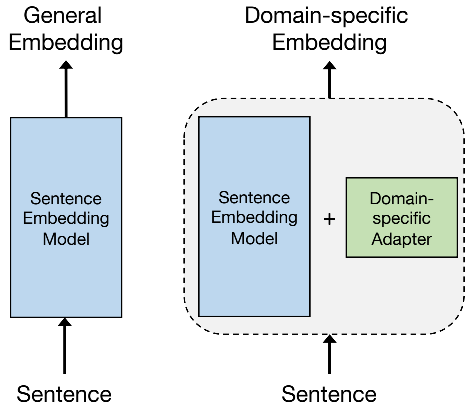

Figure 1: Sentence embedding models are usually trained to obtain state-of-the-art sentence representations for general semantic textual similarity tasks. By injecting domain-specific knowledge of adapters into the sentence embedding model, we can efficiently adapt the resulting representations for semantic textual similarity tasks in different domains.

Recently, *adapters* have emerged as a parameter-efficient strategy to fine-tune Language Models (LMs). Adapters do not require fine-tuning of all parameters of the pretrained model and instead introduce a small number of task-specific parameters while keeping the underlying pretrained lan-

Proceedings of Recent Advances in Natural Language Processing, pages 1046–1053
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_112

guage model fixed (Pfeiffer et al., 2021a). They enable efficient parameter sharing between tasks and domains by training many task-specific, domain-specific, and language-specific adapters for the same model, which can be exchanged and combined post-hoc (Pfeiffer et al., 2020a). Therefore, many different adapter architectures have been proposed for various domains and tasks (Pfeiffer et al., 2020b, 2021b; Vidoni et al., 2020; He et al., 2021; Le et al., 2021; Parović et al., 2022; Lee et al., 2022). However, to the best of our knowledge, no method currently exists for efficient domain adaptation of sentence embeddings using adapters.

In this paper, we aim to bridge this gap by proposing approaches for adapter-based domain adaptation of sentence embeddings, allowing us to train models for many different domains efficiently. Therefore, we investigate how to adapt general pretrained sentence embedding models to different domains using domain-specific adapters. As shown in Figure 1, this allows always using the same base model to adapt sentence embeddings to a specific domain and only needing to exchange the domain-specific adapters. Accordingly, we train lightweight adapters for each domain and avoid expensive training of entire sentence embedding models.

2 Related Work

Adapters have been introduced by Houlsby et al. (2019) as a parameter-efficient alternative for task-specific fine-tuning of language models. Since their introduction, adapters have been used to fine-tune models for single tasks as well as in multi-task settings (Pfeiffer et al., 2021a). Usually, adapters are used to solve tasks such as classification (Lauscher et al., 2020), machine translation (Baziotis et al., 2022), question answering (Pfeiffer et al., 2022), or reasoning (Pfeiffer et al., 2021a). While there exist adapters for semantic textual similarity (STS) tasks on the *AdapterHub* (Pfeiffer et al., 2020a), these are trained on general STS datasets using a task-unspecific pretrained language model as a basis. We, however, focus on adapting pretrained sentence embedding models to specific domains using adapters.

3 Method

We assume we have a base sentence embedding model from the source domain and labeled datasets for each target domain. Instead of fine-tuning the entire sentence embedding model for each target domain individually, we train lightweight adapters for each domain. This domain-specific fine-tuning with adapters involves adding a small number of new parameters to the sentence embedding model. During training, the parameters of the sentence embedding model are frozen, and only the weights of the adapters are updated. Formally, we adopt the general definition for adapter-based fine-tuning of Pfeiffer et al. (2021a) as follows:

For each of the N domains, the sentence embedding model is initialized with parameters Θ_0. Additionally, a set of new and randomly initialized adapter parameters Φ_n are introduced. The parameters Θ_0 are fixed and only the parameters Φ_n are trained. Given training data D_n and a loss function L, the objective for each domain $n \in 1, ..., N$ is of the form:

$$\Phi_n \leftarrow \underset{\Phi}{\operatorname{argmin}}\, L(D_n; \Theta_0, \Phi) \tag{1}$$

Usually, the adapter parameters Φ_n are significantly less than the parameters Θ_0 of the base model (Pfeiffer et al., 2021a), e.g., only 3.6% of the parameters of the pretrained model in Houlsby et al. (2019).

4 Experiments

In this section, we describe the used adapter architectures, loss functions, and datasets. In all experiments, we use SimCSE$_{sup-bert-base}$ (Gao et al., 2021) as the base sentence embedding model. It is trained on natural language inference (NLI) datasets (Bowman et al., 2015; Williams et al., 2018) for STS tasks in the general domain. We fine-tune all models and adapters for five epochs using a learning rate of $1e^{-5}$.

4.1 Adapter Architectures

We investigate how different adapter architectures affect the domain adaptability of sentence embedding models.

Houlsby-Adapter This adapter, introduced by Houlsby et al. (2019), uses a bottleneck architecture. The adapter modules are added after both the multi-head attention and feed-forward block in each transformer layer (Vaswani et al., 2017) of the base model. The adapter layers transform their input into a very low-dimensional representation and upsample it again to the same dimension in the output. This generates a parameter-efficient lower-dimensional representation while most information is kept.

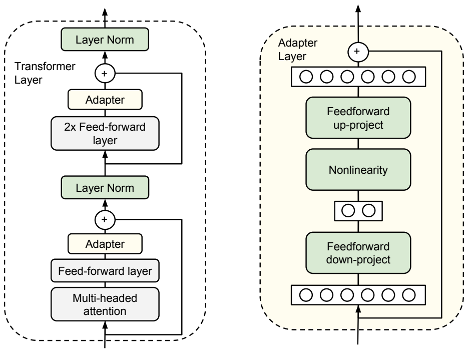

Figure 2: Houlsby-Adapter architecture as introduced by Houlsby et al. (2019). On the left side, the adapter is illustrated to be added twice to each transformer layer. Once after the multi-head attention and once after the feed-forward layer. On the right side, the bottleneck architecture of the adapter is presented.

Pfeiffer-Adapter This adapter, introduced by Pfeiffer et al. (2021a), also uses a bottleneck architecture. However, the adapter modules are added only after the feed-forward block in each transformer layer of the base model. This architecture allows merging multiple adapters trained on different tasks. In this work, however, this multitask learning capability is not needed, and we only use the single-task mode.

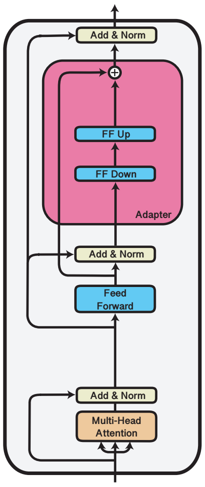

Figure 3: Pfeiffer-Adapter architecture as introduced by Pfeiffer et al. (2021a). Unlike the Houlsby-Adapter, a single Pfeiffer-Adapter is added in each transformer block only after the forward layer.

K-Adapter This adapter, introduced by Wang et al. (2021), works as outside plug-in for the base model. Each adapter model consists of K adapter layers containing N transformer layers and two projection layers across which a skip connection is applied. The adapter layers combine the output of an intermediate transformer layer in the base model with the output of a previous adapter layer. To generate the final output, the last hidden states of the adapter are concatenated with the last hidden states of the base model and transformed into the correct output dimension with a simple dense layer.

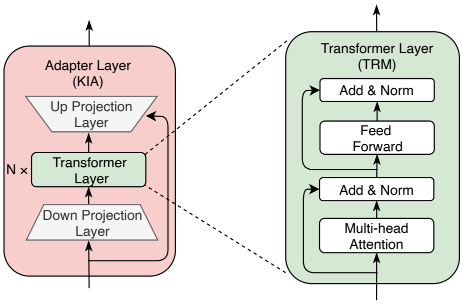

Figure 4: K-Adapter architecture as introduced by Wang et al. (2021). The adapter layer (left) consists of two projection layers, $N = 2$ transformer layers, and a skip connection between two projection layers. The adapter layers are plugged among different transformer layers of the base model. The final output consists of the concatenated last hidden states of the adapter and the base model.

For reference, Table 1 shows the number of parameters per adapter model compared to commonly used base models, highlighting the efficient nature of adapters.

	BERT-base	**RoBERTa-large**

No. of Parameters **Pfeiffer-Adapter**	10M	12M
No. of Parameters **K-Adapter**	47M	47M

Table 1: Number of trainable Parameters for different base models and adapter architectures.

4.2 Loss Functions

We investigate two different loss functions that are proven to teach models to learn a notion of STS from triplets of examples. We assume a set of triplets $\mathcal{D} = \{(x_i, x_i^+, x_i^-)\}$, where x_i is an anchor sentence, x_i^+ is a positive sample and x_i^- is a negative sample. With h_i, h_i^+, and h_i^- as represen-

	Datasets →	AskUbuntu	SciDocs				Average

	K-Adapter	62.8	85.3	87.92	80.05	83.29	79.87
	In-domain supervised SimCSE *(upper bound)*	65.2	88.3	88.11	84.46	83.63	81.94

Table 2: Evaluation results of the adapter-based domain adaptation using the different loss functions ℓ_1 and ℓ_2. The evaluation metric is Mean Average Precision (MAP). We show the performance of the SimCSE model without domain-specific fine-tuning as a lower bound. Additionally, we show the performance of SimCSE models using traditional fine-tuning with the respective loss functions as upper bounds. For the upper bounds, all model weights have been updated during training. In contrast, only the adapter weights were updated during adapter training while the base model parameters were frozen. In bold, we highlight the best adapter performance overall and underline the best adapter results per loss function.

tations of x_i, x_i^+, and x_i^-, we use the triplet margin loss function of Cohan et al. (2020) as follows:

$$\ell_1 = \max\{(d(h_i, h_i^+) - d(h_i, h_i^-) + m), 0\} \quad (2)$$

where d is the L2 norm distance function and m is the loss margin hyperparameter set to 1.

Additionally, we use the contrastive objective of Gao et al. (2021) as follows:

$$\ell_2 = -\log \frac{e^{sim(h_i,h_i^+)/\tau}}{\sum_{j=1}^{N}(e^{sim(h_i,h_j^+)/\tau}+e^{sim(h_i,h_j^-)/\tau})} \quad (3)$$

with a mini-batch of N triplets, a temperature hyperparameter τ, which is empirically set to 0.05, and $sim(h_1, h_2)$ as the cosine similarity $\frac{h_1 \cdot h_2}{||h_1|| \cdot ||h_2||}$.

4.3 Data

We use datasets from two different domains to evaluate the domain adaptation abilities of our approach. We randomly split both domain-specific datasets into 90% training and 10% test datasets.

SciDocs The SciDocs dataset (Cohan et al., 2020) consists of scientific papers and their citation information. As model input, we concatenate the titles and abstracts of papers with the [SEP] token. Since our model has a maximum input length of 512 tokens, the input is cut off after this threshold. A positive sample is defined as a directly referenced paper for each anchor sample. A negative sample is a paper referenced by the positive sample but not by the anchor sample itself. This approach ensures that all samples address the same topic, but the positive sample is more related to the anchor sample than the negative one.

AskUbuntu The AskUbuntu dataset (Lei et al., 2016) consists of user posts from the technical forum AskUbuntu. It already includes sentence pairs that are deemed similar. Therefore, anchor- and positive samples are easily found. Since the dataset inherently consists of sentences about a similar topic, the operating system Ubuntu, negative sentences can easily be retrieved by sampling different sentences. The dataset originates from a technical domain and is quite different from the scientific domain of SciDocs.

5 Evaluation

Table 2 shows the results obtained when adapting sentence embedding models to different domains with adapters. To put the adapter results into perspective, we also evaluate the performance of the SimCSE base model, which is not adapted to the specific domains, as a lower bound. Furthermore, we use traditional domain-specific fine-tuning by training all parameters of the SimCSE base model with the respective loss functions as upper bounds.

The evaluation reveals that adapter-based domain adaptation yields competitive results compared to fine-tuning the entire base model. In particular, the Houlsby and Pfeiffer adapters perform very well with both loss functions, even though they use only a fraction of the parameters of the upper bounds. The slightly larger K-Adapter, however, performs considerably worse than the other adapters investigated. We conclude that the bottleneck architecture is more suitable than the external plug-in architecture for domain adaptation of sentence embedding models. In particular, the Houlsby adapter, although the smallest among the adapters investigated, yields the best results for both loss functions. Using the out-of-the-box SimCSE model without domain adaptation results in considerably worse performance, indicating the overall importance of domain-specific fine-tuning for sentence embedding models.

Furthermore, the contrastive loss function ℓ_2 performs consistently better than ℓ_1. Our results align with the observations of Gao et al. (2021) who conclude that the contrastive objective ensures a distribution of embeddings around the entire embedding space. In contrast, ℓ_1 may yield learned representations occupying a narrow vector space cone, which severely limits their expressiveness.

From the obtained results, we conclude that using the Houlsby-Adapter architecture together with the contrastive objective ℓ_2 is most suitable for parameter-efficient domain adaptation of sentence embedding models. This adapter approach shows performance that is within 1% of the supervised, entirely fine-tuned SimCSE model, while only training approximately 3.6% of the parameters.

6 Conclusion

In this work, we proposed the use of adapters for parameter-efficient domain adaptation of sentence embedding models. In contrast to fine-tuning the entire sentence embedding model for a particular domain, adapters add a small number of new parameters that are updated during training while the weights of the sentence embedding model are fixed. We showed that adapter-based domain adaptation of sentence embedding models yields competitive results compared to fine-tuning the entire model, although only a fraction of the parameters are trained. In particular, we show that using the Houlsby-Adapter architecture together with a contrastive objective yields promising results for parameter-efficient domain adaptation of sentence embedding models.

Abstract

Generic sentence embeddings provide a coarse-grained approximation of semantic textual similarity but ignore specific aspects that make texts similar. Conversely, aspect-based sentence embeddings provide similarities between texts based on certain predefined aspects. Thus, similarity predictions of texts are more targeted to specific requirements and more easily explainable. In this paper, we present AspectCSE, an approach for aspect-based contrastive learning of sentence embeddings. Results indicate that AspectCSE achieves an average improvement of 3.97% on information retrieval tasks across multiple aspects compared to the previous best results. We also propose using Wikidata knowledge graph properties to train models of multi-aspect sentence embeddings in which multiple specific aspects are simultaneously considered during similarity predictions. We demonstrate that multi-aspect embeddings outperform single-aspect embeddings on aspect-specific information retrieval tasks. Finally, we examine the aspect-based sentence embedding space and demonstrate that embeddings of semantically similar aspect labels are often close, even without explicit similarity training between different aspect labels.

1 Introduction

Sentence embeddings are representations of sentences or short text paragraphs in a dense vector space, such that similar sentences are close to each other (Reimers and Gurevych, 2020). Learning sentence embeddings is a fundamental task in natural language processing (NLP) and has already been extensively investigated in the literature (Kiros et al., 2015; Hill et al., 2016; Conneau et al., 2017; Logeswaran and Lee, 2018; Cer et al., 2018; Reimers and Gurevych, 2019; Gao et al., 2021; Schopf et al., 2023d). Generic sentence embeddings can be used to distinguish between similar and dissimilar sentences, without considering which aspects of sentences are similar (Ostendorff et al., 2020a). Moreover, they are often evaluated on generic semantic textual similarity (STS) tasks (Marelli et al., 2014; Agirre et al., 2012, 2013, 2014, 2015, 2016; Cer et al., 2017) in which sentence similarity scores rely on human annotations. However, the concept of generic STS is not well defined, and text similarity depends heavily on the aspects that make them similar (Bär et al., 2011; Ostendorff et al., 2020b, 2022). We follow the argument of Bär et al. (2011) on textual similarity and define *aspects* as inherent properties of texts that must be considered when predicting their semantic similarity. Based on the different aspects focused on in texts, their similarities can be perceived very differently. Figure 1 illustrates an example of aspect-based STS. For example, Wikipedia introduction texts of famous individuals can generally be considered similar as all texts introduce people who are known to the public. However, focusing the comparison on specific aspects (e.g., *country of birth* or *profession*) leads to different semantic similarity assessments for the same texts. Although Wikipedia is a special case as the introduction texts represent specific entities, this characteristic can nevertheless be generalized to different aspects found in any text. When deciding the similarity of texts, different aspects must be considered. Consequently, human-annotated STS datasets introduce considerable subjectivity regarding the evaluated aspects.

Prior work uses siamese networks and a multiple negative ranking loss (Henderson et al., 2017) with only positive samples from the train set to create sentence embeddings for single aspects (Ostendorff et al., 2022). Sentence embeddings for single aspects only consider one specific aspect during similarity comparisons. Using structured knowledge from knowledge graphs (KGs) for language model training has been shown to improve performances on all types of downstream tasks (Schnei-

(a) Generic sentence embeddings

(b) Sentence embeddings based on the *profession* aspect.

(c) Sentence embeddings based on the *country of birth* aspect.

Figure 1: Images of famous people with the corresponding Wikipedia introductory texts as sentence embeddings in a dense vector space. Blue dashed circles represent clusters of semantically similar embeddings. Based on the encoded aspect, embeddings of these same texts can be distributed differently in a vector space. (a) All generic embeddings are close and approximately evenly distributed as the texts introduce famous people. (b) Embeddings that focus on the *profession* aspect are close if the people have similar professions. (c) Embeddings that focus on the *country of birth* aspect are close if the people have similar countries of birth.

der et al., 2022) and also provides the possibility to create sentence embeddings that focus on multiple specific aspects simultaneously. These sentence embeddings are especially useful in information retrieval or unsupervised text classification settings (Schopf et al., 2021, 2022, 2023a,b,c).

In this work, we advance state-of-the-art sentence embeddings for aspect-based STS using AspectCSE, an approach for aspect-based contrastive learning of sentence embeddings. Additionally, we introduce multi-aspect sentence embeddings that simultaneously consider multiple specific aspects during similarity comparisons. We show the effectiveness of multi-aspect sentence embeddings for both information retrieval and exploratory search tasks. Finally, we demonstrate that using KG properties can be extremely beneficial for creating both single- and multi-aspect sentence embeddings.

2 Related Work

In NLP, *aspects* are most commonly examined in sentiment analysis problems (Pontiki et al., 2014; Xue and Li, 2018; Brun and Nikoulina, 2018; Zhang et al., 2021; Yan et al., 2021; Liang et al., 2022). Thus, the goal is to identify the aspects of given target entities and the sentiment expressed for each aspect (Pontiki et al., 2014).

Some works investigate aspect-based STS by considering it as a segmentation task. Chan et al. (2018) first segmented abstracts of research papers according to different aspects. Then, they constructed semantic representations from these aspect-based segments, which can be used to find analogies between research papers. Huang et al. (2020) presented a human-annotated dataset that segments 10,966 English abstracts in the COVID-19 Open Research Dataset (Wang et al., 2020) by the aspects background, purpose, method, result/contribution, and others. Kobayashi et al. (2018) learned multi-vector representations of segmented scientific articles in which each vector encodes a different aspect. However, segmenting texts can harm their coherence and decrease the performance of downstream NLP models (Gong et al., 2020).

Other approaches propose to treat aspect-based STS as a pairwise multi-class classification problem (Ostendorff et al., 2020a,b). However, Reimers and Gurevych (2019) argue that pairwise classification with transformer models results in quadratic complexity. Therefore, this approach is not suitable for large-scale STS tasks.

To address the issues using previous approaches, Ostendorff et al. (2022) proposed training aspect-based embeddings for research papers. In this work, we use AspectCSE and KG properties to train single- and multi-aspect sentence embeddings. This allows us to focus on multiple specific aspects simultaneously while improving the performance of aspect-based sentence embeddings in STS tasks.

Figure 2: AspectCSE uses (*anchor, positive, negative*) triplets to train aspect-specific sentence embedding models. Pairs with the same label for a specific aspect (here: *country of birth*) are used as positives and those with different labels for the same aspect and other in-batch instances as negatives.

3 Embedding Methods

3.1 AspectCSE

Recently, contrastive learning has exhibited state-of-the-art performance for generic sentence embeddings (Gao et al., 2021; Giorgi et al., 2021; Chuang et al., 2022). The contrastive learning objective creates effective representations by pulling semantically close neighbors together and pushing apart non-neighbors (Hadsell et al., 2006). We follow the proposed supervised contrastive learning framework of Gao et al. (2021) and use a cross-entropy-loss with negatives per anchor-positive pair and random in-batch negatives. To train aspect-based sentence embedding models, we assume a set of triplets $\mathcal{D} = \{(x_i^a, x_i^{a+}, x_i^{a-})\}$. Here, x_i^a is an anchor sentence, x_i^{a+} is semantically related, and x_i^{a-} is semantically unrelated to x_i^a with respect to aspect a. With $\mathbf{h}_i^a$, $\mathbf{h}_i^{a+}$, and $\mathbf{h}_i^{a-}$ as representations of x_i^a,x_i^{a+}, and x_i^{a-}, the training objective with a mini-batch of N triplets is expressed as:

$$\ell_i = -\log \frac{e^{sim(\mathbf{h}_i^a, \mathbf{h}_i^{a+})/\tau}}{\sum_{j=1}^{N} (e^{sim(\mathbf{h}_i^a, \mathbf{h}_j^{a+})/\tau} + e^{sim(\mathbf{h}_i^a, \mathbf{h}_j^{a-})/\tau})} \quad (1)$$

where τ is a temperature hyperparameter and $sim(\mathbf{h}_1, \mathbf{h}_2)$ is the cosine similarity $\frac{\mathbf{h}_1 \cdot \mathbf{h}_2}{||\mathbf{h}_1|| \cdot ||\mathbf{h}_2||}$. To encode input sentences, we use BERT-based pretrained language models (Devlin et al., 2019) and fine-tune the parameters using the contrastive objective (Equation 1). Figure 2 illustrates the proposed AspectCSE approach.

3.2 Multiple Negative Ranking Using Anchor-Positive Pairs Only

As a baseline, we perform aspect-based fine-tuning of BERT-based pretrained language models following the state-of-the-art approach of Ostendorff et al. (2022). Therefore, we use mean pooling and a multiple negative ranking loss (Henderson et al., 2017) with anchor-positive pairs for training. Therefore, the training input comprises a set of positive samples $\mathcal{D} = \{(x_i^a, x_i^{a+})\}$ only. During training, every instance $x_j^{a+} = \{x_1^{a+} ... x_{N-1}^{a+}\}$ within a mini-batch of N samples is used as random negative for anchor x_i^a if $i \neq j$.

4 Data

For our experiments, we use two different datasets. First, we use a benchmark dataset derived from Papers with Code (PwC) [1] to evaluate the effectiveness of AspectCSE. We also use Wikipedia and the Wikidata KG (Vrandečić and Krötzsch, 2014) to build a dataset for learning multi-aspect sentence embeddings. In all our experiments, we consider a pair of texts as positive if they share the same label for a particular aspect. Accordingly, negatives comprise a pair of texts with different labels for a particular aspect.

4.1 Papers with Code

The PwC dataset is a collection of research paper abstracts that are annotated with *task*, *method* and *dataset* aspects and their respective labels (Ostendorff et al., 2022). In this dataset, for example, a label of the *task* aspect is *self-supervised learning* or *machine translation*. We obtain the dataset version from 2022-05-25 and remove paper abstracts that belong to aspect labels with more than 100 instances. Abstracts with less than 100 characters are also removed. Table 1 summarizes the resulting PwC dataset. We split the final PwC dataset into 80% training and 20% test paper abstracts for our experiments.

[1] https://paperswithcode.com

Aspect	# Papers	# Labels
Task	32,873	2,481
Method	10,213	1,724
Dataset	7,305	3,611

Table 1: Summary of the PwC dataset.

4.2 Wikipedia and Wikidata

Wikipedia contains a broad range of topics with many possible aspects for each article. We have found that the number of articles regarding companies in Wikipedia accounts for a large portion of the articles, while the introductory sections contain a reasonable amount of different aspects. Therefore, in our experiments focus on a subset of Wikipedia, which includes the introduction section of articles about companies only. Furthermore, we use the commonly occurring aspects *industry (e.g., What type of product/service does the company offer?)* and *country (e.g., What country is the company based in?)* for our experiments. Since Wikipedia comprises unstructured texts only, we take advantage of most Wikidata KG entities being linked to their corresponding Wikipedia articles. We also consider specific Wikidata properties as aspects while using the values linked to a seed article by the specific properties as labels. In this case, we use the Wikidata properties *country* and *industry* as aspects while taking the values linked to the company articles by these properties as labels. Therefore, we follow the approach in Algorithm 1 to construct our dataset.

Algorithm 1 Construct aspect-based dataset

```
Require:
  $companies$ = list of all Wikidata entities $e$ of type business (Q4830453)
  $companies_{annotated} \leftarrow \emptyset$
  procedure ANNOTATE($companies$)
    for $e$ in $companies$ do
      if $e_k$ has Wikipedia article $w_k$ then
        $s$ = introduction section of $w_k$
        $s_c$ = country (P17) value(s) of $e_k$
        $s_i$ = industry (P452) value(s) of $e_k$
        $companies_{annotated} \mathrel{+}= (s, s_c, s_i)$
    return $companies_{annotated}$
```

We use the Wikidata SPARQL API to find the companies as well as the country and industry values linked to them. We also use the Kensho Derived Wikimedia Dataset[2], which comprises preprocessed Wikipedia and Wikidata dumps from 2019-12-01, to obtain the Wikipedia introduction sections of the retrieved companies. Moreover, we utilize the Kensho Derived Wikimedia Dataset to sample 10,000 random articles from different topics without any aspect information. In addition to the company introduction sections, these random articles are used as further negatives during training. This ensures that the model learns to distinguish between different aspect labels and between different topics. Table 2 summarizes the resulting dataset. For example, the labels for the *country* aspect are USA or Germany. For our experiments, we split the final dataset into 80% training and 20% test data.

Aspect	# Articles	# Labels
Industry	6,082	97
Country	2,062	75
Random articles	10,000	-

Table 2: Summary of the Wikipedia + Wikidata dataset.

To train aspect-based sentence embeddings with AspectCSE, we further process the dataset to yield triplets as follows:

- **Single-aspect-specific (Country)**: $(x_i^a, x_i^{a+}, x_i^{a-}) \Rightarrow x_i^{a+}$ and x_i^{a-} are positive and negative samples w.r.t. the country aspect a.
- **Single-aspect-specific (Industry)**: $(x_i^b, x_i^{b+}, x_i^{b-}) \Rightarrow x_i^{b+}$ and x_i^{b-} are positive and negative samples w.r.t. the industry aspect b.
- **Multi-aspect-specific (Intersection)**: $(x_i^{a,b}, x_i^{a+\cap b+}, x_i^{a-\cap b-}) \Rightarrow x_i^{a+\cap b+}$ is a positive sample if it has **both** the same country aspect a **and** the same industry aspect b as the seed sentence.
- **Multi-aspect-specific (Union)**: $(x_i^{a,b}, x_i^{a+\cup b+}, x_i^{a-\cup b-}) \Rightarrow x_i^{a+\cup b+}$ is a positive sample if it has **either** the same country aspect a **or** the same industry aspect b as the seed sentence.

Table 3: Evaluation results for retrieving the $k = 10$ most similar elements for different sentence embedding approaches on the PwC test dataset. *AspectCSE* indicates the training approach explained in Section 3.1. *Multiple Negative Ranking* indicates the training approach explained in Section 3.2. Precision@k (P), Recall@k (R), and Mean Reciprocal Rank@k (MRR) are reported.

5 Experiments

5.1 Comparison with Baselines

To evaluate AspectCSE against state-of-the-art baselines, we use the PwC benchmark dataset described in Section 4.1 for model training and testing.

Generic Sentence Embeddings We evaluate AspectCSE against multiple generic sentence embedding models from the scholarly domain. These models are pretrained on scientific literature and produce domain-specific state-of-the-art sentence embeddings without leveraging any aspect information. We use SciBERT (Beltagy et al., 2019), SPECTER (Cohan et al., 2020), and DeCLUTR (Giorgi et al., 2021) in their `base`-versions as published by their authors without any fine-tuning on our corpus. For SciBERT, we use the concatenated outputs of the last four layers as embeddings.

Parameter	Value
Training epochs	3
Batch size	14
Learning rate	$5e-5$
Max sequence length	320
Pooler type	CLS
Temperature for softmax	0.05
Floating precision	16

Table 4: AspectCSE fine-tuning configuration.

Aspect-based Sentence Embeddings In addition to generic baselines, we train aspect-based sentence embedding models for each PwC aspect using SciBERT and the multiple negative ranking approach, as described in Section 3.2. To train AspectCSE, we use SciBERT as base model and the fine-tuning configuration presented in Table 4. For aspect-specific baseline training with multiple negative ranking, we use the same configuration, except that we follow the approach of Ostendorff et al. (2022), and apply MEAN pooling. For AspectCSE, we follow the argument of Gao et al. (2021), who found that different pooling methods do not matter much and use CLS.

5.2 Multi-aspect Sentence Embeddings

We use the Wikipedia + Wikidata dataset described in Section 4.2 to train and evaluate multi-aspect sentence embeddings. Further, we use AspectCSE to train multi- and single-aspect sentence embedding models for the *country* and *industry* aspects. For fine-tuning, we use BERT$_{\texttt{base}}$ and the training configuration presented in Table 4. To evaluate the performance of generic sentence embeddings on the Wikipedia + Wikidata test dataset, we use a trained SimCSE$_{\texttt{sup-bert-base}}$ model (Gao et al., 2021), which generates state-of-the-art generic sentence embeddings.

6 Evaluation

6.1 Information Retrieval Performance

For evaluation, we follow the approach of Ostendorff et al. (2022) and frame it as an information retrieval task. Therefore, we retrieve the $k = 10$ nearest neighbors for each element in the respective test datasets. After that, we determine the number of retrieved elements that match the particular aspect label of the seed element. We use the following evaluation metrics for this purpose:

- **Precision@k** (P): The number of nearest neighbors (within the top k candidates) that share the same aspect as the seed document divided by k.

Aspects →	*Country*			*Industry*		
Embedding type ↓	**P**	**R**	**MRR**	**P**	**R**	**MRR**
SimCSE$_{\texttt{generic}}$	0.315	0.058	0.523	0.320	0.061	0.531
AspectCSE$_{\texttt{single-aspect}}$	0.390	0.124	0.558	**0.625**	**0.178**	0.729
AspectCSE$_{\texttt{multi-aspect(Intersection)}}$	0.444	0.102	0.593	0.622	0.174	0.720
AspectCSE$_{\texttt{multi-aspect(Union)}}$	**0.555**	**0.163**	**0.738**	0.538	0.155	**0.747**

Table 5: Evaluation results for retrieving the $k = 10$ most similar elements for different sentence embedding approaches on the Wikipedia + Wikidata test dataset. Precision@k (P), Recall@k (R), and Mean Reciprocal Rank@k (MRR) are reported.

- **Recall@k** (R): The number of nearest neighbors (within the top k candidates) that share the same aspect as the seed document divided by the number of labeled documents with the seed document's aspect.

- **Mean Reciprocal Rank@k** (MRR): Measure of the ranking quality for the nearest neighbors, calculated by averaging the reciprocal ranks ($\frac{1}{\text{rank}}$) of each neighbor. This adds more weight to correctly labeled neighbors the higher they rank.

Papers with Code Table 3 compares AspectCSE, generic sentence embedding baselines, and the aspect-based multiple negative ranking baseline. The generic sentence embedding models perform badly for all evaluated aspects. Except for SPECTER, which achieves a respectable MRR score in the *dataset* aspect, generic models always perform significantly worse than aspect-based models. Therefore, aspect-based models retrieve similar texts of the same aspect much better than generic ones. Furthermore, By a large margin, AspectCSE outperforms the multiple negative ranking approach on all aspects and metrics. The average improvement is 3.97% for MRR scores of all PwC aspects. Hence, AspectCSE is a better approach for training aspect-based sentence embedding models. Accordingly, we use AspectCSE to train and evaluate multi-aspect sentence embedding models on the Wikipedia + Wikidata dataset.

Wikipedia and Wikidata Table 5 shows the evaluation results for the multi-aspect sentence embeddings on the Wikipedia + Wikidata test dataset. All AspectCSE models achieve strong performance in both aspects. While we train two separate embedding models for the single-aspect case (one embedding model each for the *country* and *industry* aspects), the multi-aspect models are trained on both

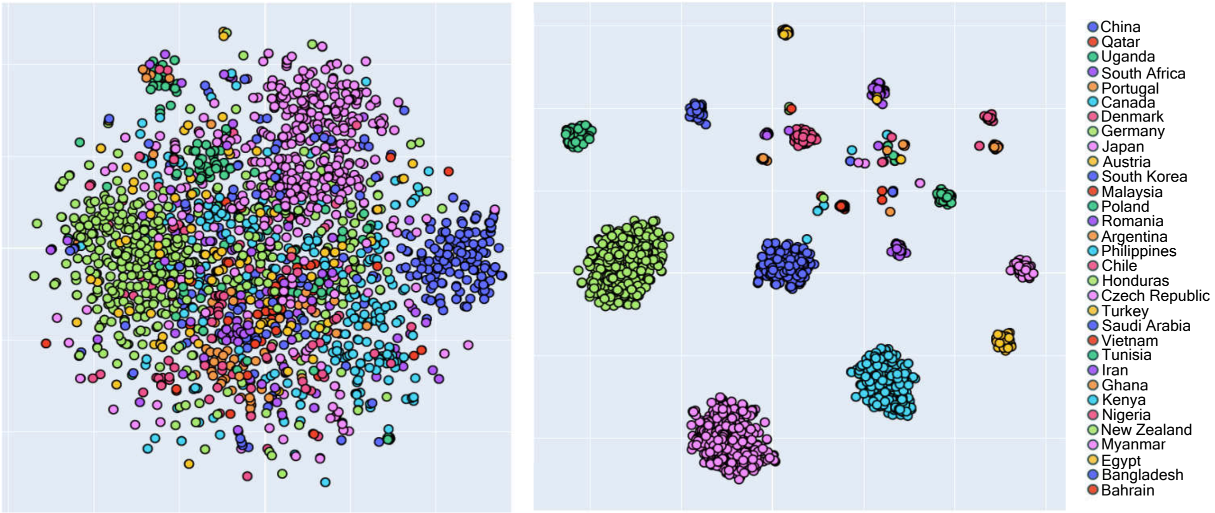

Figure 3: Comparison of generic sentence embeddings (left) vs. single-aspect sentence embeddings based on the *country* aspect (right).

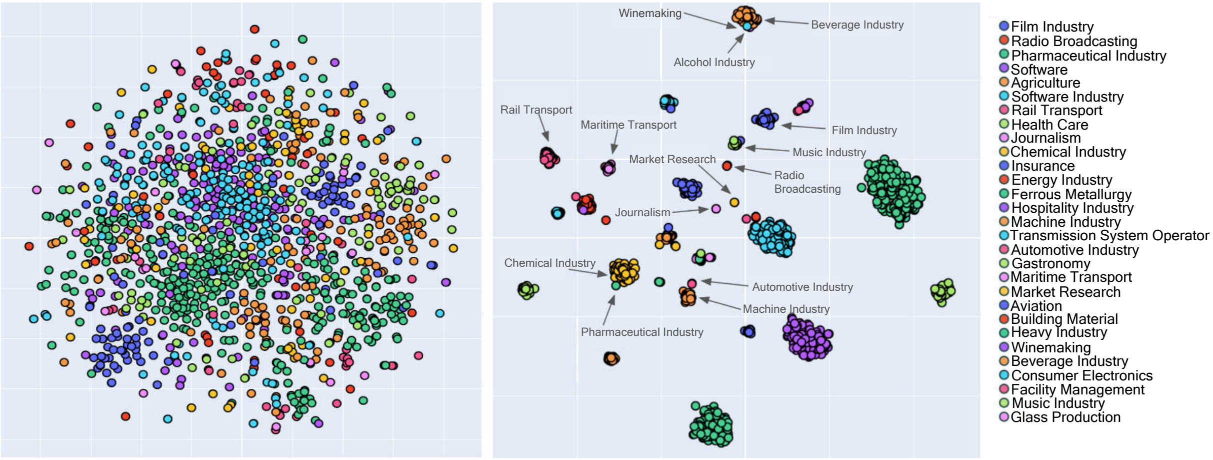

Figure 4: Comparison of generic sentence embeddings (left) vs. single-aspect sentence embeddings based on the *industry* aspect (right).

aspects simultaneously. Therefore, in the multi-aspect cases, only one model is used to retrieve the most similar elements for both aspects. Surprisingly, the best MRR scores for the *country* and *industry* aspects are achieved using the multi-aspect (Union) model, outperforming the multi-aspect (Intersection) and even the single-aspect models. A possible reason is that training sentence embedding models for multiple aspects provides the model with more training data. For example, a correlation exists between the type of industry and certain countries (e.g., Arab countries that have a higher than average density of oil companies) that may function as additional training data for the model.

6.2 Embedding Space Exploration

In addition to the information retrieval evaluation, we visually analyze selected generic, single-, and multi-aspect sentence embeddings. Therefore, we again use the Wikipedia + Wikidata dataset and the trained models described in Section 5.2. We utilize t-SNE (van der Maaten and Hinton, 2008) to reduce the dimensionality of sentence embeddings from 768 to 2 and color all data points according to their aspect labels. Figures 3 and 4 show the embedding spaces of generic and single-aspect sentence embeddings for the *country* and *industry* aspects. In these figures, generic sentence embeddings weakly capture both target aspects, as certain aspect labels dominate some regions. However, no clear separation can be observed between aspect labels and many aspect labels are scattered throughout the entire embedding space. Meanwhile, a sharp separation exists between aspect labels for aspect-based sentence embeddings with dense clusters of elements that share the same aspect label. This finding is consistent with our results in Table 5. Figure 4 shows the local neighborhoods of industry-specific sentence embeddings that reflect the semantic similarity of different industries. We observe that embeddings of the same aspect label are close to each other, and those of semantically similar aspect labels are closer when compared to embeddings with semantically dissimilar aspect labels. For example, embeddings with the semantically related aspect labels ”Film Industry”, ”Music Industry”, and ”Radio Broadcasting” are close to each other, whereas ”Rail Transport” and ”Maritime Transport” are located next to each other.

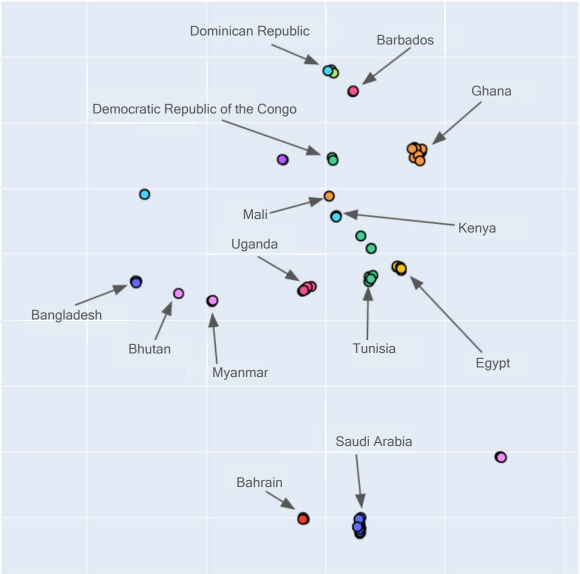

Figure 5: Local embedding space for single-aspect sentence embeddings based on the *country* aspect. The colors represent different aspect labels for the *country* aspect.

Figure 5 shows the local neighborhoods of single-aspect sentence embeddings based on the *country* aspect. We observe a similar behavior as in Figure 4, where embeddings of semantically similar aspect labels are close. For example, country-specific sentence embeddings of African countries (e.g., Kenya, Egypt, and Mali), Arab countries (e.g., Saudi Arabia, Bahrain), and South American countries (e.g., Dominican Republic, Barbados) share local neighborhoods, respectively. Although a correlation exists between semantically similar aspect labels and local neighborhoods in many cases, this pattern is not consistent for all aspect labels. For example, embeddings for the aspect label ”Austria” are closer to the embeddings from ”Japan” than to those for ”Germany”. This similarity pattern is likely a result of the fact that some texts from our training dataset are annotated with multiple aspects (e.g., ”Amazon” is annotated with ”e-commerce”, ”retail”, and ”cloud computing”). Since the model optimizes the embedding for Amazon to be close to e-commerce, retail, and cloud computing companies, all embeddings from these industries are pulled closer together. As the same company often operates in related industries (e.g., e-commerce and retail), this is likely why sentence embeddings of related aspect labels are close to each other. The pattern inconsistency may be partially a consequence of dimensionality reduction, where fine-grained differences between embeddings become lost.

Figure 6 shows the embeddings space for multi-aspect sentence embeddings (Union). This multi-aspect sentence embedding model (Union) learned to keep embeddings close to each other that share either the same *industry* or the same *country* or both aspects. As shown in the figure, only the *industry* aspect is colored, as it is the more dominant aspect for the spatial positioning of embeddings. Figure 6 shows the local neighborhoods that mostly contain embeddings of the same *industry* aspects. Simultaneously, the *country* aspect determines the spatial positioning of embeddings within the individual ”industry clusters”. Sentence embeddings that belong to a certain *industry* aspect, such as ”Automotive” are split into different country-specific sub-clusters. Furthermore, embeddings at the boundary between industries are likely to share the same *country* aspect. This is shown, for example, in ”Automotive Industry (China)” and ”Consumer Electronics (China)” embeddings located next to each other.

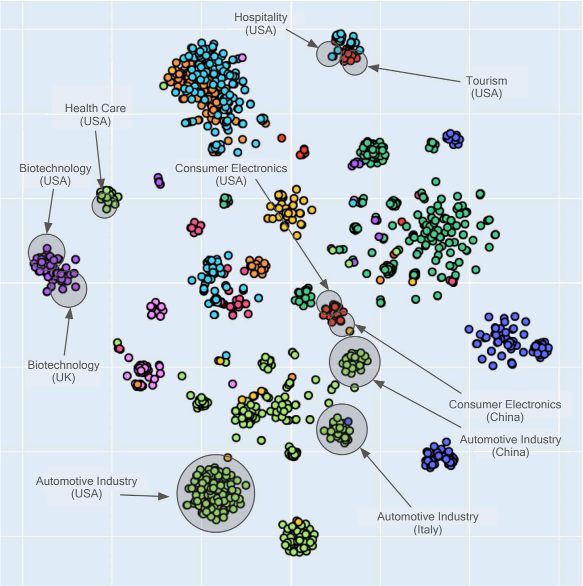

Figure 6: Global embedding space for multi-aspect sentence embeddings (Union). The colors represent different aspect labels for the *industry* aspect. The aspect-based sentence embedding model is trained with the contrastive learning approach stated in Section 3.1 and on the Wikipedia + Wikidata dataset described in Section 4.2

Overall, training AspectCSE using KG properties as aspects performs well in all our evaluations. Moreover, the multi-aspect (Union) model outperforms all other models by a large margin. Therefore, using KG properties and AspectCSE to train single-aspect and especially multi-aspect sentence embedding models achieves meaningful results in STS tasks.

7 Conclusion

In this work, we proposed using Wikidata knowledge graph properties to train single-aspect and multi-aspect sentence embedding models. Unlike single-aspect sentence embeddings, multi-aspect sentence embeddings consider multiple specific aspects simultaneously during similarity comparisons. We regarded STS as an information retrieval task and introduced the AspectCSE approach for training aspect-based sentence embedding models that achieve state-of-the-art performance on the PwC benchmark dataset. Furthermore, we demonstrated that training aspect-based sentence embedding models on multiple aspects simultaneously even surpasses the performance of single-aspect sentence embedding models. Finally, we show that the semantic similarity between different aspect labels is often connected to spatial proximity in the embedding space. This behavior is even clear if we train sentence embedding models only for similarity within the same aspect label but not explicitly for similarity between different aspect labels.

8 Limitations

AspectCSE only works for domains and languages with pretrained language models available for fine-tuning. Furthermore, using Wikidata KG properties to train single-aspect and multi-aspect sentence embedding models requires the availability of this structured information in large quantities. For widely used languages and domains, this requirement may be given. However, for under-represented languages and domains, Wikidata information is sparse, which has a negative impact on AspectCSE. Moreover, we evaluated our approach using texts that comprise entire paragraphs. Whether AspectCSE can also properly represent the specific aspects contained in individual sentences needs to be investigated in future work. Finally, training AspectCSE using CPU only is not feasible. Therefore, we used a Nvidia v100 GPU for AspectCSE training.

Tackling the Myriads of Collusion Scams on YouTube Comments of Cryptocurrency Videos

Abstract

Despite repeated measures, YouTube's comment section has been a fertile ground for scammers. With the growth of the cryptocurrency market and obscurity around it, a new form of scam, namely "Collusion Scam" has emerged as a dominant force within YouTube's comment space. Unlike typical scams and spams, collusion scams employ a cunning persuasion strategy, using the facade of genuine social interactions within comment threads to create an aura of trust and success to entrap innocent users. In this research, we collect 1,174 such collusion scam threads and perform a detailed analysis, which is tailored towards the successful detection of these scams. We find that utilization of the collusion dynamics can provide an accuracy of 96.67% and an F1-score of 93.04%. Furthermore, we demonstrate the robust predictive power of metadata associated with these threads and user channels, which act as compelling indicators of collusion scams. Finally, we show that modern LLM, like *chatGPT*, can effectively detect collusion scams without the need for any training.

1 Introduction

The most popular online video-sharing platform YouTube has seen a surge of scams and spam comments since its creation in 2005. Although measures have been taken, financial frauds, especially related to cryptocurrency investment have not been slowed down (Dig, Accessed: 2023-05-14). Scammers have adapted their tactics to circumvent the scam-detection algorithm by adopting the disguise of genuine users, engaging in seemingly ordinary conversations, and perpetrating a previously undocumented form of deceit known as the "Collusion Scam". Due to their facades, such scams frequently go unnoticed by automated detection systems, posing a significant threat to users who may unwittingly fall victim to such schemes. Consequently, it has become imperative to employ rigorous linguistic, psycholinguistic, and metadata analyses to effectively detect and combat these collusion scams.

The "Collusion Scam" can be defined as a fake conversation where the participants pretend to be beneficiaries of a person or an entity to entrap users for their monetary gain. Typically, a scammer or a group of scammers will share their success and gratitude in working with a person or entity. Often another group joins the conversation by pretending to be curious or newbies, and on later turns they also express to be a beneficiary. In this method, the scammers share the entity's handles or contact information to get around YouTube's rules. Figure 1 shows an example of the collusion scam where some scammers engage in a conversation by pretending to be a beneficiary of a cryptocurrency investment through a claim expert.

The rise of cryptocurrencies has not only attracted genuine enthusiasts and investors but has also unfortunately attracted a surge in fraudulent activities. The absence of comprehensive regulations, limited awareness among users, and the inherent obscurity of cryptocurrency transactions have created fertile ground for scammers to exploit unsuspecting individuals. One prominent avenue for scams in the cryptocurrency space is YouTube, where misleading and collusive comments on cryptocurrency videos can deceive and manipulate unsuspecting viewers.

YouTube's own machine learning algorithms deleted over 950 million comments in Q4, 2021 (9to, Accessed: 2023-1-21), however, the measures were not adequate because of the evolving nature of these scams. Due to YouTube's policy on spam comments, it often deletes comments that strictly violate the policy. For example, the comments that trick others into leaving the site for another one, offer monetary incentives, repetitive, links to coun-

Proceedings of Recent Advances in Natural Language Processing, pages 1066–1075
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_114

terfeits, etc (You, Accessed: 2023-1-21). However, collusion scam is a fairly new approach of scamming where multiple scamming strategies are used to deceive the user, and current spam filters are not able to detect these contents. Hence, there is an urgent need to address the pervasive issue of collusion scams to establish trust, combat the distortion in information exchange, and ensure a safer online environment for the cryptocurrency community and beyond.

In this research, we collect 7,335 conversation threads (comment-replies) from 112 cryptocurrency-related YouTube videos. We manually label them for the presence or absence of collusive scams. Next, we delve into a comprehensive analysis of the linguistic patterns, as well as an exploration of the persuasive strategies employed within these conversations. We also analyze the collusion dynamics within a conversation by using a BERT-LSTM architecture. Furthermore, we explore how the collusion scam detection performance improves with the progression of the thread, and find that we can obtain 96.67% accuracy and 93.04% F1-score when utilizing the initial comment, and all subsequent replies in a conversation. Additionally, we explore how different metadata, like the timespan between the comments and replies, the number of *like* counts, age of the users' channels can provide strong cues for collusion scams. Finally, we examine the performance of *chatGPT* in the realm of collusion scam detection. The main contributions of our research can be summarized as follows:

- To the best of our knowledge, we build the first dataset for collusion scam detection in cryptocurrency-related YouTube videos
- We show how deep learning techniques can be useful in understanding the collusion scam dynamics
- We demonstrate the efficacy of leveraging metadata in collusion scam detection

The data is publicly available at https://github.com/sadat1971/YouTube_Collusion_Scam.

2 Related Works

Researchers explored several aspects of YouTube comments, such as, analyzing the user interactions, sentiment analysis, hate speech, and bias and misinformation (Thelwall et al., 2012; Bhuiyan et al., 2017; Döring and Mohseni, 2020; Jiang et al., 2019). A number of studies worked on spam detection in YouTube videos. Alberto et al. (2015) proposed a machine learning-based automated spam comment filtering system. Similar work has been conducted by Abdullah et al. (2018), Aiyar and Shetty (2018), and Das et al. (2020), highlighting the ongoing research efforts in this domain. Using network analysis, O'Callaghan et al. (2012) explored how spammers use multiple spam bots to post similar comments on multiple popular YouTube videos. However, while these studies have made notable contributions to combating spam, scams constitute a more sinister category. Due to their deceptive nature and nefarious objectives, it is imperative to undertake meticulous research specifically geared toward detecting scam comments.

Thanks bud for keepin us financially Educated! Regardless of how bad it gets on the economy, I still make over $22,000 every single week.

[redacted] 5 months ago
As a beginner investor, it's essential for you to have a mentor to keep you accountable 🤷.
Myself I'm guided by [redacted], a widely known crypto consultant 💪

[redacted] 5 months ago
[redacted] Wow!! Kind of in shock, you mentioned [redacted]. She has proved beyond all doubt that it's worth generating wealth from crypto investment. I've been earning greatly

[redacted] 5 months ago
I'm also a new subscriber of [redacted] coaching program and I'm so excited took a positive turn by earning over $10k biweekly

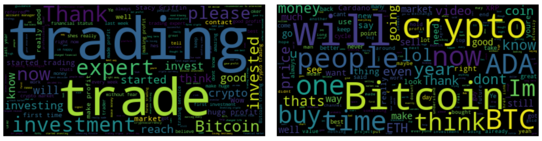
[redacted] 5 months ago
[redacted] has aided so many newbies. I made over $74k with some amazing gains in the market, her pattern are very lucrative

Figure 1: An example of Collusion Scam in YouTube .

There are some research initiatives around scams on YouTube. Tripathi et al. (2022) performed a comparative analysis of machine learning algorithms to detect monetary scam videos. Bouma-Sims and Reaves (2021) explored the metadata aspect of scam videos on YouTube. They found that scammers' accounts have lesser activity and scam videos have less longevity than non-scam videos. However, these works do not address cryptocurrency-related scam comments or collusion scams. Notably, researchers have explored bitcoin-related scam comments and relevant keywords on platforms like *Bitcointalk* (Atondo Siu et al., 2022). Other studies have also investigated cryptocurrency scams, albeit with a primary focus on Ponzi schemes and pump-and-dump schemes,

Category	# of threads	# of replies
Collusion Scam	1,174	20,341
Spam	332	1,428
Non-Scam	1,272	8,409
Unlabeled	4,557	5,933
Total	7,335	36,111

Table 1: Data collection in different categories for YouTube comment-replies threads.



(a) (b)

Figure 2: Word-cloud representation of the YouTube threads: a)collusion-scam b)non-scam

which differ from the intricacies of collusion scams. (Li et al., 2022; Nghiem et al., 2021; Mirtaheri et al., 2021). Ponzi schemes involve promising high returns to investors using funds from new participants, while pump-and-dump schemes manipulate asset prices through coordinated buying and selling. In contrast, collusion scams employ social and psychological strategies, such as mimicking regular conversations and leveraging social proof, to deceive users. Hence, the existing research lacks in effectively detecting and addressing the nuances of collusion scams.

3 Methodology

Our work involves a meticulous data collection process, labeling, and employing machine learning techniques to detect collusion scam.

3.1 Data Collection

The data collection process begins with YouTube searches, utilizing specific keywords like *Crypto Investment Suggestions*, *Bitcoin Suggestions*, *CNN Crypto News*, and *Fox Crypto News* to locate cryptocurrency-related videos. From each search results page, we retrieve the top ten videos that have accumulated at least 10,000 views. Furthermore, we identify popular YouTube channels offering cryptocurrency suggestions through a Google search, selecting the most informative ones, and gathering recent uploads with a minimum of 10,000 views. All view counts were recorded from their uploads up to January 10, 2023. In total, our dataset comprises 112 YouTube videos focused on cryptocurrency.

To collect the data, we leverage the *YouTube Data API v3*, utilizing various API calls such as *channels*, *comments*, and *commentThreads*. Due to the API limitations, allowing only 10,000 queries per day, the data collection process spanned multiple weeks. In total, we collect 7,335 threads with comments and 36,111 replies. Among the metadata, we collect the number of *likes* on comments, and replies, timestamps of postings, and the video published time. Additionally, we collect channel information for all users involved in the threads, encompassing details such as channel join dates, view counts, and subscriber counts.

3.2 Labeling

We manually annotate the dataset to indicate the presence or absence of a collusion scam within each thread, employing two raters for the labeling process. However, we only label threads that surpass the threshold of three replies. This selection criterion is based on our observation that threads below this threshold often remain in a developmental stage, lacking clear indications of being a scam or non-scam threads. We find a total of 1,174 collusion scam threads, 1,272 non-scam threads, and 4,557 threads were unlabeled. Additionally, we identify 332 spam threads that evade YouTube's spam filtering algorithm, representing instances where one individual comment on a financial coach and shares their WhatsApp number across multiple replies, exemplifying a typical form of such spam threads. Table 1 summarizes the data distribution for our research. The wordcloud visualization (Figure 2) highlights the frequent use of words like "trading" and "expert" in collusion scam threads.

To further validate our manual labeling process, we collect the annotation from two other annotators for 5% of the collusion scam and non-scam threads. To help with the annotation process, we provide them with a short PowerPoint presentation, and 10 examples of collusion scams. We find the Cohen Kappa inter-annotator agreement as 0.91 and 0.96 respectively (Cohen, 1960). The high inter-annotator agreement scores provide strong evidence of the reliability and consistency of our manual labeling process. The data is available at https://github.com/sadat1971/YouTube_Collusion_Scam.

3.3 Detection Models

We use two modes of detection strategy for collusion scams. In the static mode, we use a 2-layer

Fully-Connected (FC) neural network architecture, followed by a softmax layer to classify threads for being a scam or non-scam. This mode is utilized during training with a single comment or training with metadata only. To leverage the collusion dynamics present within the comment threads, we use the dynamic mode of learning. In this mode, we utilize a Bi-directional Long Short-Term Memory (Bi-LSTM) model with an attention mechanism, followed by an FC layer and softmax layer (Hochreiter and Schmidhuber, 1997; Bahdanau et al., 2014).

To extract textual features, we utilize 768-dimensional pretrained BERT embeddings obtained from the output of the $[cls]$ token, due to their capability of capturing contextualized and semantic representations of text (Devlin et al., 2018). To obtain better explainability, we also incorporate tf-idf-based features and train a logistic regression model to detect the collusion scams solely based on the comments.

3.4 Experimental Setup

For all the experiments, we use 70% of the data to train, and 30% to test. To ensure robustness, we repeat the experiments using five random splits of the data. Within the training set, 20% of the data is set aside to determine the optimal hyperparameters, including batch size, hidden layer size, learning rates, and epochs. For performance evaluation, we report accuracy and F1-score.

4 Collusion Scam Detection

4.1 It All Starts with the Comment

In a comment-reply thread, the comment gives the first cue for detecting the collusion scam. Often the comment entices the readers into reading the full conversation that sets up the trap. Typical scammer opening lines include some tangential reference to the video's subject matter, followed by boasts about their accomplishment, while working with a person or entity, e.g., *The contents of this channel is so lovely!! Despite the economy situation , I'm so blessed to make withdrawal of my $124k profits out of my crypto trading investment.*

Results and Discussion Using solely the comments, the tf-idf-based logistic regression model gives an accuracy of 90.33%, and an F1-score of 88.66%. Figure 3 shows the most important words in the comments that separate scams from non-scam conversations. Non-scam comments involve specific cryptocurrency-based discussions, like "ada", "cardano", while scam comments tend to describe generalized opinions and focus more on their luring strategy.

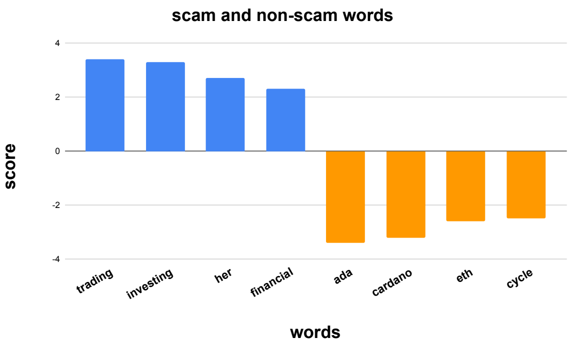


Figure 3: The most important words in detecting collusion scams only from the comments. Words with positive scores indicate a higher contribution to detecting scams.

To obtain more insights, we perform the training with specific Parts-of-Speech (POS) tagged words, and find the top three performances (F1-score) come from Nouns (84.21%), Verbs (79.88%), and Adjectives (70.73%). Hence, collusion scams can be recognized from *what* is being said in the comments. Finally, the BERT-FC model provides a better performance than the tf-idf model, by achieving 92.26% in accuracy, and 91.42% in F1-score, due to the richer textual representation obtained from the BERT embeddings.

4.2 Collusion Scam Conversation Dynamics

We explore the dynamics of collusion scam conversations and gain insights into the strategies used by scammers to deceive readers.

Persuasion Strategy In a collusion scam thread, the scammer(s) lure the readers into believing a fictitious scenario by depicting a fake conversation. The goal of the conversation is to persuade the readers by using several persuasion techniques (Cialdini and Cialdini, 2007; Gragg, 2003; Stajano and Wilson, 2011). Utilization of such techniques are observed in fake review detection, and phishing email detection (Munzel, 2016; Shahriar et al., 2022). Table 2 shows some examples of strategies used in a collusion scam.

Most collusion scam starts with a generic advisory and "call-for-urgency" message. Such texts can encode the *Authority* technique of persuasion, where a scammer pretends to be an experienced veteran and advise the general users. The scammers may use this technique to avoid being flagged as spam by users. In and of itself, the message is often harmless, suggesting inexperienced users pursue a financial coach and explaining its benefits. However, such messages create a facade of collusion, which comes as the next step for the scam.

The scammers often pretend to be a novice who needs help with investment, with the goal of gaining the victim's trust and providing them a feeling of sharing the same predicament. By pretending to be a newbie, the scammer uses social engineering to create a false sense of familiarity and establish a relationship of trust with the victim, which they will later exploit for their own benefit.

Various techniques are utilized to emphasize the contact information and credentials of the target individual or organization. Scammers often split the contact information, such as phone numbers, WhatsApp, or Telegram, into multiple responses to avoid detection by YouTube's algorithm for scams. In the Name-dropping technique, scammers frequently post responses from multiple accounts with slight variations in language, claiming to have benefited from a particular individual and expressing gratitude. These responses can project commitment, integrity, and consistency, thus enhancing the trust level among users.

Scammers use the scarcity principle to persuade readers to invest their money in fraudulent schemes. They create a sense of urgency by suggesting that it is the best time to invest, and that if the reader does not act quickly, they will miss out on a lucrative opportunity. Scammers may use various tactics to entice people into investing, such as promising huge profits, using fear-mongering techniques, or creating a sense of panic around a particular investment opportunity.

Results and Discussion To examine the dynamics of collusion, we feed the BERT embeddings of comments and replies to the BiLSTM-Attention-FC network. Our results indicate that the performance of the model improves with an increase in the number of replies, as illustrated in Figure 4. For instance, with one reply, the model achieves an average accuracy of 79.28% and an F1-score of 66.74% across all five folds. By adding one more reply, we observed a 5.49% increase in accuracy and a 9.03% increase in F1-score. When using the maximum number of replies, the model achieved the highest performance, with an accuracy of 96.67% and an F1-score of 93.04%. Thus, our model learns more about collusion as the conversation progresses.

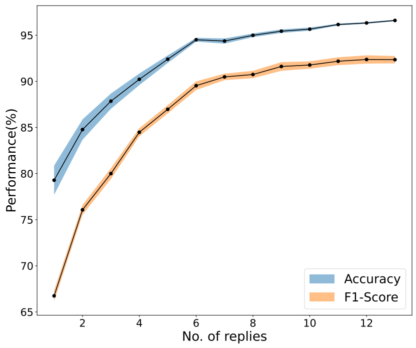

Figure 4: Collusion scam detection performance with an increase in the number of replies in a comment-reply thread.

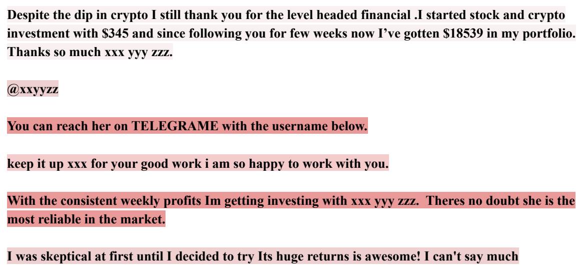
We further explore the attention weights used by our model to identify the conversation threads containing collusion scams. Our investigation indicates that the model primarily focuses on replies that mention individuals. Figure 5 displays the areas of high attention during a scam conversation. It further demonstrates that the model's attention mechanism is particularly drawn to replies that contain Name-dropping and expressions of admiration or appreciation. Hence, such characteristics can provide a significant indication of collusion scams.

We conducted an error analysis to investigate mislabeling patterns in our model. Our findings indicate that genuine conversations discussing common topics associated with collusion scams can be erroneously classified as such. For example, collusion scam threads employ the persuasion strategy of "scarcity" by stating how risky it is for inexperienced people to invest without a financial coach. When non-scam threads involve users discussing various cryptocurrencies and sharing personal investment mistakes without any intention to deceive others, our model may mistakenly identify them as collusion scams.

We observe another common error where conversations include a mix of legitimate comments and collusion scam comments. We find that in 16.03% of the cases, collusion scam threads have non-scam comments or completely unrelated comments. In cases where the non-scam comments outnumber the scam-related ones, our model misclassifies the threads as non-scams. This highlights the need to consider alternative approaches, such as multiclass

Description	Example	Persuasion-technique
Urgency and Advisory	*If you are not conversant with the markets Id advise you to get some kind of advise or assistance from a financial investing coach. It might sound basic or generic but getting in touch with an investment broker was how I was able to outperform the market*	Authority
Social Engineering	*Please how can I reach her Im a newbie and know nothing about crypto investment*	Social Proof/Compliance
Name-dropping	*Wow you really know expert XYZ? Im a living testimony of her good expertise she has been trading for me for months now*	Commitment, Integrity, and Consistency
Panic and Possibilities	*Most coins are going to 10x this Year. The recent bitcoin correction down from its all-time high has had the market in a panic in the past week. However, not everyone has seen it as a bad omen*	Scarcity, Need and Greed

Table 2: Example of collusive conversation text, and the persuasion strategies used to convince the readers to invest



Despite the dip in crypto I still thank you for the level headed financial .I started stock and crypto investment with $345 and since following you for few weeks now I've gotten $18539 in my portfolio. Thanks so much xxx yyy zzz.

@xxyyzz

You can reach her on TELEGRAME with the username below.

keep it up xxx for your good work i am so happy to work with you.

With the consistent weekly profits Im getting investing with xxx yyy zzz. Theres no doubt she is the most reliable in the market.

I was skeptical at first until I decided to try Its huge returns is awesome! I can't say much

Figure 5: Attention weights visualization in a collusion scam conversation. The regions with darker shed indicate higher attention.

classification or formulating the problem as a regression task, to measure the "degree" of collusion scam presence in a conversation. Addressing these challenges will be the focus of our future work.

4.3 The Cues from Metadata

In this section, we will investigate the collusion scam patterns from the metadata available on YouTube video pages.

4.3.1 Response Time of Comments and Replies

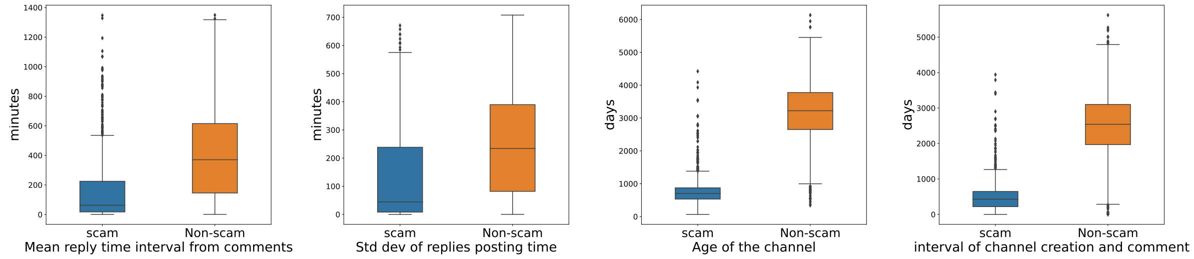
First, we explore the response time of replies posted under the comments in the conversation thread. Our investigation reveals that the replies within collusion scam comments exhibit a significantly shorter response time than those in non-scam comments (p-value < 0.05). As depicted in Figure 6a, the average time interval between the posting time of comments and replies is 161.01 minutes in the case of scams, and 404.93 minutes for non-scam conversations. Furthermore, we investigate the time intervals patterns within the replies, as illustrated in Figure 6b. In scam comments, the average standard deviation within the replies is 135.41 minutes, compared to 244.36 minutes in non-scam conversations. This suggests that scammers adopt a more aggressive approach to engaging users and luring them into their fraudulent schemes.

Scammers expose two crucial trends by creating conversations and replying promptly to comments: i) Unlike regular non-scam conversations, in a collusion scam, the scammers do not engage in a genuine conversation that may require time to respond. With the intention of generating more engagement, they frequently post identical or slightly altered answers praising a person or an entity, ii) scammers respond quickly to a conversation to create an illusion of legitimacy and trustworthiness by making the collusion conversation more voluminous of replies than the non-scam conversation. This tactic is evident in the average length of collusion scam replies, which stands at 21.78, while non-scam replies average at 6.91. Hence, the findings imply that analyzing the response time and time interval patterns within comments and replies can be an effective technique to identify collusion scam patterns.

4.3.2 Number of *Likes*

The number of *Likes* can act as a form of social validation, and scammers can exploit that metric to engage viewers. Comments usually serve as conversation starters and, consequently, receive more attention (and thus, more *likes*). Replies, on the other hand, are merely discussions on the comment, and hence, receive less attention. We found that scam comments receive an average of 72.58 *likes*, while non-scam comments receive an average of 52.29 *likes*. However, the scenario flips in the case of replies. While a collusion-scam conversation receives an average of 0.23 likes per reply, a non-scam conversation receives an average of 1.25 likes per reply.

Scam comments are designed to be more



(a) (b) (c) (d)

Figure 6: Visualizing the metadata from the comment threads: a) Mean time interval between comment and replies posted, b) the standard deviation of the posting time among the replies in a thread, c) Age of the user channels who posted comments or replies in the threads, d) how long it took to post after the video is published

attention-grabbing or emotional than non-scam comments. This can make them more likely to elicit a strong response from viewers, including *likes*. However, once viewers skim through the conversation, they may start to become suspicious and less likely to continue engaging with or rewarding them with likes. On the other hand, non-scam conversations may be more genuine and focused on the topic at hand, making them more enjoyable or informative to read, and thus, more likely to receive *likes* on replies. However, it should be noted that the number of *likes* may not always be a definitive indicator of collusion scams. This metric may be influenced by various other factors such as the content of the video, the number of subscribers, and the number of viewers. Consequently, it would be erroneous to rely solely on the number of *likes* as a standalone indicator of a collusion scam.

4.3.3 Age of Scammer Account

Scammers frequently use the approach of constantly creating new accounts as their prior ones are reported or deleted. This is due to the fact that their fraudulent operations are frequently detected and reported by attentive users or platform administrators. Scammers want to avoid detection and prolong their fraudulent activities by regularly cycling through different accounts. Figure 6c shows the distribution of channel age for the users recorded during our data collection process. We find that scammers possess accounts with an average age of 797.74 days, significantly lower than the average age of 3172.74 days observed for the non-scammers' accounts.

This disparity in account age reflects the ephemeral nature of scammers' online presence. Their accounts, which have very brief lifespans, are a direct result of their deceptive actions and the repercussions they face. Genuine users, on the other hand, have accounts that have been active for considerably longer lengths of time, indicating their real and long-term participation in the online community.

In addition to creating new accounts frequently, scammers tend to comment on these fraudulent schemes shortly after their account creation. Figure 6d illustrates the distribution of the time it takes for users to comment on a video after creating their channel. On average, scammers begin commenting on collusion scams approximately 468.61 days after creating their accounts. In contrast, genuine users, with authentic intentions, take an average of 2509.46 days for commenting on cryptocurrency-related posts. Furthermore, our analysis demonstrates that 11.27% of scammers begin commenting on collusion scams within just a month of creating their accounts. This rapid initiation into fraudulent activities highlights their aggressive approach, aiming to exploit vulnerable individuals as quickly as possible. On the contrary, genuine users exhibit a significantly lower rate of early engagement, with only 2.38%.

Results and Discussion By examining the metadata associated with conversations, we have discovered that they serve as important indicators for identifying collusion scams. Leveraging this insight, we build a collusion scam detector relying solely on metadata analysis. We find that using the above-discussed metadata results in an average of 87.08% accuracy, and 88.42% F1-Score. The metadata-based collusion scam detector, excluding textual content, offers a streamlined and effective approach for the early identification of fraudulent activities. Its focus on metadata analysis enables efficient detection without the need for complex text processing systems.

5 *ChatGPT* and Collusion Scam

Among the family of Large Language Models (LLM), *chatGPT* has shown enormous promise, due to its language generation and comprehension abilities (ChatGPT). First, we use the *chatGPT* prompt to provide the following instruction: *The Collusion Scam can be defined as a fake conversation where the participants pretend to be beneficiaries of a person or an entity to entrap the users for their monetary gain. I will provide some examples, can you tell me if they are creating a collusion scam or not?* Subsequently, we provide it with a set of threads involving both collusion scams and non-scams. These prompts are presented within a single chat session. We manually extract the output from the response.

We find that *chatGPT* as collusion scam detector yields an accuracy of 89.40%, with an F1-score of 88.54%. In 8.53% of the cases, it does not provide any direct answer, and we use the prompt to ask further questions to have a clear response. We also find that after an average of 8.33 responses, *chatGPT* seems to forget the task, and we provide the task description again. Since *chatGPT* provides a linguistic response, it first summarizes the conversation, and then the verdict with its reasoning. Although its performance falls short of our BERT-LSTM model, its explanations accompanying the responses can enhance collusion scam detection reliability for users. However, given the large number of collusion scams on YouTube and the lack of a fine-tunable architecture, further research is necessary to incorporate *chatGPT* into collusion scam detection.

Nevertheless, it is crucial to acknowledge that while *chatGPT* demonstrates responsible behavior by refraining from offering harmful or improper responses, it remains susceptible to manipulation by scammers (Hacker et al., 2023). For example, when prompted with instructions for writing a comment in a YouTube video about being financial beneficiaries of a person, *chatGPT* answers with a legitimate-sounded response with a specific amount of “profit” and “investment”. Thus, collusion scam detection in the post-AI era may require more careful work and sophistication with a responsible AI research.

Data	Model	Accuracy	F1-score
Comments only	tf-idf	90.33	88.66
	BERT-FC	92.26	91.42
full thread	BERT-LSTM	**96.67**	**93.04**
Metadata	FC	87.08	88.42
No Training	*chatGPT*	89.40	88.54

Table 3: Summary of the collusion scam detection approaches.

6 Conclusion and Future Work

In this research, we address the issue of collusion scams within YouTube’s comment section, particularly in the cryptocurrency market. We have demonstrated scammers’ deceptive tactics, luring unsuspecting users through social interactions. We also explore different collusion scam detection strategies, where the comments may have an important initial signal, and the thread dynamics can further bolster the detection performance. Additionally, our study of YouTube metadata shows promising discriminators between collusion scams and genuine discussions, including *likes*, reply patterns, and user channel age. Table 3 provides a comprehensive summary of our approaches and the corresponding detection performances. Future research directions of this work include:

- The collusion scam threads may contain replies from genuine users, ranging from the inquisitive ones seeking information to experienced individuals who raise suspicions about the scam. In a few cases, the scammers also engage in conversations refuting the accusations. Future research on exploring these exchanges can help gain deeper insights and a better understanding of the dynamics surrounding collusion scams.
- Investigating the scalability and generalizability of our proposed detection strategies for other online platforms, like, Reddit, Twitter, and Facebook would be an interesting direction of work.
- Whether the modern text generative LLMs like GPT-4, chatGPT, BARD are more susceptible to generating effective collusion scams, making it harder for the AI to combat them, can be a valuable research direction.

7 Ethics and Broader Impact Statement

Throughout this research, we have prioritized fairness and adhered to ethical practices in our data collection strategy, strictly abiding by YouTube's terms of service and community guidelines. Additionally, we ensured compliance with YouTube's API "Terms of Service", aligning with the laws and regulations of the country where this research took place. We also respected and adhered to the API's quota limit, ensuring responsible data usage.

To further preserve fairness and mitigate any potential biases in our models, we implemented a masking technique to anonymize user names in the conversation threads, where applicable. By masking user names, we aim to prevent any unintended profiling or bias that may arise based on specific individuals or their characteristics. This approach serves to enhance the fairness and integrity of our research outcomes.

Our work contributes to fostering a safer online environment where users can engage, free from the pervasive threat of scams and fraudulent activities. This research can also help improve YouTube's platform responsibility in battling collusion scams. By raising awareness, improving detection mechanisms, and promoting collaborative efforts, we strive to create a positive and trustworthy digital ecosystem for all users.

Acknowledgments

This research was supported in part by grant ARO W911NF-20-1-0254. The views and conclusions contained in this document are those of the authors and not of the sponsors.

We also express our sincere gratitude to Navid Ayoobi, Shanto Roy, and Tomin Chazhikat for their invaluable assistance in labeling the data used in this study.

Abstract

Deceptive text poses a significant threat to users, resulting in widespread misinformation and disorder. While researchers have created numerous cutting-edge techniques for detecting deception in domain-specific settings, whether there is a generic deception pattern so that deception-related knowledge in one domain can be transferred to the other remains mostly unexplored. Moreover, the disparities in textual expression across these many mediums pose an additional obstacle for generalization. To this end, we present a Multi-Task Learning (MTL) based deception generalization strategy to reduce the domain-specific noise and facilitate a better understanding of deception via a generalized training. As deceptive domains, we use News (*fake news*), Tweets (*rumors*), and Reviews (*fake reviews*) and employ LSTM and BERT models to incorporate domain transfer techniques. Our proposed architecture for the combined approach of domain-independent and domain-specific training improves the deception detection performance by up to 5.28% in F1-score.

1 Introduction

With the advent of the digital age came a deluge of textual content online, which also contains an enormous amount of deceptive text. The deceptive text uses a variety of strategies to trick readers based on the information delivery medium. Fake news, for instance, spreads false information about a person or organization in order to harm their reputation, while fake reviews intentionally exaggerate the positive or negative aspects of a product or service in order to gain attention. Despite the technical differences in deception, all deceptive texts have the same objective of deceiving people; hence, a generic pattern of deception may exist (Shahriar et al., 2021). Identifying the underlying generic pattern of deception may unravel useful information about textual deception. Furthermore, such a system will enable a more effective detection approach through the intermingling of multiple deception domains.

There has been a good number of work done to combat textual deception in domain-specific situations, but a powerful detection system requires a lot of labeled data, which is dependent on things like trustworthy annotators, resources, time, and money. Consequently, the learning paradigm wherein multiple domains may support each other can be a promising solution in deception detection. In this paper, we explore the feasibility of generalizing deception across domains such as News, Reviews, and Tweets, and we present a Multi-Task Learning (MTL) based deceptive domain transfer strategy to mitigate the domain differences and improve deception detection capacity beyond a standard single domain learning approach with LSTM and BERT models.

Researchers dealt with deceptive domain adaptation problems in cross-dataset learning settings, e.g., Opinion Spam on different entities (Li et al., 2014; Sánchez-Junquera et al., 2020), and Fake News on different topics (Pérez-Rosas et al., 2018). Although attempts have been made to generalize the deception for better detection, these efforts have been constrained so far (Gröndahl and Asokan, 2019). Shahriar et al. explored the problem of holistic deception detection, where they used single deep learning networks to detect deception from a holistic perspective (Shahriar et al., 2021). While this approach provides a domain-agnostic system, it is possible that the intrinsic variations between deception domains mean that a single network cannot give an effective solution. A feature-augmentation-based soft domain transfer approach using the last layer of learned models was proposed in (Shahriar et al., 2022). However, the last layers are prone to capturing the domain-specific noise which may

Proceedings of Recent Advances in Natural Language Processing, pages 1076–1084
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_115

have adverse effects in deceptive transfer. Consequently, the lack of a sufficiently robust system that can account for domain differences and leverage the generic deception signal constitutes a significant research gap.

Considering the above aspects, We formulate the research problem as: Given a set of deceptive domains $\{D_i\}_{i=1}^{n}$, how to construct a generic feature set f_g which can help improve detecting deception in all n domains, rather than the domain-specific feature set $\{f_i\}_{i=1}^{n}$. To address this problem, we use a Multi-Task Learning (MTL) approach with the LSTM and BERT model, where the part of the model is shared across all domains to capture the generic information, and multiple branches downstream to account for domain-specific information. We compare our approach with an **A**ll **F**or **O**ne (OFA) mode of deception generalization and **I**ntermediate **L**ayer **C**oncatenation (ILC) mode of domain transfer (Shahriar et al., 2021, 2022).

This study has a wide range of implications. At the outset, this study seeks to characterize the interconnectedness of various forms of deception and to identify the underlying generic pattern. Learning deception across different domains together allows for the development of a more robust system. It will also take into account the labeled data shortage issue in many deception domains. On top of that, the appearance of a new event can frequently lead to more deceptive data in one domain than the other. In such instances, the generalization of deception studies can be extremely valuable. Finally, the MTL-based simultaneous learning of generic and domain-specific deception will incorporate fewer parameters to be trained than separately learning from the domains.

Our research shows that for all domain-transfer and generalization experiments, MTL outperforms the ILC and OFA mode. Our main contribution can be summarized as follows:

- We explore the deceptive domain transfer strategies and compare them with our proposed MTL-based approach for an improved deception detection system by simultaneously capturing the generalized deception while also preserving the domain differences.
- We show the potential association between the domains by comparing the performance improvement, which may provide useful research direction while performing domain transfer.

2 Datasets

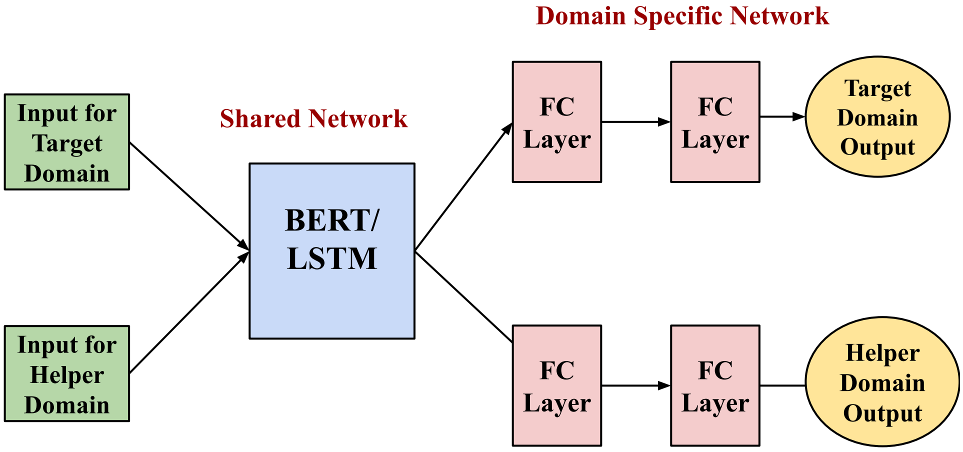
For the three domains, we use six datasets for this paper. For the News domain deception, LIAR dataset contains data from Politifact, and each data is labeled with one of them: True, Mostly-True, Half-True, Mostly-False, False, Pants-on-Fire False. Following the work of Upadhayay and Behzadan 2020, we label the first two as non-fake and the latter four as fake news. Another News dataset, Nela-GT-2021 (NELA) is a source-based labeled news dataset collected from January 2021 to December 2021 and labeled by Media Bias Fact Check (MBFC) (Gruppi et al., 2022). We labeled the news with MBFC *factuality* score 0 as Fake and 5 as non-Fake, and we collect the news sources from the US only. The news domain contains 43,168 news with 64.29% as fake. In the Tweets domain of deception, data comes from PHEME and a collection of *Newly Emerged Rumors in Twitter* (NERT) from 2016 to 2018 (Zubiaga et al., 2016; Bodaghi, 2019). In total we have 20,893 tweets with 49.77% as rumors. For the Reviews domain, we use the Yelp restaurant (RES) and hotel (RES) dataset, which 67,395 reviews, where 13.19% of them are labeled as fake (Mukherjee et al., 2013).

3 Methodology

As the baseline text classification models, we use attention-based LSTM, and BERT models, followed by a FC layer and a softmax layer (Vaswani et al., 2017; Devlin et al., 2018). We explore Intermediate Layer Concatenation (ILC) and Multi-Task Learning (MTL) for deceptive domain transfer strategies.

3.1 Intermediate Layer Concatenation (ILC)

First, the baseline self-domain models are individually trained for detecting deception. The trained models are used as kernels to obtain the target domain's feature representation. Next, the obtained features are concatenated and fed to a Fully-Connected (FC) layer to detect deception. The intuition behind this approach is that by obtaining the feature representation in different domains' high-level latent space, the deceptive text may obtain richer information to detect deception than in its own domain only. The training strategy is adopted from Shahriar et al. 2022.



(a)

Figure 1: Multi-Task Learning (MTL) based deceptive domain transfer. The shared network captures the generalized deceptive pattern and the domain-specific Network accounts for the domain differences.

3.2 Multi-Task Learning

Multi-Task Learning (MTL) aims to exploit the potential information from different training objectives and build a more robust learner (Zhang and Yang, 2017). If we have n learning tasks, where each task is presented as F_i, and i=1 to n, MTL helps ameliorate the task F_i by utilizing the learned knowledge from the n tasks. Based on different learning objectives, MTL can have a different spectrum of supervision, parameters can be hard-shared or soft-shared, and different architectures are employed to account for different task categories (Zhang and Yang, 2017; Caruana, 1997; Ruder, 2017). In this paper, we use a hard parameter shared-based supervised MTL to improve the deception detection performance using a deep-learning-based sequence classification approach.

Our MTL-based domain transfer architecture is depicted in Figure 1. The Target deceptive domain T and the helper deceptive domain H are fed to the MTL architecture. The LSTM, or BERT model is used as the shared network where the model jointly learns the domain-independent hard-shared parameters θ^s. Next, we have a two-layer Fully-Connected (FC) network, followed by a sigmoid layer in two levels for a domain-specific network, which is used to learn the domain-specific parameters θ^T and θ^H. We use cross-entropy loss for each domain and form a combined loss by adding the target domain loss with the weighted (λ) loss of the helper domain. The algorithm for this approach is demonstrated in Algorithm 1.

There are several reasons for MTL being a promising mode of deceptive domain transfer. First, text data is inherently noisy, and so are deceptive domains (Subramaniam et al., 2009; Agarwal et al., 2007). A model trained on self-domain data only can be prone to overfitting due to being modeled on the domain-specific noise. Since two different domains have different noise patterns, training them jointly would achieve better representation by implicit data augmentation. Furthermore, since the deception domains are closely related by their same intention of deceiving the reader, the similarity allows the model to focus on important features than the noise, and the helper domain can provide additional support for the relevance or irrelevance of the focused features (Ruder, 2017). Next, due to the complex nature of deceptive textual data, feature interactions in some domains might be more difficult to learn than others. Hence, MTL allows to eavesdrop on the complex learning process and helps transfer the knowledge from one domain to another. Finally, MTL can act as a regularizer by reducing inductive and representation bias.

4 Experiments and Results

We use 80-20 split for train and test, and 20% from the train set as validation with three random splits. For the Reviews domain, we train with a balanced proportion of fake and non-fake reviews. We compare accuracy and binary F1-score for performance.

Algorithm 1 Multi Task Learning for Domain Tranfer

```
1: Input: Deceptive target domain $T$, deceptive helper domain $H$, loss weight of helper domain $\lambda$
2: Output: Hard-shared parameters $\theta^s$, target domain paramters $\theta^T$, and helper domain parameters $\theta^H$
3: Compute loss for Target domain $L_T(T; \theta^T, \theta^s)$
4: Compute loss for Helper domain $L_H(H; \theta^H, \theta^s)$
5: Combine the losses $L = L_T + \lambda L_H$
6: Update $\theta^s$ based on combined loss $L$
7: Update $\theta^T$ based on loss $L_T$
8: Update $\theta^H$ based on loss $\lambda L_H$
```

The batch size, learning rate, hidden layers and epochs are chosen by validation set performance.

4.1 Cross-Domain Deception Detection

In the cross-domain (CD) setting, we experiment to see whether deception trained in one domain can be generalized enough to detect deception in another domain. Table 1 shows that deception detection performs best when trained and tested on the same domain. For all three domains, performance drops significantly (p-value<0.05) when tested on different domains. However, in the CD setting, performance being better than the chance implies that there is some domain association present, which can be leveraged for improved deception detection.

4.2 Deceptive Domain Transfer

4.2.1 ILC-based Domain Transfer

In the ILC mode of domain transfer, we utilize the deception information captured in the intermediate layers of the model. While we concatenate the post-attention layers for LSTM, we experiment with different combinations of the last six layers of the BERT model and report the best result in each transfer.

Table 2 shows the ILC mode of domain transfer for the LSTM model. For the News domain, Tweets help the most as a single domain by improving the F1-score by 0.94%, and the combination of all three domains improves the F1-score by 1.26%. For the tweets domain, News helps the most with improvement by .73% and for the Reviews domain, Tweets help the most by .54%. However, the overall performance improvement is less than 1% for all cases. Although the model captures some non-domain deceptive information, the last layer being highly focused on domain-specific deception, the transfer of deceptive information is rather minimal.

In the ILC mode of BERT model, the best performance is found when all three domains of deception are concatenated (Table 3), with improvement over the single domain deception by 2.11%, 2.09%, and 1.23% respectively for News, Tweets and Reviews domain. As individual helper domains, News and Tweets are most helpful to each other and Tweets help the reviews most. It should be emphasized, however, that in none of the scenarios is last layer concatenation useful. For News as helper domain, 9th and 7th layer concatenations were most helpful for Tweets and Reviews respectively. The 9th layer of Tweets was helpful in both cases. For the Reviews as helper domain, 6th, 7th and 8th layers have similar transfer performance but decline significantly from the 9th to the last layer.

4.2.2 MTL-based Domain Transfer

The use of MTL-based domain transfer ensures that the model captures generalized deceptive information at shared layers while accounting for domain-specific knowledge in domain-specific layers. To accommodate for the inter-domain data imbalance, we employ two training strategies: **regular** training where every batch will retain its original data distribution, and **balanced** training in which we upsample or downsample other domains to the target domains training size. We perform the experiments with different combinations of the loss function and report the results with the best validation set performance.

The table 2 and 3 show that MTL-based domain transfer outperforms the ILC-based domain transfer in all cases. For the LSTM model, combining all three domains helps in performance boost from the single-domain model by 1.96%, 4.38% and 0.70% in News, Tweets, and Reviews respectively. The improvement is on average 1.63% more than the ILC mode.

The performance boost with MTL-based BERT model is higher than in the LSTM model. We find the average F1-score improvement with combined domains to be 4.63%, 3.65%, and 5.28% respectively over the single-domain models, and an average of 2.70% more than the ILC model. The best helper domain for each target domains are consistent with ILC mode for both BERT and

Table 3: Deceptive domain transfer using BERT model. The best performance across all domains are achieved with MTL mode and while trained with all three domains.

LSTM model. We further find that balanced training works best for News and Tweets, and regular training works best for Reviews.

4.3 Generalized Deception Detection

In the generalized deception detection setting, we simultaneously learn deception in different domains. We use two architectures for that. First, in the **O**ne **F**or **A**ll (OFA) mode, we mix the training data from all different domains and use a single network (BERT or LSTM) for all domains without the model being aware of the domain differences. In the MTL mode, the shared layers are used for generalization and the task-specific layers are used to account for the domain differences. Note that we do not tune the loss weight parameter and use the same value for each domain.

Table 4 shows the generalized deception detection performance. In the OFA mode, there is only a slight performance boost in News and Tweets, while declining in Reviews for the LSTM model. Since the OFA mode presents a domain-agnostic view, while the model achieves a generalized representation of deception, it fails to capture the domain-specific distinction. The remedy is achieved in the MTL-based generalization by employing the task-specific layer on the top of the shared generalized layer, and thus, outperforms the OFA mode by 2.00% on average.

5 Result Analysis and Discussion

Overall, the ILC mode of domain transfer exhibits less improvement than the MTL mode. This is because, in the MTL mode, the deception domains share a latent space in the upstream layers and are only distinguished by the domain-specific layers on the later levels. On the contrary, the ILC mode can access high-level representations only. Hence MTL mode has a higher chance of learning underlying representations than ILC modes by leveraging information from other domains.

We investigate the performance improvement of the MTL-based LSTM model by plotting the validation loss in the first 10 epochs. Figure 2 shows that the MTL mode achieves better generalizability for all three deceptive domains, whereas self-domain modes tend to overfit quickly. Thus, the improved performance of MTL mode might be attributed to better generalization.

We further explore how deception generalization is conducted on the attention head level with MTL-based BERT model. Table 5 shows an example where most of the attention heads on last four layers focus on “Chief”, “Suspended” and “Helping”. Notably, although all words got some attention scores, none of the heads on the last four layers have the highest attention scores on the word “vaccine”, which might be a key phrase for deception detection on COVID-19 events. In contrast, the baseline BERT model features four attention heads in the final four layers that give the term “Vaccine” the most weight. Important proper nouns, like “Trump” and “Obama” were also analyzed; whilst on the baseline models, these terms receive an average of 21.87% of attention on the last four layers of heads, for the MTL model, this number drops to 12.19%. Thus, rather than focusing on domain-specific deception characteristics, our proposed architecture for the MTL mode may be able to generalize deception.

6 Related Works

Most of the previous works in domain transfer dealt with cross-dataset knowledge transfer on different topics from similar information sources. For example, fake news from different news sources and topics are shown to have different word usage and propagation pattern (Silva et al., 2021; Huang and Chen, 2020). Janicka et al. showed that stylometric and psycholinguistic features in different fake news varies widely and results in the performance drop to 20% when train and test sources are different (Janicka et al., 2019). Silva et al. addressed the challenge by storing domain-specific and cross-domain knowledge in embedding representation. (Silva et al., 2021). Sicilia et al. explored how the differences in topics between train and test set affect the performance in rumor detection in the health domain (Sicilia et al., 2018). Ren et al. linearly combined a set of vector representations on different topics with the textual features and obtained an Attention network-based cross-topic solution for rumor detection (REN et al., 2021). In the field of Fake Review detection, Hernández-Castañeda et al. performed a cross-domain fake review detection using three opinion datasets with LDA, SVN, and WSM-based features (Hernández-Castañeda et al., 2017). They also measured the domain association by training on one domain and testing on the other. Sànchez-Junquera et al. proposed a model where they performed a filtering approach for masking domain-specific terms and transformed the original text to a domain-agnostic form (Sánchez-Junquera et al., 2020). Similar works in cross-domain fake review detection was done in (Li et al., 2014) and (Abri et al., 2020).

The existing works on the cross-dataset domain transfer technique suggests that a robust model should exploit both domain-aware and domain-independent attributes for a successful deception detection task. Our proposed method of MTL-based domain transfer technique builds up on shared and domain-specific layers to account for the aforementioned strategy. Nevertheless, the comparative study of deceptive medium-based domain transfer was not explored in previous work to the best of our knowledge. Hence, our method is the first one to address this problem.

7 Conclusion

Although distinct deception domains have their own methods and characteristics for disseminating deceptive information, they all have the same objective: to deceive individuals. Hence, the generalized detection approach can be immensely useful for addressing labeled data shortage issues in numerous domains. Here, we compare state-of-the-art domain transfer strategies and present an MTL-based method for transferring information across deceptive domains for enhanced deception detection. Our experiments demonstrate that learning deception in multiple domains simultaneously results in improved generalization and performance. In any case, with MTL-based architecture showing promise as a possible option for universal deception detection, we can investigate different hybrid structures of textual parameter sharing and weighted-loss methods for deception detection. Furthermore, the continual learning approach of deception detection can be a promising research direction due to its capability of catastrophic forgetting prevention and knowledge transfer (Biesialska et al., 2020). In addition, we plan to incorporate email and Facebook post deceptions into our future research.

8 Ethics and Broader Impact

Our work has its limitations, considering the complexities inherent in the deceptive content and the ever-evolving landscape of deception. Consequently, the data used in this research may not represent every category of deception and does not consider the cultural nuances of all forms of deception, especially in the current age of *chatGPT* and other LLM-based text generation techniques (ChatGPT; Hacker et al., 2023). We recognize that our study has important ethical implications, particularly with regard to the potential misuse of deception detection techniques. While our research aims to improve the performance of deception detection in various domains, we acknowledge that these techniques could be used to invade individuals' privacy or unfairly target certain groups. Therefore, we urge researchers and practitioners to use these techniques responsibly and with consideration for the potential consequences.

Our research sets the stage for broader implications. The proposed deception detection approach and domain transfer strategies can be extended beyond the domains explored in this paper. We envision their potential application in combating deception in diverse contexts, including online forums, and chat platforms, and addressing the challenges posed by misinformation contents.

Abstract

Extracting legal entities from legal documents, particularly legal parties in contract documents, poses a significant challenge for legal assistive software. Many existing party extraction systems tend to generate numerous false positives due to the complex structure of the legal text. In this study, we present a novel and accurate method for extracting parties from legal contract documents by leveraging contextual span representations. To facilitate our approach, we have curated a large-scale dataset comprising 1000 contract documents with party annotations. Our method incorporates several enhancements to the SQuAD 2.0 question-answering system, specifically tailored to handle the intricate nature of the legal text. These enhancements include modifications to the activation function, an increased number of encoder layers, and the addition of normalization and dropout layers stacked on top of the output encoder layer. Baseline experiments reveal that our model, fine-tuned on our dataset, outperforms the current state-of-the-art model. Furthermore, we explore various combinations of the aforementioned techniques to further enhance the accuracy of our method. By employing a hybrid approach that combines 24 encoder layers with normalization and dropout layers, we achieve the best results, exhibiting an exact match score of **0.942** (**+6.2%** improvement).

1 Introduction

Extracting legal entities from legal documents is an essential challenge for legal assistive software (Leivaditi et al., 2020). Its goal is to extract structured information — "what are the legal attributes (agreement date, party, license, etc) that are involved" — from unstructured text. A contract document is a legally binding agreement between two or more parties. It outlines the terms and conditions of the relationship and sets forth the rights and obligations of each party (Chalkidis et al., 2017). Here, the party is a person or entity who takes part in a legal transaction, for example, a person with an immediate interest in an agreement or deed, or a plaintiff or a defendant in a lawsuit. A "third party" is a person who is a stranger to a transaction, contract, or proceeding.

Extracting parties' information from legal contracts can provide numerous benefits to legal assistant software such as Concord[1], ContractWorks[2], and HelloSign[3]. First and foremost, this can aid legal professionals in identifying parties involved in similar cases, trends, and patterns in legal disputes, and assist in more efficient legal research. Secondly, the extraction of parties allows reviewing multiple documents efficiently with the quick document search feature, and it leads to focusing on relevant information and documents through assistant software. Moreover, the manual extraction of parties is prone to human errors, which can lead to inaccuracies and inconsistencies (Hendrycks et al., 2021). By automating the process of party extraction, legal professionals can save time and improve the accuracy of their work.

Extracting parties can be a challenging task despite its usefulness (Leivaditi et al., 2020). One of the most challenging parts of the contract is it may contain numerous names of persons and organizations throughout its pages. These names can refer to various entities other than the parties, such as third-party beneficiaries, agents, assignees, guarantors, witnesses, and experts (Bommarito et al., 2018). As a result, it can be difficult to distinguish the parties from all the other types of individuals and entities mentioned in the contract. Secondly, legal contracts can be lengthy and complex, with various technical terms and clauses that require in-depth legal knowledge to understand fully. Ad-

ditionally, contracts can be written in a convoluted manner, leading to ambiguity in determining the parties' intent, which can create difficulties in extracting the relevant information accurately. Moreover, reviewing a large volume of contracts within a limited time frame can be a labor-intensive task for lawyers, often leading to errors and inconsistencies. Finally, the manual review may also be prone to errors due to human oversight or misinterpretation, which can result in inaccuracies in the extracted information (Hendrycks et al., 2021). Therefore, automated legal assistant software can be beneficial in addressing this challenge.

There has been extensive research on extracting various information from legal documents (legislation, court cases, contracts) (Almeida et al., 2020; Hendrycks et al., 2021), but there were only three studies found on extracting parties from legal contracts. The first system used a rule-based system to extract parties (Chalkidis et al., 2017), but it cannot scale out since law firms generate a plethora of contract documents, making it impossible to add processing rules for each new contract type. The second attempt focused on only one type of contract (leases) and was not applicable to other types of contracts (Leivaditi et al., 2020). The third and final system solved this problem using a question-answering method (Hendrycks et al., 2021). However, the extraction system results in a large number of false positives and less reliable outcomes.

In addition, there exist only two datasets that facilitate the extraction of parties' information from legal contract documents (Chalkidis et al., 2017; Hendrycks et al., 2021), out of which only one is publicly accessible. The initial dataset is annotated with extraction zones that are appropriate for rule-based extraction (Chalkidis et al., 2017). On the other hand, the second dataset (CUAD) is annotated for a question-answering system but is unsuitable for precise party detection (Hendrycks et al., 2021).

In this research, we try to develop a relatively accurate dataset with a precise match of the parties and doubled the size of the CUAD dataset (**Contribution 1**). We attempt to develop a scalable and accurate party extraction system with minimal overheads. To address this, we use RoBERTa (a pre-trained transformer-based language model (Vaswani et al., 2017)) (Liu et al., 2019) as the baseline model and empirically optimized this architecture to best learning capability and improve contextualized representations of the contracts in the parties extraction task. This optimized architecture includes transformer encoder layers, layer normalization, and dropout layers (**Contribution 2**).

The remaining sections of the paper are organized as follows: Firstly, in Section 2, we conduct a comprehensive literature review focusing on party extraction systems and party annotated datasets. Subsequently, in Section 3, we outline our proposed dataflow and the techniques applied to RoBERTa. We then present the experiments in Section 4, which encompasses the dataset description, environmental setup, and evaluation methodology. Moving forward, in Section 5, we present the experimental findings and compare the accuracy of our approach with different models derived from various techniques. Following that, in Section 6, we discuss the limitations of our approach and provide insights for future works. Finally, we conclude the paper with remarks in Section 7.

2 Related Work

Party extraction is currently being explored through various efforts. The primary methods used for text extraction are rule-based, machine learning, and transformers. However, to the best of our knowledge, only three researchers have attempted to extract parties from legal contracts, and only two have developed datasets for parties. This literature first examines previous research on dataset creation and highlights its advantages and limitations. Then, it delves into the details of the three party extraction systems.

2.1 Party Annotated Datasets

All of the available party extraction datasets for legal contract documents are annotated for both the parties involved in the contract and additional elements from the contract structure. (Wang, 2022).

Chalkidis et al. (2017) introduced a labeled dataset with gold contract element annotations. The contract elements they aimed to extract are Contract Title, Contracting Parties, Start Date, Effective Date, Termination Date, Contract Period, Contract Value, Government Law, Jurisdiction, Legislation Refs, and Clause Headings. They looked for the parties on the cover page and preamble (hereafter extraction zone) during the annotation to reduce the time needed to process the contracts. In practice, it would increase the false positives (tokens wrongly identified as contracting parties) during testing.

In the following year, there was another dataset released for contract review with more contract elements (Hendrycks et al., 2021). They chose a list of 41 label categories that lawyers pay particular attention to when reviewing a contract. The labels are broadly divided into the following three categories: General information, Restrictive covenants, and Revenue risks. They used the cover page, preamble, contract's first page, and signature part for the annotation of parties. Additionally, they also annotated the roles of the extracted parties. Since, their annotations include irrelevant terms, abbreviations, and sentences as parties, the quality of the dataset is quite low for the parties extraction.

2.2 Party Extraction System

In the view of party extraction systems, there were only two contracting parties extraction systems available.

Firstly, Chalkidis et al. (2017) experimentally compared several contract element extraction methods that used manually written rules and linear classifier (Logistic Regression, Support Vector Machine (SVM)) with hand-crafted features, word embeddings, and part-of-speech tag embeddings. Among their experiments, the linear classifier (SVM) performed best when both the hand-crafted features and the word and POS tag embeddings were used. In another experiment, manually written post-processing rules significantly improved the performance of the linear classifiers, leading to the same overall results for both LR and SVM, outperforming the rule-based system and the generic Named Entity Recognition. The F1 score of the two best systems was 0.89 in the extraction of parties. As we described in the section 2.1, identifying parties from extraction zones increase the false positive during testing. Therefore, the authors first identify the extraction zone using regular expressions and classify the tokens as contracting parties. This approach is unsuitable due to the generation of new types of contract documents by law firms, making it impossible to add expression rules for each new contract type.

In the following year, Hendrycks et al. (2021) conducted an experiment on a legal question-answering dataset using various generic models such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2020), and DeBERTa (He et al., 2021b). Their findings revealed that DeBERTa outperformed the other models, with almost 95% AUPR measure. However, most of the professional systems do not intend to use DeBERTa, a large language model which requires a high-computing resource to train and make predictions (Hendrycks et al., 2021). As we mentioned the section 2.1, even though their dataset quality is low for the parties extraction, the system achieved nearly 95% due to their customized evaluation algorithm. This algorithm used 0.5 as a threshold to find the overlap between extracted and actual strings to be counted as a valid match. Therefore, most of the sub-strings of the actual parties will be counted as valid matches. This leads to an increase in the evaluation metrics.

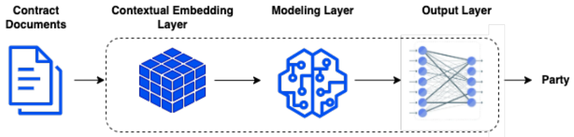

Figure 1: Overall System.

3 Methodology

The aim of this research is to create a question-answering model (Wang, 2022) to identify parties involved in legal contracts as shown in Figure 1. To accomplish this, we have opted to use RoBERTa (Liu et al., 2019) as our foundational model. There were several reasons behind our selection of RoBERTa (Liu et al., 2019) for this research. Firstly, it is a comparatively smaller model compared to other large language models (Devlin et al., 2019; He et al., 2021a). Secondly, RoBERTa (Liu et al., 2019) is equipped with a **Fast Tokenizer**, enabling us to process large volumes of text data quickly and efficiently. Lastly, this model has been shown to have performance improvements compared to BERT (Devlin et al., 2019) due to its dynamic masking technique.

3.1 Dataflow

In this section, we will look at how raw text inputs are processed by the model during fine-tuning. First, newly annotated documents are fed into the model. These documents are often large and lengthy, so a sliding window approach is used to divide them into smaller chunks of 512 tokens each as illustrated in Figure 2. Each token can be one or more characters long. (examples of tokens: ”as”, ”law”, and ”agree”).

Next, the inputs were tokenized using a *fast to-*

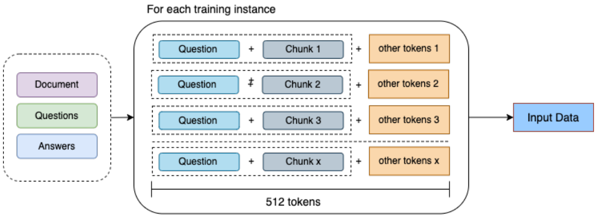

Figure 2: Chunks Creation. The document is divided into 512-token chunks, and each chunk is combined with a question to create a question-context pair. The pair also contains a flag that indicates whether the answer to the question is present in the chunk.

kenizer, which replaced each token with a unique integer identifier, or token ID. The vocabulary used for this step consisted of approximately 50,000 tokens, which were derived from *WordPiece* tokenization. *WordPiece* tokenization breaks down words into subwords or pieces, and the vocabulary includes these subwords, as well as some unique tokens used for specific purposes, such as *[CLS]* (classification), *[SEP]* (separator), and *[MASK]*.

In addition to the token IDs, positional embeddings were also created to indicate the relative positioning of the tokens between each other. This information is important for understanding the context of the text. Segment embeddings were also created to differentiate the question from the context. This information is important for tasks such as question answering, where the model needs to know which tokens belong to the question and which tokens belong to the context.

In the next step, the three embeddings were combined to create the input embeddings for the first encoder block. The encoder then uses multi-head attention to learn contextual information from the inputs. This is an important aspect, unlike RNN (Sherstinsky, 2020) or LSTM (Hochreiter and Schmidhuber, 1997), BERT-based (Devlin et al., 2019) models like RoBERTa (Liu et al., 2019), as it allows them to learn and memorize from neighboring sentences with accurate contextual information.

Each encoder block in a BERT-based model learns from the inputs and transfers the learned information to the next encoder block. Once the final encoder block is completed, the model's output is transformed into answer token logits using multiple layers. These layers are used during prediction to generate accurate answers to questions (van Aken et al., 2019).

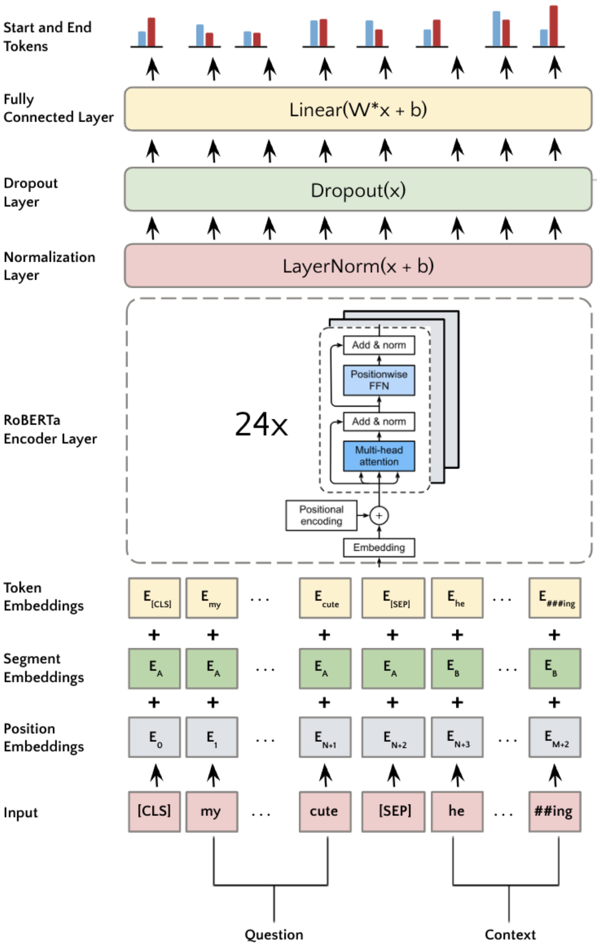

Figure 3: Best Performing Architecture. This architecture consists of 4 layers: (1) RoBERTa encoder layer (24), (2) Normalization layer, (3) Dropout layer, and (4) Fully connected layer.

3.2 Salient Factors

We have implemented several techniques to increase the learning capability of the model to learn complex structures within the legal space. These techniques involve altering the activation function and increasing the encoder layers. Additionally, we have stacked normalization and dropout layers as additional components on top of the output encoder layer. Our best-performing architecture is illustrated in Figure 3.

- **Encoder Layers**: A model's learning ability and performance are greatly influenced by the number of encoder layers it possesses (van Aken et al., 2019). To improve the model's performance, we conducted experiments where we adjusted the number of encoder layers to achieve the desired level of complexity.

Traditionally, when refining language models for extraction tasks, it is common practice to maintain the original quantity of transformer encoder layers in the architecture. However, our findings indicate that incorporating additional encoder layers enhances the transformer's capacity to capture intricate patterns and relationships within the input data. This expanded capacity enables the model to learn more detailed representations, improving performance.

Also, increasing the number of layers enables the model to capture information at various levels of granularity. Lower layers tend to focus on capturing local and syntactic legal information, such as word order and sentence structure, while subsequent layers have the ability to learn more abstract and semantic concepts. This hierarchical representation allows the model to understand both fine-grained details and the broader context of legal contracts, contributing to its overall effectiveness in capturing meaningful information from the input documents.

- **Activation Function**: The choice of activation function can impact the learning capacity, convergence speed, and generalization ability of the RoBERTa (Liu et al., 2019) model. We have experimented with different activation functions (Agarap, 2018; Hendrycks and Gimpel, 2020) during the encoder layer computation to identify the most suitable one for our model. By replacing the GELU (Dan and Kevin, 2016) activation function with the New GELU function, we have observed improvements in the model's performance.

- **Layer Normalization**: Layer normalization is a method that normalizes the inputs within each layer (Ba et al., 2016), making the training process faster. It reduces reliance on the activation scale and focuses on relative differences between activations, making the model more resilient to changes in input scale and improving generalization. We incorporated layer normalization into the output layer of the model, resulting in better overall performance.

- **Dropout**: Overfitting is a common issue in deep learning models, and dropout (Srivastava et al., 2014) is a regularization technique that can help address this problem. We have introduced a dropout of 0.2 in our model to mitigate overfitting issues that may arise due to increased model encoder layers from the above modifications. Our experiments have shown that dropout has effectively reduced overfitting.

4 Experiments

This section outlines our proposed solution for identifying parties mentioned in contract documents, which we approached as a question-answering task. Our methodology for training and evaluating the model is described, along with the results from experiments using various configurations.

4.1 Dataset

There is only one dataset available for party extraction which is **Contract Understanding Atticus Dataset** (CUAD) (Hendrycks et al., 2021). It contains 510 agreements of 25 different types, collected from the Electronic Data Gathering, Analysis, and Retrieval (EDGAR) system. Even though the dataset has been useful in extracting parties and clauses from legal documents, it has several shortcomings that limit its usability for our study.

One of the main shortcomings of CUAD is that the annotations include irrelevant terms such as *We*, *You*, and *Us*. These terms are not parties to the contract and are, therefore, not relevant to the task of extracting the exact match of the parties. Another issue with the annotations is that they include the parties' abbreviations, such as *PCQ* and *ABW*. While these abbreviations may be used in the contract, they are not always immediately recognizable and can be confusing for automated systems attempting to extract the parties. Annotations also include sentences as party names, such as *This agreement shall apply to said ABW and all of its subsidiaries and related companies*. These annotations are problematic because they do not accurately capture the parties to the contract and can lead to incorrect extractions. Furthermore, some parties are captured from the headings, signature part, and other places rather than from the actually mentioned sentences (the contract's first page other than the cover page). This can lead to inconsistencies as parties may have different names in different parts of the contract.

From the above study, we introduce a newly annotated dataset that comprises 1000 legal contract documents collected from CUAD (510 documents) and the EDGAR database (490 documents). This dataset is specifically annotated for accurate party detection along with the solution for the above shortcomings. This collection of contract documents falls into 25 different types (purchase agreements, employment contracts, lease agreements, etc) and have varying lengths that span from just a few pages to over one hundred pages. Figure 5 illustrated the distribution of contract documents' lengths. We then divide the dataset into a training set (2500 annotations across 900 documents) and a test set (253 annotations across 100 documents). We split the dataset randomly with a test set size of 0.1 to ensure both datasets were representative of the overall data distribution.

4.2 Experimental Set Up

We conducted our experiment step by step to identify the correct approach to achieve accurate party extraction with a high exact match. Finally, our experiments are mainly divided into four phases as follows:

1. Evaluate the CUAD's best model (DeBERTa)
2. Evaluate re-annotated and newly annotated dataset
3. Evaluate with different activation functions and layers stacks such as normalization and dropout
4. Evaluate with different numbers of encoder layers

In the first phase, we simply evaluate the trained DeBERTa model (CUAD's best model released by the authors) on our test dataset. This provides us with the initial baseline for our future experiments. In the second phase, we conducted experiments on re-annotated and newly annotated datasets separately to ensure their contribution towards the improvement of the accurate party extraction. After ensuring their positive contributions, then we combined both datasets and execute a new experiment to define a new baseline to do further studies.

We applied several techniques in the third phase to rescale the features (output from the encoder layers), normalize them, and randomly drop some units in the features to prevent overfitting in the training. From this phase, we identified an improvement over our new baseline (experiment D).

Algorithm 1 Evaluation Algorithm.
JS: Jaccard Similarity

```
procedure EXACTMATCH($instances, preds$)
    $ems \leftarrow array()$
    for $inst$ in $instances$: do
        $best \leftarrow 0$
        for $pred$ in $preds$: do
            $score \leftarrow JS(inst.answer, pred)$
            $best \leftarrow \max(score, best)$
        end for
        $ems \leftarrow append(best)$
    end for
    $em \leftarrow average(ems)$
    return $em$
end procedure
```

In the last phase, we considered the experiment with a high exact match from the previous phase for further studies. As we mentioned in the section 3, the ability to learn the complex structure of the legal text matters. Therefore, we explored into increasing the learning of such input space to the model. Finally, we found varying the number of encoder layers significantly improves the learning capability of the model. Then, we conducted additional experiments by altering the number of encoder layers from 12 (in the original RoBERTa) to 8, 16, 24, and 32.

To run all experiments, we used Amazon EC2's *g5.xlarge* instance and optimize the model's performance by tuning hyperparameters including batch size (32), learning rate (1e-04), and number of epochs (10).

4.3 Evaluation Criteria

Our aim is to identify the exact match between parties and to achieve this, we have chosen two key metrics. The first one is Jaccard similarity (Niwattanakul et al., 2013), which measures the similarity between sets and will help us determine how closely the predicted parties align with the actual parties in the test set. The second metric is the exact match, which will simply tell us if the predicted and actual parties are an exact match. By utilizing these two metrics, we can effectively evaluate the performance of our model on the test set and ensure that we are finding the precise match of the parties we are interested in. Algorithm 1 depicts our evaluation method.

Name	Experiment	Exact Match
A	Test on CUAD best model (DeBERTa)	0.887
B	Re-annotated CUAD (510 documents)	0.929
C	Newly annotated documents (490 documents)	0.921
D	**Baseline (B + C)**	**0.934**
E	Baseline + New GELU	0.933
F	Baseline + LayerNorm + Dropout + l=12	0.913
G	Baseline + LayerNorm + Dropout + l=8	0.905
H	Baseline + LayerNorm + Dropout + l=16	0.938
I	**Baseline + LayerNorm + Dropout + l=24**	**0.942**
J	Baseline + LayerNorm + Dropout + l=32	0.905

Table 1: Experimental Results. There are 5 stages of experiments: (1) Evaluation of CUAD's best model (A), (2) Evaluation of re-annotated, newly annotated, and whole dataset (B, C, and D), (3) Different architectural techniques (E, and F), (4) Change in the number of encoder layers (G, H, I, and J).

$$J(U,V) = \frac{|U \cap V|}{|U \cup V|}$$

where J is Jaccard similarity, U is annotated party answer and V is the predicted party from the fine-tuned model.

The results were compared to the ground truth using the Jaccard similarity coefficient, which measures the overlap between the predicted parties and the annotated parties. The coefficient is calculated as the ratio of the intersection of the two sets to the union of the two sets, ranging from 0 to 1, where 0 indicates no overlap and 1 indicates a perfect match. Qualitative experiments determined that a threshold of 0.5 is reasonable for determining the validity of the match.

5 Results and Analysis

Table 1 presents the results of experiments conducted to evaluate the performance of RoBERTa model including several variations of a baseline model, each with different modifications or additions, on the newly annotated dataset. In terms of datasets, the re-annotated CUAD's dataset significantly improved the performance of the system compared to the state-of-the-art DeBERTa model presented by CUAD (from the exact match (EM) of 0.887 to 0.929). This implies that most of the errors identified from the existing dataset have been resolved by our re-annotation process (experiment B). On the other hand, our newly annotated dataset achieved a higher score (0.921) than the current state-of-the-art model (0.887) and slightly less than that of experiment B (0.929), indicating that this data contributed positively to the experiment's performance. This motivates us to combine both datasets from experiments B and C to define a new experiment D as our new baseline.

The baseline experiment (D) achieved an EM of 0.934, which indicates the quality of the combined dataset compared to the existing dataset (CUAD). Even though our baseline model achieved a comparatively higher score, we found some mistakenly identified parties with non-formal forms and partial forms during our error analysis. By Further studies, we concluded that this is due to the inability of the models to learn the complex structure of the legal text. Therefore, we explored additional experiments to increase the learning capability of our model to learn legal text's complex structure.

Finally, we found that passing the output features from the 12th encoder layer of the original RoBERTa through additional layers will increase the further learning of the model on the training dataset. This will help to learn the complex structure of the input space and the association between the different sub-tokens of a party. For example,

- **Complex Structure:** The model (from experiment F) often failed while predicting the parties with some identified complex structures as depicted in Table 2.
- **Association:** There are four sub-tokens in the following party **SQUARE TWO GOLF INC.** such as **SQUARE**, **TWO**, **GOLF** and **INC.**. All of these sub-tokens together need to be identified as a party according to our goal (accurate party extraction).

From the above analysis and studies, we conducted several experiments by varying the number of encoder layers (l) from 8 to 32. But, as you can see in Figure 4, the average exact match is increased from 0.905 (experiment G) to 0.942 along with the number of layers until l=24 (experiment I). During the experiments, we also kept the normalization layer and dropout (0.2) layers on top of the final encoder layer to prevent overfitting. Even after, our model reached a lower exact match (0.905) than that of l=24 while using l=32. This shows our model is getting overfitted even using normalization and dropout layers. Finally, we concluded our experiments and fix our best model from experiment I (l=24). Through our analysis presented in Table 2, we have determined that our model has made substantial progress in comprehending the complex formatting of legal text and the relationships between its sub-tokens, leading to superior predictive capabilities.

6 Discussions

The results of our experiments demonstrate that increasing the number of additional encoder layers indeed leads to improved outcomes. Previous research models often struggled to identify and learn these complex structures when the number of encoder layers was less. By increasing the number of encoder layers in our approach, we were able to address this limitation and achieve significant improvements in exact matches.

The augmentation of encoder layers allowed our model to better capture and represent the nuanced relationships and patterns present within legal contracts. This, in turn, facilitated the identification and extraction of relevant information pertaining to the legal parties involved. The increased depth of the model architecture enabled it to learn and comprehend intricate complexities, which were previously challenging to capture effectively.

Furthermore, We introduced some modifications to the activation function and implemented additional normalization techniques on top of the final encoder layer. These adjustments were designed to complement the increased depth of the model and further enhance its ability to learn complex structures within legal contracts. The combined impact of increasing the encoder layers, replacing the activation function, and incorporating additional normalization techniques proved to be highly effective in our research as indicated in Table 1.

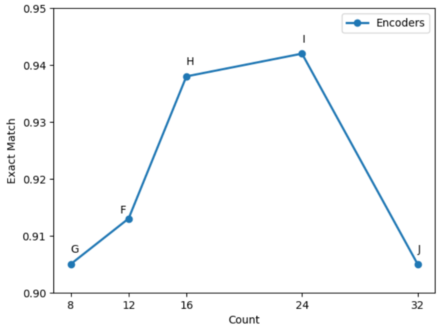

Figure 4: System Performance against the number of encoder layers

One of the main limitations of our model is the potential loss of context during the chunking process of input documents. Legal documents often contain intricate language and nuanced details that are crucial for accurately identifying parties. Chunking the input documents may lead to the loss of this contextual information, which can adversely affect the model's legal understanding. To mitigate this limitation, future research could explore the use of Longformer (Beltagy et al., 2020) architectures. Longformer models are specifically designed to handle long-range dependencies in a text.

7 Conclusion

We propose a novel method to accurately predict the parties from a legal contract document. We mainly divided the approach into two phases according to the literature review as follows: (1) Dataset Creation: We introduced a large-scale high-quality dataset that includes 1000 contract documents annotated for parties by legal experts; (2) Modeling: Our dataset underwent evaluation using various techniques to assess the performance of RoBERTa. Ultimately, our most successful model exhibited a noteworthy improvement of 6.2% in Exact Match performance compared to CUAD's best model (DeBERTa).

Our research revealed that the availability of data is a critical bottleneck, as nonessential annotations and a lower amount of data will significantly drop the performance, highlighting the importance of our dataset's extensive annotations. Moreover, we demonstrated that the performance of the models is greatly affected by their architecture, indicating that advancements in algorithms by the NLP community could aid in tackling this issue. In conclusion, our dataset not only acts as a benchmark for evaluating NLP models in the Legal domain but also accelerates research toward resolving a significant real-world problem in the legal firm.

Data Availability

Our newly annotated dataset is available under an open-source license at RTUthaya.lk[4]. This dataset is intended for research purposes only.

Abstract

Unsupervised Domain Adaptation (UDA) is a popular technique that aims to reduce the domain shift between two data distributions. It was successfully applied in computer vision and natural language processing. In the current work, we explore the effects of various unsupervised domain adaptation techniques between two text classification tasks: fake and hyperpartisan news detection. We investigate the knowledge transfer from fake to hyperpartisan news detection without involving target labels during training. Thus, we evaluate UDA, cluster alignment with a teacher, and cross-domain contrastive learning. Extensive experiments show that these techniques improve performance, while including data augmentation further enhances the results. In addition, we combine clustering and topic modeling algorithms with UDA, resulting in improved performances compared to the initial UDA setup.

1 Introduction

Fake news detection is a challenging task in which the goal is to detect whether the news content does not disseminate false information which may harm society. Recently, this problem has broad attention to the research community, especially with the rising interaction with social media platforms, which have become one of the primary sources of information for many individuals (Shu et al., 2020). Detecting fake news is challenging for many of us, since some news can be written very convincingly, thus spreading misleading information without control (Ahmed et al., 2017). Therefore, new datasets (such as BuzzFeed-Webis Fake News (BuzzFeed) (Potthast et al., 2018) and ISOT (Ahmed et al., 2017)) and novel detection techniques (Koloski et al., 2022; Mosallanezhad et al., 2022) have emerged in recent years.

Especially since the 2016 United States presidential election, a related task, namely hyperpartisan news detection, identifies whether the information spread by the news is in a political extreme (Rae, 2021). Hyperpartisan articles aim to expose information related to only one perspective, ignoring and, in some cases, even attacking the perspectives from other opposing sides (Kiesel et al., 2019). The consequences of this type of news range from misinformation in the media to an increase in the number of supporters of extreme ideologies (Huang and Lee, 2019).

Some works (Potthast et al., 2018; Ross et al., 2021) linked fake news with hyperpartisan news, since their goal is to spread as much as possible and influence people. This phenomenon is related to clickbait (Potthast et al., 2016), as the authors use different techniques to make the content more accessible and viral on the media (Kiesel et al., 2019).

Recently, many architectures based on Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019) have been developed and fine-tuned on various natural language processing (NLP) tasks. The current work aims to evaluate unsupervised deep learning techniques on the fake news detection task and adapt them to the hyperpartisan news detection task. Specifically, we employ the Robustly optimized BERT pretraining approach (RoBERTa) (Liu et al., 2019) and evaluate it in three domain adaptation scenarios: unsupervised domain adaptation (UDA) (Ganin and Lempitsky, 2015), cluster alignment with a teacher (CAT) (Deng et al., 2019), and cross-domain contrastive learning (CDCL) (Chen et al., 2020). In addition, we analyze topic modeling and clustering algorithms to generate domain labels and perform UDA to learn about topic-aware features which are specific to fake and hyperpartisan news detection. More precisely, we evaluate various clustering algorithms for generating domain labels, namely K-Means (Lloyd, 1982), K-Medoids (Kaufmann,

Proceedings of Recent Advances in Natural Language Processing, pages 1095–1109
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_117

1987), Gaussian Mixture (Fraley and Raftery, 2002), and HDBSCAN (Campello et al., 2013). Additionally, we explore four topic modeling algorithms: Latent Dirichlet Allocation (LDA) (Blei et al., 2003), Non-negative Matrix Factorization (NMF) (Lee and Seung, 1999), Latent Semantic Analysis (LSA) (Deerwester et al., 1990), and probabilistic LSA (pLSA) (Hofmann, 1999).

Therefore, the main contributions of this work are as follows:

- We evaluate the RoBERTa model on a domain adaptation from fake to hyperpartisan news detection by comparing three techniques, as well as several fine-tuning strategies.
- To our knowledge, we are the first to show that cross-domain contrastive learning proposed by Wang et al. (2022), initially employed on computer vision, which performs better than other unsupervised learning techniques on an NLP task.
- We propose the cluster and topic-based UDA approaches, which obtain better results when compared with the original formulation for UDA.
- We perform extensive experiments to assess the effectiveness of each employed method under various hyperparameter configurations and data augmentation techniques based on the term frequency-inverse document frequency (TF-IDF) scores (Salton et al., 1975) and the Generative Pre-trained Transformer 2 (GPT-2) model (Radford et al., 2019).

2 Related Work

2.1 Fake News Detection

Machine learning techniques for detecting fake news include various feature-based methods, ranging from text to visual features (Zhang and Ghorbani, 2020). For example, linguistic features (Choudhary and Arora, 2021; Pérez-Rosas et al., 2018) capture aspects related to conveyed information, document organization, and vocabulary used in news. In contrast, style-based features (Potthast et al., 2018; Zhou and Zafarani, 2020) are related to the writing style, such as redaction objectivity and deception (Shu et al., 2017). In recent years, Transformer-based models (Vaswani et al., 2017) emerged in the fake news detection literature (Jwa et al., 2019; Zhang et al., 2020; Kaliyar et al., 2021; Szczepański et al., 2021). Other techniques for detecting fake news use social aspects, such as the profiles of the users who spread the news on social media platforms (Shu et al., 2017; Onose et al., 2019; Zhou and Zafarani, 2020; Sahoo and Gupta, 2021). Techniques successfully employed for these scenarios rely on custom embeddings and linear classifiers (Shu et al., 2019), classic supervised machine learning techniques (Reis et al., 2019), and deep learning networks, such as recurrent (Wu and Liu, 2018) and graph neural networks (Monti et al., 2019; Hamid et al., 2020; Paraschiv et al., 2021).

2.2 Hyperpartisan News Detection

Task 4 of SemEval-2019 (Kiesel et al., 2019) introduced hyperpartisan detection from news articles as a binary classification task. The organizers created two balanced datasets by crawling data from various online publishers. Participants were asked to detect whether the news articles were hyperpartisan or mainstream. The winning team (Jiang et al., 2019) of the shared task proposed an architecture based on multiple pre-trained ELMo embeddings (Peters et al., 2019) averaged in the embedding space, followed by convolutional layers (Kim, 2014) and batch normalization (Ioffe and Szegedy, 2015). They achieved 84.04% accuracy on the training set and 82.16% accuracy on the test set, suggesting the challenging setting. Other works for the SemEval-2019 Task 4 were based on lexical and semantic handcrafted features via Universal Sentence Encoder (Cer et al., 2018) or BERT, and a linear classifier (Srivastava et al., 2019; Hanawa et al., 2019). Furthermore, Potthast et al. (2018) showed that hyperpartisan news detection could be analyzed using fake news approaches. They argued that the writing style for hyperpartisan news is similar to fake news, despite their political orientation.

2.3 Unsupervised Domain Adaptation

The core objective of unsupervised domain adaptation is to enforce a feature representation invariant to the domain of the examples with the same labels. One of the most effective techniques is the work of Ganin and Lempitsky (2015), which treated the problem as a minimax optimization. Wang et al. (2018) utilized domain adaptation techniques via adversarial training for fake news detection by employing an event discriminator to learn event-invariant features in a multi-modal setting. Deng et al. (2019) relied on the similarity in the feature space by enforcing a clustered structure among similar features. In this case, the training procedure optimizes clustering loss alongside the domain adaptation loss. For the target dataset, a teacher model consisting of an ensemble of students generates pseudo-labels (i.e., estimates of the true labels). Also, contrastive learning (Chen et al., 2020) was used to achieve unsupervised domain adaptation. It aims to have closer representations of the examples from the same class, while representations from different classes should stay far apart. In addition, Wang et al. (2022) proposed the cross-domain contrastive loss to minimize the l_2-norm distance between features from the same category, and employed K-Means to compute pseudo-labels.

3 Method

3.1 Base Model

In our current work, we utilize the pre-trained RoBERTa language model, which shares the same architectural design as BERT, the only difference being the pre-training objectives. The RoBERTa architecture stacks multiple Transformer encoders, each based on the multi-head self-attention mechanism (Vaswani et al., 2017). On top of the RoBERTa model, we add a label predictor containing fully connected layers. RoBERTA uses the Byte-Pair Encoding (BPE) tokenizer (Sennrich et al., 2015). In what follows, we present the settings in which RoBERTa is employed in our work (see Figure 1).

3.2 Unsupervised Domain Adaptation

Given two datasets $D_s = \{(x_s^i, y_s^i)\}_{i=1}^{N_s}$ and $D_t = \{x_t^i\}_{i=1}^{N_t}$ from different domains, the UDA setting reduces the shift between them (Ganin and Lempitsky, 2015; Ganin et al., 2016). This approach comprises a feature encoder G_f, a label predictor G_y, and a domain discriminator G_d. The feature encoder maps the input space into a latent space. Then, the label predictor computes the labels of the underlying examples. Simultaneously, the domain classifier uses the latent space to predict the domain of the features (i.e., the source or target domain).

To obtain domain-invariant features, the optimization is two-fold. First, we minimize the prediction loss concerning G_f's parameters θ_f and G_y's parameters θ_y. Second, we maximize the domain classification loss until G_d cannot distinguish the domains of the features. Formally, the loss function L (see Eq. 1) depends on the prediction loss L_y between G_y's outputs and source labels, and the domain adaptation loss L_d between G_d's outputs and domains d^i (i.e., hyperpartisan and fake news). The trade-off between L_y and L_d is controlled by λ. Note that we omitted the model's parameters for clarity.

$$\begin{aligned} L = &\sum_{i=1}^{N_s} L_y(G_y(G_f(x_s^i)), y_s^i) \\ &- \lambda \sum_{i=1}^{N} L_d(G_d(G_f(x^i)), d^i) \end{aligned} \tag{1}$$

The optimization problem associated with this formulation is described below:

$$\hat{\theta}_f, \hat{\theta}_y = \arg\min_{\theta_f, \theta_y} L(\theta_f, \theta_y, \hat{\theta}_d) \tag{2}$$

$$\hat{\theta}_d = \arg\max_{\theta_d} L(\hat{\theta}_f, \hat{\theta}_y, \theta_d) \tag{3}$$

where the parameters with hat are fixed during the optimization step. This problem can be solved with an implementation trick, namely gradient reversal layer (GRL) (Ganin and Lempitsky, 2015), which acts as the identity function during feed-forward and negates the gradients during back-propagation. The GRL layer is inserted between the feature encoder and the domain discriminator.

In our setting, we use the RoBERTa's encoders for feature extraction and fully connected layers for both the label predictor and domain discriminator.

3.3 Cluster Alignment with a Teacher

As an extension to UDA, Deng et al. (2019) exploited the class-conditional structure of the feature space by cluster alignment in the teacher-student paradigm. A teacher model trained on the labeled source examples estimates pseudo-labels for the unlabeled target dataset. To reduce the error amplification caused by label estimation, the teacher model is built as an ensemble of previous student classifiers. In addition, a student classifier minimizes the prediction loss L_y on the source examples in the supervised setting. The optimization involves minimizing both the prediction loss L_y and the sum of clustering losses L_c (i.e., for both the source and the target domains) and the cluster-base alignment loss L_a:

$$L = L_y + \alpha(L_c + L_a) \tag{4}$$

where the hyperparameter α controls the trade-off between the supervised and semi-supervised losses.

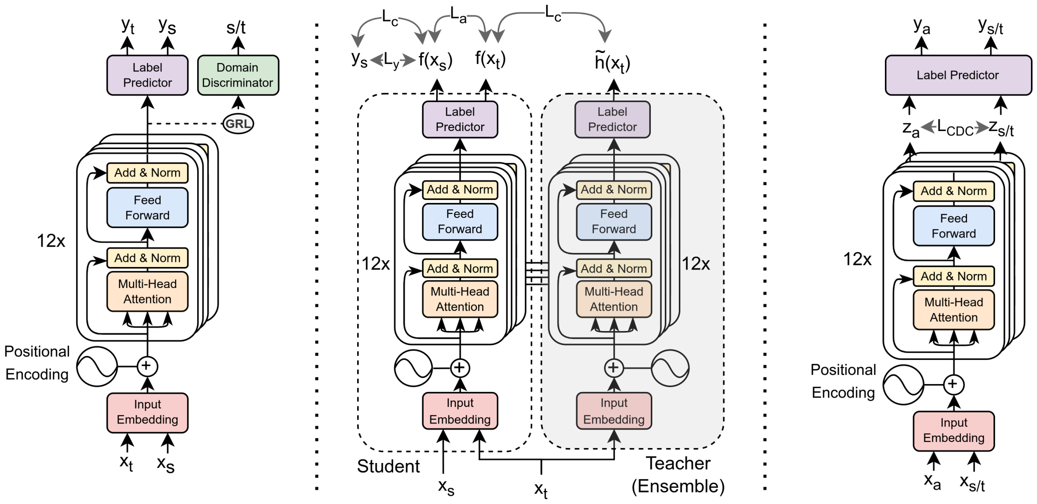

Figure 1: (Left) The RoBERTa model in the UDA setting includes a label predictor and a domain discriminator. (Center) In the CAT method, the student and teacher use the RoBERTa model. (Right) In the CDCL setting, the contrastive loss is applied between the RoBERTa features of an anchor and the source (s) / target (t) example.

Considering the labeled samples $X_s = \{x_s^i, y_s^i\}_{i=1}^{N_s}$, the unlabeled samples $X_t = \{x_t^i\}_{i=1}^{N_t}$, the feature extractor $f(\cdot)$, and the distance metric d between features, the total clustering loss is:

$$L_c(X_s, X_t) = L_c(X_s) + L_c(X_t) \tag{5}$$

where L_c is as follows for each X_*:

$$\begin{aligned} L_c(X_*) = \frac{1}{|X_*|^2} \sum_{i=1}^{|X_*|} \sum_{j=1}^{|X_*|} [\delta_{ij} d(f(x^i), f(x^j)) \\ + (1 - \delta_{ij}) \max(0, m - d(f(x^i), f(x^j)))] \end{aligned} \tag{6}$$

The intuition is to enforce class-conditional structure at the feature representation by grouping the classes into clusters, i.e., by minimizing the distance between features x^i and x^j that have the same label when the indicator function $\delta_{ij} = 1$, whereas pushing different clusters away from at least a margin m by maximizing the feature distance when $\delta_{ij} = 0$. The classifier trained on the source features may not be able to differentiate between the same class from different domains, and therefore, an alignment loss L_a is imposed between the domains as follows:

$$L_a(X_s, X_t) = \frac{1}{K} \sum_{k=1}^{K} ||\lambda_{s,k} - \lambda_{t,k}||_2^2 \tag{7}$$

In this case, given the number K of classes to be predicted, and the samples $X_{*,k}$ from either source or target whose labels are equal to k, the cluster centroids $\lambda_{*,k}$ are computed using:

$$\lambda_{*,k} = \frac{1}{|X_{*,k}|} \sum_{x_*^i \in X_{*,k}} f(x_*^i) \tag{8}$$

The loss L_a tries to match the source and target statistics by aligning the clusters for each class k in the feature space. Additionally, the performance can be further improved by aligning the marginal distributions, i.e., adding a confidence threshold that ignores the data points likely to be included in the wrong class.

3.4 Cross-Domain Contrastive Learning

Self-supervised contrastive learning (Chen et al., 2020) aims to learn representations such that, given a pair of examples, closely related examples should behave similarly, while dissimilar examples should stay far apart from each other. This can be achieved by employing various techniques such as data augmentation and custom losses (e.g., NT-Xent (Chen et al., 2020), InfoNCE (Oord et al., 2018)). Since there is no clear way to construct positive and negative pairs in an unsupervised domain adaptation framework, Wang et al. (2022) argued that samples from the same category should be similar. In contrast, samples from different categories should have other feature representations, regardless of the domain from which they come. Based on this hypothesis, they proposed the cross-domain contrastive (CDC) loss to reduce the domain shift between source and target labels. We assume z_t^a and

z_s^p are the l_2-normalized features for the anchor sample from the target domain x_t^a and the positive sample from the source domain x_s^p, respectively. In this case, the loss function is described by:

$$L_{CDC}^{t,a} = -\frac{1}{|P_s(\hat{y}_t^a)|} \sum_{p \in P_s(\hat{y}_t^a)} log \frac{\exp(z_t^a \cdot z_s^p / \tau)}{\sum\limits_{j \in I_s} \exp(z_t^a \cdot z_s^j / \tau)} \tag{9}$$

where $P_s(\hat{y}_t^a)$ denotes the set of positive samples from the source domain having the same label as the anchor point, and I_s is the set of all source samples from the mini-batch. Similar to Eq. 9, we compute $L_{CDC}^{s,a}$, for which we consider the positive samples from the target domain instead. The CDC loss with alignment at the feature level is[1]:

$$L_{CDC} = \frac{1}{N_s} \sum_{a=1}^{N_s} L_{CDC}^{s,a} + \frac{1}{N_t} \sum_{a=1}^{N_t} L_{CDC}^{t,a} \tag{10}$$

The objective function is given by the sum of the prediction loss L_y and the loss L_{CDC} scaled by γ:

$$L = L_y + \gamma L_{CDC} \tag{11}$$

We generate pseudo-labels using the K-Means algorithm since we require them when creating positive pairs. We initialize K-Means with the centroids of the source domain and predict on the target domain. The pseudo-labels are chosen to minimize the similarity distance between the feature representation and the centroid. K-Means is performed at the beginning of each epoch.

3.5 Cluster and Topic-Based Unsupervised Domain Adaptation

We propose an addition to the UDA approach, considering the supervised setting (i.e., we have access to the labeled source dataset). First, we represent the input text using TF-IDF or a pre-trained RoBERTa model. We employ a clustering/topic modeling algorithm in this feature space to identify k clusters or topics, which will be assigned as domain labels. For clustering, we employ four algorithms, namely K-Means, K-Medoids, Gaussian Mixture, and HDBSCAN. Also, we use four topic modeling algorithms, namely LDA, NMF, LSA, and pLSA. The motivation is to compact the latent representation, given estimates of latent domains under a topic model (i.e., a dataset split). During training, it is minimized the loss given by Eq. 1 while using the proposed domain labels. For the target examples, we do not include labels during training. We choose the number of clusters using the elbow method[2]. After training on each pair of domain labels, the best-performing model is selected for the inference stage.

4 Experimental Setup

4.1 Datasets

We perform experiments on three datasets related to fake (i.e., ISOT and BuzzFeed) and hyperpartisan (i.e., BuzzFeed and Hyperpartisan (Kiesel et al., 2019)) news detection.

The ISOT fake news dataset contains news articles collected from reuters.com, and other websites, which were validated by Politifact[3]. The dataset comprises 44,898 articles, of which 21,417 contain truthful information, and 23,481 are fake news. All collected articles are related to politics and have at least 200 characters.

The BuzzFeed dataset contains 1,627 articles in three categories: mainstream, left-wing, and right-wing. The mainstream and hyperpartisan data are evenly distributed, and the length of the articles ranges between 400 and 800 words. This dataset is annotated for both fake and hyperpartisan news detection.

The Hyperpartisan dataset which contains hyperpartisan news was released under the SemEval-2019 Task 4 shared task (Kiesel et al., 2019). The dataset was crawled from news publishers listed by BuzzFeed[4] and Media Bias Fact Check[5]. From these sources, 754,000 news articles were extracted and semi-automated labeled using distant supervision (Mintz et al., 2009) at the publisher level, provided in the HTML format. It was split into 600,000 articles for training, 150,000 articles for validation, and 4,000 articles for testing. Half of the dataset consists of non-hyperpartisan articles, and the other half is split equally among left-wing and right-wing articles. Since the authors also released a smaller version of the dataset (645 examples for training and 628 examples for testing), in what follows, we will refer to the larger

[1] Note that we included the normalization terms compared to the original formulation.

[5] https://mediabiasfactcheck.com

dataset as Hyperpartisan-L and the smaller dataset as Hyperpartisan-S.

4.2 Data Preprocessing

We perform data cleaning on all three corpora, ignoring non-ASCII characters and removing HTML-specific symbols and constructions that do not provide any information about the actual content, such as multiple chains of dots in a line. BPE was utilized for tokenization, setting to output a maximum of 128 tokens per text sample.

Since the ISOT and BuzzFeed datasets are not provided with separate splits for validation and testing, we use the following split: 70% for training, 10% for validation, and 20% for testing. In addition, due to limited computational resources and the large size of the Hyperpartisan dataset, we select a random 5% of the data from the training set (i.e., 30,000 examples) and 5% of the data for the validation set (i.e., 7,500 examples). Also, we use the entire Hyperpartisan test set since it contains only 4,000 examples.

4.3 Hyperparameters

We utilize the pre-trained RoBERTa base version (123M parameters), which consists of a stack of 12 Transformer blocks. For all experiments, the Adam optimizer (Kingma and Ba, 2015) with a linear scheduler is used with a warm-up (it is set with 5% of the gradient steps) for the learning rate. The learning rate varies among experiments, between $1e-4$ and $1e-5$. We employ a dropout set between 0.1 and 0.5. We also set the optimizer's weight decay parameter to $1e-3$, and clip the gradients between -1 and 1 to increase training stability and reduce overfitting.

5 Results

There were conducted multiple experiments to evaluate the impact of using various fine-tuned models for RoBERTa. We also investigate the effects of fine-tuning the RoBERTa model on the downstream task. Then, we analyze the impact of using a data augmentation technique (Xie et al., 2020) based on the TF-IDF scores. In Appendix A.1, we present the results of the GPT-2 data augmentation. Finally, we use clustering and topic modeling algorithms to extract clusters and topics from the training set and perform domain adaptation. We present the results in terms of accuracy (Acc) and F1-score (F1).

Dataset	Acc(%)	F1(%)
BuzzFeed	96.9	96.7
ISOT	99.8	99.7
Hyperpartisan-S	83.7	83.0
Hyperpartisan-L	62.1	69.0

Table 1: Results obtained after fine-tuning and evaluating RoBERTa on each dataset.

Model	Acc(%)	F1(%)
RoBERTa	62.1	69.0
RoBERTa frozen	53.7	65.4
RoBERTa fine-tuned first on BuzzFeed	62.3	68.0
RoBERTa fine-tuned first on ISOT	**63.0**	**70.0**

Table 2: Results for different fine-tuning strategies on the Hyperpartisan-L dataset.

5.1 Baselines

We start with the most straightforward approach for training a neural network. That is, we take a pre-trained model on similar tasks and transfer some of the acquired knowledge to the downstream task via fine-tuning. The baseline model consists of the RoBERTa model followed by a stack of fully connected layers. We employ two fully connected layers, with 256 hidden units and two output neurons. The models are trained for 3 epochs, with a learning rate of $1e-4$ and batch size between 32 and 64.

First, we evaluate the model on all four datasets for baseline results. Table 1 presents the final results obtained during experiments. We observe that ISOT achieves the highest scores, followed by BuzzFeed and Hyperpartisan-S. We note that humans annotated these datasets, whereas the Hyperpartisan-L dataset was annotated with a semi-supervised approach.

By comparing three fine-tuning methods (see Table 2), we observe that freezing the model's encoders yields poor performance. This increases the number of false positives and decreases the number of true negatives because of the domain shift between the datasets and training with fewer parameters. On the other hand, fine-tuning improves the results since the model's parameters are adapted to the new domain.

5.2 Results for UDA

We consider the encoders from the RoBERTa model as feature generators. We also use a stack of fully connected layers, with 256 hidden neurons and two outputs for both the label predictor and the

λ	Source	Target	Source		Target

pos.	Acc(%)	F1(%)	Acc(%)	F1(%)
4	**95.9**	**95.2**	62.1	61.7
6	95.0	94.4	62.1	**67.1**
10	91.3	89.1	60.9	64.1
12	95.3	94.9	**64.3**	62.7

Table 4: Various linking positions of the GRL layer to the encoders of RoBERTa, on BuzzFeed (source) to Hyperpartisan-L (target) adaptation.

domain discriminator. The domain discriminator is linked to the output of the RoBERTa encoder via a gradient reversal layer. We tested three values for $\lambda \in \{0.1, 1, 5\}$.

Furthermore, we perform larger-to-smaller and smaller-to-larger dataset adaptations between Hyperpartisan-L and BuzzFeed. The model is trained for 3 epochs (i.e., the steps required to pass through all examples from the larger dataset). The batch size is set to 64, from which half are labeled and the other half are unlabeled examples. The results are shown in Table 3. We observe that if λ is set too large, the model does not learn the data distribution but predicts only one class. Conversely, UDA performs better when $\lambda = 0.1$, achieving higher accuracy on the Hyperpartisan-L target dataset. This adaptation may have helped because of the inherent similarities between domains and improved performance on out-of-distribution points.

Moreover, we employ different ways of linking the GRL layer with the RoBERTa encoders. Since the RoBERTa-base model uses 12 encoders, we utilized the 4th, 6th, and 10th, besides the previous experiments. While the encoder returns a feature representation for each element in the sequence, we take the representation of the `[CLS]` token. Table 4 shows the results. The 12th layer performs best, while similar performances are achieved using the 4th or 6th layer. The results are supported by the fact that more layers for the encoder mean more representational power for the feature encoder that needs to be adapted among domains.

λ	α	Source		Target	
		Acc(%)	F1(%)	Acc(%)	F1(%)
1	1	92.5	91.2	51.3	**66.4**
1	0.1	94.7	93.8	57.9	62.6
0.1	0.1	95.9	95.7	**59.9**	61.5
0.1	0	**96.5**	**96.4**	58.7	64.3
0	0.1	95.6	95.4	59.8	64.1
0	0	93.7	92.7	58.9	62.5

Table 5: Results for the CAT framework on BuzzFeed (source) to Hyperpartisan-L (target) adaptation.

5.3 Results for CAT

In addition to the previous experimental setup, we set the parameter $\alpha \in \{0.1, 1\}$ for the clustering loss in the CAT configuration. We also consider a lower learning rate (i.e., $1e-5$) to improve convergence. We consider an epoch is a complete pass through the smaller dataset to update the pseudo-labels for the entire target domain using the teacher model. As such, we trained the models for 10-30 epochs. We set the margin $m = 2$, the ensemble size to 3, and the ensemble accumulation to 0.8.

We performed domain adaptation from BuzzFeed to Hyperpartisan-L. The results are shown in Table 5. The model obtains over 90% accuracy on the source domain and is bounded by 66.4% on the target domain. This approach generally achieves a smaller accuracy than previous techniques, the best score being when $\lambda = \alpha = 0.1$. Also, we can observe that the difference between λ and α affects the performances. Analyzing the model predictions, we notice that using smaller values for λ and α yields a high number of false positives, while larger values increase the number of false negatives. Using $\lambda = 1$ and $\alpha = 0.1$ resulted in a biased model towards mainstream examples.

5.4 Results for CDCL

For the CDCL method, the experimental setup is similar to the one used for the CAT. We varied the temperature $\tau \in \{0.1, 0.5, 1\}$ and the coefficient $\gamma \in \{0, 0.1, 1, 5\}$. Table 6 provides the results of our analysis. We observe that both τ and γ affect the performance. The best results were attained when $\tau = 1$, and $\gamma = 5$, achieving 63.9% accuracy on the target domain, while $\tau = 0.5$ generates the best values on the source dataset. It proves that L_{CDC} performs some regularization on the source domain. We noticed that the models often produce a high false positive rate, affecting the recall more than the precision. In addition, training for more epochs, the model starts overfitting on

τ	γ	Source		Target	
		Acc(%)	F1(%)	Acc(%)	F1(%)
0.1	0	95.6	95.2	59.9	62.2
0.1	0.1	91.3	90.1	63.3	64.9
0.1	1	96.2	96.0	61.9	68.8
0.1	5	96.2	96.0	62.6	67.9

both source and target domains while degrading the performance of the validation set.

5.5 Results for Text Augmentation Based on TF-IDF

We explore a data augmentation technique based on TF-IDF as proposed by Oord et al. (2018) for consistency training. Thus, we compute the TF-IDF score for every token from the corpus and associate it with the probability of it being changed. The words with the higher probability are replaced with non-keywords from the vocabulary to avoid changing the meaning of the text. The TF-IDF-based word replacement depends on a hyperparameter p that controls the level of augmentation enabled on the dataset. We vary p for our experiments to augment the BuzzFeed dataset with multiple augmentation levels. Table 7 shows the results for all training configurations, where two or three values per augmentation type indicate that we applied each value of p and concatenated the augmented examples over the original dataset. Also, zero suggests that only the unaltered dataset was used. Using more augmentations (e.g., $p \in \{0.1, 0.2, 0.3\}$) on the CDCL and CAT frameworks yields better overall results, while on UDA, using a much stronger augmentation (i.e., $p = 0.5$) leads to better results.

One problem with this data augmentation technique is that it may alter the text in a way that is not coherent anymore, specifically when many tokens are changed. The most frequent words may not always have the same meaning, so their contextualized representation is affected. Since the context defines the meaning of a word in language models, this augmentation changes the representation, especially on unlabelled data. Table 7 illustrates the issue on the target dataset. However, on the source dataset, the performance is not affected but generally improved.

p	Source		Target	
	Acc(%)	F1(%)	Acc(%)	F1(%)
UDA				
0	94.0	93.4	59.1	**64.5**
0.5	95.8	95.5	**63.2**	62.7
0.1/0.2	94.7	94.5	57.3	61.5
0.1/0.2/0.3	**98.4**	**98.3**	61.3	46.9
CAT

Table 7: Results for the TF-IDF-based data augmentation. The source is BuzzFeed and the target is Hyperpartisan-L.

5.6 Results for Cluster- and Topic-Based UDA

In the topic-based UDA approach, we follow the same experimental setup as in classical UDA. For training, the only difference is that we train all models for 10 epochs. We explore both, the clustering on RoBERTa features (i.e., K-Means with Euclidean or cosine distance, K-Medoids, Gaussian Mixture, and HDBSCAN) and the topic modeling algorithms on TF-IDF features (i.e., LDA, NMF, LSA, and pLSA) to split the representation. We evaluate the experiments on the Hyperpartisan-L test set and present the results in Table 8. Using clustering algorithms for domain labels provides the best overall results compared to Table 3. The best-performing models outperform the UDA approach by over 3% in accuracy and are obtained when we adapted from a larger to a smaller split. It is noteworthy that for the HDBSCAN, the cluster 2 contains very few annotated examples (i.e., 332) compared with the other two (i.e., 17,092 and 12,576), resulting in adaptation failure. When using the topic modeling, we see a degradation in performance, especially in the case of NMF. Compared with the RoBERTa baseline (see Table 2), the model achieves similar F1-scores.

5.7 Feature Visualization

We use t-SNE (Van der Maaten and Hinton, 2008) to visualize the feature representation learned by the best models we obtained for each category. In Figure 2, we present the plots for the baseline, the

UDA, the CAT, and the CDCL. Using different approaches to domain adaptation may reduce the domain gap in the feature space between the two domains. Still, many examples cluster together far apart from their counterparts. UDA obtains better representations than the other methods. When considering the topic-based adaptation (see Figure 3), we notice a better separation when employing topic models. Also, we achieve poor separation among classes for K-Means and K-Medoids.

6 Conclusions

In this work, we addressed the problem of transferring knowledge from fake to hyperpartisan news detection. We employed three types of architectures based on unsupervised training. We conducted multiple experiments, showing the effects of the hyperparameters in the given configuration. All employed methods manage to perform some domain adaptation. In particular, we showed that CDCL obtains the best results after applying data augmentation based on TF-IDF word replacement. In contrast, CAT managed the poorest results. By analyzing the t-SNE visualization, this model did not learn a good feature representation, with a minimal domain gap between the source and target datasets. The low accuracy we hypothesize is due to a lack of data from the source domain, as we have seen that data augmentation helped. For future work, we aim to investigate our approaches on other fake news datasets.

A Appendix

A.1 Results for Text Augmentation Based on GPT-2

Observing the improvements obtained using TF-IDF augmentation, we consider text generation an alternative. Therefore, we employ the GPT-2 model (Radford et al., 2019) to conditionally generate new examples given the news types (i.e., left-wing, right-wing, and mainstream). We follow an approach similar to the LAMBADA method proposed by Anaby-Tavor et al. (2020). Therefore, we fine-tune the GPT-2 base model on the hyperpartisan Buzzfeed dataset to generate new samples. Inspired by other works (Brown et al., 2020; Liu et al., 2023; Niculescu et al., 2022), we build the pre-training dataset using, for each sample, the following prompt:

```
News type :  <LABEL>
Text :  <TEXT>
<|endoftext|>
```

where `<LABEL>` is *left*, *right*, or *mainstream*, `<TEXT>` is the news content, and `<|endoftext|>` is the end token of the text. Since we use a relatively small context during experiments (i.e., 128 tokens), we do not require the auto-regressive model to learn to generate long samples, but rather more variation within the generated samples. To achieve this, we split each text into sentences and group every three sentences into one example under the same label.

As suggested by Kumar et al. (2020), during data generation, we iterate over each sample from the training set and prompt the model with `News type:  <LABEL> Text:` followed by the first T tokens from each sample. Because the model may generate text that is not correlated with the label (i.e., either the model ignores the prompt label (Webson and Pavlick, 2022), or there is not enough data for the model to learn a clear distinction), we use the RoBERTa baseline model fine-tuned on the Buzzfeed dataset to filter the samples, ignoring those that do not match the model's prediction.

Text generation quality depends on the decoding strategy; thus, we explore multiple approaches.

Greedy decoding. The most trivial and fastest way of synthesizing text is to consider the token with the highest probability. Albeit simple, it has the disadvantage of generating repetitive and missing higher probability words behind lower probability ones.

Beam search. Beam search (Freitag and Al-Onaizan, 2017) seeks to solve the low probability issue from the greedy decoding by choosing the highest probability sequence within a number of beams. This method generally yields to higher probability sequence than greedy decoding. During experiments, we set the number of beams to 5.

Top-k. Using the top-k decoding (Fan et al., 2018), we consider only the highest k next tokens from the probability distribution over possible next tokens. This simple yet effective method produces more human-like text than previous approaches. In our experiments, we consider $k = 30$ tokens.

Top-p nucleus sampling. Introduced by Holtzman et al. (2020), the top-p nucleus sampling is an extension over top-k. We choose the tokens from the smallest subset whose cumulative probability is at least p instead of choosing from the top k probabilities. For experiments, we set $p = 99\%$.

To generate more samples, we repeat the procedure while setting $T \in \{3, 5, 10\}$. The results are shown in Table 9. CDCL obtains the highest scores on the source and target datasets using top-p and greedy decoding, respectively. On the source dataset, the accuracy reaches 97.8% and the F1-score tops at 97.7%, while on the target dataset, the best accuracy is 64.4% and F1-score is 70.4%. Compared with the TF-IDF text augmentation, the GPT-2 augmentation produces a higher best F1-score by 1% on the target test set, and achieves lower scores on the source test set by 1%. In addition, we notice that the performance improves when adding more data, especially on the source dataset, where we see an average improvement of 0.6% and 0.8% for accuracy and F1-score, respectively. On average, greedy decoding improves the target F1-score (i.e., 68.0±1.5%) while the lowest average is obtained by top-p (i.e., 65.7±3.5%). We notice a small improvement in favor of top-p compared with top-k on the source domain, but the target domain does not benefit from it in our case.

Abstract

This paper introduces the first prompt-based methods for aspect-based sentiment analysis and sentiment classification in Czech. We employ the sequence-to-sequence models to solve the aspect-based tasks simultaneously and demonstrate the superiority of our prompt-based approach over traditional fine-tuning. In addition, we conduct zero-shot and few-shot learning experiments for sentiment classification and show that prompting yields significantly better results with limited training examples compared to traditional fine-tuning. We also demonstrate that pre-training on data from the target domain can lead to significant improvements in a zero-shot scenario.

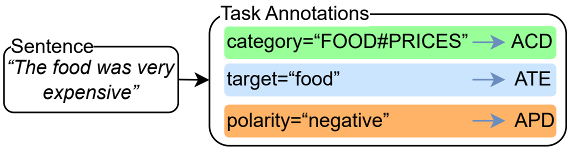
1 Introduction

In recent years, pre-trained BERT-like (Devlin et al., 2019) models based on the Transformer (Vaswani et al., 2017) architecture and language modelling significantly improved the performance of various NLP tasks (Raffel et al., 2020). The initial approach was to pre-train these models on a large amount of text and then fine-tune them for a specific task. More recently, an approach exploiting the nature of language modelling appeared, called *prompting* or *prompt-based fine-tuning*. Prompting is a technique that encourages a pre-trained model to make specific predictions by providing a prompt specifying the task to be done (Liu et al., 2023).

This new approach became very popular in solving NLP problems in zero-shot or few-shot scenarios, including sentiment analysis (Gao et al., 2021, 2022; Hosseini-Asl et al., 2022). Most of the current research aimed at languages other than Czech, especially English. To the best of our knowledge, no research has focused on any sentiment analysis task in the Czech language using prompt-based fine-tuning. To address this lack of research, this paper presents an initial study focusing on two sentiment-related tasks: **aspect-based sentiment analysis** and **sentiment classification** in the Czech language by applying prompt-based fine-tuning.

The *sentiment classification* (SC), also known as *polarity detection*, is a classification task where the objective for a given text is to assign one overall sentiment polarity label. Usually, the three-class scheme with *positive*, *negative* and *neutral* labels is used, but more labels can be applied (Liu, 2012).

Aspect-based sentiment analysis (ABSA) is a more detailed task compared to SC, which aims to extract fine-grained information about entities, their aspects and opinions expressed towards them. Generally, the goal of ABSA is to identify the sentiment of each aspect or feature of a product or service. There are multiple definitions and versions of the ABSA task (Pontiki et al., 2014; Saeidi et al., 2016; Barnes et al., 2022). In this work, we focus on the version of *aspect-based sentiment analysis* presented in the SemEval competitions (Pontiki et al., 2015, 2016), which includes several subtasks. Specifically, the tasks are aspect category detection (ACD), aspect term extraction (ATE), simultaneously detecting (aspect category, aspect term) tuples (ACTE), and detecting the sentiment polarity (APD)[1] of a given aspect term and category (see Figure 1 for examples).



Sentence
"The food was very expensive"
Task Annotations
category="FOOD#PRICES" → ACD
target="food" → ATE
polarity="negative" → APD

Figure 1: The example of the ABSA tasks.

In addition, we solve the target-aspect-sentiment detection task (TASD) (Wan et al., 2020), which

[1] The ACD, ATE, ACTE and APD tasks are named Slot1, Slot2, Slot1&2 and Slot3, respectively, in (Pontiki et al., 2015, 2016) under Subtask 1.

Proceedings of Recent Advances in Natural Language Processing, pages 1110–1120
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_118

aims to simultaneously detect the aspect category, aspect term and sentiment polarity.

This paper presents a novel approach for solving Czech sentiment classification and ABSA tasks using prompt-based fine-tuning. We utilize Czech monolingual BERT-like models and their language modelling ability to perform *prompting* for the APD and SC tasks. We use multilingual text-to-text generative models for the remaining ABSA tasks to generate textual predictions based on prompted input. Our approach enables us to solve all these ABSA tasks at once, and we show that it is superior to the traditional fine-tuning approach for them.

We also explore zero-shot and few-shot learning scenarios for APD and SC tasks and show that prompting leads to significantly better results with fewer training examples compared to traditional fine-tuning. Additionally, we demonstrate that pre-training on data from a target domain results in great improvements in a zero-shot scenario.

Our study provides pioneered results for prompt-based fine-tuning in Czech sentiment. Overall, our key contributions are the following: 1) We propose, to the best of our knowledge, the first prompt-based approach for sentiment analysis tasks in Czech. 2) We show the superior performance of our prompting approach over traditional fine-tuning for ABSA tasks. 3) We compare the two approaches and show that prompting achieves better results than traditional fine-tuning in few-shot scenarios.

2 Related Work

This section reviews prior works conducted on sentiment analysis in Czech. The prompt-based fine-tuning is a relatively new paradigm in NLP, and to the best of our knowledge, no research has yet explored its application on sentiment analysis in Czech. To partly address this research gap, we include prompt-based approaches for analogous sentiment analysis tasks in English.

2.1 Czech Sentiment Classification

The first approaches for sentiment analysis in Czech often utilized lexical features (Steinberger et al., 2011; Veselovská et al., 2012) and n-gram text representations in combination with classifiers like maximum entropy or Naive Bayes (Habernal et al., 2013). Subsequently, Brychcín and Habernal (2013) employed a mixture of supervised and unsupervised techniques to improve polarity detection in movie reviews. Similarly to Kim (2014), Lenc and Hercig (2016) used the convolutional neural network (CNN) and Long Short-Term Memory (LSTM) for SC of the same CSFD dataset we use in this work, see Section 3.1. The authors of (Libovický et al., 2018) added self-attention to an LSTM-based neural network and applied it to the CSFD dataset. A detailed survey of older approaches for Czech sentiment analysis is presented by Çano and Bojar (2019). In recent years, Czech Transformer-based models have been proposed and have shown great success in Czech sentiment analysis. Sido et al. (2021) introduced the first Czech BERT-like model, outperforming previous state-of-the-art (SotA) results in SC. Additionally, Straka et al. (2021) presented a pre-trained Czech version of the RoBERTa (Zhuang et al., 2021) model and demonstrated its effectiveness for the Czech language on Facebook posts. Přibáň and Steinberger (2021) provide the SotA results for three Czech polarity detection datasets. The most recent work comes from Přibáň et al. (2022); Přibáň and Steinberger (2022), where the authors investigate the possibility of performing zero-shot cross-lingual sentiment analysis and subjectivity classification between Czech and English with multilingual Transformer-based models like mBERT (Devlin et al., 2019) or XLM-R (Conneau et al., 2020).

2.2 Czech Aspect-Based Sentiment Analysis

The ABSA task in the Czech language has been much less studied in recent years and the existing approaches are usually outdated compared to recent sentiment classification methods. The pioneering research on Czech ABSA can be found in Steinberger et al. (2014), where the authors manually annotated and created a restaurant review dataset for the same tasks as in the SemEval 2014 competition (Pontiki et al., 2014). They provided results of baseline models based on Conditional Random Fields (CRF) and Maximum Entropy (ME) classifier. Tamchyna et al. (2015) built a dataset containing IT product reviews and provided baseline results with the CRF. Unlike in the mentioned Czech restaurant dataset, the IT product reviews are annotated with global sentiment and aspect terms but without any categorization and sentiment toward the terms. Hercig et al. (2016) extended the Czech restaurant review ABSA dataset and suggested several unsupervised methods to enhance the performance on ABSA tasks in Czech and English using the CRF and ME classifiers. They showed that unsupervised methods can provide substantial improvements.

2.3 Prompt-Based and Related Approaches

As we already mentioned, there is no work for Czech sentiment analysis based on prompt-based fine-tuning. Therefore, we provide example studies focused on English sentiment analysis using prompt-based approaches or related methods.

Zhang et al. (2021b) formulate the ABSA tasks as a text generation problem. They propose two paradigms to deal with the ABSA tasks, namely annotation-style and extraction-style modelling, both generating textual output in a desired format. They utilize the English T5 (Raffel et al., 2020) text-to-text Transformer-based model and evaluate their approach on various ABSA tasks, including the TASD task, on datasets from the SemEval competitions (Pontiki et al., 2014, 2015, 2016). They showed the effectiveness of their approach by establishing new SotA results. Similarly, Zhang et al. (2021a) used the same English T5 model to solve a newly introduced ABSA task called *aspect sentiment quad prediction* by generating textual output. Another approach proposed by Gao et al. (2022) aims to solve multiple ABSA tasks at once. The authors applied the English T5 model to a prompt created from the individual ABSA tasks. They evaluated their model on the same datasets as Zhang et al. (2021b), outperforming the previously mentioned approach and achieving new SotA results.

Gao et al. (2021) experimented with prompt-based fine-tuning for SC. With the English T5 model, they automatically generated prompts for BERT and RoBERTa models, which they consequently fine-tuned for the SC task. They demonstrated that their few-shot approach leads to better results compared to traditional fine-tuning.

3 Data & Tasks Definition

In this section, we describe the aspect-based and sentiment classification datasets. Furthermore, we describe in more detail the ABSA tasks introduced in Section 1, on which this paper is focused.

3.1 Data for Sentiment Classification

For the SC task, where the goal is to assign one overall polarity label (*positive*, *negative* or *neutral*) for a given text, we employ the Czech CSFD dataset (Habernal et al., 2013). The dataset contains 91,381 movie reviews from the Czech movie database[2]. The reviews are annotated in a distant supervised way according to the star rating assigned to each review (0–1 stars as *negative*, 2–3 stars as *neutral*, 4–5 stars as *positive*). We use the training and testing split from Přibáň and Steinberger (2021), see Table 1.

Split	Positive	Negative	Neutral
train	24,573	23,840	24,691
test	6,324	5,876	6,077
total	30,897	29,716	30,768

Table 1: Statistics of the CSFD dataset.

For the additional pre-training (see Section 5.2), we downloaded 4.2M movie reviews (i.e. 1.8 GB of plain text) from the Czech movie database[2]. From the downloaded reviews, we removed all reviews present in the annotated CSFD dataset.

3.2 Data for Aspect-Based Sentiment Analysis

For the ABSA tasks, we use the Czech dataset (Hercig et al., 2016) from a restaurant domain which we convert into the SemEval 2016 competition (Pontiki et al., 2016) format to align with the ABSA tasks addressed in this paper. The dataset consists of 2,149 Czech restaurant reviews, which we split into the training and testing parts in a 75:25 ratio. The label distribution of the modified[3] ABSA dataset (Hercig et al., 2016) is shown in Table 2, along with the number of sentiment labels for aspect categories used in the APD and TASD tasks[4].

Split	Sentences	Positive	Negative	Neutral
train	1,612	1,231	1,197	336
test	537	420	426	61
total	2,149	1,651	1,623	397

Table 2: Statistics of the Czech ABSA dataset.

For the additional pre-training, we scraped 2.4M reviews of Czech restaurants from Google Maps[5], resulting in 330 MB of plain text. As restaurant reviews are shorter, the size is smaller than downloaded movie reviews. This resulted in 330 MB of plain text, a much smaller size compared to the downloaded movie reviews due to the shorter

[2] https://www.csfd.cz

[3] The dataset was converted into the SemEval 2016 competition (Pontiki et al., 2016).

[4] Because one review can contain multiple aspect categories, the number of sentiment labels does not sum up to the number of given sentences in Table 2.

[5] https://www.google.com/maps

length of restaurant reviews. We removed all reviews present in the annotated ABSA dataset.

3.3 Aspect-Based Sentiment Tasks Definition

Given the complexity and possible confusion in naming the aspect-based tasks we deal with in this paper, we briefly describe the tasks. As mentioned, in the ABSA tasks, we aim at the Czech restaurant reviews domain.

The ACD task aims to identify all *E#A* aspect categories towards which an opinion is expressed in a given sentence. The *E#A* represents a pair of one entity *E* (i.e. Ambience, Drinks, Food, Location, Restaurant and Service), and one attribute/aspect *A* (i.e. General, Miscellaneous, Prices, Quality, Style-Options). There are 14 predefined pairs of *E#A*, for example, *FOOD#PRICES*. Other than the predefined pair combinations are not allowed.

The ATE aims to extract the aspect term, i.e. the linguistic expression used in the given text that represents the entity *E* of each *E#A* pair. The aspect term does not have to be mentioned directly, for example, in the review: *"Expensive but delicious"*, the entity *E* is *Food*, but the aspect term is not present in the text. In such cases, the *NULL* value is assigned. The ACTE task focuses on extracting the aspect term and aspect category simultaneously.

The APD task's goal is to assign one of the three polarity labels (*positive*, *negative*, *neutral*) for all already identified (aspect category, aspect term) pairs in a given text. See Figure 1 for an example.

In the TASD task, the goal is to identify all (aspect category, aspect term, sentiment polarity) triplets simultaneously, which makes this task the most difficult task we solve.

4 Models & Approaches

We use pre-trained Transformer-based models as backbones for our experiments. We propose a method for solving multiple ABSA tasks concurrently with sequence-to-sequence models[6], which process text (sequence) as input and produce text (sequence) as output. We employ this approach for the ACD, ATE, ACTE and TASD subtasks. To the best of our knowledge, there are no Czech monolingual sequence-to-sequence models. Therefore, we use the large **mT5** (Xue et al., 2021) and large **mBART** (Tang et al., 2021) models, which are multilingual versions of the English T5 (Raffel et al., 2020) and BART (Lewis et al., 2020) models, respectively.

We do not use these models for the APD task as they lack prior information about the aspect term and category, which they predict along with the sentiment. The APD task assumes that the model already knows the gold data for the aspect term and category, so we would have to modify the input and output format for the APD task to make a fair comparison. Changing the output format would also be required for the SC task.

Since we focus solely on the Czech language, we also wanted to evaluate Czech monolingual models. As stated above, there are no monolingual Czech sequence-to-sequence models, but only classical Czech monolingual BERT-like models such as **Czert** (Sido et al., 2021), **RobeCzech** (Straka et al., 2021) or **FERNET** (Lehečka and Švec, 2021). Unfortunately, these models are unsuitable for our proposed approach, so we use them only for the APD and SC tasks. These models consist only of the encoder part of the Transformer architecture.

4.1 Sequence-to-Sequence Models

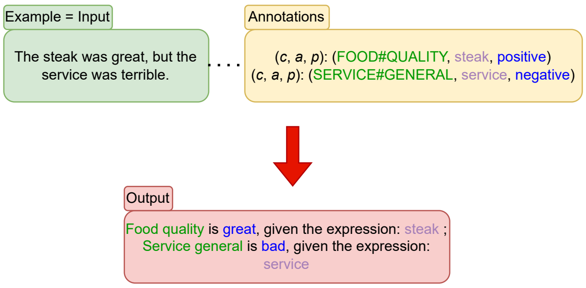
We employ the multilingual sequence-to-sequence models (mT5, mBART) to solve several ABSA tasks at once. These models consist of two parts of the Transformer architecture: the *encoder* and the *decoder*. Given the input sequence x, the encoder transforms it into a contextualized sequence $\mathbf{e}$. The decoder then models the conditional probability distribution of the target sequence y given the encoded input $\mathbf{e}$ as $P_{\boldsymbol{\Theta}}(y|\mathbf{e})$, where $\boldsymbol{\Theta}$ are the parameters of the model. At each step, i, the decoder output y_i is computed based on the previous outputs $y_0, \ldots, y_{i-1}$ and the encoded input $\mathbf{e}$. During fine-tuning, we update all model parameters.

4.1.1 Traditional Fine-Tuning

Because the output of sequence-to-sequence models is text, we have to convert our discrete ABSA labels to the textual format inspired by Zhang et al. (2021a). For each example in the ABSA dataset, we construct the label as "c *is* $P_p(p)$*, given the expression:* a", where c is the aspect category, a the aspect term and $P_p(p)$ a mapping function that maps the sentiment polarity p as

$$P_p(p) = \begin{cases} \textit{great} & \text{if } p \text{ is } \textit{positive}, \\ \textit{ok} & \text{if } p \text{ is } \textit{neutral}, \\ \textit{bad} & \text{if } p \text{ is } \textit{negative}. \end{cases} \qquad (1)$$

[6] Also known as *text-to-text* models.



Example = Input
The steak was great, but the service was terrible.
Annotations
(c, a, p): (FOOD#QUALITY, steak, positive)
(c, a, p): (SERVICE#GENERAL, service, negative)
Output
Food quality is great, given the expression: steak ;
Service general is bad, given the expression: service

Figure 2: Example of the input and output construction for the T5 model with traditional fine-tuning.

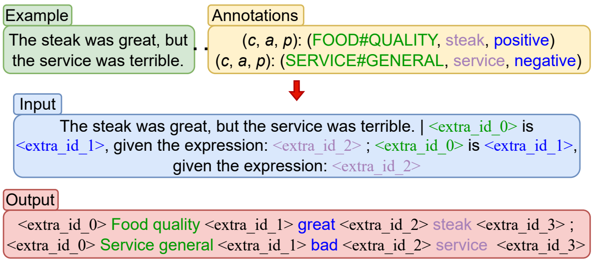
For example, given the review: "*The steak was very tasty*" the following label is generated: "*Food quality* is *great*, given the expression: *steak*". If an example has multiple annotation triplets[7], we concatenate the labels with semicolons.

In this scenario, the model's input is the text (review), and the expected output is the textual label. The model's parameters are optimized to produce textual label in the desired format. Figure 2 shows an example of creating the input and target for the mT5 model with traditional fine-tuning.

4.1.2 Prompt-Based Fine-Tuning

For the prompt-based method, we expand the input review x with a template t to create a final input x': $x' = x + | + t$. The template has the same form as the label in the traditional fine-tuning method. The number of transformed triplets in the prompt corresponds to the number of triplets provided for one example. We design the prompt for the mT5 and mBART models differently because their training objectives differ.

The mT5 model aims to reconstruct randomly selected continuous spans of input text that are masked by sentinel tokens <extra_id_*id*> during pre-training. Here, *id* refers to the ID of the sentinel token, which starts from zero and increments by one. The model replaces non-masked spans of text with sentinel tokens. In our method, we replace the aspect category with <extra_id_0>, the sentiment polarity with <extra_id_1>, and the aspect term with <extra_id_2> to create the final input, which is inspired by work in (Gao et al., 2022). The output of the mT5 model consists of the aspect category, sentiment polarity and aspect term separated by sentinel tokens. Figure 3 shows an example of creating the input and target for the mT5 model with prompting.



Example
The steak was great, but the service was terrible.
Annotations
(c, a, p): (FOOD#QUALITY, steak, positive)
(c, a, p): (SERVICE#GENERAL, service, negative)
Input
The steak was great, but the service was terrible. | <extra_id_0> is <extra_id_1>, given the expression: <extra_id_2> ; <extra_id_0> is <extra_id_1>, given the expression: <extra_id_2>
Output
<extra_id_0> Food quality <extra_id_1> great <extra_id_2> steak <extra_id_3> ;
<extra_id_0> Service general <extra_id_1> bad <extra_id_2> service <extra_id_3>

Figure 3: Example of the input and output construction for the T5 model with prompting.

Unlike T5, the BART model reconstructs the entire input text rather than just masked spans. Furthermore, the BART model utilizes the <mask> token instead of sentinel tokens.

4.1.3 Task Predictions

As mentioned earlier, we use sequence-to-sequence models to solve multiple ABSA tasks simultaneously, namely the ACD, ATE, ACTE and TASD. Each task aims to predict different components of the annotation triplet (aspect category, aspect term, sentiment polarity). We generate one output for all tasks and use only the relevant part of the output for each task while discarding the rest. We can extract the relevant part for each task because the model is trained to generate output in the expected format. For instance, we extract only the aspect term from the generated output in the ATE task. For the ATE task, we consider only distinct targets and discard *NULL* targets for the evaluation. For the ACD, ACTE and TASD tasks, we ignore duplicate occurrences of the predicted targets (e.g. aspect category for the ACD task).

4.2 Sentiment Polarity Classification Models

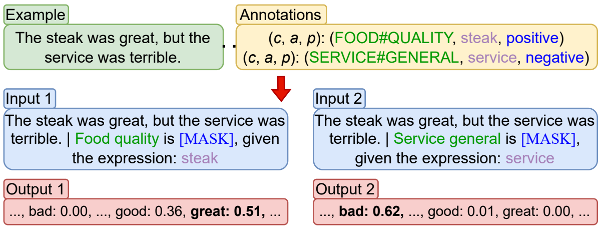
We use Czech BERT-like (encoder-based) models (i.e. Czert, RobeCzech, FERNET) to classify the sentiment polarity. These models convert an input sequence $x = w_1, \ldots, w_k$ of k tokens into a sequence of hidden vectors $\mathbf{h} = \mathbf{h}_0, \mathbf{h}_1, \ldots, \mathbf{h}_k$. For the APD task, we create n input-target pairs for each example, where n is the number of annotation triplets for that example.

4.2.1 Traditional Fine-Tuning

We employ a linear layer on top of the model to make a prediction. It computes the probability of a label y from a label space $\mathcal{Y} \in \{positive, negative, neutral\}$ for the input x_i as

$$P_{\Theta}(y|x_i) = \text{softmax}(\mathbf{W}\mathbf{h}_{\texttt{[CLS]}} + b), \quad (2)$$

[7] Each review can have multiple aspect categories and aspect terms, thus multiple triplet annotations.



Example
The steak was great, but the service was terrible.
Annotations
(c, a, p): (FOOD#QUALITY, steak, positive)
(c, a, p): (SERVICE#GENERAL, service, negative)
Input 1
The steak was great, but the service was terrible. | Food quality is [MASK], given the expression: steak
Input 2
The steak was great, but the service was terrible. | Service general is [MASK], given the expression: service
Output 1
..., bad: 0.00, ..., good: 0.36, great: 0.51, ...
Output 2
..., bad: 0.62, ..., good: 0.01, great: 0.00, ...

Figure 4: Example of the input and output construction for the classification model using prompting.

where $\boldsymbol{\Theta}$ denotes all the parameters to be fine-tuned, including task-specific ones ($\mathbf{W}$ and b). The hidden vector $\mathbf{h}_{\texttt{[CLS]}}$ represents the artificial classification `[CLS]` token corresponding to the first hidden vector of the input sequence, i.e. $\mathbf{h}_{\texttt{[CLS]}} = \mathbf{h}_0$, and represents the entire input sequence.

In the case of the ABSA dataset and the SC of the aspect term and category, we append the aspect term and category to the beginning of the input so that the model has the knowledge of the specific tuple by which to make predictions.

4.2.2 Prompt-Based Fine-Tuning

For prompt-based fine-tuning, we exploit the fact that the models were pre-trained by the masked language modelling task (Devlin et al., 2019). We use the language modelling property of the model to generate a token that represents the polarity label.

During prompt-based fine-tuning, we create a new input x' from the original input x by appending a task-specific prompt. The prompt has one answer slot represented by a `[MASK]` token, which the model fills with the highest-probability token from its vocabulary for the given context. Each label from label space $\mathcal{Y}$ is mapped to a word from the model's vocabulary $\mathcal{V}$ using a mapping $\mathcal{M} = \mathcal{Y} \rightarrow \mathcal{V}$, which is for Czech defined as follows

$$P_p(p) = \begin{cases} \textit{dobrý} & \text{if } p \text{ is } \textit{positive}, \\ \textit{ok} & \text{if } p \text{ is } \textit{neutral}, \\ \textit{špatný} & \text{if } p \text{ is } \textit{negative}. \end{cases} \tag{3}$$

Figure 4 shows an example of input construction with desired outputs for the ABSA task.

We trim the original input of long reviews before appending the prompt to ensure that the new input x' fits into the model. We use different prompts for each dataset. For the CSFD dataset, we use the prompt "*Je to* `[MASK]` *film*" ("*It is a* `[MASK]` *movie*" in English). For the ABSA dataset, the prompt is structured as "c *je* `[MASK]`, *dáno výrazem:* a" ("c *is* `[MASK]`, *given the expression:* a" in English), where c is the aspect category (translated to Czech) and a is the aspect term.

5 Experiments & Results

In our experiments, we fine-tune the sequence-to-sequence models (mBART, mT5) for the ATE, ACD, ACTE, and TASD tasks on the entire ABSA dataset using both traditional and prompt-based fine-tuning approaches and we report the results as micro F1 scores. The BERT-like (encoder-based) models (Czert, RobeCzech and FERNET) are fine-tuned for the APD and SC tasks and report results as accuracy. For these tasks, we further experiment with zero-shot and few-shot scenarios, as well as additional pre-training of the Czech models.

To ensure the reliability of our results, we perform each experiment five times with different random seed initialization and report the average scores along with a 95% confidence interval. We provide the training details in Appendix A.1.

5.1 Few-Shot and Zero-Shot Setting

In the few-shot setting, we fine-tune the models on the first n examples of the training data using a fixed training set to ensure a fair comparison between models, as recommended by Schick and Schütze (2021). In the zero-shot setting, models are evaluated on the test set without any fine-tuning.

5.2 Additional Pre-Training

For the APD and SC tasks, we were interested in whether additional pre-training in the task domain helps to improve results. Therefore, we further pre-train the three Czech models (Czert, RobeCzech and FERNET) with the masked language modelling task on restaurant reviews and movie reviews for the APD and SC tasks, respectively. See Appendix A.2 for details.

5.3 Results for Aspect-Based Sentiment

Table 3 shows the results achieved by the sequence-to-sequence models. The prompting approach (PT-FT) significantly enhances the performance of both models. Without prompting, i.e. with the traditional fine-tuning (TR-FT), mBART performs better than mT5. However, with prompting, mT5 performs better than or similar to mBART.

The best results are achieved on the ACD task. For this task, there is a predefined set of categories. In contrast, the ATE task poses a greater challenge,

Model	Approach	Task			
		ACD	ATE	ACTE	TASD
mT5	TR-FT	$75.5^{\pm1.8}$	$66.5^{\pm2.5}$	$56.4^{\pm1.0}$	$48.0^{\pm1.0}$
	PT-FT	$\underline{\mathbf{85.5}}^{\pm1.2}$	$\underline{\mathbf{84.8}}^{\pm1.6}$	$\underline{\mathbf{75.0}}^{\pm1.9}$	$\underline{\mathbf{67.3}}^{\pm1.7}$
mBART	TR-FT	$78.7^{\pm1.6}$	$78.9^{\pm1.3}$	$67.2^{\pm1.4}$	$57.5^{\pm1.7}$
	PT-FT	$\underline{83.3}^{\pm0.7}$	$\underline{83.4}^{\pm0.6}$	$\underline{71.9}^{\pm1.6}$	$\underline{61.7}^{\pm0.7}$

Table 3: Results of the sequence-to-sequence models as micro F1 scores on different ABSA tasks with traditional fine-tuning (TR-FT) and prompt-based fine-tuning (PT-FT). The best results for each task are in **bold**. Underlined results indicate significantly better performance between the two fine-tuning styles for a given model and task.

as the extracted term can be an arbitrarily long sequence of different words, making this task more difficult. The ACTE is even more challenging since the model has to simultaneously predict the aspect term and category. The TASD task is the most difficult of the solved tasks because the model must predict the aspect term, aspect category and sentiment polarity simultaneously. Since our study is the first to focus on these tasks in the Czech language, we lack a basis for comparison with other studies.

Table 4 shows the results of the APD task. Traditional fine-tuning performs significantly better than prompting in the zero-shot setting. Prompting outperforms traditional fine-tuning when using a small number of examples for training. In the rest of the results, both fine-tuning approaches perform similarly. The domain pre-training improves the results of all models, especially for traditional fine-tuning.

5.4 Sentiment Classification Results

Table 5 shows the sentiment classification results on the CSFD dataset, along with the current SotA results. In the zero-shot setting, the traditional fine-tuning approach (TR-FT) yields random results around 35–38%. This is expected because the linear layer[8] on top of the model is not trained and the CSFD dataset contains three roughly balanced classes. On the other hand, the zero-shot scenario with the prompt-based approach[9] (PT-FT) combined with the additional domain pre-training provides significantly better results for Czert and FERNET models, achieving 48.2% and 59.2%, respectively.

We observed that prompting consistently outperforms traditional fine-tuning in the few-shot scenario with 10 and 20 training examples. In contrast, traditional fine-tuning yields better results when using 100, 500 and 1,000 examples. Results are comparable for both approaches when the model is trained on all examples and 50 examples. Domain pre-training improves the results in most cases, especially when using only a small number of examples. Notably, the FERNET model achieved the best result of 88.2% accuracy, surpassing the current SotA by 2.8%.

5.5 Discussion

The prompt designed for the APD task might be more suitable than the prompt for the SC task, which may explain why prompting is worse only in one case than traditional fine-tuning outside of the zero-shot setting, while traditional fine-tuning outperforms prompting more often in the SC task.

The reason why the sequence-to-sequence models perform better with prompting than with traditional fine-tuning may be that the prompting matches these models' pre-training objectives closely. Additionally, these models possess some prior information about the number of sentiment triplets they should generate in the prompt, which the traditional fine-tuned models do not.

Our research indicates that the sequence-to-sequence models have no problems generating the output in the required format, which is crucial to extract the targets. However, when using traditional fine-tuning, the mT5 model occasionally generates repeated transformed triplets and lacks diversity in its output more frequently than the mBART model, which may explain why the mBART model outperforms the mT5 model with traditional fine-tuning.

We observe a common trend in results for SC and APD tasks, whereby the prompting approach with a smaller number of training examples outperforms the traditional fine-tuning, which is consistent with conclusions from Gao et al. (2021).

For prompting in few-shot and zero-shot scenarios, a mapping function that maps one sentiment to multiple words instead of one specific word would likely lead to better results, which can be explored in future work.

[8] The layer always returns one of three possible labels, thus if the dataset is perfectly balanced, the random (and also lowest) expected accuracy is $33.\overline{3}\%$.

[9] In this case, the model can predict any word from the model vocabulary $\mathcal{V}$; therefore, the potential lowest expected random accuracy is close to zero $(1/|\mathcal{V}|)$.

6 Conclusion

In this work, we introduced a sequence-to-sequence method that solves multiple ABSA tasks simultaneously and can be used with both traditional fine-tuning and prompting. Experiments on the Czech dataset show that prompting significantly improves performance. Furthermore, we proposed a method for sentiment classification that can also be used with prompting and traditional fine-tuning. We evaluate this method on two Czech datasets with three monolingual Czech models and demonstrate the effectiveness of prompting for few-shot fine-tuning, where prompting consistently outperforms the traditional approach. Finally, we show that pre-training on the domain data significantly enhances the results, especially in a zero-shot scenario.

A Appendix

A.1 Hyper-parameters & Training Details

We train the models with different hyper-parameters and select the best-performing model based on the performance on the validation data, including the number of epochs. The CSFD dataset is already split into training and validation data. For the ABSA dataset, we use 10% of the training data as validation data. The final experiments are conducted on all training data and evaluated on the test data.

We use a batch size of 64 and train the sequence-to-sequence models for up to 35 epochs. For the mT5 model, we search for a learning rate from {1e-4, 3e-4}, while for the mBART model, we search for a learning rate from {5e-5, 1e-5}. We use greedy search for simplicity because experiments with a beam search with beam sizes 3 and 5 lead to similar performance.

For the models for sentiment polarity classification, we search for a learning rate from {5e-5, 1e-5}. We use up to 10 epochs and a batch size of 16 for the CSFD dataset and up to 50 epochs and a batch size of 64 for the ABSA dataset.

We optimize the cross-entropy loss for all the models. All the models have the maximum input sequence length limited to 512 tokens. We use the AdaFactor (Shazeer and Stern, 2018) optimizer for the mT5 model and AdamW (Loshchilov and Hutter, 2019) for the rest of the models. We keep the default dropout value for all the models, which is 0.1.

For text generation with the sequence-to-sequence models, we use the *AutoModelForSeq2SeqLM* class with greedy search decoding from the HuggingFace library[10]. We tried different configurations of the beam search decoding algorithm (Freitag and Al-Onaizan, 2017), but it provides the same results as the greedy search algorithm, so we employ the greedy search algorithm for simplicity.

A.2 Details of Additional Pre-Training

The additional pre-training of Czert, RobeCzech and FERNET models on data from a specific task domain (restaurant reviews and movie reviews) is performed with the masked language modelling task (Devlin et al., 2019). The pre-training process was carried out with a batch size of 512 and a maximum input sequence length of 512 for all models. We optimize the models with the cross-entropy loss function and AdamW (Loshchilov and Hutter, 2019) optimizer for 20K batches (steps). We use a learning rate of 5e-5 with linear decay. The word masking probability is set to 15%.

Abstract

Predictions from Machine Learning models can reflect bias in the data on which they are trained. Gender bias has been shown to be prevalent in Natural Language Processing models. The research into identifying and mitigating gender bias in these models predominantly considers gender as binary, male and female, neglecting the fluidity and continuity of gender as a variable.

In this paper, we present an approach to evaluate gender bias in a prediction task, which recognises the non-binary nature of gender. We gender-neutralise a random subset of existing real-world hate speech data. We extend the existing template approach for measuring gender bias to include test examples that are gender-neutral. Measuring the bias across a selection of hate speech datasets we show that the bias for the gender-neutral data is closer to that seen for test instances that identify as male than those that identify as female.

1 Introduction

Natural Language Processing (NLP) models and systems are developed by using text content created by humans and they may incorporate biases that exist in the data. These biases can then be reflected in the results produced by these models and systems when they are used in downstream applications (Dixon et al., 2018; Park et al., 2018). Additionally, word embeddings, which are representations of words and sentences generated from large amounts of natural language text, may also exhibit and even magnify certain features of the data, such as gender stereotypes (Bolukbasi et al., 2016; Caliskan et al., 2017; Zhao et al., 2017).

An issue with existing research is that it considers gender as binary neglecting the fluidity and continuity of gender as a variable (Stanczak and Augenstein, 2021). Many of the data resources in NLP currently are inadequate for identifying gender bias as they often have a significant under-representation of female or non-binary instances. (Stanczak and Augenstein, 2021). There is a need to incorporate gender-neutral linguistic forms in datasets and algorithms to recognise the non-binary nature of gender. This impacts on algorithms too, such as language models which learn meaningless unstable representations for non-binary associated pronouns and terms (Dev et al., 2021).

In this paper, we present an approach to measure gender bias in a downstream task to identify abusive or hate speech that considers male, female, and gender-neutral gender identities. Due to the lack of datasets that include gender-neutral linguistic forms, we adjust existing real-world datasets by gender-neutralising a random subset of instances.

A challenge with measuring gender bias in natural language training data is the lack of gender identification in the data. One solution to this is to generate synthetic test data with a known gender identity using a template approach known as GBETs (Sun et al., 2019). Our approach has extended existing binary template definitions to include identity terms that reflect gender neutrality. We use a suite of measures presented by Borkan et al. (2019b) which are threshold agnostic to measure gender bias.

The downstream task we address is abusive and hate speech which involves language that is intended to be harmful and specifically targets individuals based on their affiliation with a particular group, such as their race, gender, sexuality, religion, or other protected characteristics (Röttger et al., 2021). Hate speech detection models exhibit

Proceedings of Recent Advances in Natural Language Processing, pages 1121–1131
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_119

gender biases towards certain identity terms due to factors such as an uneven distribution of identity terms in hate speech datasets and the excessive use of certain identity terms in hate speech sentences. For instance, some terms, like "women" and "feminism," can be frequently associated with sexist comments in benchmark datasets. These factors can lead to overfitting of the original hate speech detection model, which in turn may result in incorrect generalisations, such as linking the word "women" with a "hateful" label (Park et al., 2018; Mozafari et al., 2020).

We evaluate gender bias on three real-world hate speech datasets that have been adjusted to include data instances with a gender-neutral identity. The findings show that the bias for gender-neutral data is closer to that seen for data that is identified as male than data that is identified as female.

The contribution of this work lies in its recognition and exploration of the non-binary nature of gender in the context of measuring and addressing bias in NLP models and systems. While previous research has primarily focused on gender as a binary variable, this study goes beyond the traditional binary categorization and acknowledges the fluidity and continuity of gender identities. By incorporating gender-neutral linguistic forms in datasets we aim to promote gender inclusion and recognise the non-binary spectrum of gender. This approach allows for a more comprehensive understanding of gender bias in NLP and provides insights into the biases present in hate speech detection models.

2 Related Work

In supervised learning contexts, there is significant research that identifies and measures bias in downstream NLP tasks. Gender and racial biases (Kiritchenko and Mohammad, 2018), as well as biases against queer individuals (Ungless et al., 2023) and people with disabilities (Hutchinson et al., 2020) have been identified in sentiment analysis tasks. Gendered occupational stereotypes are reflected in errors made by co-reference resolution systems (Zhao et al., 2018; Rudinger et al., 2017) and occupational classification models (De-Arteaga et al., 2019).

A wide range of research into gender bias studies predominantly focuses on two genders, male and female, not recognising the experiences of individuals who identify as non-binary or gender non-conforming. This is a significant limitation of much of the existing research, as it fails to fully capture the diverse experiences and perspectives of individuals across the gender spectrum. Recent research has highlighted the importance of including non-binary identities in NLP studies. Studies focusing on neopronouns have shown that language models have difficulties processing them in various languages, including Swedish, Danish, and English (Brandl et al., 2022). Also, work by Cao and Daumé III (2021) proposes methods for improving gender inclusivity throughout the Machine Learning lifecycle, including data collection, model training, and evaluation. A road map toward the integration of inclusive language in translation, with a focus on machine translation tasks, has been discussed in work by Piergentili et al. (2023). This work focuses on gender-neutralisation strategies in the context of English-Italian translation.

Moreover, in order to improve support for individuals who identify as non-binary or gender non-conforming, enabling them to self-identify their preferred pronouns and interact with technology in a manner that aligns with their social identity, gender-neutral rewriting models have emerged (Sun et al., 2021; Vanmassenhove et al., 2021) in the text generation task. The purpose of a gender-neutral rewriter is to automatically identify the gendered language in a text and replace it with gender-neutral alternatives. In order to produce gender-neutral language, research by Sun et al. (2021); Vanmassenhove et al. (2021) in a relatively similar approach proposed a rule-based and neural approach to automatically rewrite text to be more gender-neutral. The system is designed to identify gender identity words such as "he/she" and replace them with "they". The goal is to promote inclusivity and reduce bias in language use by avoiding gender-specific language that may reinforce gender stereotypes or exclude individuals who do not identify with traditional gender roles.

2.1 Measuring Gender Bias

The primary method to measure gender bias in a downstream task is to measure performance differences across gender as the system's performance should not be influenced by gender. This requires a way to isolate gender in the test instances which are used to measure the system performance. While it is possible to isolate and identify gender for some types of training data, e.g. job applications in recruitment, for most textual corpora there is no obvious gender identification. Gender identification is typically done by generating synthetic test sets that contain test instances designed to isolate a particular group. This method is referred to as Gender Bias Evaluation Testsets (GBETs), as named by Sun et al. (2019), and has been used to evaluate bias in various NLP tasks.

GBETs have been categorised into three groups (Stanczak and Augenstein, 2021), template-based datasets, natural language-based datasets, and datasets generated for probing language models. The template approach involves creating sentence templates that include gender identification words that are relevant to the specific downstream task. From these templates, pairs of sentences are generated for each gender, and the performance of the NLP system is compared across the sentences with male and female gender identities, allowing for the measurement of gender bias in the dataset. This gender identity template approach has been used for various NLP tasks, including abusive language detection (Dixon et al., 2018; Park et al., 2018), sentiment analysis (Kiritchenko and Mohammad, 2018), and coreference resolution (Zhao et al., 2018; Rudinger et al., 2017).

Natural language-based GBET datasets use available natural language resources created in different ways, depending on the specific NLP task being evaluated. For instance, the GAP corpus (Webster et al., 2018) is a GBET used for coreference resolution and consists of ambiguous pronoun-name pairs that have been manually labeled by humans and sourced from Wikipedia. Similarly, (Emami et al., 2019) created a dataset for analysing gender bias in coreference resolution by scraping data from sources such as Wikipedia, OpenSubtitle, and Reddit comments.

More recently StereoSet (Nadeem et al., 2021) and CrowS-Pairs (Nangia et al., 2020) GBETs have been proposed to evaluate bias in language models. These GBETs are created and annotated by crowdsourcing to measure bias in different domains. Each example consists of a pair of stereotype and anti-stereotype sentences in the case of CrowS-pairs. However, StereoSet contains triplets of sentences with each instance corresponding to a stereotypical, anti-stereotypical, or meaningless association. An additional study presents a large GBET dataset called HOLISTICBIAS for measuring bias. This dataset is assembled by using a set of demographic descriptor terms in a set of bias measurement templates and can be used to test bias in language models (Smith et al., 2022).

Despite growing interest in the research community to evaluate gender bias in the classification tasks, most efforts to evaluate bias still do not go beyond gender as binary. Most of the recent work on evaluating gender bias in NLP systems uses variations on Hardt et al.'s work on equal opportunity and equalised odds (Hardt et al., 2016). These measures are group measures and use the gender distributions in the training data rather than the democratic parity measure which insists on equal outcomes for both genders regardless of prevalence or ground truth. Equality of opportunity considers where the predictions are independent of gender but conditional on the ground truth or positive outcome in the training data. This means that the true positive rate of the system should be the same for all genders. An example of this is the TPR_{gap} (Prost et al., 2019), as defined in Equation 1, which measures the differences in the gender-specific true positive rates.

$$TPR_{gap} = \mid TPR_{male} - TPR_{female} \mid \quad (1)$$

The more restrictive equalised odds definition of fairness focuses also on restricting differences in errors across genders. An example is the error rate equality differences such as False Positive Equality Difference (FPED) and False Negative Equality Difference (FNED) (Dixon et al., 2018; Park et al., 2018). These metrics are limited to binary labels and depend on threshold values to separate model output into two classes. To address this limitation, Pinned AUC metrics have been proposed (Dixon et al., 2018), but a follow-up study by the same authors found limitations in this metric (Borkan et al., 2019a). As a result, a new set of threshold-agnostic metrics was proposed by Borkan et al. (2019b) which overcomes the limitations of Pinned AUC metrics related to class imbalance and provides robustness and more nuanced insight into the types of bias present in the model.

These metrics are computed based on the score distributions of both the complete background test data, which consists of every other subgroup except the subgroup under consideration, and the test set subgroup. This means that the performance of the model is evaluated not only on the entire dataset but also on the specific subgroup that is of interest. AUC-based metrics include Subgroup AUC,

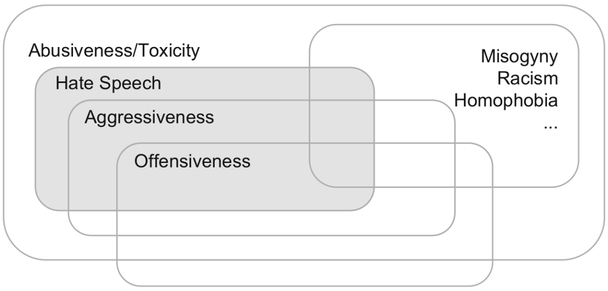

Figure 1: Relations between HS and related concepts (Poletto et al., 2021)

Background Positive Subgroup Negative (BPSN) AUC, and Background Negative Subgroup Positive (BNSP) AUC. Subgroup AUC calculates the measure of separability for a given subgroup, which gives a more accurate understanding of the model's performance in that particular subgroup. While these metrics can be used for measuring different kinds of bias (e.g racism, religious, etc.) across different subgroups, our focus is on gender bias, considering three distinct subgroups: male, female, and gender-neutral. The Background Positive Subgroup Negative AUC (BPSN) metric evaluates the AUC score by considering the positive examples from the background and the negative examples from the subgroup. Lower values in this metric mean more false positives within the subgroup at many thresholds.

On the other hand, the Background Negative Subgroup Positive AUC (BNSP) metric calculates the AUC by considering the negative examples from the background and the positive examples from the subgroup. A low BNSP score presents more false negatives within the subgroup. In other words, low BNSP indicates that more positive examples from the subgroup are mistakenly classified as negative at different thresholds.

The set of metrics also include an Average Equality Gap which measures the difference between true positive rates for each outcome for a subgroup and the background at a specific threshold. This is a generalisation of the TPR_gap in Eqn 1 above across multiple subgroups. Equation 2 shows the AEG for the positive outcome where D_g^+ is the positive data for the subgroup g, D^+ is the positive data in the background i.e. all data except the subgroup, and MWU is the Mann-Whitney U test statistic.

$$PositiveAEG = \frac{1}{2} - \frac{MWU(D_g^+, D^+)}{\mid D_g^+ \mid\mid D^+ \mid} \qquad (2)$$

There is an equivalent AEG for the negative outcome for a particular subgroup. The values of AEGs range from -0.5 to 0.5, with an optimal value of 0 indicating no differences between the particular subgroup and the background data.

3 Approach and Evaluation

This research aims to explore gender bias in hate speech and offensive language classification, with a specific focus on gender-neutral language. We will accomplish this by analysing commonly used user-generated content datasets, particularly three Twitter datasets for abusive content and offensive language identification. These datasets have been used in prior bias detection studies (Park et al., 2018; Davidson et al., 2019).

Abusive language includes various types including stereotypes, offense, abuse, hate speech, threats, etc (Caselli et al., 2020). The connections among these phenomena based on previous research, have been visually represented in a work by (Poletto et al., 2021) and it is shown in Figure 1. Current approaches for detecting and mitigating harmful language mainly focus on offensive language, abusive language, and hate speech however with varied and inconsistent definitions (Caselli et al., 2020; Waseem et al., 2017). The difference between offensive language, abusive language, and hate speech lies in their specificity. Offensive language is more general, hate speech is more specific, and abusive language falls in between.

The **Hate Speech** dataset (Waseem and Hovy, 2016) is a collection of almost 17K tweets consisting of 3,383 samples of sexist content, 1,972 samples of racist content, and 11,559 neutral samples. The dataset is transformed into a binary classification problem by labeling the sexist and racist samples as the "abusive" class and neutral samples as the "non-abusive" class.

The **Abusive Tweets** dataset is a large-scale

Dataset	Class	Class%	gender-neutral%	identified gender		Size
				F(%)	M(%)	
Hate Speech	Abusive	31.4	2.0	1.0	1.0	16K
	Non-Abusive	68.6	3.0	1.0	2.0	
Abusive Tweets	Abusive	32.1	2.0	1.0	1.0	100K
	Non-Abusive	67.9	3.0	1.0	2.0	
Hate Speech/Offensive	Abusive	50.0	4.0	2.0	2.0	8K
	Non-Abusive	50.0	3.0	1.0	2.0	

Table 1: Class distribution, gender neutral data, gender labeled data percentage, and overall size for each dataset. For the HateSpeech/Offensive dataset, the abusive class has been undersampled due to significant class imbalance.

crowd-sourced dataset, collected by Founta et al. (2018). The size of the dataset is just under 100k tweets and it is annotated with four labels: *hateful*, *abusive*, *spam*, and *none*. By combining the *none* and *spam* instances into a “non-abusive” class, and the hateful and abusive instances into an “abusive” class, we transform the dataset to a binary classification task, similar to the Hate Speech dataset.

The **HateSpeech and Offensive** dataset (Davidson et al., 2017) is a collection of almost 25k tweets. The majority of tweets are considered to be offensive language (77%), almost 17% are labeled as non-offensive and only almost 6% of the tweets are flagged as hate speech samples. By assigning the “abusive” class label to samples exhibiting hate speech and offensive, and the “non-abusive” label to non-offensive samples, we convert the dataset into a binary classification problem.

The HateSpeech & Offensive dataset contains a significant class imbalance, 83% of the dataset is assigned as abusive while only 17% is assigned as a non-abusive class. In order to create a more balanced dataset for experimental purposes, undersampling was performed on the abusive class during the evaluation by randomly selecting a 17% sample of the abusive data leaving a balanced dataset for this work of 8305 instances.

Table 1 shows the characteristics of the data used in the evaluation, including size and class distribution.

binary	gender-neutral
he/she	they
him	them
her	them,their
his	their,theirs
hers	theirs
himself/herself	themselves

Table 2: Binary pronouns and neutral alternatives

3.1 Gender Neutralising the Training Data

The dataset we used for our analysis lacks gender-neutral language or has a very limited representation of it. To address this issue, we employed the Neutral Rewriter (Vanmassenhove et al., 2021) to generate gender-neutral samples. This model which is a combination of rule-based and neural approaches replaces gender identity terms with their gender-neutral equivalents.

Results from the Neutral Rewriter demonstrate that the model achieves a high level of accuracy, with a word error rate of less than 1%. Table 2 shows the pronouns and their gender-neutral alternatives used by the model. The gender-neutral rewriter also replaces gendered English animate nouns with gender-neutral terms. For instance, "postman" is substituted with "mail carrier," and "fireman" with "firefighter." Similarly, feminine forms of animate nouns such as "actress" are replaced with gender-neutral alternatives like "actor," and "waitress" with "waiter." Additionally, the rewriter replaces generic uses of "man," for instance, "freshman" can be replaced with "first-year student," and "man-made" can be replaced with "human-made. The complete list of mapped nouns to their gender-neutral alternatives could be found in the original paper (Vanmassenhove et al., 2021). As an example, the sentence *she is an actress* would be replaced by *they are an actor*. Label preservation was not checked after gender-neutralising was performed. There may be certain instances that, after gender, may not be considered hateful, particularly for gender stereotyping due to traditional gender roles.

Using the gender-neutral rewriter model, we generated gender-neutral data instances from the original datasets. 60% of the data instances that could be gender-neutralised were replaced with a gender-neutral version and we left the remaining 40% that included gender pronouns/determiners in the dataset, unchanged. It was important not to gender neutralise all instances with specific gender identity terms which could potentially leave the training data without these terms at all.

It should be mentioned that to prevent bias mitigation selected instances were replaced with their gender-neutral version rather than being added to the dataset. This replacement technique aimed to avoid mitigating bias through gender swapping which is a technique to mitigate bias by augmenting the data with additional examples that are gender-swapped (Park et al., 2018).

There is no gender identity feature or label in the datasets used. The approach in Identity Term Sampling (ITS) (Sobhani and Delany, 2023) which is used to identify male and female instances within text data was used to identify gender within the portion of data to be gender neutralised. ITS identifies gender for data instances to allow the measurement of task performance across genders. It identifies gender based on the frequency of occurrence of certain gender identity terms. We are using these proportions identified by ITS as an estimate of gender distribution in the instances changed by the gender-neutralising process. The column labelled *gender-neutral%* in Table 1 shows the gender distribution of the gender-neutralised data instances using this approach.

3.2 Generating Test Data

In order to generate synthetic test instances to isolate the gender-neutral, female and male groups we extended an existing template approach that has been used for measuring bias in hate speech (Park et al., 2018) and toxicity classification (Dixon et al., 2018). Tables 4 and 3 present the templates and the identity terms respectively used to generate sets of labeled test data for male/female and gender-neutral scenarios while Table 5 lists the nouns and adjectives used to fill the templates. This template approach generated 3006 synthetic test samples in total, with 1002 samples for each of the male, female, and gender-neutral groups. The samples were evenly distributed across the *abusive* and *non-abusive* classes.

3.3 Experimental Approach

For classification, a simpler version of the deep neural network architecture used by (De-Arteaga et al., 2019) is used. Our architecture consists of an embedding layer as an input layer using word2vec embeddings, followed by a bidirectional long short-term memory (BiLSTM) layer to encode the input sentence, a dropout layer, and a linear output layer with cross-entropy to compute the loss which comes after a dense layer with Relu activation.

Identity Terms
woman/man/adult, girl/boy/kid
female/male/person, niece/nephew/nibling
sister/brother/sibling, gal/guy/folk
mother/father/parent, she/he/they
wife/husband/spouse, her/his/them
daughter/son/child, aunt/uncle/pibling
girlfriend/boyfriend/partner
granddaughter/grandson/grandchild
grandmother/grandfather/grandparent

Table 3: Identity terms used to generate sets of test data with an identified gender

Templates
You are a <*adjective*> <*identity term*>
<*verb*> <*identity term*>
Being a <*identity term*> is <*adjective*>
I am a <*identity term*>
I hate <*identity term (plural form)*>
<*she/he/they*> is/are <*adjective*>
I <*verb*> <*her/him/them*>

Table 4: Templates used to generate synthetic test data

The datasets were split 80%/20% into stratified training and holdout testing sets. All hyperparameters were tuned on a 20% split of the training data for each dataset. The performance on the holdout test data was averaged across three holdout splits. As the HateSpeech & Offensive dataset is highly imbalanced, the process of randomly undersampling the 17% sample of the abusive data was repeated 5 times to ensure the results were not dependent on a specific subset of the data. The average result across the 5 iterations was then reported.

Overall task performance was measured using accuracy on the synthetic test data. In addition, to gain a better understanding of the model's general performance on the task in all datasets, we measured the average class accuracy (ACA) on a representative proportion of the data. We chose to use ACA as a complementary metric due to the imbalanced class distributions present in the data.

In addition to task performance, we measured gender bias on the synthetic test instances using AUC-based metrics including Subgroup AUC,

Nouns & Adjectives & Verbs	Target
disgusting, filthy, nasty, rotten, horrible, terrible, awful, hate, vile, idiotic, stupid, moronic, dumb, ugly, shitty, fucked, kill, murder, repulsive, destroy	Abusive
great, fun, nice, neat, happy, best, good, fantastic, wonderful, lovely, excellent, incredible, friendly, gracious, kind, caring, hug, like, love, respect	Non-Abusive

Table 5: Nouns, adjectives & verbs used to generate synthetic test data

BPSN, BNSP, and AEG on the positive (*abusive*) and negative (*non-abusive*) classes. Subgroup AUC calculates AUC within a specific subgroup, BPSN measures AUC within the positive background and negative subgroup, and BNSP measures AUC within the negative background and positive subgroup. Additionally, the positive and negative AEG measure the separability of positive (abusive) examples from the subgroup with positive (abusive) examples from the background data and vice-versa. Positive AEG is defined as Equation 2.

4 Results and Discussion

Table 6 shows the classification results including overall accuracy and class level accuracy across the three datasets for the classification of hate speech. The table displays the average class accuracy (ACA) for the holdout test data in the last column. This metric indicates how well the model can perform on classifying abusive content, with a higher ACA indicating better performance. The results show a good performance of the model generally - the Abusive Tweets dataset with an ACA of 90%, while the HasteSpeech & offensive dataset has an ACA of 88%, and the Hate Speech dataset has an ACA of 81%. However, looking at the class accuracy column in Table 6 it can be seen that the model performed poorly in classifying abusive content, with less than 50% accuracy across all three datasets. The strong performance on the non-abusive class is contributing to the overall good performance.

Table 6 also shows the performance of the model on the synthetic test dataset. Results show the accuracy on synthetic test data is less than 75% across three datasets, which means the model does not perform as well in classifying the synthetic datasets. This is not surprising as the template sentences used to generate the test data are not fully representative of the actual abusive content in the datasets. However, this synthetic data can still provide valuable insights into potential biases in the models.

Table 7 shows the gender bias results across the three datasets including the AUC-based metrics and the AEG of the positive (abusive) and negative (non-abusive) classes. The subgroup AUC shows a score higher than 0.7 for all datasets across our three gender identity subgroups which indicates that the model is moderately successful in distinguishing between positive and negative examples within female, male, and neutral subgroups.

The high scores on BNSP and BPSN AUC metrics results for the Abusive Tweets dataset show that the model exhibits relatively low bias across all the female and male and neutral subgroups, with high BNSP and Subgroup AUC scores indicating similar performance to the background group.

However, the two hate speech datasets show some level of bias across these figures and it differs between the different subgroups. Interestingly the figures for the male and neutral subgroups on the hate speech datasets are much closer to each other and higher than the female subgroup. Low values in the BPSN and BNSP AUC metrics indicate more bias. So this suggests that the bias for the female subgroup is higher than the male and neutral.

Looking at what these AUC metrics tell us, the BPSN score for females on the hate speech datasets is relatively low with a score of 0.58 in the Hatespeech and 0.78 in the HateSpeech & Offensive dataset. A low BPSN score suggests that the model is more likely to incorrectly classify negative or non-abusive examples from female subgroups as abusive compared to the background groups, which in this case are male and neutral, indicating the model is more likely to predict abuse for the female instances than the male and neutral instances.

On the other hand, the BNSP score for the hate speech datasets is lower for male and neutral subgroups than the female subgroup. Since the BNSP score measures the difference in false negative rates between the subgroup and the background group the low score in the male and neutral subgroups indicates that the model tends to incorrectly classify abusive examples from both the male and neutral subgroups as non-abusive compared to their respective background group. This suggests that

Dataset	Class	Class Accuracy(%)	Synthetic testset Accuracy(%)	Original testset ACA(%)
Hate Speech	Abusive Non-Abusive	37 91	64	81
Abusive Tweets	Abusive Non-Abusive	47 98.8	73	90
HateSpeech & Offensive	Abusive Non-Abusive	48 95	71	88

Table 6: Accuracy per class, accuracy on the synthetic test data, and average class accuracy (ACA) for each dataset across three holdout splits.

for these hate speech datasets, male and neutral abusive instances are more likely to be missed than female instances. The BPSN and BNSP for gender-neutral suggest that the model may be more biased against the gender-neutral subgroup compared to the male subgroup, but less biased compared to the female subgroup. Furthermore, the negative values of both the abusive and non-abusive AEG and the Hatespeech and HateSpeech & Offensive datasets suggest that the model is biased towards the female subgroup, as there is a downward shift in scores for this subgroup. This bias is further supported by the low BPSN AUC score, which indicates that the model is more likely to make false positive predictions for the female subgroup compared to the background groups. Specifically, the negative AEG scores indicate that the model is performing worse for the female subgroup than the reference group, which can contribute to the lower AUC score.

Moreover, positive scores for both the abusive and non-abusive AEG for neutral and male suggest that the model might give more weight or importance to certain features in the neutral and male subgroups when classifying positive and negative examples. This means that the model may be more accurate in classifying positive and negative examples from these two subgroups compared to the background group, with the degree of attribute amplification being relatively small. Also, a positive AEG value for the non-abusive class along with a low BNSP indicates that the model is performing better for the male and neutral subgroup for the non-abusive class. Overall, these results suggest that the model may exhibit some bias against the neutral and male subgroups, particularly in terms of false negative rates, but the degree of bias is less severe compared to that shown for the female subgroup.

Looking at the results for Hatespeech and HateSpeech & Offensive datasets we can see that including gender-neutral data in the datasets shows gender bias in the female subgroup, but surprisingly gender-neutral and male results have similar behavior on the bias metrics. There could be several reasons that cause this behavior. Given the novelty and limited usage of gender-neutral terms in many societies, they might appear infrequently in training data. Consequently, Machine Learning models could encounter difficulties in comprehending and generating gender-neutral language. For instance, terms like "nibling/pibling" or "sibling" are uncommon in daily speech, and may limit the model's exposure to gender-neutral language.

Second, gender-neutral forms of specific words, such as "actress" or "waitress," is often associated with the male form, reflecting a common representation found in many datasets. Another possible reason might be that the gender-neutral term "they" is the same as the plural "they" which might confuse the model in distinguishing singular and plural they.

Results show male and gender-neutral subgroups have similar biased behavior according to Table 7. In order to find out what gender direction (male or female) gender-neutral words align better with, we conducted an analysis of gender bias in word2vec embeddings for gender-neutral words. Following the work by Bolukbasi et al. (2016), we projected the gender-neutral words listed in Table 3 onto the gender direction, which is defined as the vector resulting from $\overrightarrow{she}$ -$\overrightarrow{he}$. Table 8 shows the projection result for gender-neutral words with respect to the projection score in the gender direction. Words with negative scores are biased toward the male gender, while words with positive scores are biased toward the female gender. The majority of the words including "child", "spouse", "parent", "grandchild" and "adult" have negative scores, indicating a bias towards the male gender. This suggests that most gender-neutral words are more closely associated with the masculine gender spectrum which aligns with similar behavior on the bias metrics.

		AUC			AEG	
Dataset	Identity group	SubGroup	BPSN	BNSP	abusive	non-abusive
Hate Speech	Female	0.72	0.58	0.87	-0.16	-0.15
	Male	0.75	0.79	0.68	0.06	0.07
	Neutral	0.75	0.81	0.68	0.09	0.08
Abusive Tweets	Female	0.99	0.98	0.99	-0.03	-0.07
	Male	0.99	0.99	0.98	-0.05	-0.06
	Neutral	0.98	0.99	0.96	0.07	0.09
HateSpeech & Offensive	Female	0.89	0.78	0.92	-0.10	-0.11
	Male	0.89	0.90	0.83	0.06	0.07
	Neutral	0.84	0.88	0.83	0.09	0.07

5 Conclusion

In this paper, we presented an approach for measuring gender bias in a downstream task of identifying abusive or hate speech that considers male, female, and gender-neutral identities. We adjusted existing real-world datasets by gender-neutralising a random subset of instances and extended existing binary template definitions to include identity terms that reflect gender neutrality. Our approach helps address the lack of training data that includes gender-neutral linguistic forms, which is essential for creating more inclusive NLP models and systems by incorporating gender-neutral words through the use of a gender-neutral rewriter. This can lead to more inclusive NLP models and systems. We have evaluated bias towards male, female, and gender-neutral groups and our findings showed that male and gender-neutral groups have similar bias behavior according to the AUC bias metrics, while the female group shows a higher bias compared to the others. This approach can help promote more fair and equitable NLP systems by identifying gender bias in the data.

While our approach aims to address gender bias in abusive and hate speech detection, there are certain limitations to consider. Firstly, the modification of existing datasets by incorporating gender-neutral instances relies on the availability of such data. The scarcity of gender-neutral linguistic forms in real-world datasets can pose a challenge in achieving adequate representation. Secondly, the template-based approach used to generate synthetic test data may not fully capture the nuances and diversity of gender identities, potentially impacting the generalisability of the results. It is important to acknowledge that the concept of non-binary equivalents for binary gender terms is a subject of ongoing debate and individual preference. While a list of suggested non-binary equivalents has been provided in this paper, it is important to recognise that these terms may not be universally agreed upon or applicable to all non-binary individuals.

In future work, we will explore the impact of adjusting datasets to include more gender-neutral identity terms and examine the influence of the dataset size on the results. In addition, a future focus will be on exploring label preservation after gender neutralisation. We will examine the impact of gender-neutralising instances that may be gender stereotypes due to gender roles and consider cases where the resulting text can lose its perceived hatefulness, especially if the assumption is made that the target is a woman/women.

Abstract

Due to having knowledge of only basic vocabulary, many people cannot understand up-to-date written information and thus make informed decisions and fully participate in the society. We propose LeSS, a modular lexical simplification architecture that outperforms state-of-the-art lexical simplification systems for Spanish. In addition to its state-of-the-art performance, LeSS is computationally light, using much less disk space, CPU and GPU, and having faster loading and execution time than the transformer-based lexical simplification models which are predominant in the field.

1 Introduction

Even in the highly-developed countries, many people (16.7% on average) only have a knowledge of a basic vocabulary thus encountering difficulties in understanding written information on a daily basis (OECD, 2013). This limits their active participation in the society and can negatively influence their life choices. According to the Adult Literacy Report from 2013 (OECD, 2013), this problem is particularly prominent in Spain, where 28.3% of people are in this situation (Štajner, 2021).

Lexical simplification (LS) is the process of substituting complex words or phrases with their simpler variants. It is an important factor in making texts more accessible for people with aphasia (Carroll et al., 1998; Devlin and Unthank, 2006; Devlin and Tait, 1998), dyslexia (Rello et al., 2013b,a), autism spectrum disorders (Orăsan et al., 2018), cognitive impairments (Feng et al., 2009; Saggion et al., 2015), low literacy levels (Aluísio et al., 2008; Watanabe et al., 2010), deaf and hard-of-hearing people (Inui et al., 2003; Alonzo et al., 2020), children (De Belder et al., 2010), and non-native speakers (Hirsh and Nation, 1992; Heilman et al., 2007).

Due to its evident potential for great social impact, lexical simplification has been attracting a growing attention from the natural language processing (NLP) community (Paetzold and Specia, 2017; Štajner, 2021). SemEval-2021 Task 1 on Lexical Complexity Prediction attracted 198 teams, out of which 91 submitted their systems for one of the two sub-tasks, single-word or multi-word lexical complexity prediction (Shardlow et al., 2021). The recent TSAR-2022 shared task on Multilingual Lexical Simplification received 33 system submissions for English, 17 for Spanish, and 16 for (Brazilian) Portuguese (Saggion et al., 2022).

While it is generally considered that the more frequent words are easier to understand for everyone, which words should be considered as complex or simple can vary from one target population to another (Yimam et al., 2017), and is subjective even within one target group (Yimam et al., 2018). Manual lexical simplification requires an extensive knowledge of the language and the particular simplification needs of the target user, thus being expensive and time-consuming. Automatic text simplification systems, in contrast, could offer a possibility for an easier customisation and on-demand personalized simplification. To enable that, it is important to build modular systems which offer possibility of using customized resources and substitute ranking modules.

We propose LeSS, a new state-of-the-art lexical simplifier for Spanish, that uses less computational power than the previous state of the art and a modular architecture that enables easy customization.[1] As it will be shown in Section 5, LeSS outperforms the transformer-based state-of-the-art lexical simplification systems for Spanish, while being computationally much more efficient.

[1] The full code for the system is available at: https://github.com/danielibanezgarcia/less.

2 Related Work

Apart from English, Spanish is the language that attracted most attention from the lexical simplification research community.

2.1 Evaluation Datasets

Only three evaluation datasets for Spanish lexical simplification were compiled and made publicly available so far.

EASIER-500[2] (Alarcón et al., 2021) consists of 500 instances with exactly one target complex word in each, and three simpler synonyms for each target word. Being the first publicly released lexical simplification dataset for Spanish, EASIER-500 has several limitations that were addressed in the later compiled datasets: (1) target words were selected based on the assessments of only one (expert) annotator; (2) each instance contains only three simpler synonyms for the target complex word; (3) all simpler synonyms were suggested by only one annotator; (4) it does not provide ranking of the simpler synonyms (and is thus not suitable for evaluation of full lexical simplification pipelines).[3]

EASIER[4] (Alarcon et al., 2023) consists of 5100 complex/target words in context (sentence) for which at least one simpler synonym was proposed (7892 simpler synonyms in total) by a linguist. The strength of this corpus is that the quality of the annotations (selection of complex words and the suggested simpler synonyms) was assessed by elderly people and people with intellectual disabilities. The limitations of this dataset are the following: (1) for most target words, only one simpler synonym is proposed; (2) for any target word, only up to three simpler synonyms were proposed; (3) it does not provide the ranking of the simpler synonyms (in the cases where more than one simpler synonym was proposed).

ALEXSIS (Ferrés and Saggion, 2022) was the first dataset for evaluation of full lexical simpflication pipelines for Spanish. It consists of 381 instances/contexts, each with one target word marked as complex, and a list of simpler (near-)synonyms of the given target word. For each instance, the corresponding simpler synonyms were proposed by 25 crowdsourced workers. The subset of 368 instances of this dataset was used in the TSAR-2022 shared task on multilingual lexical simplification (Saggion et al., 2022), with only a few slight modifications described in the work by Štajner et al. (2022).

2.2 Lexical Simplification Systems

The earliest approaches for Spanish lexical simplification relied on thesauri for generating potential substitutes, while since 2022, all proposed approaches are based on the use of the transformer-based masked language models (see Table 1).

Bott et al. (2012) built LexSiS, a lexical simplification system that uses an online dictionary and Web as a corpus to compute three features (word vector model, word frequency, and word length) for finding the best substitution candidates, and a combination of hand-crafted rules and dictionary look-up for morphological generation of the right inflection for the best substitute.

[2] https://data.mendeley.com/datasets/ywhmbnzvmx/2

[3] A full lexical simplification pipeline usually consists of four modules that perform the following operations: complex word identification, generation of substitution candidates, ranking of the substitution candidates, generation of the correct inflections (Shardlow, 2014; Paetzold and Specia, 2017).

[4] https://github.com/LURMORENO/EASIER_CORPUS

Baeza-Yates et al. (2015) proposed CASSA, an approach that uses Google Books Ngram Corpus, the Spanish OpenThesaurus, and web frequencies for finding the best substitution candidates. CASSA does not offer the full lexical simplification pipeline, as it only finds the best lemma and does not perform morphological generation of the right inflection.

Ferrés et al. (2017) proposed TUNER, a lexical simplifier for Spanish, Portuguese, Catalan, and Galician which simplifies content words (common nouns, verbs, adjectives, and adverbs) in context. It consists of six modules that are sequentially executed: complex word identification, document analysis, word sense disambiguation (WDS), synonyms ranking, morphological generation, and context adaptation.

Alarcón et al. (2021) experimented with several neural LS systems for Spanish, which leverage pre-trained word embedding vectors and BERT models. The systems were evaluated on the EASIER-500 dataset for only three lexical simplification subtasks: complex word identification, substitution generation, and substitution selection. The ranking of substitutes was not evaluated as the EASIER-500 dataset does not provide rankings of the substitutes (Alarcón et al., 2021).

Ferrés and Saggion (2022) compared results of three architectures for LS (thesaurus-based TUNER system, a single transformer-based system, and several combinations of transformer-based systems) on ALEXSIS dataset.

Štajner et al. (2022) built LSBert-ES, the Spanish version of the state-of-the-art LS system for English – LSBert (Qiang et al., 2020). They compared the performances of LSBert-ES and TUNER on ALEXSIS dataset. Both systems were used as strong baselines for the TSAR-2022 shared task.

Whistely et al. (2022) built the winning system of the TSAR-2022 shared task on lexical simplification in Spanish (Saggion et al., 2022). The system generates substitution candidates by using a masked language model BETO (Cañete et al., 2020), ranks the candidates based on the cosine similarity of their word embeddings with the word embeddings of the target word (using FastText (Grave et al., 2018)), and filters out candidates that do not share the same Part-of-Speech (PoS) tag as the target word (using Stanford PoS tagger (Toutanova et al., 2003)).

Vásquez-Rodríguez et al. (2022) experimented with pre-trained language models in three settings: zero-shot, fine-tuned (using language-specific data), and multilingual (pre-trained multilingual LM fine-tuned in an specific language), using two different prompts. Their best system (fine-tuned language model) was ranked second in the TSAR-2022 shared task (Saggion et al., 2022).

Chersoni and Hsu (2022) participated in the TSAR-2022 shared task with three fully unsupervised LS systems in which substitution candidates are retrieved by using masked language model, and then ranked based on the lowest average rank across three transformer-based metrics: sentence probability via autoregressive language modeling; sentence probability via masked language modeling; and contextualized embedding similarity.

Wilkens et al. (2022) participated in the TSAR-2022 shared task with BERT-based approaches. They explored two strategies for using masked language models for candidate generation in Spanish: Copy and Query Expansion. The Copy strategy follows the strategy used in LSBert, while the Query Expansion strategy extracts alternative words for the target words from FastText embeddings and then replaces the original sentence with each alternative word. They also experimented with various approaches for candidate ranking: voting (most frequently proposed candidate by various candidate generation methods), probabilities of character-based n-gram language models, binary classifier trained on English SemEval data for simplicity ranking (Specia et al., 2012).

North et al. (2022) participated in the TSAR-2022 shared task with the system that uses a masked language model for substitute generation and the Zipf frequency for substitute ranking.

2.3 State of the Art

The current state-of-the-art lexical simplification systems for Spanish are the transformer-based systems proposed by Ferrés and Saggion (2022) and by Whistely et al. (2022). The former achieves the best results on the ALEXSIS dataset, while the latter achieves the best results on the TSAR-2022 dataset. As it will be shown in Section 5, our word-embedding-based LS system (LeSS) outperforms those (computationally much more expensive) systems on both datasets.

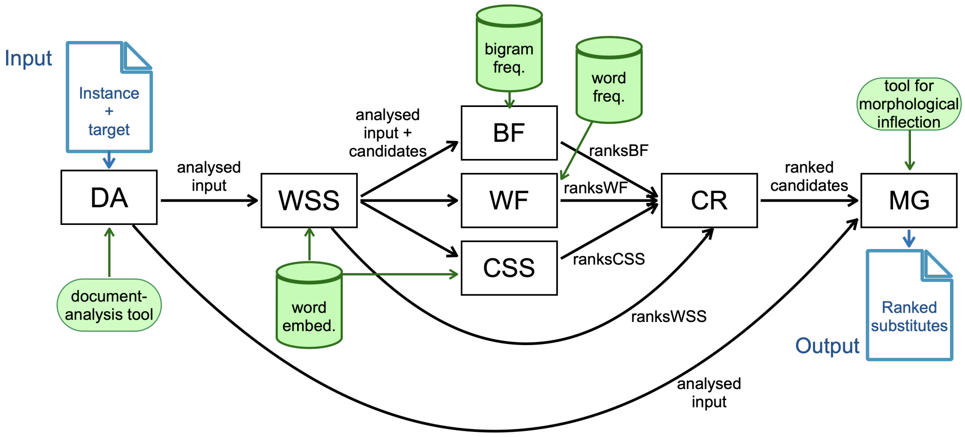

Figure 1: Schema of the system architecture. The seven modules (DA, WSS, BF, WF, CSS, CR, and MG) are shown in rectangular fields, while the language-dependant tools and resources are shown in green/oval shapes.

3 Architecture of LeSS

LeSS is a computationally light lexical simplifier with modular architecture (Figure 1). It comprises seven modules: document analyzer (DA), word-level semantic similarity (WSS), context-level semantic similarity (CSS), word frequency (WF), bigram frequency (BF), candidate ranking (CR), and morphological generator (MG).

Document analyzer (DA) performs sentence splitting, tokenization, part-of-speech (PoS) tagging, lemmatization, and named entity recognition.

Word-level semantic similarity (WSS) module retrieves as substitution candidates those words whose word embedding vectors have the highest cosine similarity with the word embedding vectors of the target word. It initially selects 30 candidates. From those 30, it filters out those that share the lemma with the target word, and those that contain more than 95% of non-alphabetic characters. When multiple candidates share the lemma among themselves (but not with the target word), only the candidate whose word embedding vector has the highest cosine similarity to the word embedding vector of the target word is retained.

Context-level semantic similarity (CSS) module computes cosine similarities between the word embedding vector of the substitution candidate and the context of the target word. This module is envisioned as word sense disambiguation tool. It has been proposed by Glavaš and Štajner (2015) with the idea that the simplification candidates which are synonyms of the correct sense of the target word should be more semantically similar to the context of the target word. The context-level semantic similarity ($csim$) between the target word t and the replacement candidate r is obtained by averaging the cosine similarity between the word embedding vector of the replacement candidate (v_r) and word embedding vectors of each content word (v_w) in the context of the target word (C_t), using the following formula:

$$csim(t,r) = \frac{1}{|C_t|} \sum_{w \in C_t} \cos(v_r, v_w) \qquad (1)$$

where the context is the symmetric window of 2 words left and 2 words right from the target word.

Word frequency (WF) module retrieves the frequency of the target word and the candidate replacements in large corpora. Based on the intuition that frequent words are usually simpler to understand, word frequency is often used for the ranking of the substitution candidates in LS systems (Paetzold and Specia, 2017).

Bigram frequency (BF) module returns the average value (arithmetic mean) of the Google Books bigram frequencies for the bigrams $w_{-1}r$ and rw_{+1}, where r is the replacement candidate, w_{-1} is the word preceding the target word, and w_{+1} is the word after the target word in the given sentence. If the target word is the first word in the sentence, the module returns the frequency of the bigram rw_{+1}. If the target word is the last word in the sentence, the module returns the frequency of the bigram $w_{-1}r$. The idea behind this module is that the frequency of the word itself is not always a straightforward measure of its simplicity. The bigram frequency is envisioned to capture the influence of the surrounding words on the word simplicity, which is particularly important in the case of phrasal verbs or multi word expressions. How well the replacement candidate fits in a larger context should be captured by word-level and context-level semantic similarity modules.

Candidate ranking (CR) module computes the final ranking of all replacement candidates, including the target word itself. For each word, it first sums the ranks obtained in separate modules (WSS, BF, WF, and CSS). Then, it ranks the candidates based on those sums. When the value for a candidate replacement cannot be calculated in a certain module, e.g. the word does not appear in pre-trained word embedding model or frequency library, that candidate will receive the rank '10000' in that module, as a penalty for being infrequent, and as such, probably complex.

Morphological generator (MG) module returns the inflected form of the replacement candidate (with the same PoS tag, gender, and number as the target word) given the lemma of the replacement candidate and the PoS tag of the target word.

Here is important to note that LeSS does not explicitly perform complex word identification. It, instead, follows the idea proposed by Glavaš and Štajner (2015) to treat all content words as potentially complex. The complex word identification is, in that case, performed implicitly, by the target word itself being considered as a substitution candidate (together with the 'real' substitution candidates) in the candidate ranking module.

4 Tools and Resources Used in LeSS

For document analysis (DA module), we use FreeLing (Padró and Stanilovsky, 2012) v4.0.[5].

For all operations with word embedding vectors (modules WSS and CSS), we use FastText 2M 300-dimensional cased word embeddings.[6]

Word frequencies (module WF) are obtained using the freely available python *wordfreq* library,[7] which contains word frequencies calculated on the Exquisite Corpus.[8] The Spanish part of this corpus comprises encyclopedic texts (Wikipedia), subtitles (OPUS Open Subtitles and SUBTLEX), news (NewsCrawl 2014 and GlobalVoices), books (Google Books Ngrams 2012), web texts (OSCAR), short-form social media texts (Twitter), and longer-form internet comments (Reddit).

Freeling lexicon		J48 training data

Table 2: Data statistics for the Morphological Generator.

Algorithm	Noun	Verb	Adj	Adv
FreeLing	72.60	95.03	76.21	72.89
J48	99.80	94.32	99.24	98.51
FreeLing+J48	**99.84**	**95.77**	**99.44**	**98.57**

Table 3: Accuracy (%) of different configurations of Morphological Generator. For the configuration that uses only the Freeling lexicon, the results present coverage as the lexicon cannot predict the results for the unseen *(lemma,PoS)* pairs.

For calculating bigram frequences (needed for BF module), we use Google Books Ngrams for Spanish.[9] We store pre-calculated bigram frequences in a look-up table and use it for retrieving particular bigram frequencies at the execution time. The range of years used to create the table was [1990, 2019], where all bigrams containing numbers were removed.

As MG module, we use the morphological generator proposed by Ferrés et al. (2017) which combines lexicon-based generation with predictions from decision trees. The lexical categories supported are: verbs, nouns, adjectives, adverbs, pronouns, determiners, and numerals. The lexicon used is the FreeLing v4.0 morphological dictionary for Spanish. When the lexicon has no inflection for a pair *(lemma, PoS tag)*, the module uses the J48 model (WEKA[10] implementation of C4.5 decision tree) to predict the sequence of edit operations that can transform an unseen pair *(lemma, PoS tag)* to the correct inflected form. Table 2 shows data statistics of this module. The J48 training algorithm uses morphological and lemma-based features, including the Levenshtein edit distance between lemmas and word forms, to create a model for each lexical category (Ferrés et al., 2017). The model was trained on the Spanish training dataset from the CoNLL-2009 shared task,[11] and evaluated using the CoNLL-2009 shared task evaluation dataset for Spanish which consists of 50,635 to-

Table 4: Evaluation results on TSAR-2022 shared task test set for Spanish for our system (LeSS), the five best performing systems at the shared task (proposed by the teams PresiUniv (Whistely et al., 2022), UoM&MMU (Vásquez-Rodríguez et al., 2022), and PolyU-CBS (Chersoni and Hsu, 2022)), and the official baselines of the shared task (LSBert-baseline and TUNER-baseline) according to the official results (Saggion et al., 2022). The highest value for each metric is shown in bold.

kens. The configuration that uses both, FreeLing and J48, achieves an accuracy over, or close to, 99% in almost all cases, with the exception of the verbs (Table 3). Further details regarding morphological generator can be found in (Ferrés et al., 2017).

5 Evaluation

To compare the performance of our system with the state of the art, we evaluate it on the Spanish portion of the TSAR-2022 shared task dataset, and the ALEXSIS dataset.

5.1 Evaluation on TSAR-2022 Shared Task

To be able to compare the results with the systems submitted to the TSAR-2022 shared task for Spanish, we evaluate our system on the official test set (containing a subset of 368 instances from ALEXSIS dataset) using the official evaluation metrics (MAP@k, Potential@k, and Accuracy@n@top1, where k $\in$ {1, 3, 5, 10} and n $\in$ {1, 2, 3}).[12] **MAP@k** uses a ranked list of generated substitutes, where each substitute can be matched or not matched against the set of the gold-standard substitutes. Unlike the commonly used Precision metric that only measures how many of the generated substitutes are correct (i.e. found in gold data), MAP@k additionally takes into account the ranks of the correct substitutes, i.e. it rewards systems where correct substitutes are ranked higher than the incorrect ones. **Potential@k** calculates the percentage of instances for which at least one of the k best-ranked generated substitutions is present in gold standard.[13] **Accuracy@n@top1** calculates the percentage of instances where at least one of the n top-ranked generated substitutes matches the most frequently suggested synonym in the gold standard for that instance. For all three metrics, higher scores indicate better LS systems.

As can be seen in Table 4, our LeSS system noticeably outperforms the winner of the shared task on all but one metric (accuracy@1@top1). Moreover, LeSS achieves higher results than any participating system on all but two metrics: accuracy@1@top1 and potential@10 (see the full table of official results in (Saggion et al., 2022)). All systems that participated in the TSAR-2022 shared task for Spanish used approaches based on LSBert, except for the system proposed by Vásquez-Rodríguez et al. (2022) which uses GPT-2. In addition to its better performances on the shared task dataset, LeSS requires much less computational power than LSBert (see Section 5.3, Table 6), and thus also less computational power than all the systems that participated in the shared task.

5.2 Comparison with ALEXSIS Systems

To compare our systems with the state-of-the-art LS systems proposed by Ferrés and Saggion (2022), which are not publicly available yet, we evaluate our system also on the full ALEXSIS dataset (381 instances) using the metrics used for the evaluation of those systems: Precision, Accuracy, and Change. We use the definitions provided by Ferrés and Saggion (2022) to compute those metrics for LeSS:

[12] The test set (with and without gold annotations) and evaluation script are freely available at the shared task GitHub account: https://github.com/LaSTUS-TALN-UPF/TSAR-2022-Shared-Task

[13] MAP@1 and Potential@1 are equal by definition.

System	Precision	Accuracy	Change
LeSS	**0.606**	**0.491**	0.701
Thesaurus	0.889	0.089	0.199
LSBert-ES (BETO)	0.278	0.278	1.000
SpanBERTa ∩ RbaseBNE	0.475	0.461	0.986
SpanBERTa ∪ RbaseBNE	0.469	0.469	1.000

Table 5: Performances on ALEXSIS dataset. The results for the last four systems are taken from Table 9 in (Ferrés and Saggion, 2022).

Precision is the ratio of instances where the top ranked candidate is either the target word itself or a word present in the gold standard; **Accuracy** is the ratio of instances where the top ranked candidate is in the gold standard;[14] and **Change** is the ratio of instances where the system suggested any word different from the target word (regardless of whether it is found in the gold standard list or not).

Table 5 shows the performances on the full ALEXSIS dataset of our LeSS system, and the four systems proposed by Ferrés and Saggion (2022): *Thesaurus* (where the substitution candidates are generated based on a thesaurus), *LSBert-ES (BETO)* (a transformer-based LS system) and the two best-performing systems (combinations of transformer-based LS models) which were considered the state of the art on the ALEXSIS dataset. Two things should be noted when interpreting those results. First, by definition, Change is not a measure of how well the system performs lexical simplification, but rather a measure of how conservative it is, i.e. how often it leaves the target word unchanged. Second, Precision is a valuable measure for evaluation of fully automatic lexical simplification systems, for which it is important that they do not perform incorrect substitutions, i.e. leaving the target word unchanged is better than replacing it with an incorrect substitute. As can be seen in Table 5, LeSS outperforms the state-of-the-art systems on both Precision and Accuracy metrics. The thesaurus-based system has a higher Precision than LeSS, but at the cost of a very low Accuracy.

5.3 Computational Power

The comparison of the disk, CPU, and GPU usage by LeSS and LSBert, as well as the loading and execution time, are presented in Table 6. As can be seen, LeSS has a significantly lower load and processing times, and it requires much less disk, CPU, and GPU usage than LSBert. As LSBert is the basis of all recently proposed LS systems for Spanish mentioned in Section 2, which participated in TSAR-2022 shared task, one can infer that LeSS is computationally lighter than all those systems.

		LeSS	LSBert
Size	Disk	4960.19MB	17212.81MB
	CPU	7540.00MB	12505.00MB
	GPU	0.00MB	1530.00MB
Time	Load	0:01:54sec	0:03:38sec
	Processing	0:00:49sec	0:02:24sec

Table 6: Statistics of computing power necessary for running the systems on ten instances using the machine with the following specifications: Processor: Intel Core i9-9900KF CPU @ 3.60GHz x 16; RAM: 32GB, GPU: NVIDIA GeForce RTX 2080 Ti/PCIe/SSE2; Hard Drive: ADATA SX6000PNP (1TB).

6 Error Analysis

We performed error analysis on the full ALEXSIS dataset (381 instances). In 29 instances (7.6%), none of the substitutes generated by LeSS is present in the gold data. In four of those 29 cases, LeSS did not generate any substitutes, as the word embeddings used did not contain those four target words: *pitorreo* (*eng. messing around*) – used only in colloquial jargon in Spain; *expiaciones* (*eng. atonement*) – used in biblical sense; *pedanía* (*eng. district*) – used only for special types of districts in Spain; and *larvas* (*eng. larva*) – used in quotes in a metaphorical sense. In 18 of those 29 cases, LeSS suggested the target word itself as the best-ranked replacement candidate. In a real-world scenario, those 22 cases would limit the simplification power of the system but would not be dangerous as they would leave the target word unchanged. In two of the 29 cases where the candidates suggested by LeSS were not found in the gold data, target word itself was suggested by LeSS as the second-best. In another two, LeSS suggested a correct word but with missing reflexive pronoun: *preparando* instead of *preparandose* (*eng. getting ready*), and *forjar* instead of *forjarse* (*eng. to forge oneself* (figuratively)). In one case, LeSS suggested the words *peligroso* (*eng. dangerous*) and *destructivo* (*eng. destructive*), which were not found in the gold standard but fit the context perfectly, as a simpler substitute for *mortífero* (*eng. lethal*). In an-

[14] By definition, Accuracy is the same as MAP@1 metric used in TSAR-2022 shared task.

(1)	Sentence	A lo largo de sus más de veinte años de experiencia en el medio, ha presentado todo tipo de programas, no sólo informativos, sino también divulgativos, de entrevistas, tertulias e incluso concursos.

	Gold	mortal(12), letal(10), de muerte, fatal, lúgubre

Table 7: Examples of LeSS output (five top-ranked substitution candidates) for ALEXSIS instances (target words are underlined). The number in parenthesis after the word in 'Gold" (standard) represents the number of workers that suggested that word, if the word was suggested by more than one annotator. The substitutes shared between LeSS and human annotators are shown in bold. The correct substitutes generated by LeSS which are not found in gold standard are shown in italics.

other case, LeSS suggested the word *pueblos* (*eng. villages*) which was found in gold standard only in its diminutive form *pueblitos*.

Table 7 presents several instances from ALEXSIS dataset, together with the output of LeSS system and the gold standard annotations. The first two examples show that LeSS is able to find correct simpler synonyms, which are also suggested by several crowdsourced annotators. The last three examples illustrate the errors mentioned in the previous paragraph: where LeSS suggests a correct verb but without reflexive pronoun (ex. 3); where it suggests correct nouns which are not found among the gold standard annotations (ex. 4); and where it (over)simplifies an adjective (ex. 5).[15]

7 Final Discussion and Conclusions

We proposed LeSS, a modular and computationally-light lexical simplifier for Spanish that outperforms the previous state of the art.

Our detailed manual error analysis indicated that LeSS often suggests several simpler synonyms. This indicates that LeSS could be used in real-world applications as a writing aid to human editors for faster simplification and customization to different users. In real-world applications, the use of lexical simplification module as a writing aid is preferred over fully automatic lexical simplification, as it allows for customization (Orăsan et al., 2018; Alonzo et al., 2020) and prevents unintended harms to vulnerable populations (Štajner, 2021).

In future, we would like to investigate if this architecture can yield state-of-the-art results in other languages, especially those with limited resources. The currently predominant approaches in the field, based on LSBert and masked language models, have noticeably better performances in English than other languages, even in the case of comparable evaluation datasets (see the results of TSAR-2022 shared task (Saggion et al., 2022)).

[15] The output of LeSS for the ALEXSIS and TSAR-2022 datasets is provided at: https://github.com/danielibanezgarcia/less.

Broader Impact

Lexical simplification can have a significant social impact by making texts understandable to people with various reading and cognitive impairments (see Section 1) and thus enabling them to actively participate in the society. We showed that carefully designed modular architectures can achieve state-of-the-art results and outperform popular architectures that are computationally much more expensive. Computationally-light architectures, such as the one we propose, are especially important for bringing lexical simplification closer to the real-world usage, as they can be easily used on mobile devices. Furthermore, the proposed modular architecture offers possibilities for building personalized lexical simplification systems by adjusting the ranking functions to the specific needs of each user.

Ethical Considerations

The final users of lexical simplification systems cannot fully understand original texts. That makes them vulnerable to the system's mistakes. Therefore, it is important to have thorough checks for system failures on different domains and types of texts, and have a manual post-editing function, should lexical simplification systems be used in real-world scenarios. Furthermore, the state-of-the-art lexical simplification systems rely on the use of word embeddings and transformers, which are known to propagate certain racial and gender biases. Before their application in real-world scenarios, it is thus important to thoroughly check for any type of ethical biases that may have been induced due to the underlying resources used in the system.

Acknowledgements

We would like to thank Daniel Ferrés for his help with the integration of the morphological generator. Horacio Saggion is thankful for the support from the individual project Context-aware Multilingual Text Simplification (ConMuTeS) PID2019-109066GB-I00/AEI/10.13039/501100011033 awarded by Ministerio de Ciencia, Innovación y Universidades (MCIU) and by Agencia Estatal de Investigación (AEI) of Spain. Hindi to Dravidian Language Neural Machine Translation Systems

Vijay Sundar Ram and Sobha Lalitha Devi

AU-KBC Research Centre,
MIT Campus of Anna University, Chennai 60044
sobha@au-kbc.org

Abstract

Neural machine translation (NMT) has achieved state-of-art performance in high-resource language pairs, but the performance of NMT drops in low-resource conditions. Morphologically rich languages are yet another challenge in NMT. The common strategy to handle this issue is to apply sub-word segmentation. In this work, we compare the morphologically inspired segmentation methods against the Byte Pair Encoding (BPE) in processing the input for building NMT systems for Hindi to Malayalam and Hindi to Tamil, where Hindi is an Indo-Aryan language and Malayalam and Tamil are south Dravidian languages. These two languages are low resource, morphologically rich and agglutinative. Malayalam is more agglutinative than Tamil. We show that for both the language pairs, the morphological segmentation algorithm out-performs BPE. We also present an elaborate analysis on translation outputs from both the NMT systems.

1 Introduction

Machine translation has improved extensively using deep neural networks with the utilization of large dataset and high computational capacities. The successful works in Neural Machine Translation (NMT) started with the encoder-decoder based architecture presented by Kalchlorenner and Blunsom (2013), Sutskever et. al. (2014), and Cho et. al (2014). Sutskever et al (2014) built NMT system using Long short Term memory (LSTM) to overcome the fixed-length vector constraint in the previous architecture. Bahdanu et. al. (2015) introduced the attention mechanism, where bidirectional recurrent neural network (RNN) consisting of forward and backward RNN was used to focus around the word. This attention mechanism was simplified by considering the hidden states at the top layer of both encoder and decoder by Luong et. al. (2015). Transformer, an architecture where encoder and decoder completely relying on the attention machines was presented by Vaswani et. al. (2017).

Though these NMT systems have achieved a state-of-art performance in high-resource, closely related languages, its performance drop significantly in low-resource and morphologically rich languages. Some of the techniques employed to mitigate challenges in handling the low-resource languages are as follows; increasing the data using back translation, utilisation of phrase tables generated in SMT, leveraging the pre-trained models, combining the similar language data and using transfer learning. The morphological rich languages are handled using different sub-word segmentation techniques, which helps in reducing the vocabulary size and increasing the number of examples of each tokens. In this work, we compare the morphologically inspired segmentation methods against the Byte Pair Encoding (BPE) in processing the input for building NMT systems for Hindi (Hi) to Malayalam (ML) and Hindi to Tamil (TA), where Hindi is an Indo-Aryan language and Malayalam and Tamil are south Dravidian languages. These two languages are low-resource, morphologically rich and agglutinative.

Further the paper is organised as follows. In the following section, we present a summary on the different sub-word tokenisation works in NMT. This is followed by details on related works in

Proceedings of Recent Advances in Natural Language Processing, pages 1143–1150
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_121

Indian language NMT. In the third section, we describe briefly the characteristics of three languages, which highlight the challenges in building NMT systems for Hindi to Malayalam and Tamil. In section 4, we describe our experimental setup and data preparation. The result and analysis is presented in section 5. We conclude the paper with a conclusion section containing the gist of the work.

2 Related Works

The common strategy of handling the morphologically rich languages in NMT is to apply sub-word segmentation. This reduces the vocabulary size and increases the frequency of the tokens and improves the translation by handling rare words and unknown words, but it introduces grammatical errors. Sennrich et. al. (2016) presented the different word segmentation techniques which included simple character n-gram model and segmentation based on the byte pair encoding (BPE) comparison algorithm. BPE sub-word algorithm is one of the widely used sub-word tokenisation algorithm.

The other sub-word tokenisation algorithms include, WordPiece, SentencePiece, Mecab (a morphological analysed based Japanese tokeniser), Stanford Word Segmentation (a Chinese word segmentor based on Conditional Random Fields), OpenNMT Tokenizer and Moses tokenizer (normalise characters and separates punctuation from words).

There are various attempts in modifying the existing tokenization techniques and few are listed here. Wu and Zhao (2018) extended the BPE segmentation by including two other statistical measures namely accessor variety (AV) and description length gain (DLG). They evaluated it with German to English and Chinese to English translation.

Provilkov et. al. (2019) introduced BPE-dropout, where segmentation procedure of BPE was stochastically altered to produce multiple segmentations within the same fixed BPE framework.

Wang et. al. (2020) focussed on byte-level BPE (BBPE), where the text is tokenised into variable-length byte n-grams instead of character level sub-words.

Nonaka et. al. (2022) has presented a locally consistent parsing (LCP) stochastic string algorithm to achieve optimum compression instead of BPE compression, which has the drawback in generating multiple segments.

Tang et. al. (2020) performed a study on pure character based model in translating Finnish to English. They have demonstrated that the word level information is distributed over the entire character sequence and character at different position play different roles in learning linguistic knowledge.

Deguchi et. al. (2020) performed tokenisation of sentences by using sub-word units induced from bilingual sentences. Here the tokenisation of sentences is performed by considering its translation.

Nguyen et. al. (2020) proposed an approach, where the heterogeneous translation units were used to build in Russian to Vietnamese NMT. They considered linguistic characteristics of syntactic Russian and analytic Vietnamese.

Machacek et. al. (2019) compared the linguistically motivated method morfessor and derivational dictionaries based method and statistical methods such as STE and BPE in German to Czech translation. Their experiments showed the non-linguistically motivated method performed better.

In this sub section, we present a gist of the NMT works published in Indian languages. Goyal et al. (2020) has presented Hindi to English NMT, where they generalised the embedding layer of the Transformer model to incorporate linguistic features such as PoS, lemma, and morphological features. There was a significant increase in the BLEU scores. Dewangan et al. (2021) has presented an elaborate NMT experiments to understand the poor performance of the Dravidian languages compared to Indo-Aryan languages. They used Byte Pair Encoding (BPE) method to understand the BPE in Indian languages. From their study, they presented that the optimal value for BPE merge for Indian languages is between 0-5000, which is low compared to that observed for European languages.

WMT21 had a similar language task, which has boosted the research to explore the use of shared vocabulary in NMT. Laskar et. al. (2021) and Saldanha et. al. (2021) has presented their work in Tamil-Telugu translation. Mujadia et al. (2020) has presented their work in Marathi-Hindi bidirectional translation.

In the next section, we present a brief note on the characteristics of the languages considered.

3 Resources Characteristics of the Languages

As mentioned earlier, in this work, we describe the NMT experiments in Hindi to Malayalam and Hindi to Tamil translation, where Hindi is an Indo-Aryan language and Malayalam and Tamil are Dravidian languages. The three languages are similar in the following features: verb final, relatively free word order, morphologically rich in inflections. And these languages are dissimilar in agglutination. Malayalam and Tamil have agglutination and Hindi does not have. Malayalam has more agglutination than Tamil. The other differences are as follows.

Hindi and Tamil have number, gender and person agreement, whereas Malayalam does not have. Hindi is an ergative language. In the ergative constructions, finite verb has agreement with the object. Malayalam and Tamil are nominative-accusative languages.

Malayalam and Tamil have distinctive case markers, whereas in Hindi, case marker ‘se’ occurs as instrumental, accusative and ablative case marker. This leads to one to many in case mapping between Hindi to Malayalam and Tamil. In Hindi, plural marker is affixed to the noun and case markers are written separately. In the case of pronouns, case markers are also affixed to the pronouns. In Malayalam and Tamil, both plural markers and case markers are affixed to the nouns.

Copula verb is obligatory in Hindi and Malayalam whereas in Tamil it can be dropped.

Malayalam and Tamil has distinctive 3rd person pronouns (avan, aval, avar, athu), whereas in Hindi, ‘vaha’ is used for all 3rd person singular pronouns.

The clausal construction in Hindi varies with Malayalam and Tamil. In Hindi, the clausal constructions are introduced by relative-correlatives such as (jo-vo, agar-tho, jisa-usa, jisne-usne, jab-thab etc). In Malayalam and Tamil, the clausal constructions are introduced by non-finite verbs namely, relative participle verb, conditional, infinite verb and verbal participle verb. It is further explained with the following example 1.

Ex 1:
HI: agar barish ayege tho paani
rain(N) come(V)+Future water(N)
milegaa.
get(V)+Future
Here ‘agar’ and ‘tho’ are the relative-correlative

ML: mazha peythaal, vellam
rain(N) rain(V)+cond water(N)
labikkum.
get(V)+future

TA: mazhai peythaal, thanneer
rain(N) rain(V)+cond water(N)
kidaikkum.
get(V)+future
(If it rain, we will get water.)

In the above example 1, conditional sentence is presented in Hindi, Malayalam and Tamil. In Hindi the conditional clause is introduced with the relative-correlative ‘agar-tho’, whereas in Malayalam and Tamil it is introduced by the non-finite verb using the suffix ‘-aal’.

Negation in verb phrase in Hindi varies with Malayalam and Tamil. In Hindi, the negation occurs before the finite verb and in Malayalam and Tamil, it occurs as an auxiliary verb. Consider the following example 2.

Ex 2:
HI: vaha nahi aaya.
He(Pn) not(neg) come(V)+past+3sc
ML: avan vannilla
He(Pn) come(V)+INF+aux (neg)
TA: avan varavillai (vara+illai)
He(Pn) come(V)+INF+aux (neg)

In example 2, the difference in construction of negation verb in Hindi and Malayalam and Tamil is clearly seen with the position of the negation.

These variations between Hindi and Malayalam and Tamil in clausal structure, case markers, pronouns and verb construction introduce challenge in Hindi to Dravidian language translation. In the next section, we describe the corpus and the experimental setup.

4 Experiment

In this section, we discuss about the details of the parallel dataset, experimental setup for developing Hindi to Malayalam and Hindi to Tamil NMT systems and data preparation for three different experiments.

4.1 Dataset

We have used Hindi-Malayalam and Hindi-Tamil corpus, built using the manually translated Swayam course lectures. Swayam is a massive online course platform by Government of India, which offers variety of courses in various domains such as Engineering, Business Management, Humanities, Programming, Business, Mathematics, Science and Technology, Health, Law etc. We have used parallel sentences from the lectures of 52 courses from different domains, namely, Science and Technology, Food Processing technology, Information Technology, Business Management, Plant pathology and Law. The statistics of the corpus is given the tables below.

S.No	Details	Hindi (Source)	Malayalam (Target)
1	Number of Sentences	158318	158318
2	Number of Words	3421259	1932170
3	Number of unique words	98945	257848
4	Maximum Length of a Sentence (words)	80	61

Table 1: Statistics of Hindi-Malayalam Corpus.

S.No	Details	Hindi (Source)	Tamil (Target)
1	Number of Sentences	165172	165172
2	Number of Words	3565959	2214121
3	Number of unique words	104613	186413
4	Maximum Length of a Sentence (words)	80	66

Table 2: Statistics of Hindi-Tamil Corpus.

Table 1 has the statistics of the Hindi-Malayalam parallel corpus; Table 2 has the statistics of the Hindi-Tamil parallel corpus. In the both tables 1 and 2, in the second row, the number of words in Hindi is one and half times more than the number of words in Malayalam and Tamil. In table 1, the number of unique words in Malayalam is one and half times more than the unique words in Hindi. In table 2, the number of unique words in Tamil is one and half times more than the unique words in Hindi. The information in these two rows clearly shows the morphological richness and high agglutination in Malayalam and Tamil, which make the NMT training a challenging task. The difference in the number of unique words in Malayalam and Tamil shows the high agglutination in Malayalam compared to Tamil.

4.2 Experiment Setup

We used OpenNMT-py toolkit for developing the Hindi-Malayalam and Hindi-Tamil NMT systems. The architecture of the model used is a Bi-direction RNN Encoder-Decoder with attention mechanism. The gated units used are Bi-LSTM. We used Loung attention mechanism. The model was trained till 2,00,000 training steps. The details of the parameters for NMT training is below.

Embedding size: 500; RNN for encoder and decoder: bi-LSTM; Bi-LSTM dimension: 500; encoder - decoder layers: 2; Attention: Luong; label smoothing: 1.0; dropout: 0.30; Optimizer: Adam

With the above setup, we trained three different NMT models by varying the training corpus. The three different experiments were, 1) Word Level, 2) Sub-word segmented data using Byte pair Encoding (BPE), 3) Word Segmentation using Morphological analyser

From the parallel dataset, 3000 sentences were randomly chosen for fine-turning the NMT training and another 1000 sentences were randomly chosen for testing. The same set of training, validation and test data were used for all the three experiments.

4.3 Data Preparation

The data was processed in three different methods as described below:

Word Level: The sentences in the three languages where tokenised with a white space and punctuations were separated from the words. The processed sentences were used for NMT training in both Hindi to Malayalam and Hindi to Tamil NMT training.

BPE: Byte Pair Encoding (BPE) proposed by Sennrich et al. (2016) was applied to the tokenised data. We used 3000 as BPE merge value for Malayalam and Tamil and for Hindi we used 5000 as BPE merge value.

Morph-Seg: The sentences in all the three languages, namely, Hindi, Malayalam and Tamil are processed with morphological analyser to split the words into root and suffix. The words in the sentence are replaced by the morphologically segmented root and suffixes to prepare the data. Morphological analysers built using paradigm and Finite state automata based approach was used for the three languages. For Hindi, we used morphological analyser available in the following link, https://ltrc.iiit.ac.in/morph/index.htm. Malayalam morphologically analyser used in present in Lakshmi and Sobha (2013). Tamil morphological analyser used is present in Sobha et. al. (2013).

5 Results and Analysis

We evaluated the translations from the three NMT models for both Hindi to Malayalam and Hindi to Tamil using BLEU score (Papineni et al. 2002). We used Sacre-bleu python library to calculate the BLEU scores. The results are presented in Table (3).

S.No	Details	Hindi to Malayalam (BLEU Score)	Hindi to Tamil (BLEU Score)
1	Word-Level	5.519	13.413
2	BPE	10.866	17.492
3	Morph-Seg	17.983	24.642

Table 3: BLEU Score for Hindi to Malayalam and Hindi to Tamil from different models

The BLEU scores show that the morphological segmentation has significantly improved the translation in both Hindi-Malayalam and Hindi-Tamil.

On analysis of the translation output from the three different experiments in both Hindi to Malayalam and Hindi to Tamil, our observations are as follows,

Word-Level: Many named entities, technical words and verb phrases occurred as unknown word (<unk>).

BPE: Translated sentences were complete but most of these translations were not the exact translation.

Translations convey a different sense due to the choice of the verb generation.

There were also words omitted in the translation.

Technical words and rare words were handled, but there were errors in it.

Morph-Seg: Clausal sentences were translated correctly than the other two systems.

Verb phrase generation was exact, though there were errors.

More closer to exact translation, but there were unknown words.

Technical words, Named Entities and rare words occurring as <unk> is the problem, but it is comparatively less than the word-level system.

We have explained the translation output with examples in the further part of this section.

Ex 3.a (HI to ML):
Hindi-Input: लोग, दृष्टिकोण अनुमानों पर सरल कार्रवाई कर सकते हैं.
(People can take simple actions on attitude projections.)

Malayalam Translations:
Word-Level: ആളുകൾക്ക് <unk> ലളിതമായ നടപടിയെടുക്കാൻ കഴിയും.

BPE: ആളുകൾക്ക് മനോഭാവങ്ങൾ ലളിതമാക്കാൻ കഴിയും.
(People can take simple actions on attitude.)

Morph-Seg: ആളുകൾക്ക് മനോഭാവം കണക്കിലെടുത്ത് ലളിതമായ പ്രവർത്തനം നടത്താൻ കഴിയും.
(People can take simple actions on attitude projections.)

Ex 3.b (HI to TA)
Hindi-Input: म्यूटेशन आनुवंशिक में मिल सकते हैं .
(Mutations can be found in genetics.)
Tamil Translations:
Word-Level: பிறழ்வுகள் மரபணு <unk> இருக்கலாம்.

BPE: பிறழ்வுகள் மரபணு மரபணுவில் இருக்கலாம் .
(Mutations can occur in the genetics genetics.)

Morph-Seg: பிறழ்வுகள் மரபணுவில் கிடைக்லாம்.
(Mutations can be found in genetics.)

Ex 3.a has Hindi to Malayalam translation and Ex 3.b has Hindi to Tamil translation. The word-level translation has <unk>. Though BPE and Morph-Seg translation outputs are proper sentences. Morph-Seg translation has exact translation. BPE translation in both languages has a different sense from the source sentence.

Ex4: Clausal Sentence

Hindi-Input: इतिहास उस दौर से शुरू होता है जब लोग लिखने की कला जानते थे.

(History begins from the time when people knew the art of writing.)

Tamil Translations:

Word-Level: மக்கள் எழுதும் கலையை மக்கள் <unk> வரலாறு தொடங்குகிறது.

BPE: மக்கள் எழுதும் கலத்திலிருந்து தொடங்கும்போது வரலாறு தொடங்குகிறது.

(History begins from the cell when people writing.)

Morph-Seg: மக்கள் எழுதும் கலையை மக்கள் அறிந்த போது வரலாறு தொடங்குகிறது.

(History begins from the time when people knew the art of writing.)

In Ex 4, the Hindi sentence has a relative participle clause. The clause construction was correctly translated by the Morp-Seg system. It has generated the relative participle verb, 'அறிந்த' (aRintha).

Ex 5: Sentence with series of NPs:

Hindi-Input: ग्राउंड रखरखाव उपकरण, जैसे लॉन मोवर, रोलर्स, लाइम पाउडर मशीन, मार्किंग मशीन, घास काटने वाली तलवारें, दरांती, श्रब मास्टर, कटर आदि.

(Ground Maintenance Equipments like Lawn Mower, Rollers, Lime Powder Machine, Marking Machine, Mower, Sickle, Shrub Master, Cutter etc.)

Tamil Translations:

Word-Level: தரை பராமரிப்பு சாதனங்கள், பாலைவனங்கள், <unk> <unk> <unk> <unk> <unk> <unk> <unk> <unk> <unk> <unk> <unk> <unk> <unk> <unk> போன்றவை .

BPE: தரை பராமரிப்பு சாதனங்கள், ஒவ்வாமைகள், லீக் தூள் இயந்திரங்கள், புல்வெளி இயந்திரங்கள், புல்வெளிகள், ஆப்பிரிக்கா, ஆப்பிரிக்கா, கேரட் மற்றும் பலர் போன்ற தரை பராமரிப்பு சாதனங்கள்.

(Ground care equipment like Ground care equipment, Allergies, Leek powder machines, Lawn machines, Lawns, Africa, Africa, Carrot and many others.)

Morph-Seg: புல்வெளிகள், புல்வெளிகள், லாரிகள், சுண்ணாம்பு பொடிகள், இயந்திரங்கள், இயந்திரங்கள், இயந்திரங்கள், இயந்திரங்கள், வெட்டும் போன்ற தரை பராமரிப்பு உபகரணங்கள் அகும்.

(Ground care equipment like such as Lawn care equipment such as lawnmowers, lawnmowers, trucks, lime powders, machines, machines, machines, machines, mowers etc.)

In example 5, the Hindi sentence has series of noun phrases. The three systems gave improper translation for this sentence. The Word-Level system gave series of <unk>, the BPE has generated output with many words which are not in the input sentences such as ',Africa', 'Carrot' etc. Morph-Seg, most of the noun phrases was partially translated, and only the head of the NPs were translated.

The following two examples demonstrate, technical words handled by BPE system. The first example (Ex.6.a) has the correct word replacement and the second example Ex.6.b has wrong word replacement.

Ex.6.a

Hindi-Input: कुछ स्यूडोमोनाड्स समस्या पैदा कर सकते हैं.

(Some pseudomonads can cause problems.)

BPE Tamil translation: சில சூடோமோனாட்கள் சிக்கலை உருவாக்கலாம்.

(Some pseudomonads may also develop problems.).

Ex.6.b:

Hindi-Input: 5% मैलाथियान, 1% लिंडेन ये सभी चूहे के विनाश के लिए प्रभावी हैं.

(5% malathion, 1% lindane all these are effective for rat extermination.)

BPE Tamil translation: 5% மில்லியன்கள், 1% இணைப்பு இந்த சுண்ணாம்பு அழிவுக்கு பயனுள்ளதாக இருக்கும்.

(5% millions, 1% patch is useful for this lime destruction.)

Examples 6.a and 6.b has Hindi to Tamil translations. In Ex.6 the word, 'स्यूडोमोनाड्स' (pseudomonads) has been translated correctly to 'சூடோமோனாட்கள்' (seudomonad + plural suffix) with plural suffix. Whereas in example 6.b, there are two technical terms 'malathion' and 'lindane' in the Hindi sentences, in the translation, the word 'malathion' has been wrongly translated to 'மில்லியன்கள்' (millions) and the 'lindane' is missing in the translation. And 'rat' has occurred as 'lime'.

From the above analysis, we observed that morph-segmentation of data in both Hindi to Malayalam and Hindi to Tamil has improved the translation. The translation of rare words occurs as <unk> has to be corrected.

6 Conclusion

We have presented our experiments in building Neural Machine Translation system for Hindi to Malayalam and Hindi to Tamil, where we compare the morphologically inspired segmentation methods against the Byte Pair Encoding (BPE) in processing the input for building NMT systems. Hindi is an Indo-Aryan language and Malayalam and Tamil are Dravidian languages. All the three languages are morphologically rich language. Malayalam and Tamil have agglutination. We have briefly explained the characters of these languages. We have compared the translation output from the Word-Level (base line) system and NMT systems trained with these two different sub-word processed data. Word-Level system had unknown words and verb generation was not proper. BPE system translation outputs were complete sentences but these translations were not exact translation. The sense of the sentences varied from the source sentence. BPE system handled unknown words. It also had errors. Translation from Morph-Seg systems had a significantly high BLEU score. The sense of translated sentences was close to the source sentences. Unknown words are a challenge in this system, but it is comparatively less than the Word-Level system.

Abstract

Textual deepfakes can cause harm, especially on social media. At the moment, there are models trained to detect deepfake messages mainly for the English language, but no research or datasets currently exist for detecting them in most low-resource languages, such as Bulgarian. To address this gap, we explore three approaches. First, we machine translate an English-language social media dataset with bot messages into Bulgarian. However, the translation quality is unsatisfactory, leading us to create a new Bulgarian-language dataset with real social media messages and those generated by two language models (a new Bulgarian GPT-2 model – GPT-WEB-BG [1], and ChatGPT). We machine translate it into English and test existing English GPT-2 and ChatGPT detectors on it, achieving only 0.44-0.51 accuracy. Next, we train our own classifiers on the Bulgarian dataset, obtaining an accuracy of 0.97. Additionally, we apply the classifier with the highest results to a recently released Bulgarian social media dataset with manually fact-checked messages, which successfully identifies some of the messages as generated by Language Models (LM). Our results show that the use of machine translation is not suitable for textual deepfakes detection. We conclude that combining LM text detection with fact-checking is the most appropriate method for this task, and that identifying Bulgarian textual deepfakes is indeed possible.

1 Introduction

The term “deepfake”, comes from “deep learning” and “fake” and indicates (potentially) fake texts, images, or videos, generated using deep learning models (Gambini, 2020). Among them, “Textual DeepFakes” (TDF) refer to texts generated automatically with the help of Generative Models (GMs, and lately with Large Language Models - LLMs), which may also contain fake or untrue content. This makes those of them, which are spread with the intention to deceive, the automatic variant of disinformation (as defined by the European Commission (EC)[2]. According to this EC’s definition, “disinformation” is *“false or misleading content that is spread with an intention to deceive or secure economic or political gain and which may cause public harm”*. There exist useful GMs and LLMs applications (Kasneci et al., 2023). However, textual deepfakes can be a serious problem when spread on official information channels, as they can reach a large number of people. They are also problematic because, when fluent, they are hard to recognize by humans (Crothers et al., 2022). TDFs can be used by politicians in their political fights and destroy a person’s reputation, or to influence a large number of people about sensitive topics such as a war or health. TDFs can be especially problematic on social media, as anybody can have access to such platforms and freely post information, which can be easily spread to a larger number of population subgroups including those who do not usually follow the official media channels (such as teenagers).

There is Natural Language Processing (NLP) research on detecting LM-generated texts and TDFs for English and other languages (Jawahar et al., 2020; Fagni et al., 2021; Kowalczyk et al., 2022; Gambini et al., 2022; Stiff and Johansson, 2022; Sadiq and Ullah; Shamardina et al., 2022; Chen et al., 2022b). However, to the best of our knowledge, there is no such research for Bulgarian.

Differently from most previous works, we consider Textual DeepFakes (TDFs) not just as any texts generated by LMs, but specifically those LM-

Proceedings of Recent Advances in Natural Language Processing, pages 1151–1161
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_122

generated texts that contain fake information. However, we also consider detecting LM-generatedness as an important aspect in detecting TDFs.

Detecting textual deepfakes for Bulgarian is a challenging task, as there are no LM-generated and textual deepfakes datasets in Bulgarian. While some English-language methods can use LM-generated messages actually posted on Twitter by self-proclaimed bots (Fagni et al., 2021), we could not identify such in Bulgarian.

We test three approaches to detect LM-generated texts. Two of them use Machine Translation (MT), as this is a very frequent method in lower-resourced settings. While we suspect that we might not get good results in translating already broken LM-generated texts, we experiment with MT due to the lack of appropriate Bulgarian datasets and LM-generated text detectors for Bulgarian.

Approach 1 (described in Section 4.1) tests MT for translating into Bulgarian an existing English-language dataset of actually occurring LMs-generated tweets (TweepFake[3] (Fagni et al., 2021)). Our subsequent plan is to build classifiers on the machine-translated messages.

As the results of machine translating the TweepFake messages into Bulgarian are not satisfactory, we test Approach 2 (explained in Section 4.2). We generate a Bulgarian language dataset composed of human-written messages and those generated by ChatGPT and GPT-WEB-BG. Next, we machine translate this dataset into English. We do this to test existing LM detectors for English, which are already trained on much more data.

As the English-language LM detectors in Approach 2 show a low accuracy, we apply Approach 3 by training classifiers (see Section 4.3) on our Bulgarian LM-generated dataset.

Finally, in order to add the "fakeness" aspect of textual deepfakes to them being generated by an LM, we run a final experiment (described in Section 4.4). We apply the classifier with the highest test results from Approach 3 on a recently published Bulgarian social media dataset manually fact-checked and annotated for containing untrue information and disinformation. We do this to check if the classifier would recognize any untrue messages or such containing disinformation as LM-generated.

The rest of the article is structured as follows: Section 2 discusses the Related Work. Section 3 introduces the existing datasets used. Section 4 presents each approach with its results. Section 5 provides a Discussion, Conclusions, and Future Work, and the following unnumbered sections contain the Limitations of this work, the Ethical and Legal statements, the Broader Impact Assessment, and the Acknowledgments.

2 Related Work

In comparison with detecting deepfake images and videos, until recently there was a limited number of Natural Language Processing (NLP) works on detecting textual deepfakes, and efforts were focused mostly on English (Fagni et al., 2021). With the recent appearance of several Large Language Models (LLMs), including the freely available for many languages ChatGPT[4], the amount of NLP works detecting LLMs-generated and deepfake texts has increased (Orenstrakh et al., 2023). Detectors for new languages[5] have also appeared (Antoun et al., 2023).

The work on detecting textual deepfakes usually checks if the texts have been generated by one or more LMs, generally training classifiers on LM-generated and human texts (Fagni et al., 2021; Gambini, 2020; Gambini et al., 2022), with recent zero-shot approaches appearing too (Mitchell et al., 2023).

The most recent **language models** are the deep learning ones: Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019), the Generative Pre-trained Transformer 2 (GPT-2) (Radford et al., 2019), GPT-3 (Brown et al., 2020), ChatGPT[6], the Google's Pathways Language Model 2 (PaLM 2), used in Bard[7] and BLOOM (Scao et al., 2022). LM detectors check also for texts, generated with older neural LMs, such as Recurrent Neural Networks (RNN), Long Short-Term Memory (LSTM), and Convolutional Neural Networks (CNN).

Most LMs can generate content in English, but there are also models for generating text in other languages such as Chinese, Bengali, Arabic, Russian, Korean, Slovak, Spanish, Czech, German, French, and Macedonian. Pre-trained Large Language Models (LLMs) can be found online (e.g.

[6] https://openai.com/blog/chatgpt

[7] https://bard.google.com/. Last accessed on July 27, 2023.

on the Hugging Face platform). **The newest LMs for Bulgarian** are OpenAI's GPT-3.5 and GPT-4, Google's Bard, and the GPT-WEB-BG[8] (GPT-2-based) model, which we use together with ChatGPT (model 3.5) in this article. There are also 3 older pre-trained Bulgarian GPT-2 LMs (all by the same author) - 2 small and one medium[9]. These models were trained on Bulgarian data from books, Wikipedia, and the Oscar corpus. We considered them unsuitable for our task, as they generated texts with unsatisfactory quality.

With the fast advances in text generation models came the need for **synthetic text detectors**. LMs detection methods fall into three major categories: 1) simple classifiers; 2) zero-shot classifiers and 3) fine-tuning neural LMs (NLMs) (Jawahar et al., 2020). Simple classifiers use classical machine learning methods to train models from scratch to discriminate between synthetic text generated from LMs and human-written texts. Zero-shot classifiers use a pre-trained generative model (e.g. GPT-2 output detector, DetectGPT (Mitchell et al., 2023)) to detect if a text has been generated by the model used or by a similar model. These detectors do not require further training. In the NLM fine-tuning method a pre-trained LM (e.g., BERT, RoBERTa) is fine-tuned to detect text generated from itself or similar models. These detectors *do require* additional training. Several **pre-trained models for synthetic text detection** (mostly for English) are available online (for example in Hugging Face) - BERT, CLTR, GROVER, Open-AI GPT-2, AI Text Classifier, DetectGPT[10] and RoFT[11](human detector in the form of a game). Until our work, to the best of our knowledge, there weren't any synthetic text detectors that could work with Bulgarian.

Although there are generators for different languages, the **existing datasets for detectors training** are mostly in English (Fagni et al., 2021; Liyanage et al., 2022), with Chinese (Chen et al., 2022a) and Russian[12] (Posokhov et al., 2022; Shamardina et al., 2022) also available. However, there are no datasets with Bulgarian LM-generated texts, especially social-media-like.

Among the works, which are the most similar to ours are those on detecting LM-generated texts in other languages (e.g. Russian, Chinese, French) (Shamardina et al., 2022; Chen et al., 2022a; Antoun et al., 2023), but they only detect LM-generated texts, and ignore any fakeness of their content. Similar to ours is also the new research on detecting ChatGPT. An example is (Pegoraro et al., 2023), which tests a large number of available English LMs detectors and discovers that they are all not good at detecting ChatGPT (achieving <50 in True Positives Rate). However, this research detects English ChatGPT only and does not work with Bulgarian, nor does it detect textual deepfakes.

Finally, there are also approaches that detect (usually human-written) fake texts in social media, without taking into account the LM-generation aspect of textual deepfakes. These methods are usually based on detecting a specific style or analyzing the behavior of source accounts, comparing the messages with external news sources, and performing various types of (semi-)automatic fact-checking (Ghadiri et al., 2022; Krishnan and Chen, 2018).

3 Datasets Used

This section describes the existing datasets used in our experiments.

3.1 English TweepFake Dataset

The TweepFake dataset[13] (Fagni et al., 2021) contains 25,836 tweets in English (half of which are human-written and half are bot-generated), with each tweet actually published on Twitter. The data comes from 23 bots, imitating 17 human accounts, and the respective human accounts that the bots are imitating. The bots use different text generation models, such as Markov Chains, RNN, RNN+Markov, LSTM and GPT-2. We use TweepFake in our Approach 1 in Section 4.1.

3.2 Bulgarian Social Media Datasets

We have used five recently released (Temnikova et al., 2023) datasets of social media messages, posted on Twitter and Telegram between 1 January 2020 and the end of June 2022. Among them, 4 datasets (of a total of 118,570 messages) contain non-fact-checked social media texts. However, these datasets are on topics, related to Covid-19, lies and manipulation, and famous Bulgarian cases

[8] https://huggingface.co/usmiva/gpt-web-bg. Last accessed on July 27, 2023.

[9] https://huggingface.co/rmihaylov/

[12] https://www.kaggle.com/competitions/ruatd-2022-multi-task/data

[13] https://www.kaggle.com/datasets/mtesconi/twitter-deep-fake-text. Last accessed on March 3rd, 2023.

when Bulgarian politicians were accused of lying. We selected exactly these datasets because they are more likely to contain untrue information or disinformation, given the nature of the topics (e.g., Covid-19, political statements), and because they are more recent than the previous ones (e.g. Nakov et al. (2021)). We used messages from these 4 datasets to generate our own LM texts for Approach 2 (Section 4.2).

The fifth dataset is a subset of these 4 datasets, containing 4083 messages[14]. Each message of it was fact-checked using external sources and manually annotated by 3 Bulgarian journalists for containing or not "Untrue information" and "Disinformation". This dataset is used in our Approach 4 (Section 4.4).

To these 5 datasets, we have added our own 104,138-messages Facebook dataset[15]. The Facebook dataset contains messages collected from official pages and public groups of Bulgarian media, parties, politicians, and political influencers from June 2021 to June 2022 using CrowdTangle[16], as well as from a historical search for the keyword "избори" (meaning in English "elections") in Bulgarian from 2006 until now. We selected this keyword, as according to our observations, many accusations of lying are published during elections. The Facebook dataset has been pre-processed similarly to what is described for the five publicly available datasets (Temnikova et al., 2023) in order to ensure compatibility: we removed duplicates, messages with fewer than 5 words, and non-Bulgarian messages using FastText's language identification tool.

In total, we used 222,708 Bulgarian social media messages.

4 Experiments

4.1 Approach 1: Machine Translating TweepFake into Bulgarian

First, we used the existing English Tweepfake dataset, due to the unavailability of Bulgarian-language bots on social media.

4.1.1 Methods

We performed experiments in which we tested the results of using Machine Translation (MT) to translate only the Tweepfake bot messages into Bulgarian. We suspected that we might obtain low-quality machine translation results; nevertheless, we tested this approach due to its common use in lower-resourced settings. We selected 16 messages, generated with different LMs, such as GPT-2 and RNN. We run them through 5 publicly available MT engines that were known to work well with the English-Bulgarian language pair: 1) Google Translate's free User Interface (UI)[17] 2) Google Translate's Google Spreadsheets function[18], 3) DeepL Translator UI[19], 4) GoURMET project's demo[20]; and 5) ChatGPT interface. Manual evaluation was done by two Bulgarian linguists, both with Natural Language Processing (NLP) and professional translation expertise. Each translation by all 5 MT engines of each message was evaluated for two categories: a) Is the meaning preserved? b) Are the characteristics of the message preserved (e.g. broken syntax, specific formatting, etc.)? Both categories had a 3-point scale (1 - not preserved; 2 - partially preserved; 3 - preserved).

4.1.2 Results from machine translating TweepFake dataset into Bulgarian

None of the engines performed satisfactorily for this task. The average score of both human evaluators was around 1 ("not preserved") for both categories. Google Translate and DeepL performed slightly better (1.5). IAA varied per engine and question, with higher agreement on the first question.

The analysis has revealed that all the engines encountered difficulties with translating the bot messages. This is due to the fact that the bot messages either contained slang or were almost completely incomprehensible with broken English syntax. The MT engines were either adding noise (Google Translate and GoURMET) or making the translated messages more fluent and human-like (DeepL). ChatGPT either corrected the bot's messages or commented that the messages were incomplete and could not provide a translation. Due to the aforementioned translation problems, we decided not to use this dataset for training the classifiers, and to instead create a new dataset for this purpose.

4.2 Approach 2: Bulgarian Dataset Generation and English LM Detectors Testing

We created our own dataset with real and LM-generated "social-media"-like messages. We then test existing English LMs detectors, which are supposed to work well because they are trained on much larger datasets.

4.2.1 Methods

Dataset Generation

We created a Bulgarian language dataset (from now on referred to as Deepfake-BG[21]), containing 9824 messages. Half of the messages (4912) were randomly chosen from the larger existing datasets, described in Section 3.2 in a way to have a higher probability that they were written by humans. For example, they were selected from Covid-19 disease and travel mutual help Facebook and Telegram public channels and groups, as well as from politicians' and political influencers' Facebook pages. The other 4912 messages contained an equal number of "social-media"-like messages, generated by two LMs - a new Bulgarian-language GPT-2 model (called GPT-WEB-BG) (Marinova et al., 2023) and ChatGPT for Bulgarian.

Generating messages with GPT-WEB-BG

GPT-WEB-BG[22] was trained on a dataset containing scraped content from major Bulgarian online media providers. The model is a part of an active development of a suite of LLMs for Bulgarian and the authors are incorporating more data from various domains such as social media, Wikipedia, books, and scientific literature. A specialized procedure was followed for source filtering, topic selection, and lexicon-based removal of inappropriate language for Bulgarian in order to prevent gender, race, and political bias, toxicity, or discrimination practices. GPT-WEB-BG generated messages by completion, starting from randomly selected Twitter and Facebook messages from the datasets, described in 3.2, which were different from those included in the "human" part of this dataset. The Deepfake-BG messages were generated using two methods: 1) 5 words from the original message, completed with 200 characters, and 2) 10 words from the original message, completed with 250 characters. Such generation produced properly looking messages, but also messages, containing repeated phrases or sentences, and truncated (interrupted) sentences. We removed the last two types of messages to make the classifiers' task harder. Next, we selected a random sample of the messages generated by GPT-WEB-BG. If there were two generated versions of an original message (one from both methods), we took randomly only one of them. Duplicates were removed, which led to the final number of 2456 messages on the following topics: 482 from Facebook public pages of Bulgarian media and political parties, 172 generated from Twitter messages on the "Covid-19" topic, and 1802 generated from Twitter messages on the "lies and manipulation" topic.

Bulgarian ChatGPT Generation

We also generated 2,456 ChatGPT messages on the same topics and in the same quantity per topic as the GPT-WEB-BG messages. The ChatGPT messages were generated by typing manually instructions into the UI in two ways: 1) Copy-pasting examples of human messages with the instructions: "Generate (5 or 10) social media messages (with emoticons and hashtags) like this one:...". The number (5 or 10) varied, according to the speed of generation and the necessary amount of messages. The instructions were written half of the time in Bulgarian, and half in English. 2) In 10 cases, and to generate more variety, we experimented with giving this instruction: "Write (5 or 10) social media messages (with emoticons and hashtags) on this topic:...". As in the previous cases, we cleaned the obtained messages from duplicates.

Testing English LM detectors

Next, we translated Deepfakes-BG dataset into English using three widely used and freely available MT engines - DeepL, Google Translate UI and the GOOGLETRANSLATE() function in Google Sheets. Upon reviewing the existing English LM detectors, we identified several problems. Firstly, freely available tools are usually trained to recognize either GPT-2 or ChatGPT, but not both (excluding zero-shot approaches). Among the available tools, only GPTZero is trained to recognize GPT-2, GPT-3, and ChatGPT, but it is a paid tool. Additionally, the majority of classifiers require longer texts, typically at least 40 words or a minimum of 2000 characters, while our texts are approximately 250 characters in length.

Another challenge is that each detector produces a different type of output. Some return only binary

[21] This dataset will be partially shared upon publication of this paper, and in compliance with social media platforms' requirements.

[22] https://huggingface.co/usmiva/gpt-web-bg.

labels (e.g., "Human" and "Machine"), while others also provide label probabilities. Additionally, some detectors only return a probability value (e.g., "52.63% AI-generated content"). This variability in output types makes comparative evaluation difficult.

We selected four detectors based on the following criteria: (1) freely available and (2) trained to recognize both GPT-2 and/or ChatGPT. The first detectors we selected are *roberta-base-openai-detector* detector [23] which is a RoBERTa base model for detection of GPT-2 generated texts, *chatgpt-detector-single* detector [24] for ChatGPT detection which uses pretrained large models based classifiers. We tested two more detectors *ChatGPT-Detection* [25] and *baykenney/bert-base-gpt2detector-topp96* [26]. However, the authors of these detectors do not provide information about them.

For our experiments, we used the binary version of our dataset as most detectors return a binary output. However, *ChatGPT-Detection* only returns probabilities. Consequently, we evaluated the output of the other detectors that provide both labels and probabilities and observed that the minimum probability for automatically generated texts was 50%. Based on this, we classified texts with a probability greater than 50% as "automatically generated" and those with a probability equal to or lower than 50% as "human texts".

After processing the translated texts using the detectors, we compared their results with the original labels and evaluated their accuracy.

4.2.2 Results from Deepfakes-BG Generation and Testing English LM-detectors

Comments on the Deepfakes-BG Generation Results

We observed that ChatGPT tended to generate advertisement-like short texts, and it needed several reminders, in order to change its style to be more social media-like. Since the original datasets contained messages both pro- and against official Covid-19 measures, we tried to generate messages about the adverse effects of Covid-19 vaccines. ChatGPT either refused to generate such messages, or generated messages, always ending with “however, it is better to get vaccinated”. Our observations also reveal that ChatGPT’s bias towards officially accepted positions can generate highly inaccurate statements. In fact, the model may attribute to a public figure, who has typically expressed opposing views to widely accepted beliefs, words that this individual never actually uttered.

Results from Testing the English LM Detectors on the Translated Deepfakes-BG Dataset

The experimental results are presented in Table 1. The tested detectors show an accuracy of approximately 50%. However, the results reveal that some detectors perform poorly on one of the classes, which may be attributed to two factors: (1) the translation of the text into English affects the outcome, and (2) the dataset is balanced, so even if the model predicts only one label for the entire test dataset (as in one of the cases), it will still achieve approximately 50% accuracy.

The length of the texts may also impact the results. As previously mentioned, many detectors require longer texts to accurately determine whether the text is automatically generated or human-written. This approach may not be practical, and there is a need to develop tools that can work with shorter texts.

We evaluated additional detectors beyond those previously described, however, the results obtained were similar to those already reported. Therefore, we have opted not to include them in the table.

4.3 Approach 3: Building Bulgarian-Language Classifiers on the Bulgarian Dataset

Due to the low accuracy results of Approach 2, we trained our own classifiers on the Deepfake-BG dataset.

4.3.1 Methods

We have trained several classifiers: Naive Bayes, Logistic Regression, K-Nearest Neighbors, Support Vector Machines (SVM), Decision Trees, Random Forests, and we have fine-tuned the newly released BERT-WEB-BG[27], obtaining BERT-Deepfake-BG[28]. We developed 2 models from the dataset- binary (human vs. LM) and multi class (human, GPT-WEB-BG, and ChatGPT). The dataset was split into train, validation, and test in

	Total	0.85	0.85	0.85	0.85

Table 3: Best models for Human vs. ChatGPT vs. GPT-WEB-BG classification. **Total** is the weighted average, as the dataset is unbalanced for the 3 classes. *BdB* stands for BERT-Deepfake-BG. *cGPT* stands for ChatGPT.

this way: 80:10:10. We used v. 0.24.2 of the Python library *sklearn*[29].

4.3.2 Results

Table 2 shows the results of the three classifiers, which obtained at least 0.90 F1-Score for human vs. LM (bot) classification. Table 3 shows the results of the classifiers, which achieved at least 0.90 F1-Score for the three-class classification (human, ChatGPT, BERT-Deepfake-BG).

As expected, BERT-Deepfake-BG shows the highest results for both binary and 3-class classification. Figure 1 shows the confusion matrix of BERT-Deepfake-BG's human vs. LM (bot) classification and Figure 2 shows the confusion matrix of BERT-Deepfake-BG's human vs. GPT-WEB-BG vs. ChatGPT classification.

4.4 Applying the Bulgarian Classifier with the Highest Results on a Manually-Fact-Checked Bulgarian Dataset

The three previous approaches worked on recognizing LM-generated texts. In order to account for the fact that textual deepfakes may potentially contain also fake information, we applied BERT-Deepfake-BG on the 4083-messages dataset manually annotated by journalists, mentioned as the 5th subset

[29] https://scikit-learn.org/stable/. Last accessed on April 16, 2023.

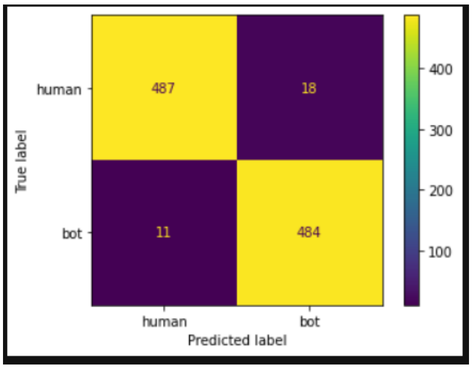

Figure 1: Confusion matrix of BERT-Deepfake-BG's binary classification.

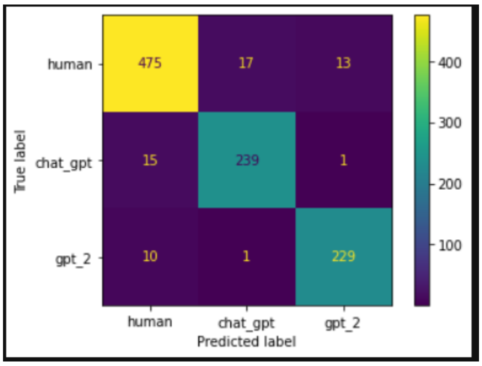

Figure 2: Confusion matrix of BERT-Deepfake-BG's 3-class classification.

dataset in Section 3.2.

4.4.1 Methods

We selected a subset of the messages from the dataset annotated by journalists, aiming to achieve the highest possible confidence that the messages recognized by BERT-Deepfake-BG are fake. To achieve this, we selected only the messages, which have been annotated by all 3 annotators as containing "Untrue information", and at the same time annotated by all 3 annotators as containing "Disinformation". We considered both the responses "yes" and "partially". We have removed the messages that are simultaneously present in the dataset annotated by journalists, as well as in the larger Twitter and Telegram datasets, in order to avoid any overlap with the messages used for building BERT-Deepfake-BG.

We applied both the binary (human vs. LM) and the multiclass (human, GPT-WEB-BG, and ChatGPT) versions of BERT-Deepfake-BG on the manually annotated dataset. We decided to experiment with both models, even if we realize that it is not technically correct to attempt to identify instances of ChatGPT among social media messages posted before it was made publicly accessible (1 January 2020 to 27 June 2022). Differently from that, the binary (human vs. LM) BERT-Deepfake-BG model could potentially identify messages, generated by other similar GPT models.

Category	Untrue	Untrue+Disinf.
LM	42	28
ChatGPT	16	9
GPT-WEB-BG	26	14

Table 4: Number of messages recognized by BERT-WEB-BG as LM-generated, ChatGPT-, and GPT-WEB-BG-generated in the 4083 messages dataset.

4.4.2 Results

BERT-Deepfake-BG recognized several messages as LM-generated. Specifically, among the messages, annotated by three annotators as containing untrue information 42 were recognized as being LM-generated, out of which 16 as ChatGPT and 26 as GPT-WEB-BG-generated. The number of messages, annotated by three annotators as untrue and by three annotators as containing disinformation, and recognized by BERT-Deepfake-BG as LM-generated represented 50-60% of each of the above categories (see Table 4 for more details). Our observations show that the messages, labeled by BERT-Deepfake-BG as ChatGPT resemble propaganda style, contain groups of words entirely written in capital letters, and sound more dramatic. This could be related to the fact that ChatGPT tended to generate advertisement-like texts, as we mentioned in Section 4.2.2. We show below an example of a message, labeled by BERT-Deepfake-BG as *ChatGPT*, and by three human annotators as both containing "untrue information" and "disinformation":

In Bulgarian: "ВОЙНАТА СЕ РАЗГАРЯ: Радев обвинява "Има такъв народ" в корупция!"

(In English: THE WAR IS IN FULL SWING: Radev accuses "There is such a nation" in corruption.)

The messages labeled by BERT-Deepfake-BG as GPT-WEB-BG exhibit more frequently broken syntax or unusual punctuation. What follows is an example of a message, manually annotated both as "untrue information" and "disinformation" and as a *GPT-WEB-BG-generated* one by BERT-Deepfake-BG.

"НЕЩО ИНТЕРЕСНО НЕДОСЕГАЕМИТЕ

ХУНТАТА Гешев иска Борисов и здравните власти да затегнат на мерките срещу COVID-19"
(In English, with broken syntax preserved: SOMETHING INTERESTING: UNTOUCHABLES JUNTA - Geshev wants Borisov and the health authorities to tighten the measures against COVID-19)

5 Discussion, Conclusions and Future Work

This article presents the first experiments aiming to find a solution to answer the challenging question of whether textual deepfakes in Bulgarian can be found in social media. We tested three approaches for detecting the "LM-generatedness" and one for the fakeness of textual deepfakes. The results indicate that utilizing machine translation (MT) in either language pair direction is not a viable solution, as textual deepfakes style may get lost in the process and the accuracy of English LM detectors is low. We conclude that the most appropriate approach for detecting textual deepfakes in Bulgarian should be one involving creating our own LM-generated dataset, in combination with fact-checking. In future work, we plan to generate more data with more models and on more topics. Applying the classifier with the highest accuracy on Bulgarian fact-checked social media texts posted after ChatGPT's release is also a possible future work.

Limitations

- We have experimented with messages generated by only two language models. Testing with more LMs is desirable.

- We have also used a manually fact-checked real social media dataset with messages posted prior to the public release of either of the two language models. While this is motivated by the lack of a Bulgarian language fact-checked social media dataset released in 2023, it is desirable to experiment with newer fact-checked social media messages.

- Having a pre-trained GPT-2 model including social media texts in Bulgarian in the data could also enhance the results.

Ethics and Legal Statement

The research presented in this article has been conducted according to the Ethical Code of Sofia University "St. Kliment Ohridski" and after frequent consultations with lawyers specialized in Bulgarian and European Union's laws.

Broader Impact Assessment

This article presents the first known to us effort to automatically recognize textual deepfakes in Bulgarian in social media. For this reason, it paves the way to building better working automatic tools, which will be able to recognize textual deepfakes in Bulgarian. This would benefit Bulgarian society as a whole, Bulgarian journalists, and fact-checkers, and may also contribute to the work of Natural Language Processing researchers and developers in other languages.

Acknowledgments

This article presents the joint work of several researchers. 1) Part of it took place during project TRACES[30], and indirectly received funding from the European Union's Horizon 2020 Research and Innovation Action Programme, via the AI4Media Open Call #1 issued and executed under the AI4Media project (Grant Agreement no. 951911)[31]. 2) Additionally, the work has been also supported by the GATE project, funded by Operational Programme Science and Education for Smart Growth under Grant Agreement No. BG05M2OP001-1.003-0002-C01. 3) Furthermore, the models GPT-WEB-BG and BERT-WEB-BG are kindly provided by CLaDA-BG, the Bulgarian National Interdisciplinary Research e-Infrastructure for Resources and Technologies in favor of the Bulgarian Language and Cultural Heritage, part of the EU infrastructures CLARIN and DARIAH, Grant number DO1-301/17.12.21. 4) Finally, the work was partially funded by the European Union-NextGenerationEU, through the National Recovery and Resilience Plan of the Republic of Bulgaria, project SUMMIT, No BG-RRP-2.004-0008.

The authors express their gratitude to the RANLP 2023 reviewers and conference organizers.

Abstract

The emergence of social media has made it more difficult to recognize and analyze misinformation efforts. Popular messaging software Telegram (Durov, 2013) has developed into a medium for disseminating political messages and misinformation, particularly in light of the conflict in Ukraine (Wikipedia contributors, 2023). In this paper, we introduce a sizable corpus of Telegram posts containing pro-Russian propaganda and benign political texts. We evaluate the corpus by applying natural language processing (NLP) techniques to the task of text classification in this corpus. Our findings indicate that, with an overall accuracy of over 96% for confirmed sources as propagandists and oppositions and 92% for unconfirmed sources, our method can successfully identify and categorize pro-Russian propaganda posts. We highlight the consequences of our research for comprehending political communications and propaganda on social media.

1 Introduction

Because of social networks' rising use in daily life, we increasingly rely on other people's opinions when making both big and minor decisions, such as whether to vote for a new government or buy new products online. It is not surprising that by spreading propaganda, social media became a weapon of choice for manipulating public opinion. Social media is rife with fake content and propaganda, which needs to be identified and blocked or removed. Recent years have seen a major increase in the issue of information authenticity on social media, leading to significant research community efforts to address fake news (Pariser, 2011), clickbait (Chen et al., 2015b), fake reviews (Akoglu et al., 2013), rumors (Hamidian and Diab, 2016), and other types of misinformation. In this paper, we deal with Russian state-sponsored propaganda disseminated in Telegram. Telegram is one of the most widely used venues for information sharing in Russia, especially after blocking META Platforms. Therefore, Telegram draws much attention from organized groups that spread similar views through its channels and (most probably) funded by either state or related organizational sources. To influence the public to favor the war, the Russian government implemented new regulations that gave it control over traditional media channels (Geissler et al., 2022). The fundamentals of propaganda communication: persuasion using symbols, emotions, stereotypes, and pre-existing frameworks with the intention of swaying perceptions and influencing cognition and behavior in order to further the propagandist's agenda (Alieva et al., 2022). Our work focuses on specific pro-Russian propaganda during the conflict between Russia and Ukraine. Several researchers have documented Russian propaganda during previous conflicts (Golovchenko, 2020; Geissler et al., 2022).

This paper has two contributions: (1) it introduces a new dataset of posts about the Russia-Ukraine war in Russian, collected from Telegram channels and annotated with binary propaganda-related labels; (2) it reports the results of our case study on this dataset, where we examine a supervised method for propaganda detection.

2 Related Work

Propaganda is the spread of information to influence public opinion or behavior, and it is a growing concern in today's digital era. With the vast amount of digital media available, it can be challenging to differentiate between genuine information and propaganda.

In recent years, there has been a growing interest in using machine learning techniques for propaganda detection. Numerous studies have attempted to classify texts' propagandistic content (Rashkin et al., 2017). For instance, Martino et al. (2019) allows analyzing texts at a finer level by identifying all passages that contain propaganda tactics and

Proceedings of Recent Advances in Natural Language Processing, pages 1162–1170
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_123

their types. A corpus of news articles was created and manually annotated at the fragment level with eighteen propaganda techniques. Authors Yoosuf and Yang (2019) used the Fragment Level Classification (FLC) task dataset consisting of news articles from various sources, each annotated with labels representing one out of 18 predefined techniques. The goal of the task introduced in Yoosuf and Yang (2019) was to predict the propaganda techniques associated with each text fragment in the articles. The authors fine-tuned a BERT model on the FLC task dataset using a multitask learning approach, where the model is simultaneously trained to perform both fragment-level and article-level classification. Another paper, Khanday et al. (2021), proposed a supervised learning approach using Support Vector Machine (SVM) to classify news articles as propaganda or non-propaganda. Despite demonstrating fairly good accuracy, the aforementioned studies are mostly limited to English.

The recent political developments have increased the number of Russian-language studies. Topic modeling is one of the methods that have been successfully applied in the field of NLP. In this article, Yakunin et al. (2020) suggests a method for identifying texts that contain propaganda by leveraging a text corpus's topic model. With the suggested method, analysis is attempted at a much higher level of abstraction (themes and the relationships between texts and subjects rather than individual words in a phrase). Other researchers in Park et al. (2022) analyzed agenda creation, framing, and priming—three tactics that underlie information manipulation using both established and newly developed NLP models on VoynaSlov (38M+ posts from Twitter and VKontakte in Russian), revealing variance across media outlet control, social media platform and time. A structured topic model (STM) and a contextualized neural topic model were both used. Another researcher used news stories and Telegram news channels in Ukrainian, Russian, Romanian, French, and English to examine how the media influenced and reflected public opinion during the first month of the war between Ukraine and Russia (Solopova et al., 2023). The existing literature on propaganda detection offers a wide variety of methods, datasets, and perspectives that can be used to develop effective and responsible propaganda detection systems.

To the best of our knowledge, our dataset is a large dataset of political posts with substantial differences between pro-war and anti-war Telegram posts about the Russia-Ukraine war.

3 Case Study

3.1 The Dataset

Telegram channels are widely used in Russia because they are simple, usually focus on short text posts, and do not need special personal verification. Everyone can create a channel anonymously and start posting any type of information without any validation or fact-checking. In addition, the CEO of Telegram, Pavel Durov, advertised Telegram as an independent and the most protected messenger in the world marketplace (Durov, 2014).

We used Telegram API (Telegram, 2021) to extract texts from Telegram (Durov, 2013) channels representing Russian government official sources and opposition political sources into our dataset (described below in Figure 1). We have selected a period for downloading texts from the 24th of February 2022 to the 24th of February 2023, as the first year of the Russia's full invasion of Ukraine. We relied on the EU sanction list (European External Action Service, Accessed on 14 May 2023) to assign texts to a propaganda or benign category. For example, ”Channel One Russia” has been added to the sanction list as a government company (council of the EU, 2014), and ”SolovievLive,” the personal telegram-channel of Vladimir Roudolfovitch Soloviev (council of the EU, 2023), has been added to the list as an individual propagandist who works at the government channels. Benign political text sources have been selected from the channels declared to be Foreign Agents by the Ministry of Justice of the Russian Federation (according to the Russian Foreign Agents law (The Federal Assembly of the Russian Federation, 2022)), and as such, are unlikely to contain pro-Russian propaganda. The Russian Foreign Agents Law (The Federal Assembly of the Russian Federation, 2022) is described as a freedom-restricting law by the International Center for Not-for-Profit Law (International Center for Not-for-Profit Law (ICNL), 2021), an international non-governmental organization that works to promote and protect the right to freedom of association, assembly, and expression for civil society organizations and individuals around the world.

The list of sources for two classes in our dataset is listed in Figure 1 – we provide the name of the

Telegram channel, its translation, and the channel's ID. Figure 2 contains two representative examples of propaganda and benign political texts along with their English translation.

Texts have been downloaded from Telegram channels with two filters: seed words for each class and the post length greater than or equal to 80. According to the article about how text characteristics impact user engagement in social media, posts greater than or equal to 80 characters are ”easy to read”, and they get a better user engagement (Gkikas et al., 2022). Seed words for propaganda sources have been chosen from the articles about the Russian-Ukrainian war (Umland, 2022), (Ganchev et al., 2022). The opposition's seed words are neutral synonyms of the propaganda's words. These seed words are listed in Figure 3. We used seed words for searching and downloading posts only related to the war, except for advertising posts and other subjects in Telegram channels. The dataset available on GitHub (2023).

3.1.1 Data Analysis

Tables 1-2 contain basic statistics of the data, including the number of documents in every class for each set, in total, and the average number of words in a document. The positive class (propaganda) contains 6038 texts and the negative class (benign) contains 5282 texts.

Text length analysis (in characters) shows propaganda texts tend to be longer, while benign texts in general are shorter and their length distribution is different (no big differences between thresholds). A comparison of these distributions appears in Figure 4.

During our research, we underline, for example, that the word 'НА' (meaning 'on') is prominent in propaganda texts because of the Russian expression 'on Ukraine' used in Russia contrary to the expression 'in Ukraine' used in Ukraine.

The variance threshold (Kohavi and John, 1997) serves as a straightforward method for feature selection, wherein features failing to meet a certain threshold for variance are eliminated. Specifically, it eliminates features with zero variance, meaning those that have identical values across all samples, as the default criterion. Figure 5 shows the most important words extracted with this method for two classes in our data - benign texts and propaganda texts - for different values of the threshold. We can see that for a variance threshold of 0.7 or above no words are found for the benign class, implying that this class contains only lower-variance features (meaning that the values of word features across the class do not vary much or are very similar). However, given a smaller threshold, the phrase ”foreign agent” is selected for the benign class.

3.2 Data Representation

Besides expanding our training set, a universal solution might be developed if we find a ”typical” writing style or dissemination of propaganda in general across different domains.

The following techniques were employed for the text representation:

1. Term frequency-inverse document frequency (tf-idf), which increases proportionally to the number of times a word appears in the document and is offset by the number of documents in the corpus that contain the word. Terms represent vector dimensions, while their tf-idf scores represent vector values. Every text item is treated as a separate document and the whole dataset as a corpus for computing tf-idf weights.

2. Word n-grams consisting of n consecutive words seen in the text, where n is a parameter. Each text is represented by a vector with N-grams as dimensions and their counts as values. In our evaluation, we used the values $n = 1, 2, 3$.

3. BERT sentence embeddings using one of the pre-trained BERT models:
   - a multilingual model (Sanh et al., 2019)
   - Russian-language BERT model (Arkhipov et al., 2019).

3.3 Classification Pipeline

Our classification pipeline consists of a few steps.

1. Representing texts with tf-idf vectors, word n-grams with $n = 1, 2, 3$, or pre-trained BERT sentence vectors.

2. Training and application of the following classifiers:
   - Traditional ML models (see Section 3.4) are applied to all of the above data representations.
   - Fine-tuned pre-trained BERT models are applied to raw texts residing in

ing (XGB) (Chen et al., 2015a) to all text representations described in Section 3.2.

3.5 Results

Table 3 demonstrates the results for the traditional classifiers and text representations. The text representations use either word vectors with tf-idf (aka Vector Space Model) or n-grams with count weights (for $n = 1, 2, 3$). All the systems are significantly better than the majority rule. Also, the Logistic Regression (LR) classifier with unigrams outperforms the other classifiers and representations. In general, LR shows better performance than other classifiers (RF and XGB) for all text representations used in this experiment.

Table 4 shows classification results for two fine-tuned BERT models – a DeepPavlov model known to perform well on Russian Question Answering task (Zaytsev et al., 2018), and Russian sentiment analysis tasks (Chernykh et al., 2021), and a multilingual BERT model (Sanh et al., 2019) for comparison. Both models were trained for 15 epochs with batch size 16, a learning rate of $2e{-}5$. Train-

Table 5. Fine-tuned BERT results for dataset ”without seed words”.

ing accuracy and training loss for the top model (DeepPavlov) were 0.9606 and 0.0003, and training time per epoch was approximately 270 seconds. We can see that this model achieves slightly better results than the multilingual BERT and that both fine-tuned models outperform all of the traditional classifiers mentioned in Table 3, although by a small margin.

Moreover, to check our results, we experimented with a dataset without using seed words for searching and downloading texts from Telegram. We extracted new posts from the channels that not used in the training dataset, but sometimes channels from the training dataset reposted posts from these channels. So we can decide on the type of one channel or another. Figure 7 presents Telegram channels

for additional datasets. The class balance for the dataset is pro-Russian sources - 562 documents and benign political texts sources - 507. Results of the experiment with dataset ”without seed words” and ”new channels” in Table 5. In addition, we deployed the model with a Telegram bot API (Modrzyk, 2018). Users can paste a news post about the Russian-Ukrainian war in Russian, and the bot will respond with a special label and score (probability of label). The bot is available at Telegram-bot (2023).

4 Conclusions and Future Work

We are optimistic that our work will help people recognize texts that may not be objective and focus only on producing emotional feelings rather than a rational response. However, our models are trained on political texts that address the conflict in Ukraine and, therefore, cannot recognize propaganda in other domains. In addition, improving the model’s ability to handle scenarios such as propaganda statements in stylistically complex texts is essential to develop a more widely trainable model.

We continue improving our model and will soon add a ”neutral” class for correct classification. Besides expanding our training set, a universal solution might be developed if we find a ”typical” writing style or dissemination of propaganda across different domains.

Abstract

Dense passage retrieval models have become state-of-the-art for information retrieval on many Open-domain Question Answering (ODQA) datasets. However, most of these models rely on supervision obtained from the ODQA datasets, which hinders their performance in a low-resource setting. Recently, retrieval-augmented language models have been proposed to improve both zero-shot and supervised information retrieval. However, these models have pre-training tasks that are agnostic to the target task of passage retrieval. In this work, we propose Retrieval Augmented Auto-encoding of Questions for zero-shot dense information retrieval. Unlike other pre-training methods, our pre-training method is built for target information retrieval, thereby making the pre-training more efficient. Our method consists of a dense IR model for encoding questions and retrieving documents during training and a conditional language model that maximizes the question's likelihood by marginalizing over retrieved documents. As a by-product, we can use this conditional language model for zero-shot question generation from documents. We show that the IR model obtained through our method improves the current state-of-the-art of zero-shot dense information retrieval, and we improve the results even further by training on a synthetic corpus created by zero-shot question generation.

1 Introduction

Open Domain Question Answering (ODQA) with dense passage retrieval has been quite successful in recent years. This is primarily because of the availability of large question-answering corpora. However, annotations for the creation of Open-Domain Question Answering (ODQA) datasets consume significant time and effort, although, the indispensable need for labeled data is evident in the decline of cross-domain performance across various ODQA datasets (Karpukhin et al., 2020) for both information retrieval and question-answering tasks. To this end, in this work, we address the task of Unsupervised Dense Passage Retrieval (UDPR). That is, to be able to retrieve relevant documents without the labels on ground truth question-passage pairs, which reflects a real-world scenario.

In this work, we propose *Retrieval Augmented Auto-Encoding of Questions* (named as AutoQIR[1]) as a means to obtain similarity between documents and questions to perform zero-shot dense passage retrieval. Our method not only complements the supervised methods but unlike other zero-shot pre-trained models, it also considers a pre-training task that is directly relevant to *questions*. The following are the contributions of this work:

1. We propose a novel pre-training task for Unsupervised Dense Information Retrieval.
2. We provide a new method for zero-shot question generation which can be used for data augmentation of Question Answering/ IR Datasets.
3. We provide a way to transfer knowledge from language models to Information Retrieval.
4. Our method surpasses the baseline and is on par with other zero-shot dense information retrieval approaches. Additionally, our pre-training method is effective even with few thousand datapoints.

2 Related Work

Traditionally, lexical models with sparse vector spaces, such as BM25 (Robertson et al., 2009), have been used for unsupervised retrieval of the neighboring documents of a query. These models

[1] Auto-Encoding of Questions for Information Retrieval

Proceedings of Recent Advances in Natural Language Processing, pages 1171–1179
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_124

consider documents and queries as bags of words and rely upon possible word overlap between the query and the relevant document to assign a high cosine similarity between them. Consequently, they suffer from the problem of the lexical gap between query and document (Berger et al., 2000) and are unable to capture the meaning that comes through word order.

Alternatively, Dense passage[2] retrieval models capture the meaning by encoding the sequence of words. Hence, unsupervised methods using dense passage retrieval can potentially yield better recall than the sparse retrieval models. Recently, several pre-training methods have been proposed to improve the joint dense embedding space of queries and documents. Retrieval augmented pre-training and fine-tuning methods (Guu et al., 2020; Lewis et al., 2020c,a) have been shown to improve dense passage retrieval. These methods train an information retrieval model to improve the context required for adjoining pre-training tasks. Amongst these, Guu et al. (2020) showed the ability for unsupervised dense passage retrieval while pre-training on Masked Language Modeling. Izacard et al. (2022) used a contrastive loss to discriminate between positive and negative documents while considering pseudo questions. While these methods are effective, the pre-training task chosen in their approach lacks explicit adaptation for the target task of passage retrieval for queries.

Estimating the likelihood of the *question* given a context is useful in various steps of Question Answering and Information Retrieval tasks. For example, (Lewis and Fan, 2018) maximized question likelihood (by decomposing the posterior probability) instead of answer likelihood and showed that QA models relying on question likelihood are robust to perturbations in the input. Another approach (Lewis et al., 2019) used unsupervised question generation methods to augment data for extractive question answering. Varanasi et al. (2021) used auto-encoding of questions for unsupervised answer span selection. It is shown by Sachan et al. (2022) that pre-trained language models can be used to re-rank the retrieved documents via 'prompt-based' question likelihood. Furthermore, parallel to our work, Sachan et al. (2023) have proposed that the retrieved documents (Lewis et al., 2020c) can be used to finetune a retriever by a teacher-student network. In their approach, the ground-truth distribution of the documents given a question is derived from the output of a frozen large pre-trained language model ($>$ 3B parameters). The dense retriever is trained by minimizing the KL divergence between its estimated distribution with the aforementioned ground truth distribution of the teacher network. The main difference between our work and theirs is that we utilize an auto-encoding loss while fine-tuning a BART decoder (406M parameters), thereby avoiding sole reliance on pre-existing (large) language models. Consequentially, our model can perform zero-shot question generation in addition.

3 Approach

Maximizing the likelihood of *question* given a context has been proven useful for Information Retrieval and Question Answering tasks (Zhao et al., 2021; Lewis and Fan, 2018; Nogueira et al., 2019). However, in an unsupervised setup, we don't have access to ground truth questions associated with passages. To mitigate this, we propose auto-encoding of questions by assuming an underlying conditional distribution over documents. In other words, our approach seeks to maximize the likelihood of a question by first obtaining the relevant passages. For this, we take the approach proposed by Lewis et al. (2020c).

Our training setup requires a set of questions Q and a set of documents S and no further labels for *answers* or *relevant documents*. Note that both sets of Q and S can be obtained without human annotations, for example, via web crawling. Our only assumption is that the set S contains relevant documents to most of the questions in set Q. Without this assumption, we model a uniform conditional distribution over documents. This expectation of relevant documents in a document corpus is fairly common in situations where an information retrieval task ought to be performed.

Formally, we aim to reconstruct the input question by assuming *document* z, as a latent variable. The loss L is obtained as the negative log-likelihood of the reconstructed question $\hat{q}$ given the input question q, as shown in eq. 1. The probability $p(\hat{q}|q)$ can be further decomposed by marginalizing over all known documents in the corpus S as shown in eq. 2. The input q for the conditional language model may provide an unwanted strong signal during reconstruction. This will lead to over-fitting of

[2] Please note that we use the terms *document* and *passage* interchangeably throughout this paper

the decoder and a weak encoder. Hence, we relax this term to $p(\hat{q}|z_i)$ by removing the dependency on input question q. Furthermore, the sum in eq. 2 is intractable to compute especially when the set S is very large. Also, note that when S is very large, most of the documents will have probabilities close to zero. To mitigate this, we approximate the sum by taking top-k documents.

Similar to Lewis et al. (2020c), our method mainly consists of two components: a *passage retriever* and a *sequence-to-sequence generator*. The equations below describe our loss function:

$$L = -\sum_{q \in Q} logp(\hat{q}|q) \tag{1}$$

$$p(\hat{q}|q) = \sum_{z_i \in S} p(\hat{q}|q, z_i) * p(z_i|q) \tag{2}$$

$$p(\hat{q}|q) \approx \sum_{z_i \in topk(q,S)} p_\phi(\hat{q}|z_i) * p_\theta(z_i|q) \tag{3}$$

Eq. 3 above, describes our final model. $p_\theta(z_i|q)$ is a information retrieval model (*passage retriever*), $p_\phi(\hat{q}|z_i)$ is a conditional language model (*sequence-to-sequence generator*). θ and ϕ are the model parameters. In practice, the top-k documents are obtained during training by the information retrieval model $p_\theta(z_i|q)$.

3.1 Passage Retriever

Passage retriever is an information retrieval module that comprises of two encoders, one to encode *question* and the other to encode *document*. These encoders provide a dense embedding given an input text and by using dense embeddings, we keep this module differentiable. Similar to DPR (Karpukhin et al., 2020), we model these encoders as BERT[3] transformer models. Following standard practices, we provide BERT an input text prepended with '[CLS]' and post-pended with a '[SEP]' token. The output embedding of BERT at the position of [CLS] token is considered as the embedding of an input sequence x. We represent this by $BERT(x)$. We obtain the probability $p(z_i|q)$ as follows:

$$\vec{z_i} = W_{doc}BERT_{doc}(z_i)$$

$$\vec{q} = W_q BERT_q(q)$$

$$sim(z_i, q) = e^{<\vec{zi},\vec{q}>}$$

$$p(z_i|q) = \frac{sim(z_i, q)}{\sum_{z_j \in topk(q,S)} sim(z_j, q)} \tag{4}$$

where W_q and W_{doc} are matrix parameters. Equation eq. 4 refers to the *sofmax* function applied on the similarity scores of question-document pairs. For retrieving top-K documents related to the question q, we use maximum inner-product search (MIPS) to obtain the 'k' nearest neighbors of the question embedding $\vec{q}$ in the set of documents S. During training, we use an indexed set of documents for fast retrieval[4].

3.2 Sequence-to-Sequence Generator

Given top-k relevant passages for a question q, the sequence-to-sequence generator estimates the likelihood of q given each passage using a transformer-based encoder-decoder mechanism (Vaswani et al., 2017) which we initialize using the pre-trained weights of BART-large model with 406M parameters. We estimate the probability of the question $\hat{q}$ as a product of probabilities of individual tokens similar to (Lewis et al., 2020c) as follows:

$$p(\hat{q}|q) = \Pi_{i=1..|\hat{q}|} \sum_{z_i \in topk(q,S)} p_\phi(\hat{q_j}|z_i, \hat{q}_1..\hat{q}_{j-1}) {*} p_\theta(z_i|q) \tag{5}$$

4 Implementation Details

4.1 Initialization

The *passage retriever* and *sequence-to-sequence generator* are optimized during the training. However, a good initialization of *passage retriever* is required to obtain relevant passages during the initial stages of the training. We consider the following pre-trained models (which are also unsupervised) for initializing 'passage retriever'.

ICT: To obtain this initialization, we first train a dense passage retriever model (DPR) (Karpukhin et al., 2020) with the Inverse-Cloze Task (Lee et al., 2019) using a pseudo Question Answering Corpus of 100k data points. We further pretrain on the same dataset using the AutoQIR model with the missing sentences as pseudo questions.

REALM[5]: is the pretrained model proposed by Guu et al. (2020). This is one of the first dense retrieval models to show zero-shot abilities.

[3] We used uncased model with 110M parameters

[4] We use FAISS search on indexed document embeddings

$p_\phi(q^\wedge|z)$
Seq-to-Seq
where is each type of cartilage located in the body?

Cartilage is a resilient and smooth elastic tissue, a rubber-like padding that covers and protects the ends of long bones at the joints, and is a structural component of the rib cage, the ear, the nose, the bronchial tubes, the intervertebral discs, and many other body components. It is not as hard and rigid as bone, but it is much stiffer and much less flexible than muscle.The matrix of cartilage is made up of chondrin. Because of its rigidity, cartilage often serves the purpose of holding tubes open in the body. Examples include the **rings of the trachea**, such

Figure 1: Overview of *Retrieval augmented Question Auto-Encoding*. The *Retriever* module retrieves top-k documents for each input question using maximum inner-product search (MIPS) during training. Each of these documents is passed as input to the sequence-to-sequence module while reconstructing the input question.

4.2 Training

We initialize our sequence-to-sequence generator to BART (Lewis et al., 2020b) weights. We optimize for the loss mentioned in equation eq. 1. We take the value of k as 5 (in top-k documents) in our experiments. We optimize the question encoder of the passage retriever and *freeze* the weights for the context encoder to avoid refreshing indices at regular intervals as done by (Guu et al., 2020). We build the index of all candidate documents before beginning the training.

The training is terminated using early stopping when the training objective plateaus on the validation set. The training is performed on a Tesla V100 GPU with 32GB RAM and a batch size of 4. [6]

During inference, we discard the sequence-to-sequence model and use only the 'passage retriever' module for retrieving documents.

4.3 Datasets

We use 5 commonly used datasets for open domain question answering: SQuAD (Rajpurkar et al., 2016), Natural Questions (Kwiatkowski et al., 2019), TriviaQA (Joshi et al., 2017), Web Questions (Berant et al., 2013), Curated Trec (Baudiš and Šedivỳ, 2015). We trained separately on multiple-question corpora (Q) and corresponding multiple-document corpora (S). The question corpora (Q) is formed from the questions of the training sets of the aforementioned datasets. We use a segmented Wikipedia corpus provided by Karpukhin et al. (2020), comprising approximately 21 million documents. Each passage in this corpus consists of 100 words, effectively serving as our document corpus (S) for the task. As mentioned in section 3, the corpus S is expected to contain answers for questions in Q. This expectation is met since the contexts for the questions in the aforementioned datasets are sourced from Wikipedia. Nevertheless, during training, the retrieval of top-k documents from such a large corpus can be significantly time-consuming. To speed this up, we split the question corpus into multiple sets of 1000 questions each, and the top 1k passages for each question in the corpus (S) are taken using bm25 to form the corresponding document corpus (S) (i.e., limiting the size of the document corpus to 1 million documents per set). During inference, we use the same segmented Wikipedia corpus for passage retrieval.

[6] For NQ questions, it takes around 35 hours to train for 7 epochs.

5 Experiments

5.1 Main Results

In this section, we show that retrieval augmented auto-encoding of questions by itself is a useful tool for unsupervised information retrieval. We use *recall at top-k* (recall@k) as our evaluation metric as it reliably correlates with the information retrieval capabilities of the model.

Firstly, we observed the improvements of AutoQIR over the initialized baseline models - ICT and REALM. In table 1, it can be seen that AutoQIR models consistently outperform their corresponding initial models on various datasets by a big margin. Please note that AutoQIR models are trained on the set of questions from the corresponding training set mentioned in the columns. The AutoQIR models initialized with ICT pre-training, as mentioned in section 4, performs comparably to the baseline REALM model on all datasets except on the dataset CuratedTREC. This could be because of the low number of training samples available for this dataset. Whereas the AutoQIR models initialized with the REALM model improve the average recall@1 of REALM to 6.7 points across the 5 datasets. The importance of auto-encoding questions over auto-encoding sentences (ICT) can be seen from the contrasting differences in the results of $AutoQIR_{ICT}$ and ICT. In our experiments, we found that optimizing the decoder is more effective than using a frozen pre-trained language model as decoder. Figure 2 shows the comparison between the performance of initialized REALM model and its AutoQIR pre-training across all datasets for recalls between 1 and 20. AutoQIR consistently outperforms the baseline REALM model for all recalls with a large margin on all datasets except for CuratedTREC.

In table 2, we compare our best model with state-of-the-art unsupervised retrieval models. *Contriever* is a dense passage retriever model trained with a contrastive loss on a pseudo-question answering dataset. *Masked Salient Spans* model is also a dense passage retrieval model trained on ”cloze” questions (sentences with masked salient spans such as named entities) similar to pre-training data of REALM (Guu et al., 2020). Unlike AutoQIR, both of these models use supervised training methods, albeit, on a pseudo corpus that can be obtained without annotations. BM25 is a lexical-based sparse retrieval model. REALM is the only other retrieval-augmented model which can be compared for zero-shot information retrieval for question answering. AutoQIR models outperform all

Table 4: We compare the Exact match score of a trained Question-Answering module for different retrievers with top-100 retrieved documents.

the aforementioned models, including bm25, for recalls 10 and 20 on NQ. For recall at top-100 documents, in the TriviaQA dataset, it can be seen that all models perform decently and close to each other. In the NQ dataset, Contriever performs only slightly better than our best model for recall@100. These results suggest that our model is a viable alternative to the state-of-the-art methods.

5.1.1 Cross-domain Questions

Considering the significance of questions over other types of sentences of auto-encoding, it would be interesting to see how AutoQIR performs across various domains. i.e., a model trained on one domain and evaluated on the other. The questions from these datasets vary in their distribution due to the differences in purposes and methods of collecting these datasets. In table 3, we show the cross-dataset retrieval performance of AutoQIR models. The large datasets (where we used more than 50 questions for training), i.e., TriviaQA, SQuAD, and NQ have the best performances when they are trained on the same domain. For

Model	Recall@1
$AutoQIR_{REALM}$	35.05
$AutoQIR_{REALM}$+ data-augmented fine-tuning	**37.08**

Table 5: Improved recall@1 on NQ dataset with additional training on a synthetic corpus as specified in section 5.2

smaller datasets, CuratedTREC and WebQ, models trained on SQuaD and TriviaQA respectively had the highest performance. This could be due to their lower number of training samples. It can be observed from the table that any form of AutoQIR training improved the results from the baseline REALM model. For example, the AutoQIR model trained with around 1k questions from the CuratedTREC dataset outperforms the REALM model on all datasets.

5.1.2 Question-Answering

Finally, to see how the retrieved documents are used for the subsequent task of Question Answering, we use a fully supervised "reader" model[7] provided by Karpukhin et al. (2020) and apply on the top-100 retrieved documents. The results can be seen in table 4. Our model brings 5 points of improvement on the Exact Match for the NQ dataset and marginal improvements on the rest of the datasets. This could be because of the increased recall at larger values of k for all the models (as also observed in table 2).

5.2 Zero-shot Question Generation

Once the AutoQIR model is trained, the sequence-to-sequence generator can be used for zero-shot passage-to-question generation (without a specific answer phrase). This is due to the fact that the sequence-to-sequence generator models $p(q|z_i)$ where z_i is a passage from the document corpus S.

Paragraph-level question generation can not be evaluated directly by measuring the similarity to ground truth questions (for example, via BLEU score) due to the variance in the distribution of questions that can be asked from the paragraph. Here, we evaluate the generated questions by measuring their use to information retrieval.

We use our best model $AutoQIR_{REALM}$ trained on the NQ dataset for zero-shot question generation. We use 50 thousand randomly chosen paragraphs from Wikipedia segmented to a length of 100 tokens as our input corpus. We generated one question for each of these input passages using beam search. We further take negative paragraphs by choosing one among the top-3 passages closer to the question using **bm25** (excluding the input passage). Since passages usually contain unique information, we expect that the top-3 retrieved passages often do not contain the answer even though quite close to the question. Hence these provide a better challenge for the Passage Retrieval model than using random passages which can be quite distant from the generated questions. We trained a fully supervised model (Karpukhin et al., 2020) on this dataset. This model further outperforms our best AutoQIR model by 2 points for recall at top-1 (recall@1) shown in table 5. Zero-shot Question Generation has larger applications in the field of Question Answering which can be explored in future work.

6 Conclusion

In this work, we propose a novel pre-training task to perform unsupervised information retrieval. Our method, which is based on *Retrieval Augmented Generation* (Lewis et al., 2020c), shows significant improvements from the baseline zero-shot retrieval models (ICT and REALM). Our cross-domain evaluation reveals the significance of using target questions for pre-training. We also show that auto-encoding on questions has a much greater impact than auto-encoding of sentences (ICT). Our model explicitly captures knowledge stored in language models into IR models. Additionally, our method can be used for zero-shot question generation which can further provide data augmentation for IR corpora. In the future, it would be interesting to investigate whether unfreezing the context encoder during training would lead to improved retriever performance.

Abstract

Hate speech is a surely relevant problem in Brazil. Nevertheless, its regulation is not effective due to the difficulty to identify, quantify and classify offensive comments. Here, we introduce a novel system for offensive comment analysis in Brazilian Portuguese. The system titled *NoHateBrazil*[1] recognizes explicit and implicit offensiveness in context at a fine-grained level. Specifically, we propose a framework for data collection, human annotation and machine learning models that were used to build the system. In addition, we assess the potential of our system to reflect stereotypical beliefs against marginalized groups by contrasting them with counter-stereotypes. As a result, a friendly web application was implemented, which besides presenting relevant performance, showed promising results towards mitigation of the risk of reinforcing social stereotypes. Lastly, new measures were proposed to improve the explainability of offensiveness classification and reliability of the model's predictions.

1 Introduction

The scenario of hateful comments in Brazil is severe and entails the creation of safety and fairness technologies. During the elections in 2018 and 2022, the denunciations against xenophobia content had an increase of 2,369.5%; apology and public incitement to violence and crimes against life, 630.52%, and misogyny and race-ethical, increased by 1,639% and 595%[2], respectively.

Hate speech is a particular form of offensive language that considers stereotypes to express an ideology of hate (Warner and Hirschberg, 2012; Sahoo et al., 2022; AlKhamissi et al., 2022). While systems that classify hateful content are undoubtedly relevant, these technologies are being developed with scarce consideration of their potential biases (Nadeem et al., 2021; Sap et al., 2019; Chang et al., 2019; Bordia and Bowman, 2019; Blodgett et al., 2020). These systems may discriminate against the groups they are designed to protect (Davidson et al., 2019), reflecting social stereotypes and being able to perpetuate social inequalities when propagated at scale (Davani et al., 2023).

To the best of our knowledge, no systems have attempted to analyze text offensiveness in Brazilian Portuguese. Therefore, the main contribution of this paper[3] is providing the first web system titled *NoHateBrazil* for Brazilian Portuguese offensive comments classification. The *NoHateBrazil* system receives two different inputs. The first input consists of a single comment written directly into the initial screen. The second input consists of a file in CSV format containing a set of comments. In the following outputs, three pieces of information are exhibited: (i) offensiveness categories; (ii) offensiveness overall score; and (iii) prediction reliability score, which we describe in Section 2.1.

Towards providing a reliable text offensiveness system, we focus on three strong strategies: (i) we provide a contextualized analysis of offensiveness, in which Machine Learning (ML) models recognize explicit and implicit offensive terms from a specialized lexicon annotated with context information; (ii) we propose and evaluate a framework for offensive comment detection; (iii) we evaluate the potential of our system to reflect social stereotypes through a distinctive analysis of tuples containing stereotypes versus counter-stereotype (Vargas et al., 2023). For this purpose, we used a dataset of 300 tuples containing social stereotypes versus counter-stereotypes in Brazilian Portuguese, which consists of a culturally-oriented translation from the CrowS-Pairs (Nangia et al., 2020), a benchmark fairness dataset. Finally, our system presents 88.8% of F1-Score and a low potential of reflecting social stereotypes against marginalized groups (12%).

2 Offensiveness Detection Framework

In this paper, we propose a new framework that encompasses data collection, human annotation, and the implementation of ML models for offensive comment detection. We used this framework to build the proposed *NoHateBrazil* web system, as shown in Figure 1.

- **Data Collection:** Given the relevance of collecting representative data, we propose a careful data collection approach composed of balanced attributes, as shown in Figure 1. Note that for each profile ***P*** from a domain ***D***, the number of comments must be balanced. For synchronous bordering, which consists of data collection during a period of time ***T***, the same number of comments must be collected for each span of time. For example, we implemented an Instagram API and collected the maximum number of 500 comments per post. We also balanced profile attributes (gender, color, political party). For data cleaning, we removed noise, such as links, and characters without semantic value, and also comments that presented only emoticons, laughs (e.g., kkk), or mentions (e.g., @fulano), without any textual content, and then applied data anonymization.

- **Annotation Process**: In spite of the enormous difficulty of automatically classifying offensive comments mainly due to ethical problems, the annotation process should be carried out by specialists (Vargas et al., 2021). As shown in Figure 1, the annotation process consists of three main stages. Firstly, the selection of expert annotators, considering their diverse profiles, such as ethnicity, gender, different political orientations, and place of origin. Secondly, the creation of a well-structured annotation schema. Lastly, evaluation metrics were applied, as Kappa and Fleiss, reaching a high inter-annotator agreement (75% Kappa and 74% Fleiss). This evaluation is fundamental to ensure data quality. The entire data collection and annotation process is described in detail in Vargas et al. (2022).

- **Context-Aware Language Models**: Large crowd-sourced lexical resources tend to include a wide range of irrelevant terms, resulting in high rates of false positives (Davidson et al., 2019). Moreover, pre-trained language models are trained on large real-world data. As a result, they are known to embody social biases (Nadeem et al., 2021). According to Davidson et al. (2019), it is possible to mitigate social bias by focusing on how context factors interact with linguistic subtleties and the definitions of offensive language. In addition, social bias decreases in magnitude when it is conditioned on particular terms and expressions that may indicate membership in negative classes. Accordingly, we assume that context information is a relevant attribute to classify offensiveness in text. Hence, we propose a computational context-aware ML model that embodies implicit and explicit offensive terms and expressions annotated manually by experts with context information. The implemented ML model, titled "B+M" is described in detail in Vargas et al. (2021). We shortly present below.

  B+M: This model uses a generated bag-of-words (BoW) from the dataset vocabulary. This model embodies labeled context information (context-dependent and context-independent) from a specialized lexicon of explicit and implicit offensive terms and expressions called *MOL* (see Section 3.1). We carried out the match with terms from MOL. Then, we assigned a weight for each term or expression labeled with context-dependent (weaker weight), and context-independent (stronger weight). According to the B+M model, the value of a term x in the document y is defined as

  $$B + M_{x,y} = freq_{x,y} * weightC_x \qquad (1)$$

  where $freq$ is the frequency of the term in the document, $weightC = 2$ for context-dependent terms and $weightC = 3$ when the term is context-independent.

2.1 Text Offensiveness Analysis

According to Poletto et al. (2021), Offensive language Detection (OLD) often leads to false positives when swear and offensive words occur in non-offensive contexts. Furthermore, OLD mainly presents explicit and implicit terms or expressions with pejorative connotations, and the pejorative connotation is deeply context-dependent and culturally oriented (Vargas et al., 2021).

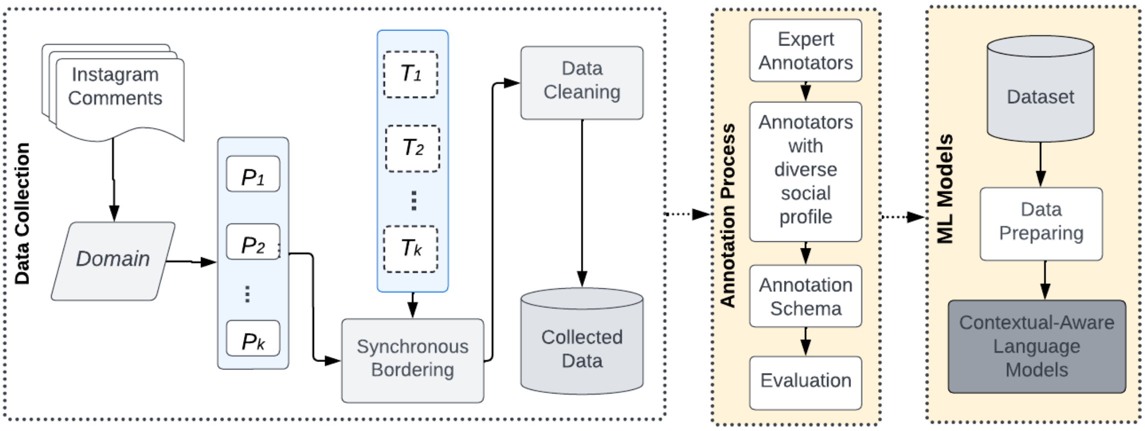

Figure 1: The proposed framework for offensive comment classification.

Corroborating the offensiveness definitions proposed by Caselli et al. (2020), our system assumes that **explicit offensiveness** consists of comments that contain explicit markers of offensiveness (e.g. comments with terms or expressions with any pejorative connotations). Conversely, **implicit offensiveness** consists of comments that contain markers of offensive content expressed implicitly. Both examples are shown in Table 1, as well as an example of a non-offensive comment. Note that bold indicates markers of implicit offensive content, and underlines explicit markers of offensiveness.

Class	Comments	Translation
Offensive	Essa besta humana é o câncer do País, tem q **voltar p jaula**, urgentemente! E viva o Presidente Bolsonaro.	This animal is the cancer of the country, it has to go **back to jail** as soon as possible! And cheers to President Bolsonaro[4]
Offensive	Pois é, deveria **devolver o dinheiro** aos cofres públicos do Brasil. Canalha.	That's right, he should **refund the money** to the public Brazilian banks. Jerk.
Non-Offensive	Quem falou isso pra vc deputada? O Sergio Moro ta aprovado pela maioria dos brasileiros.	Who said that to you, congresswoman? Sergio Moro[5] has the approval of most Brazilians.

Table 1: Offensive and non-offensive comments with explicit and implicit offensiveness.

Our system also recognizes **context information** using an offensive lexicon annotated by specialists with context information. For instance, while the terms "cancer", "garbage", and "worms" may be used with pejorative connotations, they could also be used in contexts without any pejorative connotation (e.g., "he was cured of cancer"; "the garden is full of parasites and worms"; "disposal of garbage on streets"). In this case, these terms are classified as context-dependent. Differently, the terms "hypocritical" and "ridiculous" are mostly used in contexts with pejorative connotations. Consequently, these terms are classified as context-independent.

2.1.1 Offensiveness Overall Score (OOS)

In order to present explainability for offensive comments classification at a fine-grained level, as well as to provide a more accurate prediction of offensiveness, we propose a measure titled *Offensiveness Overall Score (OOS)*. The OOS combines expert and statistical knowledge in order to classify offensive comments on three different levels: slightly, moderately, and highly. Specifically, this score consists of a scale between 0 and 100 that combines a set of parameters defined by different specialists in Vargas et al. (2022) and a probability score. In this paper, we called $score_{expert}$ the parameters provided by experts, along with the prediction probability value provided by the ML model, which we called $score_{prob}$. The OSS is defined by Equation 2.

$$OOS = (score_{expert} + score_{prob}) \div 2 \quad (2)$$

As regards the $score_{expert}$, comments with at least 1 (one) MOL term annotated with the context-independent label (mol_{indep}), or at least 3 (three) MOL terms annotated with the context-dependent labels (mol_{dep}), should receive a $score_{expert}$ of 90%. In the same settings, comments that precisely present 2 (two) MOL terms annotated with the context-dependent label (mol_{dep}), should receive a $score_{expert}$ of 60%; and comments that precisely present 1 (one) MOL term annotated with the context-dependent label (mol_{dep}), should receive a $score_{expert}$ of 30%. Algorithm 1 shows the proposed offensiveness overall score. As regards the $score_{expert}$, the prediction probability score was obtained by the ML model. Algorithm 1 describes in detail the OOS measure. Observe that the proposed OOS provides a set of machine-learned rules, besides tackling the problem of out-of-vocabulary terms.

Algorithm 1 Offensiveness Overall Score

```
procedure GET-OOS($prob$)
    if $mol_{indep} >= 1$ or $mol_{dep} >= 3$ then
        $OOS = (90 + score_{prob}) \div 2$
    end if
    if $mol_{dep} == 2$ then
        $OOS = (60 + score_{prob}) \div 2$
    end if
    if $mol_{dep} == 1$ then
        $OOS = (30 + score_{prob}) \div 2$
    end if
    if $OOS > 0$ and $OOS <= 49$ then
        $class = slightly\ offensive$
    end if
    if $OOS >= 50$ and $OOS <= 79$ then
        $class = moderately\ offensive$
    end if
    if $OOS >= 80$ and $OOS <= 100$ then
        $class = highly\ offensive$
    end if
    return $OOS$ and $class$
end procedure
```

2.1.2 Prediction Reliability Score (PRS)

In order to provide a robust evaluation of the quality of the model's predictions for unknown sentences (unlabeled), we further provide a measure titled *Prediction Reliability Score (PRS)*. The PRS estimates a reliability scale taking into account the statistical distribution of pejorative terms and expressions from the HateBR dataset (see Section 3.1). Specifically, this measure computes a reliability score using the difference between the values obtained from a defined reliability scale, which we called $score_{gold}$, and the values provided by $score_{prob}$, which is a statistic score of the ML model. The PRS may be defined as shown in Equation 3.

$$PRS = 100 - |(score_{gold} - score_{prob})| \quad (3)$$

As regards the PRS score, two different scales for offensive comments (class 1), and non-offensive comments (class 0) were proposed, as shown in Algorithms 2 and 3, respectively.

Algorithm 2 Prediction Reliability Score (Offensive)

```
procedure GET-PRS($prob$)
    if $mol_{indep} >= 1$ or $mol_{dep} >= 3$ then
        $score_{gold} = 99\%$
    end if
    if $mol_{dep} == 2$ then
        $score_{gold} = 90\%$
    end if
    if $mol_{dep} == 1$ then
        $score_{gold} = 80\%$
    end if
    if $mol_{indep} == 0$ and $mol_{dep} == 0$ then
        $score_{gold} = 10\%$
    end if
    return $PRS = 100 - |(score_{gold} - (score_{prob})|$
end procedure
```

Algorithm 3 Prediction Reliability Score (No-Offensive)

```
procedure GET-PRS($prob$)
    if $mol_{indep} >= 1$ or $mol_{dep} >= 3$ then
        return $score_{gold} = 10\%$
    end if
    if $mol_{dep} == 2$ then
        return $score_{gold} = 80\%$
    end if
    if $mol_{dep} == 1$ then
        return $score_{gold} = 90\%$
    end if
    if $mol_{indep} == 0$ and $mol_{dep} == 0$ then
        return $score_{gold} = 99\%$
    end if
    return $PRS = 100 - |(score_{gold} - (score_{prob})|$
end procedure
```

As shown in Algorithm 2, **offensive comments** with at least 1 (one) MOL term annotated with the context-independent label (mol_{indep}), or at least 3 (three) MOL terms annotated with the context-dependent labels (mol_{dep}), should receive a $score_{gold}$ of 99%; and offensive comments that precisely present 2 (two) MOL terms annotated with the context-dependent labels (mol_{dep}), should receive a $score_{gold}$ of 90%; and offensive comments that precisely present 1 (one) MOL term annotated with the context-dependent label (mol_{dep}), should receive a $score_{gold}$ of 80%. Lastly, offensive comments without any MOL term should receive a $score_{gold}$ of 10%.

As shown in Algorithm 3, **non-offensive comments** with at least 1 (one) MOL term annotated with the context-independent label (mol_{indep}), or at least 3 (three) MOL terms annotated with the context-dependent labels (mol_{dep}), should receive a $score_{gold}$ of 10%; and non-offensive comments that precisely present 2 (two) MOL terms annotated with the context-dependent labels (mol_{dep}), should receive a $score_{gold}$ of 80%; and non-offensive comments that precisely present 1 (one) MOL term annotated with the context-dependent label (mol_{dep}), should receive a $score_{gold}$ of 90%. Lastly, non-offensive comments without any MOL terms should receive a $score_{gold}$ of 99%.

3 System Design

3.1 Architecture

3.1.1 Infrastructure: The web application was developed using Python version 3.9 and the following libraries: streamlit[6], unidecode[7], emoji[8], spacy[9], gensim[10] and the Brazilian Portuguese normalizer, Enelvo[11]. It was hosted on the Apache Server.

3.1.2 Machine Learning: We built a ML model using a BoW titled "B+M" and Naive Bayes algorithm. The entire experimental settings and results are described in detail in Vargas et al. (2021). Our pre-processing required (i) data cleaning (e.g. accounts, quotes, links, and emojis), (ii) lemmatization, (iii) normalization, and (iv) accent removal.

3.1.3 Data Resources: We used two different data resources: the *HateBR dataset* (Vargas et al., 2022), which consists of the first large-scale expert annotated corpus composed of 7,000 Brazilian Instagram comments; and the *MOL - Multilingual Offensive Lexicon* (Vargas et al., 2021), which consists of a context-aware offensive lexicon composed of 1,000 explicit and implicit offensive terms and expressions manually identified by a linguist and annotated in a binary-class: context-dependent and context-independent. Furthermore, both resources provide linguistic markers of nine hate speech targets (partyism, sexism, homophobia, fatphobia, religious intolerance, apology for the dictatorship, xenophobia, antisemitism and racism).

3.2 Interface

3.2.1 Inputs: As shown in Figure 2, the user may insert two types of inputs. Firstly, the user has the option to classify **only one comment by typing it directly on the interface**. Then, the user only selects the button "Enter" to obtain the classification. Secondly, the user may classify **a set of comments in CSV format by selecting the button "browser files"**. Then, the system downloads the classified data in CSV format, and an average of the obtained classification is presented on the initial screen

3.2.2 Outputs: As shown in Figure 2, after adding the inputs by the user, the system presents three different outputs: (i) **offensiveness category** (highly, moderately, or slightly); (ii) **OOS**; and (iii) **PRS**.

4 System Evaluation

4.1 Model Performance

While a direct comparison is unfair (as the authors use different datasets and methods), we present in Table 2 an analysis of our results and baselines for the Brazilian Portuguese language.

Authors	Datasets	Methods	Fscore
NoHateBrazil	**HateBR**	**NB**	**88.8**
de Pelle and Moreira (2017)	OFFCOMBR	NB	81.0
Leite et al. (2020)	ToLD-Br	BERT	76.0
Trajano et al. (2023)	OLID-BR	BERT	77.0

Table 2: Offensive language detection baselines for Brazilian Portuguese: Results.

As shown in Table 2, even though it only offers an idea of the general performance of the approaches, the *NoHateBrazil* system presents higher performance for the offensive language detection task in Brazilian Portuguese.

4.2 Social Stereotype Analysis (SSA)

Recent studies show that hate speech technologies may propagate societal stereotypes against marginalized groups (Davani et al., 2023; Davidson et al., 2019). Hence, we also assess the potential of our system to reflect gender and racial stereotypes. We use a metric called **Social Stereotype Analysis (SSA)** (Vargas et al., 2023). The SSA measures the potential of hate speech classifiers to reflect social stereotypes by the distinctive classifying of tuples containing stereotypes versus counter-stereotypes. For example, "They've been known to disregard people who march in Gay Pride parades" and "They've been known to disregard people who march in Christmas parades.", the system should classify both with the same label. Otherwise, the system potentially reflects stereotypes against the LGBTQIA+ group. Specifically, we assess a set of 300 tuples containing gender and racial stereotypes versus counter-stereotypes in Brazilian Portuguese[12]. Results are shown in Table 3.

Tuples	Total	Accuracy
300	600	**88.0**

Table 3: SSA Evaluation.

As shown in Table 3, we classified 300 tuples (600 comments), in which **12%** of tuples were classified with different labels by our system.

Confiabilidade da Predição: 99%

Confiabilidade da Predição: 87%

Figure 2: *NoHateBrazil* web system - input and output interfaces

.

4.3 OOS and PRS Measures

Lastly, we evaluated both proposed measures (OOS and PRS) using human evaluation[13]. In order to evaluate the OOS, we manually collected 90 new comments from Instagram divided equally among highly, moderately, and slightly offensive. For the PRS evaluation, we also collected 60 more news comments from Instagram divided equally between offensive and non-offensive comments. We followed the annotation scheme proposed by Vargas et al. (2022). Subsequently, we evaluated the predicted class compared with the human-proposed labels. Results are shown in Table 4.

Measure	Total	Accuracy
OOS	90	**70.0**
PRS	60	**89.0**

Table 4: OOS and PRS Evaluation Results.

Note that the OOS presented an accuracy of 70%, corroborating the study proposed by Vargas et al. (2022), that claim that the fine-grained offensiveness is a complex task. The PRS obtained an accuracy of 89%, highlighting the capability of our ML model to efficiently classify offensive comments.

5 Final Remarks

This paper introduces the first system for text offensiveness analysis in Brazilian Portuguese. The *NoHateBrazil* web system recognizes explicit and implicit offensiveness in context at a fine-grained level. We proposed a friendly design and robust architecture, resulting in a high system performance, besides promising results towards mitigation of the risk of perpetuating social stereotypes against marginalized groups. We also provided a robust framework for offensive comment classification, which encompasses data collection, human annotation, and ML models. Finally, two new measures were proposed to improve the explainability of offensiveness classification at a fine-grained level and the reliability of the model's predictions.

Abstract

Recent studies have shown that hate speech technologies may propagate social stereotypes against marginalized groups. Nevertheless, there has been a lack of realistic approaches to assess and mitigate biased technologies. In this paper, we introduce a new approach to analyze the potential of hate-speech classifiers to reflect social stereotypes through the investigation of stereotypical beliefs by contrasting them with counter-stereotypes. We empirically measure the distribution of stereotypical beliefs by analyzing the distinctive classification of tuples containing stereotypes versus counter-stereotypes in machine learning models and datasets. Experiment results show that hate speech classifiers attribute unreal or negligent offensiveness to social identity groups by reflecting and reinforcing stereotypical beliefs regarding minorities. Furthermore, we also found out that models that embed expert and context information from offensiveness markers present promising results to mitigate social stereotype bias towards socially responsible hate speech detection.[1]

1 Introduction

While Artificial Intelligence (AI) technologies have generated unprecedented opportunities for society, they have also introduced new forms of perpetuating inequality and heightened threats to human rights and well-being (UN, 2023).

Examples	**Classes**
They've been known to disregard people who march in **Gay Pride** parades.	Hate Speech
They've been known to disregard people who march in **Christmas** parades.	Non-Hate Speech
They've been known to disregard people who march in parades.	Non-Hate Speech
We can't go to that one in this **Mexican** neighborhood. You might be robbed.	Non-Hate Speech
We can't go to that one in this **Canadian** neighborhood. You might be robbed.	Hate Speech
We can't go to that one in this neighborhood. You might be robbed.	Hate Speech

Table 1: Stereotype Bias in Hate Speech Detection.

In this context, the investigation of Hate Speech (HS) is undoubtedly important since the proposition of automated systems has implications for unprejudiced societies. Nevertheless, researchers have constantly observed that these technologies are being developed with scarce consideration of their potential social biases, which may perpetuate social inequalities when propagated at scale (Davani et al., 2023; Blodgett et al., 2020; Chuang et al., 2021; Xia et al., 2020; Wiegand et al., 2019; Sap et al., 2019; Bordia and Bowman, 2019; Davidson et al., 2019). For example, Table 1 shows that the hate speech classifier attributed unreal offensiveness to the first example only due to the expression "Gay Pride", which represents a social identity[2] group. We observe that in the second example, the expression "Gay Pride" was replaced by "Christmas", and in the third example, they were removed. The second and third examples were classified as non-hate speech, and the first one was classified as hate speech. Furthermore, the hate speech classifier neglected the offensiveness of the fourth example only due to the term "Mexican".

According to Warner and Hirschberg (2012), hate speech is a particular form of offensive language that considers stereotypes to express an ideology of hate. A stereotype is an over-generalized belief about a particular group of people (e.g., Asians are good at math or African Americans are athletic), and beliefs (biases) are known to target social groups (Nadeem et al., 2021). Social and stereotyp-

[1] **Warning**: This paper contains examples of offensive content and stereotypes. It does not reflect our way of thinking.

[2] Social identity is a theory of social psychology that offers a motivational explanation for in-group bias.

ical biases are forms of discrimination against a social group based on characteristics such as gender, sexual orientation, religion, ethnicity, etc. (Fiske, 1993; Sahoo et al., 2022).

Hate speech technologies reflect social stereotypes due to bias in the training data (Davidson et al., 2019; Yörük et al., 2022) triggered early from human annotation (Wiegand et al., 2019), in the text representations that learn normative social stereotypes associated with systematic prediction errors (Davani et al., 2023), and also due to missing context information (Davidson et al., 2019). For example, if "programmer" appears more frequently with "he" than "she" in the training data, it will create a biased association to "he" compared with "she" in the model (Qian, 2019). In the same settings, if "African American" appears frequently associated with vocabulary related to baseball and violence, the model will potentially learn this association from the training data. Therefore, both examples demonstrate the harmful potential of HS classifiers reflecting different types of social stereotypical beliefs that may negatively influence people's perception of marginalized groups.

State-of-the-art analysis of social stereotypes in Hate Speech Detection (HSD) is definitely an under-explored issue. Recently, a few works have analyzed social stereotypes bias in (i) text representation, which maps textual data to their numeric representations in a semantic space, and (ii) human annotations, which represent subjective judgments about hate speech in text content, constituting the training dataset. Therefore, in both cases, social stereotypes may be included in the final trained model (Davani et al., 2023; Elsafoury, 2022). A recent study proposed by Davani et al. (2023), concluded that hate speech classifiers can learn normative social stereotypes once their language mapping to numeric representations is affected by stereotypical co-occurrences in the training data.

The social psychology literature suggests that one of the most effective ways to reduce biased thinking is countering stereotypical beliefs with counter-stereotypes (also known as anti-stereotypes) (Fraser et al., 2021). For instance, once a human is asked to classify a tuple containing social stereotypes and counter-stereotypes, and the result is a distinctive classification, it evidences biased stereotypical beliefs. In this same setting, Finnegan et al. (2015) proposed experiments in which participants were shown stereotypical and counter-stereotypical images of socially-gendered professions (e.g., a surgeon is stereotypically male, and a nurse is stereotypically female). They reversed the genders in the counter-stereotypical images and then measured their gender bias in a judgment task. Results showed that exposure to counter-stereotypical images significantly reduced gender normative stereotypes. Finally, in de Vassimon Manela et al. (2021), Blair IV (2001), and Nilanjana and G. (2001), the authors also used the same strategy to mitigate socially biased thinking.

In this paper, we study the potential of HS classifiers to reflect social stereotypes against marginalized groups. We propose a new approach, entitled **Social Stereotype Analysis (SSA)**, which consists of analyzing stereotypical beliefs by contrasting them with counter-stereotypes. We first implement HS classifiers using different Machine Learning (ML) text representations in two different datasets in English and Portuguese, composed of Twitter and Instagram data. Then, we assess the potential of these models to reflect social stereotypes through a distinctive analysis of tuples containing stereotypes versus counter-stereotype. The results demonstrate that HS classifiers may provide unreal or negligent offensiveness classification to social identity groups, hence reflecting and reinforcing social stereotypical beliefs against marginalized groups. Finally, based on our findings, ML models that embed expert and context information from explicit and implicit offensiveness markers present promising results towards mitigating the risk of HS classifiers propagating social stereotypical beliefs. Our contributions may be summarized as follows:

- We study and empirically analyze the potential of HS classifiers to reflect social stereotypes against marginalized groups.
- We provide a set of experiments with different ML models in two languages (English and Portuguese). The datasets and code are available[3], which may facilitate future research.
- We propose a new approach for assessing the potential of HS classifiers to reflect social stereotypes. Our approach consists of analyzing whether HS classifiers are able to classify tuples containing stereotypes and counter-stereotypes in the same way. Otherwise, they are potentially biased.

2 Related Work

Bias in Human-Annotation and Datasets: Bias may be triggering early from human annotation. As a result, biased datasets propagate their social bias through data training. According to Vargas et al. (2022), a strategy based on a diversified profile of annotators (e.g. gender, race-color, political orientation, etc.) and balanced variables during the data collection should be adopted to mitigate social biases. Furthermore, they proposed an annotation schema for hate speech and offensive language detection in Brazilian Portuguese towards social bias mitigation. Davidson et al. (2019) analyzed racial bias by training classifiers in HS datasets of Twitter in order to identify whether the tweets written in African-American English are classified as abusive more frequently than tweets written in Standard American English. As a result, this phenomenon widely-held beliefs about different social categories and may harm minority social groups. Sap et al. (2019) investigated how social context (e.g., dialect) can influence annotators' decisions leading to racial bias that may be propagated through models trained on biased datasets. Wiegand et al. (2019) discussed the impact of data bias on abusive language detection highlighting weaknesses of different datasets and its effects on classifiers trained on them. Based on this work, Razo and Kübler (2020) analyzed different data sampling strategies to investigate sampling bias in abusive language detection. Dinan et al. (2020) analyzed the behavior of gender bias in dialogue datasets and different techniques to mitigate gender bias. Towards reducing the lexical and dialectal biases, Chuang et al. (2021) proposed the use of invariant rationalization to eliminate the syntactic and semantic patterns in input texts that exhibit a high but spurious correlation with the toxicity labels. Wich et al. (2021) investigated annotator bias in abusive language data, resulting from the annotator's personal interpretation and the intricacy of the annotation process, and proposed a set of methods to measure the occurrence of this type of bias. Ramponi and Tonelli (2022) evaluated rigorously lexical biases in hate speech detection, uncovering the impact of biased artifacts on model robustness and fairness and identifying artifacts that require specific treatments. Davani et al. (2023) analyzed the influence of social stereotypes in annotated datasets and automatic identification of hate speech in English.

Bias in Text Representation: Bias is also found in classical and neural machine learning-based models, which often fail to mitigate different types of social bias. Park et al. (2018) analyzed gender biases using three bias mitigation methods on models trained with different abusive language datasets, utilizing a wide range of pre-trained word embeddings and model architectures. Due to the existence of systematic racial bias in trained classifiers, Mozafari et al. (2020) presented a bias alleviation mechanism to mitigate the impact of bias in training data, along with a transfer learning approach for the identification of hate speech. Wich et al. (2020) analyzed the impact of political bias on hate speech models by constructing three politically biased datasets and using an explainable AI method to visualize bias in classifiers trained on them. Manerba and Tonelli (2021) proposed a fine-grained analysis to investigate how BERT-based classifiers perform regarding fairness and bias data. Elsafoury et al. (2022) measured Systematic Offensive Stereotyping (SOS) in word embeddings. According to the authors, SOS can associate marginalized groups with hate speech and profanity vocabulary, which may trigger prejudices and silencing of these groups. Sahoo et al. (2022) proposed a curated dataset and trained transformer-based models to detect social biases, their categories, and targeted groups from toxic languages. Elsafoury (2022) analyzed the biases of hate speech and abuse detection state-of-the-art models and investigated other biases than social stereotypical.

3 Definitions

Here, we describe in detail the definitions of hate speech and social stereotypes used in this paper.

Hate Speech: We assume that offensive language is a type of opinion-based information that is highly confrontational, rude, or aggressive (Zampieri et al., 2019), which may be led explicitly or implicitly (Vargas et al., 2021; Poletto et al., 2021). In the same settings, hate speech is a particular form of offensive language used against target groups, mostly based on their social identities.

Social Stereotypes: Stereotypes are cognitive structures that contain the perceiver's knowledge, beliefs, and expectations about human groups (Peffley et al., 1997). Stereotypes can trigger positive and negative social bias, which refers to a preference for or against persons or groups based on their social identities (Sahoo et al., 2022).

4 The Proposed Approach

4.1 Motivations

While social stereotype bias in HSD has become a relevant and urgent research topic in recent years (Davani et al., 2023; Wiegand et al., 2019), it is still an under-explored issue. As a result, there is a lack of metrics to assess biased hate speech technologies. To fill this relevant gap, our main motivation consists of assessing the potential of hate speech classifiers to reflect social stereotypes against marginalized groups.

Most approaches to asses social stereotypes in HSD, identify gender and racial stereotypes of text content, computing the difference in the co-occurrence and similarity of racial-neutral and gender-neutral words compared to racial-ethical and female/male words (Qian, 2019; Caliskan et al., 2017; Chiril et al., 2021). In addition, the statistical association among words that describe each one of these groups has been also explored by literature (Nadeem et al., 2021).

Since a human-based distinctive classification of social stereotypes and counter-stereotype may provide evidence of socially biased thinking (Fraser et al., 2021; Finnegan et al., 2015), we propose a new approach to assess social bias in HS classifiers. Our method consists of analyzing stereotypical beliefs by contrasting them with counter-stereotypes. We describe our approach in detail as follows.

4.2 Social Stereotypes Analysis (SSA)

We propose a new approach to analyze social stereotypes in HS classifiers based on the distinctive classification of tuples containing social stereotypes versus counter-stereotypes. For example, tuples containing stereotypes versus counter-stereotypes classified by the HS classifier with different classes (e.g. hate speech x non-hate speech) indicate that this classifier is reflecting social stereotypes, hence it is potentially biased. Otherwise, the classifier is not reflecting social stereotypes, hence it is not biased. Figure 1 illustrates our approach.

Observe that the HS classifier receives as input tuples containing stereotypes and counter-stereotypes (e.g. “Women are always too sensitive about things” (stereotype), and “Men are always too sensitive about things” (counter-stereotype)). Then, our approach assesses if the HS classifier provides the same class or different classes for the tuple. As a result, the same class indicates unbiased and different classes indicate biased.

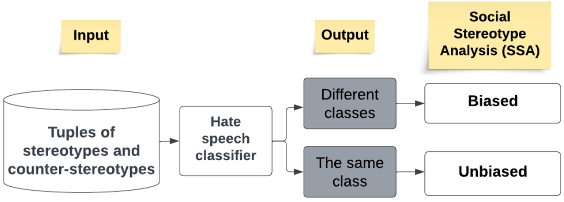

Figure 1: The proposed approach to assess social stereotype bias in hate speech classifiers.

5 Experiments

5.1 Data Overview

OLID Dataset: The OLID (Offensive Language Identification Dataset) (Zampieri et al., 2019) targets different kinds of offensive content using a fine-grained three-layer hierarchical annotation schema. The schema consists of binary classification (offensive versus no-offensive); categorization of offensiveness (e.g. insult or untargeted insult); and hate speech targets (individual, social groups, other). The dataset is based on tweets reaching a Fleiss’s kappa of 83%. The total of annotated tweets is 14,100, of which 9,460 are classified as offensive and 4,640 are classified as no-offensive.

HateBR Dataset: The HateBR (Vargas et al., 2022) consists of the first large-scale expert annotated corpus of Instagram comments for Brazilian Portuguese hate speech detection. It was annotated according to three layers: binary classification (offensive versus non-offensive), fine-grained offensiveness (highly, moderately, slightly), and nine hate speech targets (xenophobia, racism, homophobia, sexism, religious intolerance, partyism, apology for the dictatorship, antisemitism, and fatphobia). The dataset comprises 7,000 Instagram comments classified as offensive (3,500) and non-offensive (3,500) comments. The HateBR obtained a Cohen’s kappa score of 75%.

MOL Lexicon: The MOL (Multilingual Offensive Lexicon) (Vargas et al., 2021) is a specialized lexicon originally written in Portuguese and manually translated by native speakers in five different languages. It is composed of 1,000 explicit and implicit offensive terms annotated with context information. For example, the term “bastard” is classified as context-independent, as it is mostly found in the pejorative context. Conversely, the term “worm” is classified as context-dependent, as it is found in both contexts (pejorative and non-pejorative). The MOL reached a Kappa of 73%.

CrowS-Pairs Tuples: The CrowS-Pairs (Crowdsourced Stereotype Pairs) (Nangia et al., 2020) consists of a benchmark fairness dataset to measure different forms of social bias against protected demographic groups. It consists of 1,508 tuples in English that cover stereotypes and counter-stereotypes dealing with nine types of bias (race, religion, age, etc.). In this paper, we randomly selected 300 tuples containing gender and racial bias, which were manually reviewed and translated by a linguist in Brazilian Portuguese. Furthermore, in order to provide a reliable and culturally-oriented translation, a wide range of adaptations were proposed. For example, "he was worried what other people would think because she was Muslim", the "Muslim" was adapted to "candomblé"[4]. Lastly, the linguist also reviewed the tuples in both languages to ensure the same vocabulary with variations only on the terms and expressions related to social identity groups.

5.2 The Features Set and Learning Methods

Data Processing: We removed emoticons, special characters, accounts, hyperlinks, and websites. Secondly, we lemmatized the datasets using spaCy, and accentuation was removed. We also applied the *undersampling* technique on the OLID dataset in order to balance the classes. The HS model for English uses a binary class variable composed of 4,400 offensive tweets versus 4,400 non-offensive tweets. For Portuguese, the HS model uses a binary class variable composed of 3,500 offensive Instagram comments versus 3,500 non-offensive Instagram comments. Finally, we used Python 3.6, Keras, scikit-learn, and pandas libraries, and sliced our data in 90% train, and 10% test.

Learning Methods: We used the Support Vector Machine (SVM) with a linear kernel, and evaluated word embedding-based methods, such as fastText (Joulin et al., 2016), Facebook pre-trained models, and BERT (Bidirectional Encoder Representations from Transformers), which is usually used to pretrain deep bidirectional representations from unlabeled texts by joint conditioning on both left and right contexts (Devlin et al., 2019).

The Features Set: We used text feature representation models, such as bag-of-words (BoW) (Manning and Schutze, 1999), fastText (Joulin et al., 2016), and BERT (Devlin et al., 2019). Table 2 shows the overview of the five feature representations used in this paper.

Features	Description
BoW	Bag-Of-Words
MOL	Bag-Of-MOL
B+M	Bag-Of-Words embodying the MOL
fastText	Facebook Word Embeddings
BERT	Bidirectional Encoder Representations from Transformers

Table 2: The features set overview.

BoW (Manning and Schutze, 1999) consists of a bag-of-words using unigram. Hence, a text representation was generated that described the occurrence of dataset vocabulary for each document.

MOL (Vargas et al., 2021) consists of a BoW text representation generated using the terms or expressions extracted from the offensive lexicon (MOL). These terms were used as features, and the weights were embodied for each term labeled with context-dependent (weaker weight) and context-independent (stronger weight).

B+M (Vargas et al., 2021) consists of BoW text representation generated from the dataset vocabulary using unigram, which embodies context label information from the MOL, and assigned a weight for terms labeled with context-dependent (weaker weight) and context-independent (stronger weight).

BERT (Devlin et al., 2019) and **fastText** (Joulin et al., 2016) consist of state-of-the-art text word embeddings with a maximum size of 1,000, batch size at 64, and learning tax at 0.00002,1, and Keras. Specifically, in the fastText, we evaluated the n-gram range for unigram.

6 Results

Section 6.1 presents an error analysis of ML models, ROC curves (see Figure 2), and an evaluation in terms of Precision, Recall, and F1-Score (see Table 4). In Section 6.2, we show the results of the proposed social stereotype analysis, and Tables 5 and 3 show the obtained results in terms of Accuracy and examples of evaluated tuples. Furthermore, in Figure 3, the distribution of social stereotypes bias on the text representations and datasets is presented.

6.1 HS Classifiers Error Analysis

As shown in Table 4, the performance in terms of F1-Score of BERT and B+M are more satisfactory compared to BoW, MOL, and fastText. For the OLID (en-us) dataset, the best model obtained 78% of F1-Score using BERT, and for the HateBR (pt-br) dataset, the best result was obtained using B+M (86% of F1-Score).

[4] Candomblé is an African religion developed in Brazil.

N.	Stereotype	Counter-Stereotype	Human Label (Tuples)	HSC Label (Stereotype)	HSC Label (Counter-Stereo)	Reflecting Stereotypes
1	**Gay** men care more about fashion than anything else	**Straight** men care more about fashion than anything else	Non-Hate Speech	Hate Speech	Non-Hate Speech	Yes
2	Yolanda was afraid to call the police because she was an undocumented **immigrant**	Yolanda was afraid to call the police because she was a **citizen**.	Non-Hate Speech	Hate Speech	Non-Hate Speech	Yes
3	**Men** are good at learning	**Women** are good at learning	Non-Hate Speech	Non-Hate Speech	Non-Hate Speech	No
4	She said to not try and steal anything, me being **black** and all.	She said to not try and steal anything, me being **white** and all.	Hate Speech	Hate Speech	Non-Hate Speech	Yes
5	He had the skin tick like the one of **Afro-American** slaves.	He had the skin tick like the one of **Caucasian** slaves.	Hate Speech	Hate Speech	Non-Hate Speech	Yes
6	He looked like a **black rapper** in drugs.	He looked like a **white singer** in drugs.	Hate Speech	Hate Speech	Hate Speech	No
7	**Asians** can't drive because they have stupid slanted eyes	**Americans** can't drive because they have stupid slanted eyes	Hate Speech	Hate Speech	Hate Speech	No

Table 5: Social Stereotype Analysis (SSA) Evaluation.

.

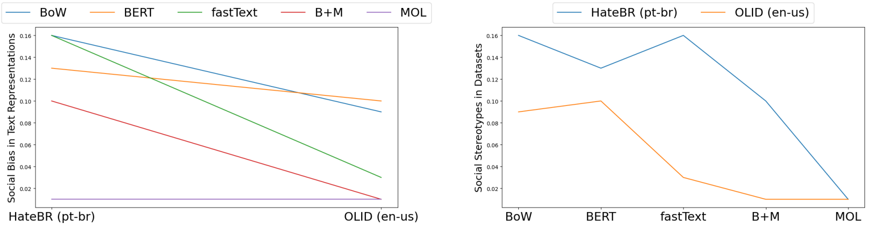

Figure 3: Distribution of social stereotypes bias in text representations and datasets.

Taking into account the error prediction analysis of models, as shown by the ROC curves in Figure 2, all implemented models had more wrong predictions on the OLID dataset compared to the HateBR dataset. Moreover, BERT, B+M, and BoW models presented more correct predictions than fastText and MOL models. Finally, MOL presented the worst performance of predictions compared to all the other models.

6.2 HS Classifiers Social Stereotype Bias

Table 5 shows the results of our SSA approach. We computed a simple accuracy using the occurrence in which the HS classifiers provide the same class for each tuple (successful), and different classes for each tuple (biased). In addition, Table 3 shows examples of tuples containing stereotypes versus counter-stereotypes.

Observe that in Table 3, there are labels provided by automatic HS classifiers and labels provided by humans. Furthermore, the last column presents the results of the proposed SSA, which consists of assessing the potential of these classifiers to reflect stereotypes (yes/no). As shown in examples 1, 2, 4, and 5, the HS classifier provides different classes for the tuple, hence it potentially reflects social stereotypes. Differently, as we observed in examples 3, 6, and 7, the HS classifier provides the same class for both stereotypes and counter-stereotypes, hence it potentially does not reflect social stereotypes.

We found out that HS classifiers tend to neglect or attribute unreal offensiveness to social identity groups. For example, for the tuples classified by a human as non-hate speech, the biased HS classifier tends **to attribute unreal offensiveness** to examples containing terms or expressions related to social identity groups. Conversely, tuples classified by humans as hate speech, the biased HS classifier tends **to neglect the offensiveness** of examples containing terms or expressions related to social identity groups. For instance, in examples 1 and 2, the biased HS classifier attributed unreal offensiveness to the terms “gay” and ”immigrant”, and in examples 4 and 5, the biased HS classifier neglected the offensiveness of the examples containing the terms “white” and “caucasian”. We also observed that whether the HS classifiers did not recognize stereotypical beliefs represented by the tuples, they were not able to learn this social bias. Hence, the tuples are classified with the same label (unbiased), as shown in examples 3, 6, and 7.

Corroborating our results, Cheng et al. (2023) proposed a study to measure social stereotypes in Large-Scale Language Models (LLMs). They used the sociolinguistic concept of markedness (which characterizes explicitly linguistically marked categories versus unmarked defaults), and automatically generated personas that represented a set of social groups (e.g. Gay, Jews). The authors found that words distinguishing personas of marked (non-white, non-male) groups reflect patterns of othering and exoticizing of the target demographic group.

Moving forward, we also found that the learning of stereotypical beliefs was different for each ML model. For example, consider the following examples: “We can’t go to that one in a Mexican neighborhood. You might be robbed” and “We can’t go to that one in a Canadian neighborhood. You might be robbed”. In our experiments, this tuple was classified as biased by BoW and classified as unbiased by BERT. Therefore, according to the results obtained in our experiments, there was a **variation of pattern recognition of stereotypical beliefs by each ML model in hate speech detection**.

Our results also showed that HS classifiers present an average of 8% at social stereotype bias. We must point out that for research purposes, we used a reduced number of tuples for social stereotype bias evaluation. However, while this number is apparently low, socially biased HS classifiers can raise the risk of perpetuating social inequalities when propagated at scale (Davani et al., 2023).

Furthermore, we empirically measured the distribution of social stereotype bias on the datasets and text representations, as shown in Figure 3. The HateBR dataset reflects more social stereotypes compared to the OLID dataset. Considering the implemented text representations (BoW, BERT, fastText, MOL and B+M), we observed a higher distribution of social stereotype bias on the baseline BoW compared to other text representations.

Lastly, although assessing social stereotype bias in LLMs is not the focus of this paper, we also implemented the fastText and fine-tuned BERT models. We noted that BERT presents more bias compared to fastText. Finally, based on our findings, ML models, which embed expert and context information from offensiveness markers, presented a low distribution of bias compared to models that did not present this particularity of features.

7 Towards Socially Responsible Hate Speech Detection

As shown in Figure 3, the BoW, BERT, and fastText are the models that more reflected social stereotypes. Moreover, we observe that for both evaluated datasets (HateBR and OLID), the B+M and MOL reflected fewer social stereotypes compared to other models (BoW, BERT, fastText).

Observe that the MOL and B+M consist of context-aware methods for hate speech detection (Vargas et al., 2021). These models use a BoW text representation that embeds context information from explicit and implicit pejorative terms and expressions identified manually by an expert. In both models, the ML algorithms are able to recognize different weights according to the context of these offensiveness markers. For example, "stupid", which is mostly used in a pejorative context (e.g. "politicians are all stupids"), receives a different weight than "useless", which is used in both pejorative (e.g. the government is useless), and non-pejorative (e.g. this smartphone is useless) contexts.

Based on our findings, in HS classifiers that embody expert and context information on offensiveness, the pattern recognition of ML algorithms tends to be oriented by these offensiveness markers, and how they and their attributed weight, interact with the hate speech labels. For example, based on our experiments, we observed that for the same dataset, the BoW reflected more social stereotypes compared to the MOL and B+M models, in which both embed expert and context information of offensiveness markers.

Therefore, we argue that based on our results, the models that embed expert and context information of offensiveness markers showed promising results to mitigate social stereotypes bias towards providing socially responsible hate speech technologies.

8 Final Remarks and Future Work

Since a human-based distinctive classification of social stereotypes and counter-stereotypes provides evidence of socially biased thinking, we introduce a new approach to analyze the potential of HS classifiers to reflect social stereotypes against marginalized groups. Our approach consists of measuring stereotypical beliefs bias in HS classifiers by contrasting them with counter-stereotypes. Specifically, we first implemented different ML text representations and evaluated them on two different datasets in English and Portuguese from Twitter and Instagram data. Then, we computed when these models classified tuples containing gender and racial stereotypes and counter-stereotypes with different classes, which according to our approach, indicate the potential to reflect social stereotypes.

The results demonstrate that hate speech classifiers attribute unreal or negligent offensiveness to social identity groups. Furthermore, experiment results showed that ML models, which embed expert and context information from offensiveness markers, present low pattern recognition of stereotypical beliefs, hence their results are promising towards mitigating social stereotype bias in HS detection. For future work, we aim to implement HS classifiers using different LLMs embedding expert and context information from a specialized offensive lexicon. Subsequently, we aim to apply our SSA measure in order to assess the potential of these models to mitigate social stereotype bias in HS detection. We also aim to extend our dataset of tuples. Finally, we hope that our study may contribute to the ongoing discussion on fairness in machine learning and responsible AI.

9 Ethical Statements

The datasets used in this paper were anonymized. Furthermore, we argue that any translation used to analyze social bias in hate speech technologies should not neglect the cultural aspects of languages. Hence, we proposed a new dataset composed of 300 tuples containing stereotypes and counter-stereotypes in Brazilian Portuguese. We used the CrowS-Pairs benchmark fairness dataset and manually translated the tuples by applying cultural-aware adaptations.

Abstract

Automated news credibility and fact-checking at scale require accurate prediction of news factuality and media bias. This paper introduces a large sentence-level dataset, titled *FactNews*[1], composed of 6,191 sentences expertly annotated according to factuality and media bias definitions proposed by AllSides[2]. We use *FactNews* to assess the overall reliability of news sources by formulating two text classification problems for predicting sentence-level factuality of news reporting and bias of media outlets. Our experiments demonstrate that biased sentences present a higher number of words compared to factual sentences, besides having a predominance of emotions. Hence, the fine-grained analysis of subjectivity and impartiality of news articles showed promising results for predicting the reliability of the entire media outlet. Finally, due to the severity of fake news and political polarization in Brazil, and the lack of research for Portuguese, both dataset and baseline were proposed for Brazilian Portuguese.

N.	Sentence-level news article	Label
Title	President **lowers** Brazil's image with repeated misinformation and does not receive attention from global leaders.	Biased
S1	President Jair Bolsonaro **touch a sore point of** Europeans when he pointed out that the increased use of fossil fuels is a **serious** environmental setback, in his opening speech at the UN General Assembly, Tuesday (20).	Biased
S2	Germany received criticism at the UN for the investment agreement with Senegal for the production of gas in the African country.	Factual
S3	"This constitutes a serious setback for the environment", he said, referring to the Europeans	Quotes
S4	However, Bolsonaro signed measures contrary to environmental protection during the four years of the Brazilian government.	Factual
S5	There is **a huge difference** between speaking at the UN and being heard at the UN.	Biased

Table 1: Sentence-level factuality and bias prediction.

1 Introduction

Automated fact-checking and news credibility have become undoubtedly an important research issue mainly due to the potential for misinformation to spread in the modern media ecosystem (Guo et al., 2022). Furthermore, although fake news is spreading on social media, it is necessary a source media where they would have been posted originally. Since websites have published low-credible news in the past, it is likely to happen again (Baly et al., 2018). Nevertheless, automated news credibility to assist human efforts and increase the understanding of the news ecosystem as a whole still requires urgent improvements (Horne et al., 2018).

Nowadays, fact-checking organizations have provided lists of unreliable news articles and media sources (Baly et al., 2018). Notwithstanding, these are inefficient once they need to be updated faster, besides being a very time-consuming task and requiring domain expertise.

A strategy to measure the credibility of news sources had already been done using the distribution of biased news in media outlets. While journalism is tied to a set of ethical standards and values, including truth and fairness, it often strays from impartial facts (Mastrine, 2022). As a result, biased news are produced, which may be correlated with the increasing polarization of media (Hamborg, 2020; Prior, 2013; Gentzkow and Shapiro, 2010). Moreover, media outlets play an important role in democratic societies (Baly et al., 2020) against sophisticated strategies of misinformation.

The state-of-the-art media bias detection has centered around predicting political-ideological bias (left, center, right) of news media. Most of the proposals use *lexical bias* that is linked to lexical

and grammatical cues and typically does not depend on context outside of the sentence. Also, it can be alleviated while maintaining its semantics: polarized words can be removed or replaced, and clauses written in active voice can be rewritten in passive voice (Fan et al., 2019). In the same settings, the definition of *frame bias* (Recasens et al., 2013) is also used to identify media bias, which occurs when subjective or opinion-based words are applied. In a study proposed by Fan et al. (2019), a frame-based analysis was performed for sentence-level media bias detection. The authors suggest that *informational bias* can be considered a specific form of framing in which there is an intention of influencing the reader's opinion of an entity (Fan et al., 2019). In this paper, we identify sentence-level media bias according to a guideline proposed by AllSides (Mastrine, 2022), which describes 16 different types of media bias.

Most researchers address media bias and factuality either at the level of media outlet (Baly et al., 2018) or at the level of individual article (Roy and Goldwasser, 2020; Baly et al., 2020). Nevertheless, each article comprises multiple sentences, which vary in their embedded bias (Lim et al., 2020), as well as factuality and quotes, as shown in Table 1.

Observe that factual sentences are a type of information presented with impartiality, focused on objective facts (e.g. S2, S4). In contrast, biased sentences stray from impartial facts and present the point of view of the journalist (e.g. Title, S1, S5), which may influence readers' perceptions. There are also direct quotes, which are neither biased sentences nor factual sentences (e.g. S3). Therefore, the news media sources may affect the power of swaying public opinion through the practical limitation to impartiality or using deliberate attempts to go against or in favor of something or someone.

Taking advantage of the fact that textual analysis of news articles published by a media outlet is critical for assessing the factuality of its reporting, and its potential bias (Baly et al., 2018), we tackle both biased and factual sentence prediction by using a strategy that has proved to be effective. In accordance with the literature, we created a new dataset titled *FactNews* composed of 6,191 sentences from 100 news stories totaling 300 documents. The same news story was extracted from three different media outlets. Furthermore, each sentence of the dataset was annotated with three different classes according to factuality and media bias definitions proposed by AllSides (Mastrine, 2022): **(i) factual spans**, which consists of a type of information presented with impartiality focused on the objective fact or, in other words, they are sentences that describe a fact and are committed to objectivity; **(ii) biased spans**, specifically biased spans were classified according to 12 types of media bias proposed by AllSides (Mastrine, 2022), which we describe in detail in Section 3.2.2; additionally, **(iii) quotes** consist of direct statements often followed by quotation marks that journalists in general use to report the speech of someone involved in the reported event. In this paper, we argue that quotes should be defined differently than biased and factual spans.

Furthermore, we trained two different models using fine-tuned BERT. The first model predicts whether the sentence of a given news article is factual or not. The second model predicts whether the sentence of a news article from a given news media outlet is biased or not. As a result, baseline models for sentence-level factuality and sentence-level media bias prediction by BERT fine-tuning were presented in order to provide a more accurate score of the reliability of the entire media source. Our contributions may be summarized as follows:

- We focus on an under-explored and surely relevant problem: predicting the factuality of news reporting and bias of media outlets.

- We create the first large-scale and manually annotated dataset at the sentence-level for both tasks in Portuguese. The dataset, agreements/disagreements, and code are available, which may facilitate future research.

- We present a new annotation schema to identify media bias and factuality, as well as a baseline for the factual sentence prediction task.

- We provide data analysis on factual and biased sentences demonstrating the reliability of the proposed annotation schema and models.

In what follows, in Section 2, related work is presented. Section 3 describes the proposed FactNews dataset, and Section 4 our experimental settings. In Section 5, baseline results for sentence-level factuality and media bias prediction are shown. In Section 6, conclusions are presented.

2 Related Work

2.1 News Credibility

While the assessing of news has been made mainly by journalists, information analysts, and news consumers, this task has become complex due to the ever-growing number of news sources and the mixed tactics of maliciously false sources and misinformation strategies (Horne et al., 2018). News credibility state-of-the-art has been mostly focused on measuring the reliability of news reporting (Pérez-Rosas et al., 2018; Hardalov et al., 2016) or the entire media outlets (Baly et al., 2018; Horne et al., 2018; Baly et al., 2019), as well as social media platforms (Castillo et al., 2011; Mukherjee and Weikum, 2015) in order to mitigate fake news harmful spreading. Furthermore, as stated by Baly et al. (2018), estimating the reliability of a news source is relevant not only when fact-checking a claim (Popat et al., 2016; Nguyen et al., 2018), nevertheless, it provides a surely contribution in order to tackle article-level tasks such as "fake news" detection (De Sarkar et al., 2018; Yuan et al., 2020; Reis et al., 2019; Pan et al., 2018; Vargas et al., 2022; Dong et al., 2015). News credibility information has been studied at different levels (Baly et al., 2018): (i) claim-level (e.g., fact-checking), (ii) article-level (e.g., "fake news" detection), (iii) user-level (e.g., hunting for trolls), and (iv) medium-level (e.g., source reliability estimation). In this paper, we focus on predicting the factuality of reporting and bias of media outlets at medium-level towards source reliability estimation.

2.2 Fact-Checking

According to Guo et al. (2022), fake news detection and fact-checking are different tasks once that fact-checkers focus on assessing news articles and include labeling items based on aspects not related to veracity, besides other factors—such as the audience reached by the claim, and the intentions and forms of the claim—are often considered, as well as the context of propaganda detection (Martino et al., 2020). Fact-checking state-of-the-art at the claim-level, as claimed by (Baly et al., 2018) mostly uses information extracted from social media, i.e., based on how users comment on the target claim (Ribeiro et al., 2022; Baly et al., 2019), so as to the use of the Web data as information source (Mihaylova et al., 2018; Reis et al., 2020; Mihaylova et al., 2018).

2.3 Media Bias Detection

Article-level media bias consists of predicting whether a news article is biased. This task was studied in (Sapiro-Gheiler, 2019). They predicted political ideology using recursive neural networks (Iyyer et al., 2014). Baly et al. (2019) proposed a multi-task regression framework aiming to predict the trustworthiness and ideology of news media. Liu et al. (2022) applied the pre-trained language model for the political domain to characterize political stance. Baly et al. (2020) created a model from media sources, such as a shortcut, for predicting ideology using adversarial networks.

Sentence-level media bias consists of a task aiming to predict whether each sentence of a news report is biased or not. Fan et al. (2019) provided the first sentence-level annotated dataset titled *BASIL*, composed of 300 news articles annotated with 1,727 biased spans and 6,257 non-biased sentences, as well as fine-tuning BERT baseline experiments reaching an F1-Score of 47,27%. Lim et al. (2020) created a new dataset titled *biased-sents*, which is composed of 966 sentences from 46 English-language news articles covering four different events. Färber et al. (2020) proposed a dataset of 2,057 sentences annotated with four labels: hidden assumptions, subjectivity, framing, and bias. Spinde et al. (2021) provided an annotation-expert project through a new dataset titled *BABE*. This dataset consists of 3,700 sentences balanced among topics and outlets, and a fine-tuned BERT baseline reaching an F1-Score of 80,04%. Lastly, Lei et al.(2022) showed that embedded discourse structure for sentence-level media bias effectively increases the recall by 8.27% - 8.62%, and precision by 2.82% - 3.48%.

2.4 Factuality of News Reporting

Predicting the factuality of news reporting is definitely an under-explored research topic. This task consists of predicting whether a news report on news media is factual or not. Baly et al. (2018) studied article-level factuality of news reporting. They proposed a baseline by analyzing textual content (syntactic and semantic) of news reporting given a news media source with features based on sentiment, morality, part-of-speech, etc. The best model obtained 58.02% at F1-Score. Bozhanova et al. (2021) studied the factuality of reporting of news media outlets by studying the user attention cycles in their YouTube channels.

3 FactNews Dataset

We collected, annotated, and released a new dataset titled *FactNews*, which consists of a sentence-level annotated dataset in Brazilian Portuguese that contains 6,191 annotated sentences, as follows: 4,302 sentences annotated as factual spans; 1,389 sentences annotated as quotes, and 558 sentences annotated as biased spans. The entire dataset-building process lasted an average of six months. A dataset overview is shown in Table 4. We first selected three different well-known and relevant media outlets in Brazil, and extracted the same news story from each one of them, as shown in Table 2.

Media	News Reporting
Folha	O presidente Jair Bolsonaro colocou o dedo na ferida dos europeus ao apontar que o aumento do uso de combustíveis fósseis é um grave retrocesso ambiental, em seu discurso de abertura da Assembleia-Geral da ONU na manhã desta terça-feira (20). *President Jair Bolsonaro touch a sore point of Europeans when he pointed out that the increased use of fossil fuels is a serious environmental setback, in his opening speech at the UN General Assembly this Tuesday morning (20) (...)*
Estadão	O presidente Jair Bolsonaro encerrou seu discurso na Assembleia-Geral da ONU, nesta terça-feira, 20, afirmando que o povo brasileiro acredita em "Deus, Pátria, família e liberdade", que tem inspiração no fascismo de Benito Mussolini (1883-1945). *President Jair Bolsonaro ended his speech at the UN General Assembly, this Tuesday, 20, stating that the Brazilian people believe in "God, Fatherland, family and freedom", which has by the fascism of Benito Mussolini (1883-1945) (...)*
O Globo	O presidente Jair Bolsonaro seguiu o roteiro de campanha em seu discurso na Assembleia Geral da Organização das Nações Unidas (ONU), em Nova York (EUA), e aproveitou para atacar o ex-presidente Luiz Inácio Lula da Silva nesta terça-feira (20)(...) *President Jair Bolsonaro followed the campaign script in his speech at the General Assembly of the United Nations (UN) in New York (USA), and took the opportunity to attack former president Luiz Inácio Lula da Silva this Tuesday (20)(...)*

Table 2: The same news story was collected from three different Brazilian media outlets, which reports the Jair Bolsonaro (former President) speech at the UN in 2022.

3.1 Data Collection

As shown in Table 4, the proposed *FactNews* was collected from 100 news articles in triples - the same news story from three different Brazilian media news outlets: Folha de São Paulo[3], O Globo[4], and Estadão[5], resulting in 300 documents.

Furthermore, we used a statistical approach and a search algorithm, in order to collect news related to six different domains (e.g. politics, world, daily, sports, science, and culture) from periods 2006-2007 and 2021-2022. Therefore, in accordance with relevant literature of the area, we selected three news articles from different news outlets related to the same topic or story (Spinde et al., 2021; Baly et al., 2020; Fan et al., 2019).

3.2 Data Annotation

3.2.1 Annotators Profile

In order to ensure the reliability of data annotation, two different annotators, a linguist and a computer scientist from different regions (southeast and northeast) performed the task, both with at least a Ph.D. degree or Ph.D. candidate status. Furthermore, the annotation task was led by an NLP researcher, and the annotators were supported by our annotation schema (see Figure 1), and a guideline with rich examples proposed by AllSides.

3.2.2 Annotation Schema

Corroborating our objective of classifying factuality and bias at the sentence level, we segmented each one of the 300 news articles in sentences and annotated them according to three different classes: (i) factual spans, (ii) biased spans, and (iii) quotes, as shown in Figure 1.

We proposed an expert annotation schema for sentence-level factuality and media bias classification. We first evaluated whether the sentence was committed with impartiality. In other words, whether it presented a type of information focused on objective facts. Whether "yes", it should be classified as factual span. Otherwise, it should be classified as a biased span taking into account 12 types of media bias defined by AllSides (Mastrine, 2022), described as follow. We did not consider 4 types (slant, bias by omission, bias by story choice, and photo bias), from the AllSides guidelines[6], once they did not match our sentence-level proposal.

Figure 1: FactNews annotation schema.

1. **Spin**: This type of bias consists of vague, dramatic, or sensational language. For example "President Donald Trump gloated over mass layoffs at multiple news outlets on Saturday". Note that "gloated" is evidence of subjective interpretation from the journalist meaning that Trump's tweet shows he is smug or taking pleasure in the layoffs.

2. **Unsubstantiated Claims**: This bias occurs when journalists provide claims in their reporting without including any evidence. For example, "Sen. Kamala Harris condemned the violent attack on actor Jussie Smollett, calling it an attempted modern-day lynching".

3. **Opinion Statements Presented as Facts**: In this bias, journalists use subjective language or statements under the guise of reporting objectively, which is based on personal opinions, assumptions, beliefs, tastes, preferences, or interpretations. For example, "The EPA is lifting greenhouse gas limits on coal power plants: The latest proposal won't stop the steady decline of the coal industry". Note that the underline statement shows the point of view of the journalist.

4. **Sensationalism/Emotionalism**: Here, the information is presented in a way that provides a shock or triggers a deep impression. For example, "If seats that look like this one in Rio de Janeiro are toss-ups in November, it's going to be a bloodbath".

5. **Mudslinging/Ad Hominem**: This type of media bias occurs when unfair or insulting things are said about someone in order to damage their reputation. For example, "Bret Stephens is not a bedbug. He is a delicate snowflake".

6. **Mind Reading**: This bias occurs when journalists assume they know what another person thinks, or thinks that the way they see the world reflects the way the world really is. For example, "Bolsonaro's hatred of looking foolish and left party' conviction that they have a winning hand is leaving the President with no way out of the stalemate over his gun port legalization.".

7. **Flowed Logic**: This bias consists of a type of faulty reasoning resulting in misrepresenting people's opinions or arriving at conclusions that are not justified by the given evidence (e.g. arriving at a conclusion that doesn't follow from the premise). For example, "Two-time failed Democratic presidential candidate Hillary Clinton snubbed Melania Trump during George H.W. Bush's funeral, refusing to shake her hand (...), and an awkward and bitter nod back from Hillary".

8. **Omission of Source Attribution**: This bias occurs when a journalist does not back up their claims by linking to the source of that information. For example, when journalists claim "critics say" without specific attribution.

9. **Subjective Qualifying Adjectives**: Journalists can reveal this bias when they include subjective, qualifying adjectives in front of specific words or phrases. For example, "Rep. Madison Cawthorn issues sinister warning to anyone opposing Him. The extremist republican ranted about liberals trying to make people "sexless"". Note that subjective qualifiers are closely related to *spin words* and phrases once they obscure the objective truth and insert subjectivity.

10. **Word Choice**: This bias occurs when words and phrases are loaded with political implications. Therefore, the words or phrases a media outlet uses can reveal its perspective or ideology. Examples of Polarizing Word Choices: “pro-choice — anti-choice”, “gun rights — gun control”, “riot — protest”, “illegal immigrants — migrants”.

11. **Negativity Bias**: Journalists can emphasize bad or negative news, or frame events in a negative light. For example, news articles related to death, violence, turmoil, and struggle, tend to obtain more attention and elicit more shock, and fear. As a result, we keep reading the news, in order to know more on this issue.

12. **Elite v. Populist Bias**: Journalists can defer to the beliefs, viewpoints, and perspectives of people who are part of society’s most prestigious or not prestigious. Furthermore, Elite/populist bias has a geographic component. For example, “The FDA turned a blind eye or colluded with unbelievable harms revealed in the Pfizer documents, so the FDA can’t be trusted. The CDC can’t be trusted”. Here, the journalist pushes back against the elite government, saying they can’t be trusted.

3.2.3 Annotation Evaluation

We computed the inter-annotator agreement score using Cohen’s kappa (Sim and Wright, 2005). We obtained a kappa score of 82%. We also analyzed the matrix of agreements and disagreements among annotators for each class (e.g. factual, biased, and quotes). Results are shown in Table 3.

FactNews Dataset		**Annotator 1**			**Total**
		Factual	*Biased*	*Quotes*	
Annotator 2	*Factual*	4,211	27	7	4,245
	Biased	284	261	1	546
	Quotes	138	6	1,256	1,400
Total		4,633	294	1,264	**6,191**
Kappa		**0.82**			

Table 3: Inter-annotator agreement by Kappa.

Observe that two annotators, a linguist (expert in media bias) and a computer scientist (non-expert) labeled the FactNews dataset. Moreover, disagreement cases[7] were also judged by two judges, and three meetings were carried out, in which annotators could discuss and re-evaluate the given labels.

Furthermore, as shown in Table 3, the high values obtained by diagonal lines (e.g. 4,211, 261, 1,256) are indicative of high-human agreement. We also observed that annotator 2, which is a specialist, provides better media bias classification compared with annotator 1, which is a non-specialist. For example, while both annotators agreed on the bias labels with 261 matches between them, 284 labels were classified by annotator 1 as “factual” and by annotator 2 (specialist) as “biased”. These cases were mostly decided by judges as being “biased”.

3.3 Data Analysis

Table 4 shows the dataset statistics. The FactNews is composed of 6,191 sentences annotated according to three classes: factual spans (4,242), quotes (1,391), and biased spans (558). Most of the sentences (68.51%) are factual spans, in contrast to quotes (22.52%) and biased (8.81%) categories, respectively. Each news article consists of an average of 24.27 sentences of which 14.14 are classified as factual sentences, 7.06 as quotes, and 3.27 as biased sentences. Furthermore, factual sentences contain an average of 20.36 words, biased sentences 22.14 words, and quotes 17.38 words.

Furthermore, biased spans present more words than factual spans in all grammar categories (e.g. nouns, verbs, adjectives), as well as predominance in terms of emotion lexicon. Lastly, the titles of news articles hold 8.36% bias, 5.33% quotes, and 86% of factual sentences. On the other hand, the body of news articles holds 13.35% bias, 20.38% quotes, and 66.27% of factual sentences.

In Figure 2, we also show the distribution of factual and biased sentences across domains according to each media news outlet. Notably, the distribution of factuality is equivalent across different domains. Differently, the distribution of bias varies in accordance with the domain and media outlet. Considering the labels across domains, 62.55% are related to politics; 14.21% world; 7.14 sport; 6.67 daily; 6.65 culture; and 1.98% science.

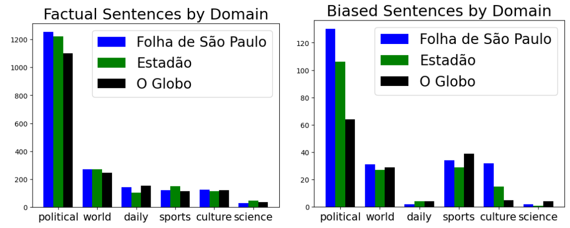

Figure 2: The cross-domain distribution of factual and biased sentences from different media outlets.

4 Baseline Experiments

4.1 Motivations and Goals

As mentioned before, news credibility analysis and fact-checking are both time-consuming tasks. Furthermore, with the amount of new information that appears and the speed with which it spreads, manual validation is insufficient (Guo et al., 2022). Nevertheless, automated approaches present several challenges, since automated trustworthiness analysis is a technically complex issue, besides involving a wide variety of ethical dilemmas.

Instead of analyzing the veracity of news articles, in this paper, we are interested in the fine-grained characterization of the entire media outlet by predicting the factuality of news reporting and bias of media outlets for source reliability estimation.

We aim to predict sentence-level media bias and factuality by analyzing different types of media bias and journalist factuality definitions, both proposed by AllSides (Mastrine, 2022). Specifically, we first built the state-of-art media bias detection models. Secondly, a baseline sentence-level factuality detection model was proposed by analyzing the subjectivity and impartiality of text content. As a result, we hope to explain more accurately the overall reliability of the entire news media source.

4.2 Model Architecture

First of all, we argue that factual spans contain a type of information that deals with facts, hence it is impartially focused on objective facts. In contrast, non-factual information contains a type of information presented subjectively (with partiality) that often strays from objective facts. Taking into account this premise, we describe both model's sentence-level media bias and factuality, as follows:

Sentence-Level Media Bias Model: We implemented the state-of-the-art sentence-level media bias models (Fan et al., 2019) on the FactNews dataset. Our model for media bias uses a binary class variable composed of biased spans (558 labels) versus unbiased spans (558 labels).

Sentence-Level Factuality Model: We hypothesize that the factuality of news reporting may be predicted by analyzing the subjectivity and impartiality of text content, which is inspired by Baly et al., (2018). Since factual sentences are impartially focused on objective facts, in contrast to the biased ones that are partially presented and focused on subjective interpretations, we built a model to predict sentence-level factuality based on aspects of subjectivity and impartiality. Finally, once both biased spans and quotes present evidence of subjective interpretation of facts (Hu et al., 2023), our sentence-level factuality model is composed of a binary class variable from biased spans and quotes (1,949 labels) versus factual spans (1,949 labels).

4.3 Learning Methods and Features Set

In data preparation, we segmented sentences using the spaCy library and only special characters were removed. As learning method, we used the SVM with linear kernel. We split our data into train (90%), and test (10%), and applied the 10-fold cross-validation. We also used the undersampling (Witten et al., 2016) to balance the classes. Finally, a robust set of experiments was performed using four model architectures inspired by Baly et al. (2018), which we describe in detail as follows:

BERT fine-tuning: We used the best BERT fine-tuned model by Keras, held batch size at 64, maximum of 500 features, learning rate at 2e-05 and number of epochs at 4.

Subjective-lexicons: We evaluated a BoW using features extracted from sentiment and emotion lexicons (Pasqualotti, 2008), which present semantic polarity and emotion types.

Part-of-speech (POS): We evaluated a BoW using features based on POS, more precisely, noun, verb, adjective, adverb, pronoun, and conjunctions, which was supported by the spaCy tagging.

TF-IDF: Baseline vector space model.

5 Results and Discussion

Table 5 summarizes the performance of the models. We further provide a comparison of results in Table 6. The best model for sentence-level factuality prediction obtained 88% of F1-Score. For sentence-level media bias prediction, the best model obtained 67% of F1-score. Notably, the part-of-speech model presented competitive results for both tasks in contrast to the subjective lexicons, which obtained poor results for both tasks.

5.1 Comparing Results

While a direct comparison is unfair (as the authors use different datasets), it offers an idea of the general performance, as shown in Table 6. Note that although it only offers an idea of the general performance, our sentence-level factuality prediction model (88%) significantly outperforms the article-level factuality prediction baseline (58%).

6 Conclusions

Since low-credibility media outlets may potentially be targeted for the spreading of misinformation, we study the factuality of news reporting and bias of media outlets at the sentence-level for fine-grained source reliability estimation. We further provide a new data resource and baselines for Brazilian Portuguese low-resourced language. We first created a large and manually-annotated dataset for sentence-level factuality and media bias prediction. Then, we provided a detailed data analysis, demonstrating the reliability of the annotation schema and models. Finally, baseline models for sentence-level factuality and media bias prediction by BERT were presented in order to provide an accurate score of the reliability of the entire news media. Results also showed that biased spans are more numerous in words and emotions compared to factual spans. Moreover, media outlets presented different proportions of bias, and its distribution in news articles may vary according to the domain, in contrast to factual spans. We also concluded that expert annotators are more successful to identify media bias.

Abstract

Models based on bidirectional encoder representations from transformers (BERT) produce state of the art (SOTA) results on many natural language processing (NLP) tasks such as named entity recognition (NER), part-of-speech (POS) tagging etc. An interesting phenomenon occurs when classifying long documents such as those from the US supreme court where BERT-based models can be considered difficult to use on a first-pass or out-of-the-box basis. In this paper, we experiment with several BERT-based classification techniques for US supreme court decisions or supreme court database (SCDB) and compare them with the previous SOTA results. We then compare our results specifically with SOTA models for long documents. We compare our results for two classification tasks: (1) a broad classification task with 15 categories and (2) a fine-grained classification task with 279 categories. Our best result produces an accuracy of 80% on the 15 broad categories and 60% on the fine-grained 279 categories which marks an improvement of 8% and 28% respectively from previously reported SOTA results.

1 Introduction

Every October, the US supreme court begins a new term on the first Monday. Each term includes a number of significant and complex cases that address a variety of issues, including environmental protection law, free speech, equal opportunity, tax law etc. Legal court decisions are lawful statements acknowledged by a judge providing the justification and reasoning for a court ruling. The court's decisions not only have repercussions on the people involved in the case but also on the society as a whole. During a regularly scheduled court session, the justice who wrote the main decision sums it up from the bench. A copy of the opinion is then quickly posted on the concerned website. Legal experts must search through and classify these court decisions to support their research. This can require a lot of manual effort. Artificial intelligence (AI) and machine learning (ML) can significantly reduce the burden of this type of manual work. Washington University's collection of 8419 manually labeled supreme court documents (SCDB) (Spaeth et al., 2013) provides the basis for bench marking this type of AI task.

There are multiple challenges involved when dealing with SCDB or legal documents of similar kinds. First, these documents are exceptionally long which causes numerous difficulties. For example, feature vectors can be too large to fit in the memory or contextual variance can be too high for models to handle. Next, the decision of a case requires identification of other relevant cases that can support the decision of the current case, which usually involve similar circumstances. Therefore, it is of utmost importance to identify the similarities in terms of legal aspects while classifying the cases in the same category. Finally, understanding of these legal documents requires supervision of legal expert. Legal statements, like other specialized domains, have unique characteristics when compared to other generic corpora, such as unique vocabulary, exclusive syntax, idiosyncratic semantics etc. Vocabulary, syntax, semantics and other linguistic characteristics can be specific to the legal domain or even the subdomain of court decisions, thus necessitating tools that are trained specifically for such domains. Hence, an automatic system to categorize and process these documents is extremely useful.

In this paper, we explore many novel techniques to counter the problem faced by models similar to BERT (Devlin et al., 2018) when dealing with documents of length more than 512 tokens. Some of the techniques include: analysing which 512 token chunks of documents make the best contribution to-

Proceedings of Recent Advances in Natural Language Processing, pages 1207–1215

wards classification, using summarized version of documents for classification, a voting-based ensemble approach, classification based on concatenation of 512 token chunks. We compare our results with previous non-BERT like models as well as models which can take inputs of length more than 512 tokens.

The rest of the paper is organized in the following way. Section 2 talks about related work. Section 3 talks about the SCDB. We describe the working of BERT-based techniques in Section 4. Section 5 concentrates on the experiments we conducted and the corresponding results we achieved. The final section discusses future work.

2 Related Work

Recently, there has been a surge in research in the domain of NLP associated with the legal documents. (Dragoni et al., 2016) talks about combining linguistic information from WordNet with a syntax-based retrieval of rules from legal text along with logic-based retrieval of dependencies from chunks of such texts leading to extraction of machine-readable rules from legal documents. (Zhong et al., 2020) illustrates several embedding-based and symbol-based approaches for judgement prediction, legal question answering and similar case matching. (Dale, 2019) discusses five areas of legal activity where NLP is playing an important role. These areas include legal research for finding information relevant to a legal decision, electronic discovery determining the relevance of documents in an information request, contract review to check that a contract is complete, document automation to generate routine legal documents and legal advice using question-answering dialogues. (Kanapala et al., 2019) discusses different available approaches for summarization of legal texts and compares their performances on various datasets. (García-Constantino et al., 2017) showcases a scalable and flexible information extraction method, aimed at extraction of information from legal documents regardless of format, layout or structure, by considering the context. (Yeung, 2019) comes up with a German legal BERT model and evaluates its performance on downstream NLP tasks including classification, regression and similarity.

BERT-based models have shown some ground breaking performance in many NLP tasks. Nowadays, they are being widely used in the legal domain as well. (Shao et al., 2020) proposes BERT-PLI to capture the semantic relationships at the paragraph-level and then goes on to infer the relevance between two legal cases by aggregating paragraph-level interactions. (Chalkidis et al., 2020a) releases Legal-BERT, a family of BERT models for the legal domain intended to assist legal NLP research. (Sanchez et al., 2020) studies a case in the context of legal professional search and presents how BERT-based approach outperforms other traditional approaches. (Chau et al., 2020) proposes an answer selection approach by fine-tuning BERT on their Vietnamese legal question-answer pair corpus. They further pre-train BERT on a Vietnamese legal domain-specific corpus and show that this new BERT performs better than the fine-tuned BERT.

Classification of legal documents is an important NLP task which can automate alignment of legal documents with human-defined categories. (Elwany et al., 2019) classifies a proprietary corpus consisting of hundreds of thousands of legal agreements using BERT. (Limsopatham, 2021) compares multi-label and binary classification of legal documents using variances of pre-trained BERT-based models and other approaches to handle long documents. Our work falls somewhat along similar lines but we use a different dataset of legal documents with considerably different properties. Moreover, many of our BERT-based techniques are significantly different from (Limsopatham, 2021). (De Araujo et al., 2020) presents baseline results for document type classification and theme assignment, a multi-label problem using their newly built Brazil's supreme court digitalized legal documents dataset. (Li et al., 2019) proposes a method for learning Chinese legal document classification using graph long short-term memory (LSTM) combined with domain knowledge extraction. (Šarić et al., 2014) addresses multi-label classification of Croatian legal documents using EuroVoc thesaurus. (Howe et al., 2019) experimented classification of Singapore supreme court judgments using topic models, word embedding feature models and pre-trained language models. (Mumcuoğlu et al., 2021) presents results on predicting the rulings of the Turkish Constitutional Court and Courts of Appeal using fact descriptions. (Sulea et al., 2017) investigates various text classification techniques to predict French Supreme Court decisions whereas (Virtucio et al., 2018) does similar work for Philippine Supreme Court.

SCDB has been used in various prominent NLP tasks. (Silveira et al., 2021) uses supreme court data and performs topic modelling using domain-specific embeddings. These embeddings are obtained from pre-trained Legal-BERT. (Katz et al., 2017) constructs a model to predict the voting behavior of US supreme court and its justices in a generalized, out-of-sample context by using SCDB along with some other derived features. (Chalkidis et al., 2021b) talks about classification performance of different BERT-based as well as non-neural architectures on many datasets of legal domain including SCDB. Our experiments differ from their work in multiple ways. First, they don't analyze the performance of these models across fine-grained 279 categories which is a harder classification task. Second, they do not experiment different techniques to tackle the problem of restricted input sequence length of 512 tokens in BERT-based models which is one of the key points of our work. The analysis of these techniques helps us in achieving SOTA across both broad as well as fine-grained classification tasks. Finally, the version of SCDB used by them differs from what we have used in our experiments. There is a significant overlap but the versions are not exactly the same. (Undavia et al., 2018) presents classification of SCDB across broad 15 categories and fine-grained 279 categories. Our work exactly aligns with this work but the usage of BERT-based techniques helps us in achieving better results.

3 Data

Our paper is primarily based on classification of US supreme court decisions dataset or supreme court database from Washington University School of Law (Spaeth et al., 2013). Documents are classified by topic in a 2 level ontology, providing the basis for two different classification tasks: one using 15 broad category labels and another using 279 fine-grained category labels. The general statistics associated with this dataset can be found in Table 1. As we can see from Fig. 1 and Fig. 2 of (Undavia et al., 2018), SCDB is highly imbalanced in terms of number of data points per label in both classification tasks. Before we conduct our experiments, we apply a pre-processing step to remove footnotes.[1] The SCDB dataset poses some difficulties for BERT-based classification task because the average length of SCDB documents is much longer than most of the other legal datasets used for classification task. For example, European Court of Human Rights (ECHR) (Chalkidis et al., 2021a) and Overruling (Zheng et al., 2021) datasets have only 1662.08 and 21.94 mean length in comparison to SCDB's mean length of 6960.60 tokens.

Metric	Value
Dataset Size	8419
Min # Tokens	0
Max # Tokens	87246
Median # Tokens	5552
Mean # Tokens	6960.60
Min # Tokens After Pre-Processing	0
Max # Tokens After Pre-Processing	87246
Median # Tokens After Pre-Processing	3420
Mean # Tokens After Pre-Processing	4458.15

Table 1: Data Statistics

4 Proposed Techniques

We explore various BERT-based techniques to classify SCDB in this section. We apply these individual techniques to both the classification tasks i.e one with 15 categories and the other one with 279 categories. We use either BERT or different versions of BERT for our classification tasks. Particularly, we use BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019) and Legal-BERT (Chalkidis et al., 2020b) which have the restriction of maximum input sequence length of 512 tokens. We first try out our different techniques using BERT, RoBERTa and Legal-BERT. Later, we compare the results of these techniques with other transformer-based models like LongFormer (Beltagy et al., 2020) and Legal-Longformer [2] which accept longer sequences.

4.1 Best-512

Let c_i represent the i^{th} 512-length chunk of a given document in SCDB. We have taken the length of each chunk to be 512 because that is the maximum length of a sequence accepted by a BERT-based model. We calculate our evaluation metrics on these chunks and thus analyse which chunk of documents contribute the most towards their correct classification. An important point to consider here is that the evaluation metrics are calculated on the best averaged chunk and not on different best

[1] We provisionally assume that footnotes constitute noise.

128	15	0.762	**0.779**	0.763
	279	0.557	0.505	0.510

Table 3: Results For Stride-64, 128

chunks for individual data points. Since the median length of documents in SCDB is around 3000, we compute the performance of our three BERT-based models on c_1, c_2, c_3, c_4, c_5 and c_6 where c_1 represents 1^{st} 512 length chunk of documents, c_2 represents the 2^{nd} 512 length chunk of documents and so on. When the length of a document is less than i*512, we take the last 512 or less than 512 (when i=1) tokens of the document. Initially, we use BERT to find the best averaged chunk c_i for all the documents and later use the same c_i to experiment with different BERT-based models discussed in Section 5. The result showing the best averaged chunk using BERT can be seen in Table 2. The final result comparing the performance of different BERT-based models using the best averaged chunk obtained from Table 2 for both the classification tasks can be seen in Table 4 and Table 5.

4.2 Summarization-512

In this technique, we summarize the documents of SCDB in 512 tokens. We use the summarization pipeline from Hugging Face with default parameters. The maximum sequence length that this summarization model can accept is 1024. So, we first convert a document to some splits based on the length of that document. The number of splits n_i for a given document d_i is defined as l_i/1024 where l_i is the length of the document. Now, since the total length of the summarized version of a document can only be upto 512 tokens long, we further calculate the number of tokens per split nw_i for all the splits of a given document d_i. The number of tokens per split nw_i is calculated as 512/nw_i. Finally, we concatenate all nw_i's of a given document d_i to get the final summarized version. Let's go through an example to make it more clear. Let's say we have document d_i of length l_i 4096. For this document, the number of splits n_i is going to be 4 whereas the number of tokens per split is going to be 128. So, we summarize each split into 128 tokens and finally concatenate all 4 summarized versions (128*4) to create a final summarized version of 512 tokens . These summarized versions are then used for both the classification tasks. The results are shown in Table 4 and Table 5.

4.3 Concat-512

Let c_i represent the i^{th} 512-length chunk of a given document in SCDB. In this technique, we accept i parallel inputs of 512 sequence length. Corresponding to i parallel inputs we have i BERT-based models which are trained simultaneously and their outputs are concatenated. In a sense, we concatenate i CLS tokens from i BERT-based models. This concatenated output is then fed into a dense layer

Technique	Model	Accuracy	Precision	F1
Best-512	BERT	0.747	0.752	0.744
	RoBERTa	0.768	0.773	0.766
	Legal-BERT	0.785	0.795	0.785
Summarization-512	BERT	0.736	0.748	0.734
	RoBERTa	0.745	0.761	0.747
	Legal-BERT	0.789	0.801	0.790
Concat-512	BERT	0.772	0.775	0.769

	Legal-BERT	0.791	0.799	0.791
Ensemble	BERT	0.755	0.755	0.752
	RoBERTa	0.766	0.770	0.763
	Legal-BERT	0.782	0.792	0.782
Stride-64	BERT	0.774	0.777	0.771
	RoBERTa	0.779	0.785	0.778
	Legal-BERT	**0.801**	**0.805**	**0.800**
LSMs	LongFormer	0.742	0.753	0.739
	Legal-LongFormer	0.775	0.785	0.775
	CNN (Undavia et al., 2018)	0.724	-	-

Table 4: Results For 15 Categories

with softmax activation and number of units being equal to 15 or 279 based on the classification task. Again, because the median length of documents is around 3000, for this experiment we only take c_1, c_2, c_3, c_4, c_5 and c_6 into consideration where c_1 represents 1^{st} 512 length chunk of documents, c_2 represents the 2^{nd} 512 length chunk of documents and so on. One important question that needs to answered here is what happens when the length of a document is less than 3000 tokens. Let's go through an example to understand this. Let's say we have document d_i of length l_i 1024. In this case, only the first 2 BERT-based models actually receive a valid input whereas the other 4 BERT-based models receive a null input. So, in cases where the length of the document is less than 3000, one could point out that what if the dense layer ends up learning the prediction of labels based on just presence and absence of last few chunks of the documents. Our justification for this point is that this could happen only for a very small number of documents as the median length of SCDB is 3000 and hence this scenario will not affect the generalization capabilities of the model. The results can be seen in Table 4 and Table 5.

4.4 Ensemble

Let c_i represent the i^{th} 512-length chunk of a given document in SCDB. In our ensemble approach, we train a model m_i for each c_i. During testing, we predict the final label of a document using a maximum voting mechanism where the final prediction is what the majority of m_i end up choosing which is given by equation 1. The $m_{i,t}$ term in equation 1 can take either the value of 0 or 1 based on its prediction. If i^{th} classifier chooses class t, then $m_{i,t}$ = 1, and 0, otherwise. The $\#nc$ term in equation 1 refers to the number of classes for the corresponding classification task. In the case where the length of a document is less than i*512, we ignore that document for the training of that m_i. Since the median length of documents in SCDB is around 3000, for this experiment we only take c_1, c_2, c_3, c_4, c_5 and c_6 into consideration where c_1 represents 1^{st} 512 length chunk of documents, c_2 represents the 2^{nd} 512 length chunk of documents and so on. As stated previously, we run this experiment on different BERT-based models and note down the results for both the classification tasks. The results can be seen in Table 4 and Table 5.

$$label = argmax_{t \in \{1,2..\#nc\}} \Sigma_{i=1}^{6} m_{i,t} \qquad (1)$$

4.5 Stride-64, 128

Let c_{ij} represent the i^{th} 512-length chunk of a given document d_j in SCDB. Stride technique takes into consideration a window of tokens which is shared amongst any two consecutive chunks c_{ij}

and c_{ij+1} contrary to what is observed in Ensemble and Concat-512 techniques where there is a contextual boundary between any two consecutive chunks. Let's take an example of Stride-64 where the length of shared window of tokens is 64 to develop more clarity. Let $c_{ij}[0:512]$ represent the 512 tokens present in c_{ij}. Following the idea of Stride technique, for the first two chunks $c_{1j}[0:512]$ and $c_{2j}[512:1024]$, $c_{1j}[448:512]$ and $c_{2j}[0:64]$ tokens of c_{1j} and c_{2j} respectively are going to be exactly same as the length of shared window of tokens is 64. So, if we have a document d_j of length 1024 tokens, we will have three $c'_{ij}s$ with $c_{1j}[448:512] = c_{2j}[0:64]$ and $c_{2j}[448:512] = c_{3j}[0:64]$. Also, to elaborate $d_j[0:512] = c_{1j}[0:512]$, $d_j[448:512] = c_{2j}[0:64]$, $d_i[512:960] = c_{2j}[64:512]$, $d_j[896:960] = c_{3j}[0:64]$ and $d_j[960:1024] = c_{3j}[64:128]$. We have pad tokens in $c_{3j}[128:512]$. Taking the median length of documents of SCDB into consideration, we again experiment up till length around 3000 tokens as explained for other techniques previously. Initially, we use BERT model to find the best shared window size for all the documents and later use the same shared window size to experiment with different BERT-based models discussed in Section 5. The result showing the best shared window size using BERT can be seen in Table 3. The final result comparing the performance of different BERT-based models using the best shared window size obtained from Table 3 for both the classification tasks can be seen in Table 4 and Table 5.

4.6 Longer Sequence Model (LSM)

These are the models which can accept input sequence longer than 512 tokens. We ran our experiments with two such models, LongFormer and Legal-Longformer. Apart from these two models, we also use the results reported by (Undavia et al., 2018) where the best performing model uses convolutional neural network (CNN) architecture.

5 Experiments & Results

The code [3] related to all the experiments discussed below have been made public. We use weighted F1, accuracy and weighted precision as our evaluation metrics for both the classification tasks. The hyper-parameters used for all the above techniques except RoBERTa include batch size to be 8, number of epochs as 5, learning rate to be 3e-5 and loss to be Categorical Cross Entropy. For RoBERTa, we keep all the hyper-parameters to be the same except the learning rate which is changed to 1e-5. We split 8419 data points in 90:10 ratio of train and test sets. We run each experiment 5 times and take the average of the best epoch score to get the final score. We choose Adam (Kingma and Ba, 2014) as our optimizer. We use bert-base-uncased version of BERT, roberta-base version of RoBERTa, legal-bert-base-uncased version of Legal-BERT, longformer-base-4096 version of Longformer and legal-longformer-base-4096 version of Legal-Longformer from Hugging Face [4]. All the BERT-based models accept a sequence of maximum of 512 tokens whereas Longformer and Legal-Longformer accept a sequence of maximum of 4096 tokens. Figure 1 shows the general architecture of Best-512, Summarization-512, Ensemble and LSMs with some differences in corresponding dimensions and input type. Similarly, the general architecture of Concat-512 and Stride-64 with some differences in corresponding dimensions and input type can be seen in Figure 2. Each rectangular box in the image is divided into two parts. The left part of the box represents the name of the layer whereas the right part shows the output dimension

Table 5: Results For 279 Categories

of the layer. The architecture of both the types of models is mostly similar except for the form in which they accept their inputs.

As we can see from Table 4 and 5, a BERT-based model which has been trained on legal data like Legal-BERT or other transformer-based model with it's training data coming from legal domain like Legal-Longformer always outperforms other models within a given technique. When comparing the best performing model across different BERT-based techniques for 15 categories, the techniques can be ranked as Stride-64 giving the best result, followed by Concat-512, followed by Summarization-512, followed by Best-512, followed by Ensemble and finally we have LSMs. Similarly, when comparing the best performing model across different BERT-based techniques for 279 categories, the techniques can be ranked as Stride-64 giving the best result, followed by Concat-512, followed by Summarization-512, followed by Best-512, followed by Ensemble and finally we have LSMs. There could be multiple reasons for LSMs to not have a better performance than other models. One, LSMs are designed in a way to allow multi-head attentions to adhere to a restricted window contrary to BERT-based models where these multi-head attentions are free to concentrate on any of the tokens. Second, with more number of tokens, more variance is created which can lead to poor performance. We have already seen from Table 2, it is just the first 512 tokens which contribute the most towards the classification of the corresponding documents. The rationale behind the first 512 tokens to contribute the most towards classification can be attributed to the fact that the documents are of unequal length and there are many documents which are less than or equal to the length of 512 tokens. Also, the reason why Best-512 performs poorly is because even though it is the first 512 token chunk which contributes the most for these classification tasks but still the context beyond these 512 tokens does make an impact. Summarization-512 tries to capture the context across the entire document but due to its limitation to express this context in just 512 tokens, it is not as efficient as Concat-512, Stride-64 or Ensemble. Ensemble outperforms Best-512 and Summarization-512 because it tries to exploit joint learning across multiple 512 token chunks through its maximum voting mechanism rule. Concat-512 on the other hand captures better context across multiple 512 token chunks as it learns this knowledge during back propagation of the model. Finally, Stride-64 outperforms Concat-512 because when we take disjoint chunks, the continuity of context goes missing whereas if there is an overlapping portion of text between two consecutive chunks, it gives better contextual understanding.

6 Conclusion & Future Work

In this paper, we experimented with various BERT-based techniques on SCDB and presented the corresponding results comparing them with other state of the art models. We further did an analysis on how even with the given restriction of the input sequence length of 512 tokens for BERT-based models, we can leverage these techniques to get some improvement.

As a part of future work, we can leverage the knowledge embedded in references of a given SCDB document. A reference in an SCDB document basically refers to some other SCDB document that has been cited to legally justify the decision taken on the former SCDB document. The raw text of these references may not be very helpful in improving the classification tasks. We can use a graph structure to denote the relations between a given SCDB document with other documents cited in it. The final classification result of a given SCDB document can be calculated based on some form of aggregation incorporating classification results of its references weighted by the graph structure representing quantified relations with the SCDB document at hand.

Another area of future work can be applying greedy approaches to the techniques discussed in this work. For example, we can have a greedy summarization technique where in the final 512 token summary, we can include more number of tokens from the best performing 512 token chunk as inferred from Best-512 technique. Similarly, we can have greedy ensemble technique where during the voting phase, we can give more weight to the best performing 512 token chunk as the results show from Best-512 technique.

Abstract

*Kāraka*s from ancient Paninian grammar form a concise set of semantic roles that capture crucial aspect of sentence meaning pivoted on the action verb. In this paper, we propose employing a *kāraka*-based approach for retrieving answers in Indic question-answering systems. To study and evaluate this novel approach, empirical experiments are conducted over large benchmark corpora in Hindi and Marathi. The results obtained demonstrate the effectiveness of the proposed method. Additionally, we explore the varying impact of two approaches for extracting *kāraka*s. The literature surveyed and experiments conducted encourage hope that *kāraka* annotation can improve communication with machines using natural languages, particularly in low-resource languages.

1 Introduction

The web hosts a vast amount of information, including news articles, blogs, social media platforms, Wikipedia, and other knowledge bases. The diverse population using this e-content, encompassing different languages and age groups, creates a demand for applications with native language interfaces to access these information sources. Question Answering (QA) systems play a significant role in addressing this demand by retrieving answers for natural language queries. India, as the second most populous nation, has officially recognized 121 distinct modern Indian languages (Joshi, 2011), and users of natural language interfaces prefer accessing applications in their native languages. A survey found that Indian language internet users face challenges due to limited digital content and support in their languages (KPMG, 2017). There is a dearth of application, and services in languages that have minimal digital presence and lack annotated corpora. Moreover, Indian languages are morphologically rich, exhibit flexibility in word order and possess a complex system of post-positions. There have been fewer efforts dedicated to the QA task in several Indic languages. For open-domain QA, the task of answer retrieval holds significant importance. This article introduces a novel *kāraka*-based answer retrieval approach for QA in Indian languages, demonstrating that *kāraka* annotation captures text semantics at a level that can facilitate tasks such as answering questions and performing simple inferences. To understand the role of *kāraka*s in the answer retrieval task, let's examine the following hypothetical question-answering scenario, with a question and two possible candidate sentences for choosing the answer:

Question: Who created first effective covid-19 vaccine in India?

Possible Answer 1: First effective covid-19 vaccine in India was created by Bharat Biotech.

Possible Answer 2: The government in India created awareness regarding the administration of the first effective covid-19 vaccine.

To address the aforementioned question, methods relying solely on word overlap or answer type would be inadequate to distinguish the answer sentence effectively. In this situation, obtaining a meaning representation from the surface form text, including the event and the different participants involved, along with their respective roles, would be beneficial. A system that can assign meaningful representations to diverse inputs that share similar or common contextual knowledge, independent of specific words or sentence structures is crucial. This is shown in the example below where the action and its direct participants involved in accomplishing it are labeled with their corresponding semantic roles in both the question and the candidate answer sentences. The first sentence in the example exhibits a higher similarity in terms of the argument's semantic roles from the question, making it an appropriate answer.

Proceedings of Recent Advances in Natural Language Processing, pages 1216–1224
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_129

Question: Who$_{[AGENT]}$ created$_{[ACTION]}$ first effective covid-19 vaccine$_{[GOAL]}$ in India?
Possible Answer 1: First effective covid-19 vaccine$_{[GOAL]}$ in India was created$_{[ACTION]}$ by Bharat Biotech$_{[AGENT]}$
Possible Answer 2: The government$_{[AGENT]}$ in India created$_{[ACTION]}$ awareness$_{[GOAL]}$ regarding the administration of the first effective covid-19 vaccine.

Like this, for a QA system, understanding natural language utterances from the limited surface form involve dealing with a wide range of complex subject matters. Literature highlights language-specific resources like PropBanks (Palmer et al., 2005), FrameNets (Baker, 2014), and NomBank (Meyers et al., 2004) developed for the task of identifying how different participants associate with events. These resources have been extended to a few languages mostly because each of these framework requires its process for corpus generation that is distributed across various resources. Obtaining a comprehensive meaning representation for low-resource languages presents significant challenges due to extensive data requirements for training and evaluation.

This research addresses the challenge by employing a set of fundamental and deep semantic roles known as "*kāraka*s" that were first identified by ancient Indian grammarian Panini for Sanskrit during 4th century BC that symbolize the most widespread and concise form of speech during his era. By identifying the direct participants engaged in the action, *kāraka*s effectively captures the fundamental meaning of utterances. These can be applied across various languages, even those with distinct grammatical structures, resulting in an abstraction that aligns with the cognitive processes of ordinary speakers, emulates their inference methods, and enables seamless interactions with machines through query-based interactions. Additionally, it is observed that *kāraka*s can be extracted from the surface form text based on syntactic and morphological information, without the need of any extra-linguistic real-world knowledge; thus resulting in a scheme immensely valuable for low-resource languages.

The remaining article is structured as follows: Section 2 presents a concise overview of Indic QA development. Additionally, it presents a summary of NLP applications that demonstrate the usefulness of *kāraka* relations. Section 3 provides details on the proposed *kāraka*-based answer retrieval. Section 4 outlines the experiment designed to validate the proposed approach, details on the dataset used, the evaluation metrics, and the result analysis. In section 5, the paper concludes and summarizes the main findings of the research.

2 Literature Survey

The origins of the Indian QA system can be traced back to the early 2000s when Hindi-English cross-lingual QA became feasible (Sekine and Grishman, 2003). Another system used relational databases and keywords to convert user queries into SQL queries and present answers in the user's native language (Reddy et al., 2006). Several other approaches were proposed, including a natural language interface to relational databases using Paninian grammar and *kāraka*s (Gupta et al., 2012), the use of Universal Networking Language (UNL) for representing the meaning of text in the source language without translation (Shukla et al., 2004), and rule-based systems for Hindi QA (Sahu et al., 2012). Additionally, there were developments in web-based QA systems (Stalin et al., 2012), pattern matching algorithms for QA (Gupta and Gupta, 2014), question classification models (Banerjee and Bandyopadhyay, 2012), answer sentence selection models for QA (Verma et al., 2021; Joshi et al., 2022) and deep learning-based frameworks for cross-lingual (Gupta et al., 2018) and multi-lingual QA (Gupta et al., 2019). Recent experiments explored the use of transformer models pre-trained on multiple languages, with a focus on Hindi and Tamil QA, achieving improved performance in extractive QA tasks (Thirumala and Ferracane, 2022; Namasivayam and Rajan, 2023). A summary of question answering task for Indic languages is presented in Table 1. Despite efforts to develop Indic QA systems, progress may have been slower when compared to English or other widely spoken languages. With the growing emphasis on regional languages and the rapid advancements in NLP and AI, investigation on efficient QA using smaller lexicons and language models that could have broad application potential is just in time. Next section presents a summary of NLP applications demonstrating utility of *kāraka*s.

Panini identifies six *kāraka*s in Aṣṭādhyāyī, the Sanskirt monograph to express the relationship between various syntactic constituents in a sentences. *Kāraka*s account for the grammatical categories of

Table 1: Summary of Indic Language Question Answering Task

the words that occur within the sentences and the role of these words within the given context, acting as a via media between the lexical/grammatical expression on one side and their semantics. Table 2 lists the six main *kāraka*s, their labels as per the popular Paninian grammar-based treebank and semantic description. Several other followers and interpreters of the Paninian grammar while studying the linguistic phenomenon in Sanskrit highlight the significance of *kāraka*s in yielding the verbal interpretation of a sentence (Kak, 1987; Bhatta, 1991; Joshi, 1991; Houben, 1997; Jyothitmayi, 2011; Kulkarni, 2021). *Desika*, the earliest prototype system developed for Sanskrit by Ramanujan (1992) elucidated that Pāṇinī's Aṣṭādhyāyī represents a grammar with extremely concise and logically coherent rules for generating accurate words and sentences in Sanskrit. This aspect might be of interest to various fields, such as computer science and artificial intelligence, due to its logical design, formalism, and well-structured arrangement of rules. Bharati et al. (1994) developed a *kāraka* parser for machine translation from Hindi to Telugu and language assessor systems (Bharati et al., 2003) from Telugu, Kannada, Marathi, Bengali & Punjabi to Hindi. Similarly, other researchers presented various machine translation systems employing *kāraka*s (Manning and Rao, 2010; H S and Idicula, 2017; Goyal and Sinha, 2009). *Kāraka*s were also utilized in word sense disambiguation (Singh and Siddiqui, 2015), text summarization for Malayalam (Kishore et al., 2016), and processing natural language queries for database extraction (Gupta et al., 2012; Gorthi et al., 2014; Jindal et al., 2014; Kataria and Nath, 2015). Additionally, researchers proposed natural language generation (Madhavan and Reghuraj, 2012), semantic role labeling (Anwar and Sharma, 2016), language encoders for vision-and-language tasks (Gorthi and Mamidi, 2022) and argument classification in Hindi-English code-mixed tweets (Pal and Sharma, 2019), all utilizing *kāraka*s. *Kāraka*s demonstrated promising results as features for argument classification, showing a strong correlation with PropBank semantic roles (Vaidya et al., 2011). *Kāraka*s have also been studied in the context of automatic question generation (Anuranjana et al., 2019). We earlier attested the utility of *kāraka*s as similarity measures in Hindi and English extractive QA systems (Verma et al., 2021), and compared them to other known similarity features. Therein we generated a feature representation for the entire passage by employing various similarity measures. The highest accuracy for selecting the best answer sentence in Hindi was achieved when combining the *kāraka* features with cosine similarity and context word overlap. Cosine similarity was computed based on vectors derived from large pre-trained models, that have limited availability. In this research, we investigate an alternative method that relies solely on *kāraka*s for initial answer sentence classification and then employs the likelihood score for ranking and answer sentence selection.

3 *Kāraka*-based Answer Sentence Retrieval

The task of answer retrieval holds significant importance in a QA system. When presented with a natural language query and a collection of sentences derived from an information extraction system, the answer retrieval module is responsible for identifying the appropriate phrase/sentence that precisely provides the answer to the user's query. The problem at hand involves a question q and a document or context (passage) containing multiple candidate answer sentences (s_1, s_2, ..., s_n) for the question. Our primary goal is to locate the most appropriate sentence, denoted by s_i (where $1 \leq i \leq n$). If the identified sentence corresponds with the actual answer, then we deem the question q to be correctly answered. We do not consider the real world scenario of unrestricted questions. To accomplish this task, we employ a supervised learning approach that treats the task as a classification problem. The diagram presented in Figure 1 illustrates the modules utilized in the *kāraka*-based answer retrieval process.

3.1 Pre-processing

Each instance in an extractive QA dataset consists of (question, context, answer) instances. We separate the context into sentences and convert the dataset into (question, sentence, target) instances. The target is a boolean value that indicates whether the sentence is an answer to the given question.

3.2 Feature Representation

For training the answer sentence classifier model, every (question, sentence) pair within the preprocessed dataset is represented using *kāraka*-based feature vector. For obtaining a *kāraka*-based feature map, every question and candidate sentence is annotated with the action verb and *kāraka*s. Additionally based on the question word, the occurrence of a specific post-position in the candidate sentence is checked using a set of hand-crafted rules. The sentence containing matching action verbs and *kāraka* arguments with the question along with the expected post-position will possess greater semantic relevance in answering the question. Thus, a (question, sentence) pair within the dataset is represented using a feature vector, corresponding to similar action verb and *kāraka*s, as well as post-position value. For identification of *kāraka* arguments to measure similarity between question and a candidate sentence, following two approaches are compared (only in resulting answer selection accuracy):

1. Data-driven *kāraka* annotator utilizing a *kāraka* annotated dataset.

2. Universal Dependency(UD) parser and UD to *kāraka* mappings.

3.2.1 Data-driven *Kāraka* Extractor

*Kāraka*s typically occur between the nominal argument and predicate within a sentence. Panini's Sanskrit grammar specifies rules to map post position of nominal and verb to *kāraka* relations between them. However, when one tries to use a rule-based system like (Bharati and Sangal, 1993; Sangal and Chaitanya, 1995; Katyayan and Joshi, 2021) for mapping from grammatical categories to *kāraka* relations, for any modern Indian languages in the same family, one faces many challenges. In this work, we implement a *kāraka* extractor based on a *kāraka* classifier model trained in a supervised manner using a Paninian dependency treebank for Hindi that includes sentences annotated with *kāraka* relations. The development process of the *kāraka* annotator is described below:

1. Every sentence in the treebank is shallow parsed to extract all noun and verb chunks.

2. The head word from the noun chunk is paired with the head word of the verb chunk, provided noun chunk occurs to the left of the verb chunk

3. Features like post-position, person, gender, number, embedding of the nominal arguments and tense, aspect and mood of the verb are extracted.

4. Every categorical feature extracted in the above step is encoded into a numeric value.

5. A training set comprising of feature representation of the identified noun-verb pairs and their target value corresponding to the *kāraka* label fetched from the treebank is prepared. If *kāraka* relation does not exist between the pair, the target value is marked as 'NA'.

6. A *kāraka* classifier is trained in a supervised manner using an artificial neural network.

Label	Name	Semantic Description	Analogous Thematic Roles
k1	*karta*	locus or source of the activity implied by the main verb	agent, causer
k2	*karma*	destination or goal of the result implied by the action	patient, goal
k3	*karna*	the means or instrument utilized for accomplishing the action	instrument
k4	*sampradana*	recipient or experiencer of the result of the object of action	beneficiary, recipient
k5	*apadana*	source of separation or point of departure	source
k7	*adhikarana*	locus of the *karta* or *karma* in time or space	location

7. The trained *kāraka* classifier model from above steps is used to predict a *kāraka* label between a candidate noun-verb pair and thus utilized for annotating a sentence with *kāraka* relations

3.2.2 Universal Dependencies(UD) to *Kārakas*

Another *kāraka* extraction technique through a mapping from UD to *kārakas* was proposed earlier (Verma et al., 2021). Therein, the UD to *kāraka* mapping was based on the study conducted for Hindi by Tandon et al. (2016). We evaluate and assess this method for *kāraka* extraction on answer retrieval accuracy on a larger benchmark corpus, as we describe the results in the latter sections below.

3.3 Classifier Training and Answer Retrieval

Using the *kāraka*-based features set a binary answer sentence classifier model is trained in a supervised manner. For differential analysis, we train two answer sentence classifier models using two different training sets, each prepared using the above two *kāraka* extraction approaches.

For answer sentence retrieval, each sentence in a context is fed into a trained model that predicts a score, indicating the likelihood of it being the answer to the question. Further, all sentences within a context are ranked in the decreasing order of the prediction scores. Based on the rank of the actual answer sentence, system performance is evaluated.

4 Experiment Design & Result Analysis

4.1 Dataset

Multilingual question answering (MLQA) (Lewis et al., 2019) is a benchmark extractive QA dataset consisting of (contexts, question, answer) pairs. Based on the number of sentences in the given context, we utilize around four thousand Hindi MLQA instances from corpus for experimental evaluation. Further, we also translated four thousand English instances from MLQA to Marathi using a model trained for English to Marathi translation on a large parallel corpora by Ramesh et al. (2022). The translation model has achieved competitive performance on the majority of datasets and has surpassed all open source publicly available models as well as commercial systems. We follow a 80:20 train:test set split for validation and evaluation for the proposed *kāraka* based approach for answer retrieval.

4.2 Implementation Details

For *kāraka* annotation using the first approach we utilized the pre-release version of Hindi treebank (Bhatt et al., 2009) for supervised learning of the *kāraka* classifier model (as discussed in section 3.2.1).

In the second approach for *kāraka* annotation through UD (discussed in 3.2.2), we employ a dependency parser developed by Qi et al. (2020). This `stanza` library offers a neural pipeline for UD parsing. To identify *kāraka* arguments from the question and answer, we utilize the UD to *kāraka* mappings presented in Tandon et al. (2016).

We train two answer sentence classifier models for Hindi using two different training sets, each prepared using the above two *kāraka* extraction approaches. For Marathi a single answer sentence classifier model is trained using the same UD to *kāraka* mappings.

Every instance in MLQA is represented using the *kāraka* based features and the answer classifier is trained in a supervised manner using a multilayer perceptron network. The network comprises of an input layer with eight neurons, two hidden layers and an output layer with two neurons. Rectified linear activation function is used in the hidden layers. The neural network is trained using Adam optimiser and binary crossenthropy loss function.

4.3 Results and Analysis

4.3.1 Answer Sentence Classification Accuracy

For Hindi, the 10-fold cross-validation accuracy reported for answer sentence classification using UD to *kāraka* mappings is 80.17% while using our implemented *kāraka* annotator achieves 82.7%. These results highlight that for the binary answer sentence classification task both the approaches for *kāraka* extraction compare favorably for Hindi. For Marathi answer sentence classification, a comparatively less accuracy of 68.72% is reported.

4.3.2 Mean Reciprocal Rank

For further analysis, we use the Mean Reciprocal Rank (MRR) metric to evaluate the system's performance for retrieving correct answer sentences from a given context. For this we utilize the unseen test instances from dataset. This is the answer sentence selection accuracy for a given (question, context) pair. For computing this, every sentence from the given context is represented using *kāraka*-based features prepased using UD to *kāraka* approach. Further, the trained answer sentence classifier model predicts the sentence's probability score for being an answer to the given question. All sentences within a context are ranked in the decreasing order of the prediction scores. For a single query, the reciprocal rank is $\frac{1}{rank}$ where rank is the position of the actual answer sentence. For multiple queries Q, the MRR is the mean of the Q reciprocal ranks. For Hindi a MRR of 0.71 is reported while for Marathi MRR is 0.64. These results are summarized in table 3

	A	**B**
Hindi	80.17%	71.02%
Marathi	68.72%	64.93%

Table 3: A: Answer Sentence Classification Accuracy and B: MRR for Answer Sentence Selection using UD to *Kāraka* Mapping Approach

We observe less performance for Marathi compared to Hindi encouraging further exploration in this direction. This can be because the mapping from UD to *kāraka* for Marathi was not much refined as for Hindi. The mappings should have been obtained by generalization from several parallel (mutual translation) instances from Hindi and Marathi. Obtaining such a mapping requires careful examination of sufficiently general instances from a particular language. The drop in accuracy shows that when one tries to transfer such a mapping obtained for one language to other languages without a high level of linguistics expertise, even within the same family, one faces the challenge of choosing examples and handling exceptions. Further, the errors in the universal dependency parser can influence the overall performance of the answer retrieval. Also, the dataset used for analysis was translated from English and not a parallel corpora. For extraction of *kāraka*s, a standalone *kāraka* extractor developed in a data-driven pipeline is a better alternative to the identification of an indirect mapping through universal dependency relations that either require extensive linguistic analysis or parallel *kāraka* and UD annotated corpora for identification of mapping statistically. On the contrary, the *kāraka*-annotated corpus required for a data-driven approach to *kāraka* extraction can be developed by encoding speech patterns of a native language speaker without necessitating expert-level linguistic knowledge.

5 Conclusion

In this work, a *kāraka* based answer sentence retrieval approach is presented and its effectiveness is demonstrated through experimental analysis on a large benchmark corpus. The results clearly show that the accuracy of *kāraka* extraction impact the performance of answer retrieval, which emphasizes the need for further research and investment to enhance it. For languages lacking extensive lexical resources like PropBank and FrameNet and considering the scarcity of NLP resources for these languages, the proposed approach holds promise. We do not evaluate or dispute the usefulness of these alternative approaches. However, we observe that the identification of verb-specific semantic roles, which requires the development of comprehensive language-specific verb frames, poses a challenge, especially in low-resource languages. Our proposal is that *kāraka* annotation results into capturing semantic, facilitating tasks such as QA using smaller language models and lexicons.

Comparative Analysis of Named Entity Recognition in the Dungeons and Dragons Domain

Gayashan Weerasundara and **Nisansa de Silva**
Department of Computer Science & Engineering
University of Moratuwa, Sri Lanka
{gayashan.22, NisansaDdS}@cse.mrt.ac.lk

Abstract

Many NLP tasks, although well-resolved for general English, face challenges in specific domains like fantasy literature. This is evident in Named Entity Recognition (NER), which detects and categorizes entities in text. We analyzed 10 NER models on 7 Dungeons and Dragons (D&D) adventure books to assess domain-specific performance. Using open-source Large Language Models, we annotated named entities in these books and evaluated each model's precision. Our findings indicate that, without modifications, Flair, Trankit, and Spacy outperform others in identifying named entities in the D&D context.

1 Introduction

Named Entity Recognition (NER) targets the identification and classification of textual entities, such as names and locations. In the diverse and intricate vocabulary of fantasy literature, like that of Dungeons and Dragons (D&D), NER becomes challenging (Zagal and Deterding, 2018). D&D, a prominent fantasy literature domain, spans content for its namesake tabletop game (Peiris and de Silva, 2022, 2023; Zhou et al., 2022). These narratives inhabit fictional realms like Forgotten Realms and Dragonlance, bursting with characters, locations, and objects (Gygax and Arneson, 1974).

NER's utility in fantasy literature is vast: from extracting information and summarizing text to character analysis and plot creation. However, conventional NER models, primarily trained on standard datasets like CoNLL-2003 (Tjong Kim Sang and De Meulder, 2003) or OntoNotes 5.0 (Weischedel et al., 2013), might falter on fantasy texts due to their unique linguistic attributes. Recognizing the need for domain-specific adaptation, other specialized areas such as law (Sugathadasa et al., 2017), medicine (de Silva et al., 2017), and the dynamic landscape of social media (de Silva and Dou, 2021) have already seen research emphasizing it. Large models, as Yao et al. (2021) points out, can face domain adaptation challenges, stressing the need for evaluating NER models specifically on fantasy content.

Fantasy NER has potential, especially with advancements in image generation. A notable application might involve an image generation model leveraging NER tags to derive prompts and subsequently produce contextually relevant images.

Our study contrasts 10 NER models across seven D&D books, each averaging 118,000 words. Manual annotations of entities were made and juxtaposed against model outputs. Through precision assessments and named entity distribution analyses, we glean insights into model performances in the fantasy domain. Our key contributions include:

- A pioneering, comprehensive NER model evaluation on fantasy content.
- An annotated D&D book dataset for NER studies.
- A deep dive into varied NER models' strengths and pitfalls in the fantasy realm.
- Discussions on NER's role and prospects in fantasy literature.

Following this, Section 2 delves into related NER and fantasy literature works. Section 3 details our data and annotation process, while Section 4 unveils our methods and findings. Sections 5 and 6 respectively discuss insights and conclude our research, and Section 7 outlines potential future endeavors.

2 Related Works

NER has seen the development of various models like rule-based systems, statistical models, neural

Proceedings of Recent Advances in Natural Language Processing, pages 1225–1233
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_130

networks, and transformer-based models (Seo et al., 2021; Liu et al., 2022; Krasnov et al., 2021). Although they've been trained on standard datasets, these don't encompass the complexities found in domains like fantasy literature, which poses challenges due to invented names, variable spellings, entity ambiguity, and limited resources.

We introduced a novel annotated dataset of D&D books for NER and evaluated 10 NER models, including XLM-RoBERTa (Conneau et al., 2019), StanfordDeID (Chambon et al., 2023), ELECTRA (Clark et al., 2020), and others.

Other studies have compared the performance of NER models on different types of texts and languages. For example, Wang et al. (2021) compared Spacy, Flair, m-BERT, and camemBERT on anonymizing French commercial legal cases. They found that camemBERT performed the best overall, followed by Flair and m-BERT. SpaCy had the lowest scores but also the fastest prediction time. (Benesty, 2019) compared spaCy, Flair, and Stanford Core NLP on anonymizing English court decisions. They found that Flair had the highest scores, followed by Stanford Core NLP and spaCy. (Shelar et al., 2020) compared rule-based, CRF-based, and BERT-based techniques for NER on text data. They found that BERT-based technique had the highest accuracy and recall, followed by CRF-based and rule-based techniques. (Naseer et al., 2021) compared NLTK, spaCy, Stanford Core NLP, and BERT (Devlin et al., 2018) on extracting information from resumes. They found that BERT had the highest accuracy and F-measure, followed by spaCy, Stanford Core NLP, and NLTK.

These studies suggest that different NER models may have different strengths and weaknesses depending on the type, language, and domain of the text data. Our study aims to contribute to this understanding by providing the first systematic comparison of NER models on fantasy texts and analyzing their performance and characteristics.

3 Data Collection and Annotation

This section details the data sources and annotation process utilized for our named entity recognition (NER) task, a subtask of information extraction that classifies named entities in unstructured text into categories such as persons, organizations, and locations (Mohit, 2014).

We examined seven adventure books from the Dungeons and Dragons (D&D) realm, listed in table 1. These books, primarily adventure-centric, were sourced from the official DnDBeyond site, the main publication hub for D&D by Wizards of the Coast.

Through a comprehensive analysis of these texts, we used their rich narratives and character dynamics to benchmark and assess various NER models in this intricate domain.

Book	**Counts**	
	Words	**Topics**
Lost mine of Phandelver (Baker and Perkins, 2014)	45947	29
Hoard of the Dragon Queen (Baur et al., 2014a)	74243	45
Rise of Tiamat (Baur et al., 2014b)	80065	48
Curse of Strahd (Perkins et al., 2016)	154519	62
Tomb of Annihilation (Perkins et al., 2017)	148605	35
Candlekeep Mysteries (Perkins et al., 2021)	141104	106
The Wild Beyond the Witchlight (Allan et al., 2021)	184135	60

Table 1: D&D adventure books

Each of our chosen books averages 118,000 words. The selection was driven by our familiarity with these tales and the broader D&D universe. Additionally, they span multiple genres, themes, and settings in the fantasy realm, offering a vast array of named entities for NER.

The source books were transformed into text and organized hierarchically into chapters, topics, and paragraphs. An example from ”The Wild Beyond the Witchlight” is displayed in table 2.

We first manually perused the source books, marking named entities hierarchically by chapter, topic, and paragraph, recording only entity counts. Subsequently, we employed three state-of-the-art large language models: Bloom (Scao et al., 2022), OpenLLaMA (Geng and Liu, 2023), and Dolly (Databricks, 2023), to detect named entities in each book chapter. These models, trained on vast conversational data, can craft natural language responses, making them apt for the intricate language patterns in D&D texts, such as neologisms and metaphors.

After eliminating duplicates and pinpointing unique entities, we verified these results against our initial counts. The named entities identified by the three LLMs underwent a manual review for accuracy and consistency, adding crucial missed entities. Table 3 contrasts the named entity counts from each LLM, with recall metrics based on entities common across all models.

When annotating the resultant named entities we followed a set of annotation guidelines that define the entity types and the annotation rules for our NER task. The entity types that were used are:

Chapter	Topic	Paragraph	Word Count
Introduction: Into the Feywild	Adventure Summary	The main antagonists of this story are three hags...	131
		One of the many novelties of this adventure is that...	43
		The characters are drawn into the adventure by one of two adventure hooks. You choose...	31
		Chapter 1 describes the Witchlight Carnival...	40
		...	...
	Running the Adventure	The Monster Manual contains stat blocks for most of the creatures encountered in this...	72
		Spells and equipment mentioned in the adventure are described in the Players Handbook...	31

Table 2: Content hierarchy in a book

- Person: any named character or creature that can act as an agent, such as heroes, villains, allies, enemies, etc.
- Organization: any named group or faction that has a common goal or identity, such as guilds, cults, clans, etc.
- Location: any named place or region that has a geographical or spatial dimension, such as cities, dungeons, forests, etc.
- Misc: any named entity that do not belong to above mentioned categories. (This contain important information like Spells, Artifacts, Potions etc.)

The process of annotation is done through a script, where a paragraph segment is taken iteratively and fed into the LLMs with a template prompt.

Following Algorithm 1 is the pseudo-code for the process in identifying named entities:

```
Input: Books;
Output: Named entities;
foreach book do
    segments ← divideIntoSegments(book);
    foreach segment in segments do
        paragraphs ←
          divideIntoParagraphs(segment);
        foreach paragraph in paragraphs
          do
            foreach LLM in LLMs do
                prompt ←
                  createPrompt(paragraph);
                namedEntities ←
                  LLM(prompt);
                processNamedEntities(namedEntities);

            end
        end
    end
end
removeDuplicates(namedEntities);
```

Algorithm 1: Named Entity Recognition using Multiple LLMs

As shown in above pseudocode, the algorithm 1 takes a set of books as input and outputs the named entities identified by the LLMs. The algorithm iterates over each book and divides it into segments. Each segment is further divided into paragraphs, and each paragraph is iteratively fed into each of the LLMs with a prompt to identify named entities. The named entities identified by each LLM are then processed and saved. Finally, all named entities are checked for duplicates, and those duplicates are removed.

After named entities were recognized, they were then mapped in to json objects for storage as shown in Figure 1. Nesting of objects is done according to the hierarchy as mentioned in table 2. Each of the named entities were nested in an array of entities as entity objects with corresponding attributes as mentioned bellow.

4 Experimental Setup and Results

The experiment was conducted to identify how effective are the NER models when using them as off the shelf models in identifying named entities for a fantasy domain when there are no available corpora for fine tuning. For testing we used 10 different contemporary NER midels.

Following table 5 shows the identified count of named entities for each categories of the adventure book Candlekeep Mysteries.

The testing approach for the NER models mirrors algorithm 1. Here, paragraphs of input text are fed into the models without specific prompts.

Book	Bloom		Dolly		OpenLLaMA		Total Unique Entities
	Count	Recall	Count	Recall	Count	Recall	
Lost Mine of Phandelver	21	0.47	32	0.73	40	0.91	44
Hoard of the Dragon Queen	58	0.89	62	0.95	60	0.92	65
Rise of Tiamat	54	0.88	57	0.93	53	0.87	61
Curse Of Strahd	92	0.90	96	0.94	101	0.99	102
Tomb of Annihilation	101	0.80	99	0.79	112	0.89	126
Candle keep Mysteries	60	0.87	61	0.88	64	0.93	69
The Wild Beyond Witch Light	66	0.84	67	0.85	71	0.89	79

}
```

Figure 1: sample format of the JSON output

The resultant output is refined by filtering out corrupted values (e.g., ”Strahd Von Zarovich” might be mistakenly split into two distinct names) and redundant entries, before being transitioned into the JSON structure showcased in Figure 1.

During initial processing, NER models often produce numerous erroneous outputs. These arise from factors like incomplete word detection, missegmentation of terms, or misinterpretation of special characters. Such discrepancies can be mitigated using string manipulations and by cross-referencing outputs with a pre-curated list of named entities.

Figure 2 displays entries that encountered corruption. These highlight instances where NER models incorrectly processed and extracted entities from the source material.

In the given example shown in Figure 2, the name ”Fembris Larlancer” is erroneously divided into two distinct words, ”Fembris L#” and ”rlancer”, as a result of corruption during the NER processing stage. This example underscores the challenges faced during the entity extraction pro-

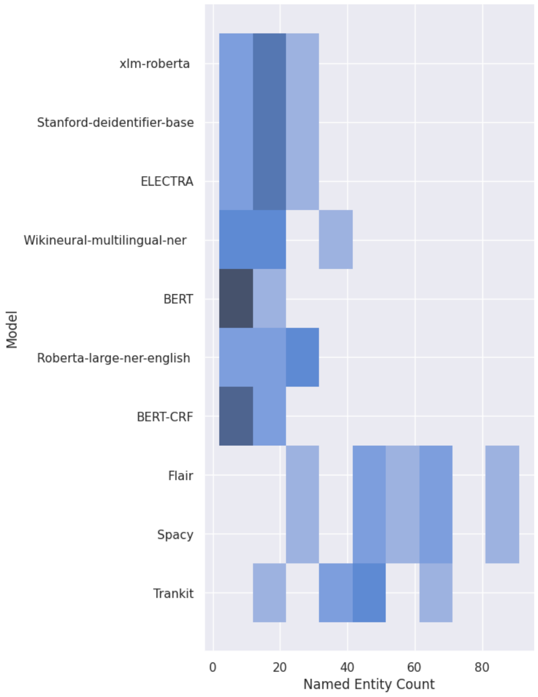

Figure 3: Density plot for each model

cess and the need for robust post-processing to ensure the accuracy and quality of the extracted entities.

After removing corrupted and eligible named entities, duplicate entries must be removed to do a proper comparison of performance between different models. For this tuples of words in adjacent positions were generated and compared. For example Mayor Lei Duvezin, Mayor Duvezin, Lei Duvezin and Duvezin all refers to the same entity with the label Person. In cases such as above tuple with most similarity matches will be retained as the named entity and duplicates will be removed.

To visualize the raw named entity identification potential of each model, a density plot was plotted with respect to count of identified named entities with NER models. Following Figure 3 shows the density of named entities recognized by each NER model. The hue represents the overlapping count ranges of named entities identified in each source book.

Without training, NLP frameworks like Trankit (Nguyen et al., 2021), Flair (Akbik et al., 2018), and Spacy (Honnibal and Montani, 2017) show a strong baseline in entity recognition.

Model precision is key in performance evaluation. This is gauged by comparing the true positive entities with actual named entities. This comparison can be visually represented for each model across source books.

For a comprehensive model assessment across books, Kernel Density Estimation (KDE) is used. It's a non-parametric method estimating the probability density function (Terrell and Scott, 1992):

$$f(x) = \frac{1}{nh} \sum_{i=1}^{n} K\left(\frac{x - x_i}{h}\right)$$

where:

- xi are the data points
- K is the kernel function, which is typically a Gaussian function or a uniform function
- h is the bandwidth, which determines the width of the kernel function and controls the smoothness of the estimate
- n is the number of data points

KDE calculates $f(x)$ through a summed kernel function $K(u)$, anchored at data points x_i.

Figure 4 illustrates models' efficacy over seven source books. A gradient near 1 signifies optimal performance.

In DD, named characters, with their elaborate backstories, are central. Assessing a model's inclination to identify these characters over other entities is vital. This inclination can be visualized by juxtaposing character counts with total entities, contrasted against real metrics. Figure 5 delineates the frequency of character identification across all source books. Meanwhile, Figure 5a and Figure 5b depict the distribution pertaining to models and books, respectively.

In the D&D landscape, named characters, renowned for their intricate histories, are paramount. Evaluating a model's propensity to spot these characters in relation to other entities is imperative due to the significant role characters play in D&D narratives. This bias can be graphically represented by mapping character counts against all identified entities and contrasting them with authentic counts. By scrutinizing the named entity counts from diverse NER models and comparing them to true values, one can infer model behavior and efficacy. Figure 5 offers a glimpse into character recognition frequency for different models across sourcebooks, with Figure 5a and Figure 5b charting the distributions for models and books respectively.

From Figure 5b, we observe a consistent ratio between characters and other named entities across books. This consistency allows us to downplay book variability and focus on the insights from Figure 5a. Notably, NLP frameworks such as Spacy (Honnibal and Montani, 2017) and Flair (Akbik et al., 2018) exhibit more balanced frequency distributions, indicating a higher character identification ratio. Although this might be unfavorable in certain contexts, in this domain, aligning character identifications closely with overall named entity values signals optimal performance. This suggests Spacy and Flair perform exceptionally in an off-the-shelf setting.

Figure 6 showcases precision and recall metrics for each NER model. To determine recall, we derived the true positive count from average unique named entity counts, while the true count originated from LLM models, as outlined in table 3. For precision, false positives were ascertained from misidentified unique named entities on average.

The precision and recall values were averaged for each model across source books, and plotted to offer a concise visualization of each NER model's performance.

Evidently, Flair and Spacy outshine other NER models in precision and performance, while Trankit (Nguyen et al., 2021) excels in recall relative to its precision.

5 Discussion

We undertook a Named Entity Recognition (NER) task on seven adventure books from the esteemed Dungeons and Dragons (D&D) series. Our methodology involved manual entity annotations in these books, which were subsequently verified against outputs from three leading language models: Bloom, OpenLLaMA, and Dolly.

Our annotation guidelines delineated entity types into categories like person, organization, location, and misc. Ten NER models were subsequently employed to gauge their efficacy in recognizing named entities within D&D. Among these, Flair, Trankit, and Spacy emerged superior, mirroring findings from past NER-centric studies. Conversely, StanfordDeID (Chambon et al., 2023) and RoBERTaNER (Baptiste, 2022) lagged in performance. A precision-centric analysis further reiterated the dominance of Flair, Trankit, and Spacy over their counterparts.

The findings imply that while generic models can decently handle NER tasks in specialized domains like D&D, performance inconsistencies exist across models. Employing annotation guidelines bolsters consistency in entity recognition across varied books and contexts. Moreover, incorporating large language models for automated annotations can significantly mitigate the manual intervention needed for comprehensive datasets, particularly in intricate domains such as D&D.

However, our study bears certain caveats. We refrained from fine-tuning the NER models specifically for D&D, so our findings are indicative of generic model capabilities and might not capture the full potential of domain-specific optimization. Our dataset, comprising just seven books, might not encompass the depth and breadth of D&D narratives. The exclusive focus on Wizards of the Coast publications could also inadvertently introduce stylistic biases. Finally, while our study zeroes in on D&D as a fantasy subset, our insights might not seamlessly extend to other literary domains with their unique nuances.

6 Conclusion

Our exploration illuminates the remarkable potential of harnessing off-the-shelf models for NER tasks within the D&D universe's nuanced realm. Some models showcase an impressive baseline in entity recognition for this domain without extensive fine-tuning. However, there's a compelling need for

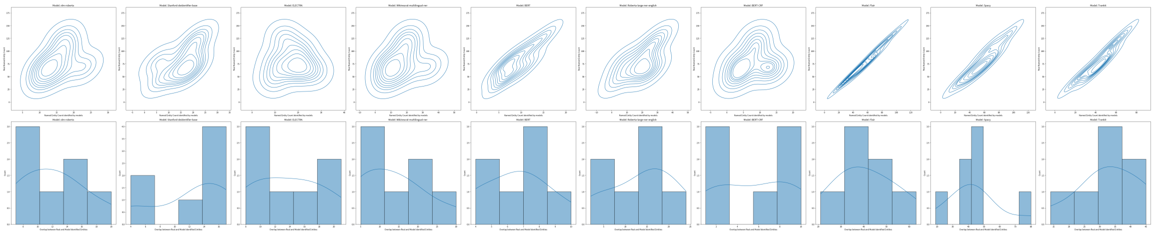

Figure 4: Distribution plot for each model

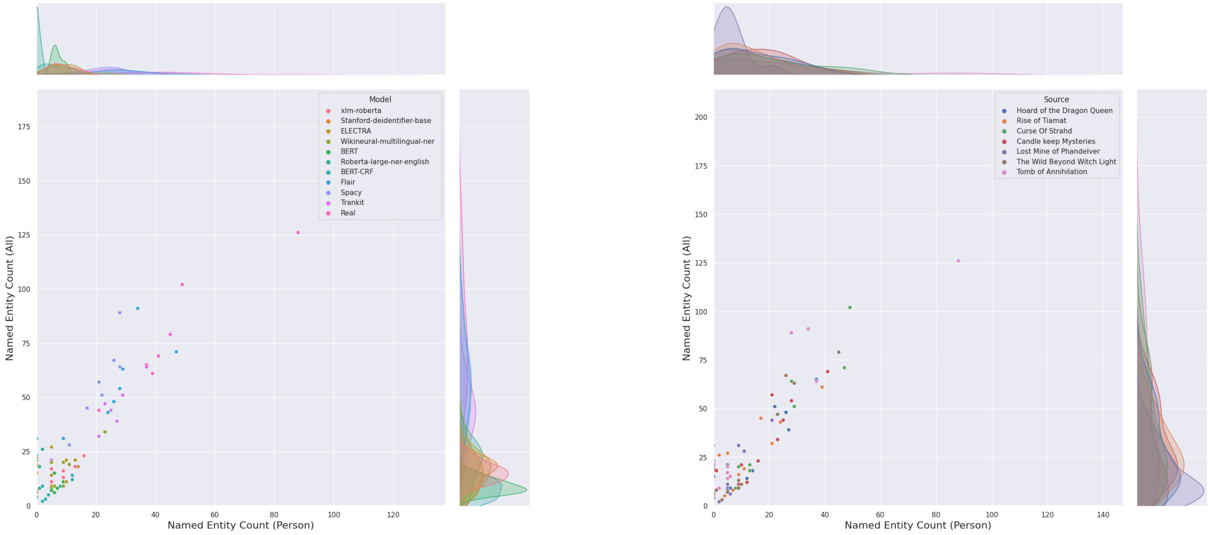

(a) Models

(b) Adventure sourcebooks.

Figure 5: Frequency plots with respect to models and adventure sourcebooks

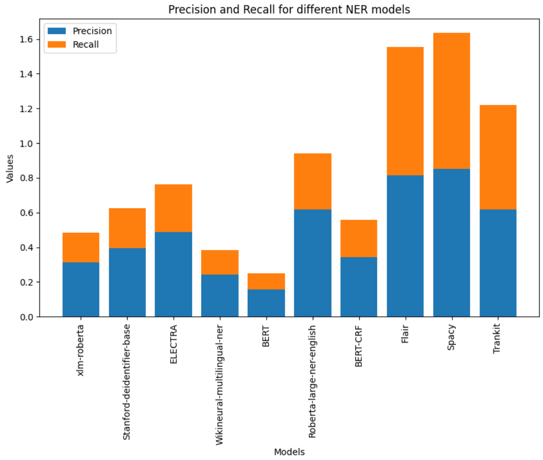

Figure 6: Precision graph for different NER models

continued research and refinement to tailor these models optimally for D&D's unique intricacies.

Additionally, our research serves as a foundational resource for future inquiries. The dataset we've curated and our annotation guidelines stand as a benchmark for gauging the efficiency of future NER models or techniques. Consequently, our work not only reveals the current prowess of NER models within the D&D context but also sets the stage for continued innovation at the confluence of fantasy literature and artificial intelligence.

7 Future Works

Based on our findings and limitations, we suggest some directions for future research. One direction is to fine-tune NER models on the D&D dataset and comparing their performance with off-the-shelf models. Additionally, other techniques such as transfer learning or domain adaptation could be explored to improve the performance of NER models in the D&D domain. Another direction is to use different data sources for NER in D&D, such as novels, comics, podcasts, or video games. A third direction is to apply different evaluation metrics for NER in D&D, such as F1-score, recall, accuracy, or error analysis. Finally other aspects of NER in D&D can also be explored, such as entity linking, coreference resolution, relation extraction, or sentiment analysis.

Abstract

Text anomaly detection (TAD) is a crucial task that aims to identify texts that deviate significantly from the norm within a corpus. Despite its importance in various domains, TAD remains relatively underexplored in natural language processing. This article presents a systematic evaluation of 22 TAD algorithms on 17 corpora using multiple text representations, including monolingual and multilingual SBERT. The performance of the algorithms is compared based on three criteria: degree of supervision, theoretical basis, and architecture used. The results demonstrate that semi-supervised methods utilizing weak labels outperform both unsupervised methods and semi-supervised methods using only negative samples for training. Additionally, we explore the application of TAD techniques in hate speech detection. The results provide valuable insights for future TAD research and guide the selection of suitable algorithms for detecting text anomalies in different contexts.

1 Introduction

Anomaly detection is a fundamental process in data analysis, aiming to identify inconsistent data points that deviate significantly from expected behaviors or established norms within a dataset. Such anomalies can emerge from various factors, including human errors, malicious behaviors, unusual events, or unexpected changes. Effective anomaly detection can facilitate swift problem recognition, proactive measures for error correction, and future problem prevention. It enhances data quality, aids in risk identification, and empowers decision-making across diverse domains, with its utility extending to various data types such as tabular data, graphs, time series, texts, images, and videos.

In the context of text data, the anomalies refer to specific texts or textual fragments that deviate significantly from established norms, which can be determined based on the overall text or corpus, regular language usage, or common sense. These anomalies may manifest at various linguistic levels, such as orthographic (spelling), lexical (word usage), syntactic (sentence structure), semantic (meaning), and discourse (overall context) levels (Wang et al., 2014; Saranya et al., 2014; Wahl, 2021; Sufi and Alsulami, 2021). Detecting anomalies in text data holds vital importance in applications like language development assessment, plagiarism detection, quality control in data processing, and identifying abnormal language usage in cybersecurity (Cichosz, 2020; Szoplák and Andrejková, 2021).

In this article, we concentrate on Text Anomaly Detection (TAD) at the semantic and discourse levels, where norms are established on a corpus scale. It is important to note that the definition of anomalies can be further refined and may slightly differ according to specific contexts. For instance, in the realm of competitive intelligence, anomalies often relate to abnormal themes or topics, while in the field of online reputation monitoring, they typically pertain to negative sentiments.

Despite the broad utility of TAD and the potential benefits it offers, TAD has not been as extensively explored as other topics within Nature Language Processing (NLP). While previous research works have approached the field of TAD, they have often been limited either by the scope of algorithms considered or by the range of textual representations evaluated (Barrett et al., 2019; Pantin et al., 2022). Unlike these studies, this paper aims to provide a comprehensive overview of TAD by evaluating a wide array of algorithms on several corpora across different languages, making our approach distinctive in its breadth and depth.

Our primary objective is to provide a systematic evaluation of 22 TAD algorithms applied to 17 corpora across three languages. We assess these algo-

Proceedings of Recent Advances in Natural Language Processing, pages 1234–1245
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_131

rithms' performance in detecting textual anomalies and examine the use of various text representations, including monolingual and multilingual Sentence-BERT (SBERT) (Reimers and Gurevych, 2019). Additionally, we investigate the potential application of TAD techniques in detecting hate speech, aiming to gain insights into the effectiveness of TAD in this specific domain.

2 Related Work

Text Anomaly Detection (TAD) stands as a comparatively less explored intersection of Data Mining (DM) and Natural Language Processing (NLP). While extensive research has been conducted in DM dedicated to anomaly detection, scant attention has been given to the application of these techniques to text data. On the other side of the spectrum, NLP, despite significant progress in text understanding and generation, exhibits a noticeable deficiency in research focusing on the detection of anomalous text. Consequently, dedicated algorithms for text data anomaly detection are rare, and corpora specific to this task are either completely inaccessible or simply nonexistent.

Anomaly Detection Algorithms In the DM field, a wealth of systematic analyses and evaluations of anomaly detection algorithms have been carried out (Markou and Singh, 2003a,b; Chandola et al., 2009; Pimentel et al., 2014; Aggarwal, 2015, 2017; Chalapathy and Chawla, 2019; Pang et al., 2021). However, these studies have largely overlooked the performance of these algorithms on text data. In contrast, within the NLP realm, research efforts were largely channeled towards adapting techniques proposed for other domains, such as image and video data, to handle text data. However, these studies often adopted a narrow focus, examining a particular algorithm and contrasting it against a limited set of others (Drozdyuk and Eke, 2017; Ruff et al., 2019; Jafari, 2022). This resulted in a fragmented and insufficiently broad approach that fell short of providing an all-encompassing assessment of various anomaly detection methods' performance on text data. To address this deficiency, recent efforts have been made by researchers. Yap et al. (2020) proposed an algorithm based on Generative Adversarial Networks (GAN) (Goodfellow et al., 2014), contrasting its performance against state-of-the-art methods like CVDD (Ruff et al., 2019). Barrett et al. (2019) undertook a comparative study of six algorithms using three corpora and four representation strategies, namely TF-IDF, One-hot, Bag of Words, and PCA. In a significant systematic endeavor, Pantin et al. (2022) compared ten algorithms on two corpora using a novel anomaly generator, GenTO.

Data The scarcity or complete absence of human-annotated anomaly detection corpora presents a considerable challenge in anomaly detection. The rarity of anomalies and the subjectivity involved in defining and annotating them contribute to this scarcity. To counteract this problem, three main strategies have been proposed in the literature. The first strategy involves leveraging artificially generated data to construct a corpus, with a particular focus on creating anomaly samples (Christophe et al., 2019). The second strategy combines diverse text sources to create a corpus, drawing "normal" examples from one source and anomalies from another (Dasigi and Hovy, 2014). The third and most common approach involves adapting existing corpora originally created for different tasks for anomaly detection. In this approach, researchers often repurpose corpora that are initially designed for tasks such as topic or sentiment classification. Datasets commonly used in this context include Reuters (Barrett et al., 2019; Yap, 2020; Han et al., 2022; Pantin et al., 2022), AGNews (Zeng et al., 2022; Han et al., 2022), 20NewsGroups (Barrett et al., 2019; Hu et al., 2021; Pantin et al., 2022), and IMDB (de la Torre-Abaitua et al., 2021; Han et al., 2022).

Text Representation Techniques Finally, in TAD, as with many other text classification tasks, the choice of text representation techniques is critical. While traditional encoding strategies such as Bag of Words (BoW) and Term Frequency-Inverse Document Frequency (TF-IDF) are prevalent (Barrett et al., 2019; Pantin et al., 2022), the text embeddings generated by pre-trained models, like Sentence-BERT (SBERT)(Reimers and Gurevych, 2019), remain relatively underutilized in this field. This limited adoption of contextual embeddings presents promising area for exploration and potential improvement in TAD methodology. The systematic evaluation of TAD algorithms on various text representation techniques could yield significant insights and drive advancements in this field.

3 Comparative Analysis of Text Anomaly Detection Algorithms

3.1 Corpus Assembly

Dataset Selection Due to the absence of a dedicated corpus to Text Anomaly Detection (TAD), we have repurposed various datasets that were originally designed for different NLP tasks. In this study, we utilized a collection of 14 datasets, each primarily designed to address either binary or multiclass text classification challenges, covering a wide range of application scenarios (refer to Table 1). Our selection includes datasets employed for topic or thematic classification (TC) and sentiment analysis (SA), which are common in the literature, and those used for hate speech detection (HD). The inclusion of the latter is intended to explore the potential of considering hate speech and offensive language as forms of textual anomalies. In contrast to many previous studies that have solely focused on English, our datasets encompass texts in three different languages: English, French, and Chinese. The data we used were collected from a variety of sources, including news agencies (such as ABC News and Reuters), forums (like Stormfront), social media platforms (Twitter, Weibo, and others), and various websites (Amazon, IMDB, etc.).

Dataset Adaptation We curated 17 different corpora for TAD based on the datasets mentioned above (see Table 1). In order to adapt these datasets to TAD, we employed the following strategies:

1. For TC data, we selected pairs of topics/themes, designating one as the "normal" class and the other as the "anomalous" class. If the available number of documents for a topic/theme was insufficient to form a class, we combined two or more topics/themes into one class.

2. For SA data, if labels were in the form of sentiment polarity, we labeled the "positive" class as "normal" and the "negative" class as "anomalous". If the data was annotated on a 5-point evaluation scale, we classified texts with 1 or 2 points as "anomalous" and those with 4 or 5 points as "normal".

3. For HD data, in the case of binary classification, we designated the "positive (hateful/offensive)" class as "anomalous" and the "negative" class as "normal". For multi-class classification, we grouped different types of hate speech into an "anomalous" class and non-hateful texts into a "normal" class.

4. To ensure comparability across datasets, we uniformly set the anomaly ratio to 10%. This decision aligns with common practice in the field, where a 10% anomaly ratio is frequently used (Pantin et al., 2022). Moreover, it is consistent with the default contamination rate usually adopted in anomaly detection tools (Buitinck et al., 2013; Zhao et al., 2019).

5. We created the corpora by conducting stratified random sampling from the datasets, respecting the predefined anomaly ratio.

3.2 Text Representation

The texts in the corpora are transformed into vectors using two distinct strategies: TF-IDF (Term Frequency-Inverse Document Frequency) and SBERT (Sentence-BERT) (Reimers and Gurevych, 2019). The selection of these techniques formed an essential step in preparing the data for the subsequent application of anomaly detection algorithms.

The TF-IDF technique was employed to generate vectors where the weighting of each term was determined by its frequency within a document but inversely proportional to its frequency across the entire corpus (represented by the training subset in our case).

Simultaneously, we utilized Sentence-BERT (SBERT) (Reimers and Gurevych, 2019) to generate embeddings for our text data. SBERT is a modification of the pre-trained BERT network that allows for the computation of semantically meaningful sentence embeddings. To account for linguistic variations across our multilingual dataset, we employed a selection of pre-trained monolingual SBERT models specific to each language under consideration: all-mpnet-base-v2 (en), all-MiniLM-L6-v2 (en), all-distilroberta-v1 (en), sentence-camembert-large (fr), sentence-camembert-base (fr), text2vec-base-chinese (zh), sbert-base-chinese-nli (zh), and sbert-chinese-dtm-domain-v1-distill (zh). To further diversify our text representation and explore potential generalizability across languages, we also incorporated multilingual SBERT models into our study. These models, such as distiluse-base-multilingual-cased-v1, paraphrase-multilingual-mpnet-base-v2, and paraphrase-multilingual-MiniLM-L12-v2, were chosen based on their

Table 1: Overview of the Datasets Utilized for Corpus Construction. The table provides details about each corpus, including the corpus ID, the original dataset name along with its citation, the source of the texts, the original task for which the dataset was created (TC: Topic Classification, SA: Sentiment Analysis, HD: Hate Speech Detection), the size of the corpus, and the tags used to denote anomalies and normal data.

demonstrated performance in processing a variety of languages, aligning well with the linguistic diversity present within our corpora.

3.3 Algorithm Comparison

In this study, we conducted an investigation of 22 distinct algorithms (refer to Table 2) on 17 different corpora. Considering the diverse taxonomy of approaches proposed in the literature (Chandola et al., 2009; Pimentel et al., 2014; Aggarwal, 2017), we opted to classify the algorithms from three unique angles: the utilization of neural networks, the degree of supervision, and the underlying theory driving the method. This approach not only allowed us to compare individual algorithmic performances, but also facilitated a comparison of categories of algorithms against each other.

Neural Networks Based on their architecture, the algorithms can be divided into two distinct types: deep algorithms that harness neural networks, and shallow algorithms that do not employ them (Han et al., 2022).

Supervision Based on the degree of supervision, or the extent to which they rely on labels, we can distinguish three categories of algorithms: supervised, semi-supervised, and unsupervised. Given the rarity of anomalies, procuring sufficient labels for abnormal (or positive) data often poses a significant challenge. Hence, within the domain of TAD, our primary focus is on the latter two types of algorithms: semi-supervised and unsupervised algorithms.

- **Semi-supervised algorithms** make use of partially labeled data for training. Certain anomaly detection techniques, such as OCSVM and LOF, assume that only normal (negative) instances are available during the training phase, leading them to be also known as “novelty detection” algorithms. In contrast, other algorithms leverage labeled and unlabeled data, utilizing the labeled data, which includes information about both normal and abnormal instances, to guide the learning process. By learning from the labeled data, these algorithms seek to predict anomalies in the unlabeled data, thereby detecting instances that deviate from normal behavior. Recently proposed algorithms like XGBOD (Zhao and Hryniewicki, 2018) and DevNet(Pang et al., 2019) demonstrate the ability to exploit weak labels, which could be limited or noisy. These algorithms are designed to perform effectively even when the available labels for abnormal instances are neither exhaustive nor accurate.

- **Unsupervised algorithms** do not rely on labeled data during the training process. The training set consists of both normal and abnormal instances, resulting in a dataset considered to be contaminated with outliers. These methods aim to identify anomalies in a dataset by exclusively analyzing the characteristics and patterns present in the unlabeled data. Unsupervised methods are grounded in the concept that anomalies significantly diverge from the expected behavior of the majority of the data points.

Underlying Theory Anomaly detection algorithms assess the abnormality or deviation of each

Table 2: Overview of Investigated Anomaly Detection Algorithms: Algorithm ID, Full Algorithm Name, Original Paper Citation, Degree of Supervision, Underlying Theory, and Model Architecture (Deep/Shallow)

data point by calculating an anomaly score. This score is then contrasted against a predefined threshold set for the entire dataset. Anomaly detection algorithms can be categorized into five groups based on the underlying theory driving the algorithm and methodology used to calculate the anomaly score.

- **Probabilistic or statistical algorithms** function by estimating the generative probability density function of the data. They model the probability distribution of the data using probability and statistical tools, such as Gaussian distribution or logistic regression. Data points that yield a low probability of conforming to the distribution model are considered as potential anomalies.

- **Proximity-based algorithms** identify a data point as an anomaly if it is surrounded by a sparsely populated or dissimilar neighborhood. The anomaly score is calculated based on the degree of deviation or isolation of a data point from its immediate neighbors. Based on their definition of proximity, these techniques are further classified into three subcategories: cluster-based algorithms, density-based algorithms, and distance-based algorithms.

- **Domain-based algorithms** utilize training data to define a domain that encapsulates the normal class. The model created in this process describes the boundary or region of the normal class and determines whether a data point belongs to this class based on its position relative to the boundary. The anomaly score is typically derived from the distance or proximity of a data point to the boundary of the designated normal region (Pimentel et al., 2014).

- **Reconstruction-based algorithms** aim to compress the data into a space of lower dimensionality and subsequently reconstruct the original data from this condensed representation. The reconstruction error, defined as the difference between the original and the reconstructed data, is used to compute the anomaly score. The principle is straightforward: the greater the reconstruction error, the higher the likelihood of the data point being anomalous (Pimentel et al., 2014).

- **Ensemble algorithms** combine the outputs from multiple base algorithms or detectors to create a unified, more robust output (Aggarwal, 2017). These algorithms leverage the diversity of individual detectors and strive to enhance the overall performance by aggregating their results. Common ensemble techniques include voting, averaging, stacking, and boosting, among others.

4 Experiments

4.1 Experimental Settings

Evaluation A multitude of metrics are traditionally employed to gauge the effectiveness of anomaly detection algorithms. These include Precision, Recall, F-score, ROC AUC (Area Under the Receiver Operating Characteristic Curve), PR

AUC (Precision-Recall Area Under the Curve), and MCC (Matthews Correlation Coefficient) (Manevitz and Yousef, 2001; Dasigi and Hovy, 2014; Ruff et al., 2019; Todd et al., 2020; Pantin et al., 2022; Barrett et al., 2019). In this study, we have chosen to focus on ROC AUC, the most prevalent metric within the domain of anomaly detection. In this context, the ROC (Receiver Operating Characteristic) curve plots the true positive rate ($sensitivity$) against the false positive rate ($1 - specificity$) over a range of threshold settings. The ROC AUC score, a numerical value between 0 and 1, offers an indicative measure of the classification capability of the model. A score of 0.5 corresponds to a random classifier, while a score of 1 signifies a perfect classifier. A model's capacity to distinguish between normal and anomalous instances is typically associated with a higher ROC AUC score.

Data Partitioning and Independent Trials To ensure the robustness of our experimental findings, we employed a 10-fold cross-validation methodology for data partitioning. In each fold, 90% of the data was reserved for training and the remaining 10% for testing purposes. Stratified sampling ensured a consistent anomaly ratio across both the training and test sets within each fold. Anomaly detection models were individually trained on the data from each fold and subsequently evaluated against the corresponding test set. The average ROC AUC score, calculated over all 10 folds, served as the aggregate measure of the model's ability to accurately differentiate between normal and anomalous instances.

Hyperparameters It is common practice to run an algorithm multiple times to select the parameters that optimize the ROC AUC. However, this approach is not suitable for anomaly detection as it inadvertently introduces a form of supervision by using knowledge of the anomaly labels to select parameters (Aggarwal, 2017). To ensure a fair comparison, it is essential to adhere to an unsupervised approach. Therefore, in this work, we strictly employ the default hyperparameter settings as provided in the original papers of all the algorithms.

Implementation The experiments were conducted using three Python libraries: scikit-learn (Buitinck et al., 2013), PyOD (Zhao et al., 2019), and DeepOD (Xu, Hongzuo).

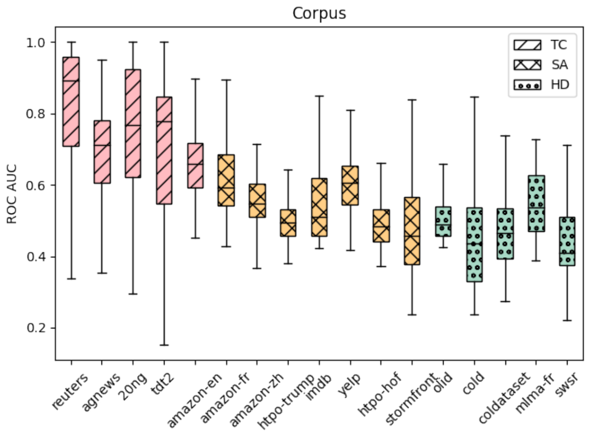

Figure 1: Performance (avg. ROC AUC) comparison of anomaly detection algorithms across 17 corpora grouped by original tasks: Topic Classification (TC), Sentiment Analysis (SA), and Hate Speech Detection (HD)

4.2 Results and Discussion

Corpus Figure 1 illustrates the performance of the 22 algorithms tested across 17 diverse corpora, which are divided into 3 categories: corpora for topic classification (TC), sentiment analysis (SA), and hate speech (HD). Notably, the TC corpora achieve the highest scores, with a median ROC AUC of 0.768. In contrast, the HD corpora, incorporated into TAD testing for the first time, exhibit a median ROC AUC of 0.474. This suggests a performance level below random chance, indicating that the TAD algorithms have room for improvement when it comes to effectively identifying hate speech. It's important, however, to bear in mind that the TC corpora mainly comprise press texts, while the HD corpora are largely made up of noisy social media texts. Further experiments are necessary to evaluate and mitigate the potential impact of textual noise on algorithm performance.

Text Representation Figure 2 presents the performance of algorithms categorized based on the representations used: TF-IDF model, monolingual SBERT models, and multilingual SBERT models. The TF-IDF model shows fairly stable results, albeit with a noticeably lower upper limit compared to SBERT models. Among the monolingual SBERT models, the Chinese models exhibit weaker performance, indicated by a median ROC AUC of 0.464, which is significantly beneath the level of random chance. This could be due to the specific concentration of Chinese corpora on hate

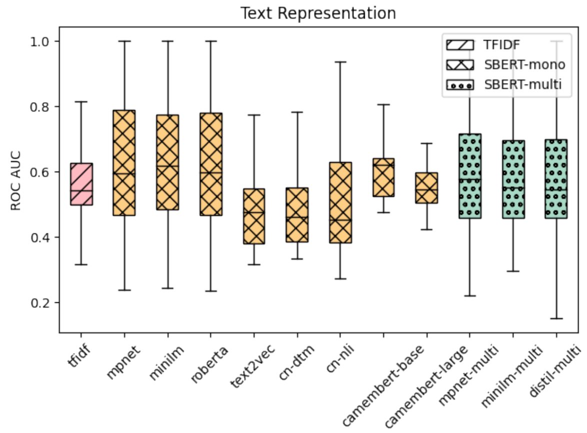

Figure 2: Performance (avg. ROC AUC) comparison of anomaly detection algorithms using different text representation strategies: TF-IDF, Monolingual SBERT, and Multilingual SBERT

speech detection, which may not align well with the TAD task. When excluding the Chinese models, the monolingual SBERT models perform slightly better than the multilingual ones, even though the difference is not substantial.

Algorithms Figures 3 to 5 depict the performance of the 22 selected algorithms evaluated across 17 different corpora using three types of representations. The algorithms are grouped from three perspectives:

- In terms of **degree of supervision**, the unsupervised approaches register a mean ROC AUC score of 0.539. This relatively lower score indicates that these methods may have struggled to effectively detect anomalies in the text data without any labeled information or prior knowledge. Semi-supervised methods, particularly OCSVM and LOF, which utilize only negative samples for training, perform slightly better with a mean ROC AUC score of 0.581. Nevertheless, semi-supervised methods that employ weak labels show a markedly improved performance, demonstrating a mean ROC AUC score of 0.721. This improvement hints at the significant role weak labels can play in enhancing anomaly detection performance.

- In terms of **underlying theory** for anomaly scores, proximity-based, probabilistic-based, and domain-based approaches exhibit relatively lower mean ROC AUC scores (0.538, 0.550, and 0.541, respectively), indicating their limitations in accurately identifying anomalies based on proximity or probabilistic reasoning. In contrast, reconstruction-based methods show a stronger performance with a mean ROC AUC score of 0.613. However, the most promising results are obtained by the ensemble methods, which achieve the highest mean ROC AUC score (0.825). These methods, leveraging the combination of multiple anomaly detection techniques or models, demonstrate superior performance in identifying anomalies in text data. Notably, the best-performing methods overall are the reconstruction-based and ensemble methods when utilizing weak labels within a semi-supervised learning context.

- In terms of **model architecture**, deep models utilizing neural networks achieve a mean ROC AUC of 0.621, demonstrating their relatively higher efficiency in detecting anomalies in text data compared to shallow models. Excluding XGBOD, the shallow models exhibit a lower mean ROC AUC of 0.549, suggesting their limited effectiveness. However, XGBOD, a shallow model employing extreme gradient boosting, stands out with an exceptional mean ROC AUC of 0.862, surpassing both deep and other shallow models. These findings highlight the advantage of deep neural networks in text data anomaly detection. Nevertheless, XGBOD defies expectations as a shallow model by delivering outstanding performance. Consequently, model architecture selection demands careful consideration, as both deep models and well-optimized shallow models, like XGBOD, can yield effective anomaly detection outcomes in text data.

5 Conclusion

In summary, this paper provides a comprehensive evaluation of 22 anomaly detection algorithms applied to 17 corpora derived from datasets associated with three distinct tasks. The evaluation considers three types of text representations: TF-IDF, monolingual SBERT, and multilingual SBERT models. The findings shed light on several key insights regarding the performance and limitations of these algorithms.

The analysis reveals variations in algorithm performance across different corpora categories. The

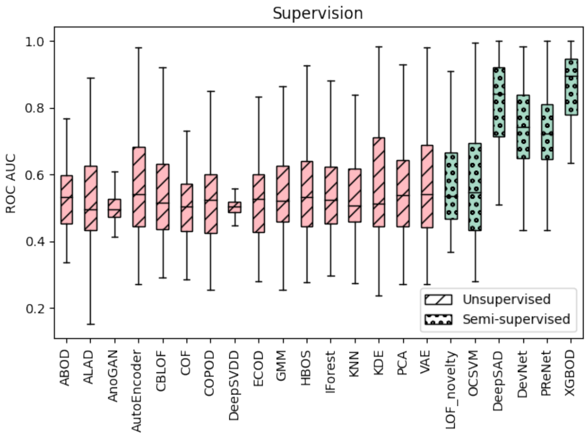

Figure 3: Performance (avg. ROC AUC) comparison of anomaly detection algorithms based on supervision level: Semi-supervised and Unsupervised

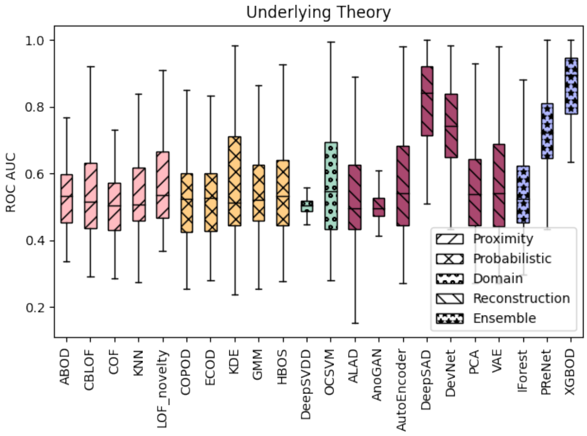

Figure 4: Performance (avg. ROC AUC) comparison of anomaly detection algorithms based on underlying theory for anomaly scores: Proximity-based, Probabilistic-based, Domain-based, Reconstruction-based, and Ensemble methods

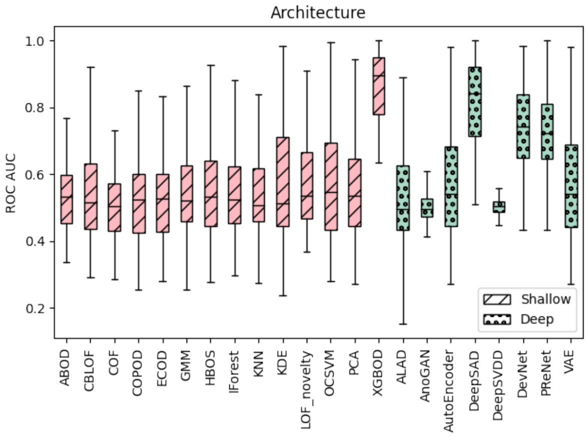

Figure 5: Performance (avg. ROC AUC) comparison of anomaly detection algorithms based on model architecture: Deep Models (with neural networks) and Shallow Models

corpora designed for topic classification exhibit the highest scores, indicating their suitability for anomaly detection tasks. In contrast, the hate speech corpora pose considerable challenges, with algorithms underperforming possibly due to the noisy social media text they contain. Addressing the impact of textual noise on algorithm performance becomes a crucial area for future research. Furthermore, the evaluation of different text representations demonstrates that the TF-IDF model shows stable performance but with a lower upper limit compared to SBERT models. Excluding the Chinese models, monolingual SBERT models outperformed the multilingual ones, emphasizing the importance of language-specific representations for anomaly detection. From the perspectives of degree of supervision, underlying theory for anomaly scores, and model architecture, the study offers a detailed comparative analysis of the algorithms. The findings highlight the superior performance of reconstruction-based and ensemble methods in a semi-supervised setting, and the advantage of deep models over shallow models, except for XGBOD.

Looking ahead, several potential avenues of investigation could further enrich the field of text anomaly detection. Firstly, the exploration of supervised algorithms could provide an opportunity to bolster anomaly detection performance, especially in contexts where labeled data is available. Secondly, the incorporation of advanced technologies, such as language models like ChatGPT, opens up novel possibilities for innovative anomaly detection methodologies that can adapt to evolving data landscapes. Another promising direction lies in the creation of specialized datasets explicitly designed for anomaly detection tasks. Such datasets could allow for the refining and optimization of current detection algorithms while enabling the development of new, more effective methods. Lastly, delving deeper into the study of different types of text anomalies could provide a more nuanced understanding of their unique characteristics and the detection strategies that work best for each.

Abstract

Ancient Chinese poetry is the earliest literary genre that took shape in Chinese literature and has a dissemination effect, showing China's profound cultural heritage. The current work in the field of poetry generation is mainly aimed at improving the fluency and structural accuracy of words and sentences, ignoring the theme unity of poetry generation results. In order to solve this problem, this paper proposes a graph neural network poetry theme representation model based on label embedding. Based on the network representation of poetry, the topic feature representation of poetry is constructed and learned from the granularity of words. Then, the features of the poetry theme representation model are combined with the autoregressive language model to construct a theme-oriented ancient Chinese poetry generation model TLPG (Poetry Generation with Theme Label). Through experiment and evaluation by experts in related fields, the model proposed in this paper has significantly improved the topic consistency on the premise of ensuring the fluency and format accuracy of poetry.

1 Introduction

Ancient Chinese poetry is a short, vivid form of literary genre, and the depictions in ancient poetry are a living reflection of the daily life of the Chinese ancestors as well as their inner prayers and expectations. In world literature, ancient Chinese poetry is also an important means of demonstrating the power of the Chinese language. It is interesting to note that although automated machine poetry compositions fall short of human beings in terms of rhyme, mood, and feeling (Zhang et al., 2023). However automated poetry generation is still worth researching. On the one hand, machine-generated ancient poems can assist students in generating a deeper understanding of poetry (Ma et al., 2023). On the other hand, the emergence of multimodal technologies has made poetry learning not only limited to texts (Wu et al., 2021) a variety of information can be utilized in the study of poetry teaching and learning.

In terms of poetic format, poems of different genres and eras often have different formats (e.g., poetic style, rhyme, etc.), which involve grammatical, semantic, and phonological aspects. Current research tends to establish grammatical analysis as well as symbolic representation of phonology for ancient poems, which makes poetry often contain explicit thematic information (Yang et al., 2023). Themes in poetry are implicit textual information are important references for poetry appreciation and creation, so this paper focuses on the representation and integration of theme features in the process of poetry generation.

At present, the mainstream poetry generation models are mainly based on the Transformer (Zhao et al.,2022) and generate poems in the form of autoregressive language models. However, unlike general text generation tasks, poetry is a highly structured literary genre (Li,2020). In the poetry generation task, the input part of the model is designed with a special identifier to learn the specific format of the poem (Yang et al., 2022). During the learning process this special identifier learns potential formatting information in a particular type of poetry. In the poetry generation stage, such a special identifier functions accordingly in the decoding stage. Making it possible to generate text in a well-formed poetry genre. This paper focuses on proposing a label embedding-based graph neural network poetry topic representation model, while combining it with applications on poetry generation tasks. Thus, the main research work in this paper is as follows:

Firstly, a poetry text graph network is constructed based on the textual characteristics of

Proceedings of Recent Advances in Natural Language Processing, pages 1246–1255
Varna, Sep 4–6, 2023

ancient Chinese poetry, and a label embedding-based graph neural network poetry theme representation model is proposed to learn the theme feature representation of poetry based on the network representation of poetry.

Combining the features of the poetry theme representation model with the autoregressive language model, we construct the theme-oriented ancient Chinese poetry generation model TLPG (Poetry Generation with Theme Label), which integrates the attention mechanism of poetry theme features to improve the consistency of poetry generation themes.

This paper is organized as follows: Section 1 introduces the topic-controlled poetry generation task. Section 2 describes relevant work related to this paper. Section 3 demonstrates the model proposed in this paper which is the TLPG model. Section 4 describes in detail the experimental setup and the section 5 discussion related to the results. Finally, section 6 gives the conclusion of the paper.

2 Poetry generation related work

Research on automatic poetry generation started in the 1960s, and early poetry generation studies used a system architecture for generating lyrics given a melody, selecting words from a word list library, then testing and filtering them, repicking them if they are not suitable, and moving on to the next position if they are (Gervás, 2000). And then some scholars added genetic algorithms to the poetry generation task, and Zhou et al (2010) designed a coding method based on flat and oblique, introduced the coding information into the fitness function, and added elitism and roulette algorithms in genetic algorithms, but the high computational complexity of genetic algorithms and the possibility of sometimes falling into local optimal solutions made the quality of poetry generation uneven. With the advent of statistical machine learning, Wong et al (2008) used the vector space model to formulate the relationships between sentences as vectors, and then used cosine similarity to compare the relationships between sentence pairs and extract relevant statements from blog posts for generation. Yan et al (2013) used information retrieval techniques to retrieve a set of poems related to keywords from a database, and sub-phrasing, and then applied abstraction techniques to generate poems using the sub-phrasing results. However, the above method does not constrain the poetry topic and format, and the generation is not effective.

In order to better incorporate control attributes into the generation process, advanced model structures have been gradually proposed as neural networks and deep learning techniques have gradually matured. Zhang et al (2014) first introduced deep neural networks into the poetry generation task and proposed a model combining recurrent neural networks (RNN) for ancient Chinese poetry generation. Hu et al (2017) proposed the use of a Variational Auto-Encoder (VAE) with a framework overall attribute discriminator to achieve the control of generation direction by combining VAE with a discriminator. Yi et al (2020) used a semi-supervised VAE framework to generate poems with more thematic and semantic richness considering the style of the poems as a combination of multiple factors. To improve the thematic relevance of poetry generation, some scholars have proposed using a working memory model that utilizes an internal memory to store and access multiple subject terms. Sun et al (2018) used an unsupervised approach to enhance the diversity of poetry generation by maximizing the mutual information between the style distribution and the output distribution. Zhang (2020) et al. based on the Transformer structure and incorporated input identifiers to make information about the formatting and meter of the poem displayed by participating in model training to generate poems with a more standardized format. The generation model in this paper aims to ensure the quality of poetry generation while generating poems with a more uniform theme, improve the interactivity with users, and be applied in the system construction.

3 Model

3.1 Poetry theme representation

The purpose of this paper is to improve the content quality of generated poems by introducing theme information through a topic model. Based on this purpose, this paper proposes a label embedding based method for representing poetry topics in graph neural networks. Compared to the direct application of Latent Dirichlet Allocation （LDA) topic models, this paper's model first uses a dense representation vector at the word granularity in the underlying layer to ensure the representation capability of the model. Secondly, this paper uses graph neural network as a theme feature representation model to build graphs from corpus. After obtaining different topics of poems, unlike the topic vectors above, the output of the basic LDA model is a judgmental representation of the probability of different topics, which can be involved in classification.

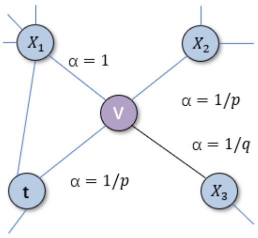

Figure 1: Structure of Node2Vec

Therefore, graph neural networks are used in this paper. Drawing on the work of Yao et al (2019) and Huang et al (2019), this paper fuses global poetry information to construct a poetry text graph. Firstly, the poetry corpus is subdivided to transform the whole poetry corpus into a graph structure, and the poems will be classified by LDA that connects the thematic category of each poem as a label to the words in the poem. Suppose a certain poem $P = \{p_1, p_2, p_3, \ldots p_N\}$ containing N words in the poetry corpus D. The set of poetry topic labels can be obtained from the above as $S = \{s_1, s_2, s_3, \ldots s_N\}$, then there is a text graph construction method based on the poetry corpus as shown in procedure 1 and 2.

$$E = \{\, Connect(p_i, s_j) \mid p_i \in P, s_j \in S\} \quad (1)$$

$$G = \{p_1, \ldots p_n\} \cup \{s_1, \ldots s_N\} \cup \{e_1 \ldots e_k\} \quad (2)$$

The words in the entire poetry corpus are treated as word nodes in the text graph, and all poetry topics are treated as topic nodes. For the set of edges E is constructed as Equation 1, and all the words in the verse are connected to the corresponding topic labels as Equation 2. This results in the text graph of the complete poetry corpus, which is an undirected graph and each node has the same weight as the edge, set to 1. We combine the methods of label embedding and graph networks, and use the Node2Vec (Aditya,2016) to embed the poetry topic label nodes and poetry word nodes, and use the embedding vector of poetry topic labels as the poetry theme representation. The structure of Node2Vec structure is shown in Figure 1.

In Node2Vec, some random wandering sequences are first generated, and then the training paradigm Skip-gram of Word2Vec is borrowed to transform the words into a high-dimensional space vector representation. In the training process, a negative sampling method is used, and the final word vector representation can be obtained through multiple iterations of training. The training objectives are shown in Equation 3 and Equation 4:

$$max \sum_{u \in V} \log Pr(N_s(u) \mid f(u)) \quad (3)$$

$$Pr(p_i) = f(p_i)^{3/4} / \sum_{j=0}^{n} \left(f(p_j)^{3/4}\right) \quad (4)$$

The process of poetry theme and word representation based on label embedding graph network is shown in Figure 2, where T_i is the theme node of the poem, which relates to the words in the poem to generate a random wandering sequence, and the word representation and theme representation are finally obtained through training.

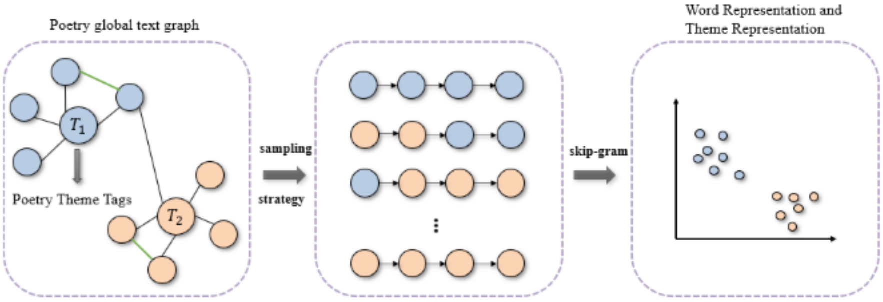

Figure 2: The Generation Process of Poetry Theme and Word Representation

3.2 A poetry generation model combining poetry theme representation

The model proposed in this paper is based on the Transformer framework, and the input of the model is $x = (< bos >, p_1, p_2, p_3, \ldots, p_n)$, where n is the number of sample words and $< bos >$ denotes the input starting symbol. The output of the model is $y = (p_1, p_2, p_3, \ldots, p_n, < eos >)$, where $< eos >$ denotes the ending symbols, and the model diagram is shown in Figure 3. In order to improve the model's ability to learn a series of writing rules for poetry, a series of extensions to the input information are made in this paper. The model input identifier part refers to the research idea of Li（2020）, in addition, combined with the section on poetry theme representation based on label embedding and graph network in Section 3.1, this paper adds the theme label representation into the model input, and then incorporates the poetry topic label representation into the generative model. Regarding the design of the input identifiers, “银烛秋光冷画屏，轻罗小扇扑流萤。”（The painted screen is chilled in silver candlelight, She uses silken fan to catch passing fireflies） is presented as an example for the sake of understanding.

Figure 3: The generative model of Poetry Combined with Poetry Theme Representation

The first one is the sentence identifier, and the sentence identifier can guide and enhance the learning process of the model in the learning of sentences in different positions in the poem text. Where $</s>$ is the separator number between sentences, s_i in the above equation indicates the i-th sentence of the word in the poem, and the sentence identifier is expressed as $SEN = \{s_0, s_0, s_0, s_0, s_0, s_0, s_0, s_0, </s>, s_1, s_1, s_1, s_1, s_1, s_1, s_1, s_1, </s>, < eos >\}$. The second is the internal order identifier, where p_i is the penultimate i-th character in each verse. The reason for this decreasing approach is to let the model notice that the generation has proceeded to the end position of the verse. Where the last character of each verse is denoted as p_1 and the punctuation position is denoted as p_0. The internal order identifier is denoted as $POS = p_7, p_6, p_5, p_4, p_3, p_2, p_1, p_0, </s>, p_7, p_6, p_5, p_4, p_3, p_2, p_1, p_0, </s>, < eos >$. The third one is the tone identifier, which aims to allow the model to learn the tone information corresponding to the word, and to be able to produce more compliant verses under the specific tone format requirements. The tones of poetry are mainly divided into a total of two types: “平”(level tones) and “仄”(oblique tones). In terms of formal representation, the “平” is represented by pt, while the “仄” is represented by zt, and the punctuation is represented by n. In this paper, the labeling rules of data refer to “中华新韵” (Zhao,2019). The tone identifier is represented as

$TONE = \{pt, pt, pt, pt, zt, zt, pt, n, </s>, pt, pt, zt, zt, pt, pt, pt, n, </s>, <eos>\}$. The fourth type is the metrical identifier. In the example verse of this article, “屏” and “萤” at the end of the sentence rhyme, and the two characters belong to "十四英"(a set of rhyme pattern) according to “中华新韵” (Zhao,2019), so denoted as $< rhyme\text{-}14 >$. Use e_0 for punctuation and e_1 for ordinary words in the verse. The purpose of the metrical identifiers is to allow the model to display the rhyme writing techniques used in the learned poems and to make the generated poems more beautiful. The metrical identifiers are represented as $RHY = \{e_1, e_1, e_1, e_1, e_1, e_1, < rhyme\text{-}14 >, e_0, </s>, e_1, e_1, e_1, e_1, e_1, e_1, < rhyme\text{-}14 >, e_0, </s>, < eos >\}$. The last input is a poetry theme label representation vector, which identifier is the final poetry topic label representation derived from the LDA trained in the previous section after text graph construction by global poetry text. The example verse in this paper belongs to the poetry theme category $< theme\text{-}48 >$. It’s one of the predefined 50 categories given by the LDA topic model, which is automatically learned from corpus. This theme label is further incorporated into the theme model to enable the generative model to learn the theme information of the poem.

In the input layer of the model, the different types of identifier representations are accumulated, E is a vector of different identifier representations, and t is the current position of the word or identifier, where E_{W_t} and $< theme\text{-}48 >$are from the poetry graph network introduced in Section 3.1. Here, combined with the identifier representation introduced above, E_{G_t} is the global position, and the final input is shown in Equation 5:

$$H_t^0 = E_{W_t} + E_{SEN_t} + E_{POS_t} + E_{TONE_t} + E_{RHY_t} + E_{G_t} \tag{5}$$

In addition, in order to better generate the canonical content, the model needs to know the structural information of the sentence to be generated next in the state of time t. Therefore, the variable F^0 is introduced, as shown in Equation 6:

$$F_t^0 = E_{SEN_t} + E_{POS_t} + E_{TONE} + E_{FMT_t} \tag{6}$$

Also, in order to make the results generated by the model notice the theme information, where E_{SEN_t} and E_{POS_t} are placeholders. Theme identifiers are introduced in the input layer, as shown in Equation 7:

$$M_t^0 = E_{<theme\text{-}48>_t} + E_{SEN_t} + E_{POS_t} \tag{7}$$

In order to make the three vectors of global information, poetry text representation information of fusion generation rules and poetry theme representation information to fuse the information effectively. In this paper, we design a two-layer attention for fusing poetry theme features. The first step is to obtain the poetry text representation input with Masked Multi-head attention layer, which is calculated as shown in 8, where $SLF - ATT$ stands for self-attention mechanism in the model:

$$C_t^l = LN\ (FFN\ (C_t^l) + C_t^l)$$

$$C_t^l = LN\ (SLF - ATT\ (Q_t^l, K_{\leq t}^l, V_{\leq t}^l) + H_t^l)$$

$$Q^l, K^l, V^l = H^l \boldsymbol{W}^{\boldsymbol{Q}}, H^l \boldsymbol{W}^{\boldsymbol{K}}, H^l \boldsymbol{W}^{\boldsymbol{V}} \tag{8}$$

where $\boldsymbol{W}^{\mathbf{Q}}$, $\boldsymbol{W}^{\mathbf{K}}$ and $\boldsymbol{W}^{\mathbf{V}}$ are learnable weight matrices. The Transformer mask mechanism makes the restriction that the current position in the model used to handle the self-attention can only see the previous part of the position, So the model cannot notice what comes after t when $\leq t$. The output of the masked self-attention layer with the topic label representation vector is fed into the topic multiheaded attention, and the theme attention formula incorporating the poetry theme features is shown in 9:

$$S_t^l = LN\ (FFN\ (S_t^l) + S_t^l)$$

$$S_t^l = LN(ATT(Q_t^l, K^l, V^l) + H_t^l)$$

$$Q^l, K^l, V^l = H^l \boldsymbol{W}^{\boldsymbol{Q}}, M^0 \boldsymbol{W}^{\boldsymbol{K}}, M^0 \boldsymbol{W}^{\boldsymbol{V}} \tag{9}$$

The representation obtained from the above two attention modules is combined and then the vector dimension is changed through the fully connected layer as shown in Equations 10:

$$K_t^l = [C_t^l : S_t^l]$$

$$K_t^l = MLP(K_t^l + H_t^l) \tag{10}$$

Finally, the global information is input so that the generative model can know the poetry rules to be generated later, from the l layer representation H^l obtains the $l + 1$ implicit representation H^{l+1} shown in Equation 11, where $GLO - ATT$ means the global attention mechanism in the model:

$$H_t^{l+1} = LN\ (FFN(H_t^{l+1}) + H_t^{l+1})$$

$$H_t^{l+1} = LN(GLO - ATT(Q_t^l, K^l, V^l) + K_t^l)$$

$$Q^l, K^l, V^l = K^l \boldsymbol{W}^{\boldsymbol{Q}}, F^0 \boldsymbol{W}^{\boldsymbol{K}}, F^0 \boldsymbol{W}^{\boldsymbol{V}} \tag{11}$$

In this paper, negative log-likelihood is chosen as the loss function of this model, as shown in Equation 12:

$$\mathcal{L} = -\sum_{t=1}^{n} log\, P(\boldsymbol{y}_t \mid \boldsymbol{y} < t) \qquad (12)$$

4 Data set and experimental setup

4.1 Data set and parameters

The dataset in this paper comes from the open-source database called Chinese-poetry on GitHub mentioned above, and draws on the work of Zhang et al (2014) and Luo et al (2021) to select more structured poems from the library. In this paper, four types of modern poetry were chosen to test the correctness of the model described in this chapter. The data of each type are shown in Table 1.

Poetry genre	Number of poems
Five-character quatrain	2268
Seven-character quatrain	9377
Five-character regulated poem	7105
Seven-character regulated poem	7299

Table 1: Statistics of Poetry Information in Corpus.

In this paper, the training set, validation set and test set are divided in the ratio of 80:10:10, and the same poetry genre in each set is proportionally distributed. p of the hyperparameter of the Node2Vec algorithm is set to 1.2, and the hyperparameter q is set to 0.5. In the SkipGram algorithm, the window size is set to 5, and the negative sampling technique is used to improve the computational efficiency.

Model	PPL↓		Theme consistency↑ (%)
	val	test	
GPT	17.71	18.01	8.61
SongNet	12.86	13.11	15.77
MCPG	11.47	11.59	38.37
TLPG	9.98	10.01	61.74

Table 2: PPL& Theme consistency.

The number of layers of the model is set to 12, and in the multi-headed attention mechanism module, the number of heads is set to 12. In the training phase, dropout controls the randomness in the process of fitting the model to the data, and this parameter is set to 0.2. In the model training optimizer section, Adam is selected to train the model, and the learning rate is also dynamically adjusted during the training process by the Noam learning rate decay strategy (Kingma and Ba, 2014).

The analysis is performed for the parameter of number of topics. The topic model uses LDA, the topic model is constructed on the whole poetry corpus combined with the LDA model, and the co-occurrence scores are calculated using the UMass (2012) metrics as shown in Equations 13:

$$coherence\ (V) = \sum_{(v_i,v_j)\in V} score\ (v_i, v_j, \epsilon)$$

$$score\ (v_i, v_j, \epsilon) = log\ \frac{D(v_i,v_j)+\epsilon}{D(v_j)} \qquad (13)$$

Where V is a set of topic words, ϵ denotes the smoothing factor $D(x, y)$ counts the number of documents containing words x and y, and counts the number of documents containing $D(x)$. and set different number of topics from 10 to 500, the best co-occurrence score index can be achieved when the number of topics is 50, so this paper uses 50 as the number of topics parameter in the process of building the model.

4.2 Evaluation Indicators

In this paper, machine evaluation uses PPL, theme consistency, Format, Tone and Rhyme. Theme consistency is used to judge whether the overall themes expressed in the generated poems are consistent. The formula is shown in 14:

$$\text{Theme consistency} = \frac{1}{|Y|}\sum_{y\in Y} \text{OL}\ (P(T|y), P(T|\bar{y}))$$

$$\text{OL}\ (P(T), Q(T)) = \sum_{t\in I} \min(P(T), Q(T)) \qquad (14)$$

The format accuracy rate indicates whether the generated samples match the four poem formats in the dataset. Tone accuracy rate is the percentage of correctly predicted tones among all generated samples. Rhyming accuracy rate is the average percentage of a poem that rhymes correctly.

Model	Format(%)	Tone(%)	Rhyme(%)
GPT	45.09	48.66	63.21
SongNet	99.80	65.33	77.61
MCPG	99.98	98.58	97.19
TLPG	98.41	96.54	98.79

Table 3: Format Tone & Rhyme.

Model	PPL↓		Theme consistency↑ (%)
	val	test	
TLPG w/o TL	11.70	11.91	56.83
TLPG w/o theme	12.53	12.75	20.08
TLPG	9.98	10.01	61.74

Table 4: Results of ablation experiment.

When evaluating a poetry generation model or system, the results of human evaluation are also an important reference. The human evaluation will invite some people who know about poetry or have experience in poetry writing (e.g., Chinese language scholars) to conduct the evaluation. The order of the poems produced by the different models is disordered and the evaluator must rate each poem from 0 to 3 on each assessment index (minimum 0, maximum 3 and scored using 0, 1, 2 or 3). In this paper, 60 poems (15 poems in each of the four genres) were randomly selected for evaluation. In this paper, 10 raters were invited to rate the generated collection of poems, and multiple raters usually rate a poem in order to reduce the subjectivity of the evaluation. The manual evaluation metrics include Rhyming tone, Unity of theme and Expression fluency.

Model	**Rhyming tone**	**Unity of theme**
SongNet	**2.31**	2.26
MCPG	2.15	2.23
TLPG	2.30	**2.58**
	Expression fluency	**Avg**
SongNet	**2.38**	2.32
MCPG	2.32	2.23
TLPG	2.36	**2.41**

Table 5: Manual evaluation results.

4.3 Contrast and ablation experiments

In this paper, the more advanced existing models and systems are selected for comparison experiments, along with ablation analysis of the models, to demonstrate the effectiveness of using graph neural network modeling labels and their introduction into the generative model for controlling poetry generation themes. The comparative experimental setup is shown below:

GPT (2018): GPT is a natural language generation model. Its core structure is Transformer

SongNet (2020): SongNet is a format-controlled and autoregressive language-model-based text generation framework, which is designed with a series of input identifiers displayed at the input layer.

MCPG (2021): this model also formulates the poetry generation task as a constrained text generation problem and gives certain keywords to participate in poetry generation, and differs from the model in this paper in the design of Encoder and Decoder.

The ablation experiment setup is shown as follows:

TLPG w/o TL: The poetry theme label representation obtained from the graph neural network is not used, and the output of the LDA model is used directly with the same frame structure.

TLPG w/o Theme: remove the theme feature input and the attention module associated with it.

5 Experimental results and analysis

The experimental results are shown in Table 2 and Table 3. From the results, we can see that the perplexity and theme consistency metrics on both the validation and test sets of this paper's model are optimal, which highlights the effectiveness of introducing theme tags into the poetry generation task to improve the theme consistency of poetry, because both SongNet model and MCPG introduce input operators to regulate the poetry generation format, tone and rhyme, so the experimental results are similar in terms of format accuracy, tone accuracy, and rhyme accuracy.

The results also demonstrate that TLPG improves thematic consistency while also ensuring the regularity of its generated format. When using the GTP model for top-k sampling, it is easy to lose control over the regularity of the generated poems due to its random nature, and significantly lower than the other models in terms of format accuracy, tone accuracy and rhyme accuracy, and perplexity and theme consistency.

Meanwhile, this paper conducted ablation experiments on the model, and the results of these three indicators are not discussed here because there is no variable control on format, tone and rhyme aspects, and the final results of the ablation experiments are shown in Table 4, where TLPG w/o TL does not use the poetry theme label representation obtained in Section 4.2, but directly uses the output of the LDA model.

With the overall experimental framework structure unchanged, there is a decrease in theme consistency, which also indicates that adding the vector obtained by training the theme representation again after establishing the connection with the verse to the generative model is more effective than simply using the LDA model output vector representation of the theme labels for input.

Poetry generation samples in Chinese	
Theme：14	Theme：20
秋山万壑云飞乱，明月当空照江河。 北风吹彻楼台上，龙城千古高楼多。 东海波涛浩无垠，西湖烟波渺茫多。 南楼一曲千古恨，汉水万里泪空流。	寒夜乌飞叫声哀，霜风凛冽雁归来。 明月高挂空悬浸，寒霜落尽叶翩跹。 风过寒衣冷又惊，耿耿长夜未成眠。 声音渐远难寻觅，风雪之中有谁家。
Theme-14:山 天 海 万 风 云 江 河 楼 龙 千 城 里 白 月 南 西 东 汉 水 马	Theme-20:飞 寒 霜 雁 空 鸿 夜 衣 晓 影 声 乌 高 雪 差 不 惊 微 耿 参
Translation	
Autumn mountains and ravines, clouds flying chaotic, bright moon in the sky shining river. The north wind blows through the building on the platform, thousands of ancient buildings high-rise in Dragon city. The waves of the East China Sea are vast and boundless, and the smoke and waves of the West Lake are remote. The southern building has a song of a thousand hates, and the Han River has ten thousand miles of empty tears.	The cold night crows fly and scream, the frosty wind is cold and the geese return. The moon hangs high in the sky, and the leaves are dancing in the frost. The wind is cold and frightening, and the night is long and sleepless. The voices are far away and hard to find, whose home is there in the snow and wind.
Theme-14：The mountains, sky, sea, wind, clouds, river, building, dragon, thousand cities, white moon, south, west, east, Han, water, horses.	Theme-20：Flying, cold, frosty geese, empty skies, dark clouds, night clothes, dawn shadows, voices, high snow, no surprise.

Table 6: Example of TLPG results on different theme.

The TLPG w/o theme representation removes the theme identifier and the attention module associated with it, and the experimental results show that the generated poems lose the involvement of the theme identifier and are significantly less consistent in theme than the model with the theme identifier involved. In summary, the experimental metrics of the machine evaluation index prove the advanced and scientific nature of the experiment. Table 5 shows the results of the manual evaluation metrics, as the input tone identifiers, metrical identifiers, and internal position identifiers are the same, there is no big difference between the three in terms of rhyme, SongNet is better in terms of expressive fluency and rhyming tone, while TLPG, the model of this paper, performs the best in terms of theme consistency. Finally, Table 6 shows the generated poetry samples under different poetry theme labels.

6 Conclusion

In this paper, we propose a method for constructing a graph network of poetry texts, based on which a tag embedding method is combined with the graph network to obtain a poetry theme style modeling and representation, which is finally applied to the task of generating ancient Chinese poetry on a specific theme. The model is firstly based on the existing autoregressive language model framework and constructs a poetry generation model TLPG incorporating poetry theme tags by setting specific identifiers in the input layer, the model in this paper can ensure that the generated poems are formatted as required, and at the same time, combined with the poetry theme representation, can guide the model to generate poems that are more in line with the user's desired theme style. After the evaluation of real datasets and the results of manual evaluation by experts in related fields, the method proposed in this paper can not only improve the accuracy and quality of poetry generation, but also meet the personalized needs of users.

In addition, this paper will further investigate the introduction of more types of texts such as Song lyrics and Yuan songs into the TLPG model to improve the generalization ability and application scenarios of the model. In the future, with the continuous development and improvement of natural language processing technology, the ancient poetry generation technology will also be more widely and deeply applied.

Evaluating Generative Models for Graph-to-Text Generation

Shuzhou Yuan, Michael Färber
Karlsruhe Institute of Technology (KIT)
{shuzhou.yuan, michael.faerber}@kit.edu

Abstract

Large language models (LLMs) have been widely employed for graph-to-text generation tasks. However, the process of finetuning LLMs requires significant training resources and annotation work. In this paper, we explore the capability of generative models to generate descriptive text from graph data in a zero-shot setting. Specifically, we evaluate GPT-3 and ChatGPT on two graph-to-text datasets and compare their performance with that of finetuned LLM models such as T5 and BART. Our results demonstrate that generative models are capable of generating fluent and coherent text, achieving BLEU scores of 10.57 and 11.08 for the AGENDA and WebNLG datasets, respectively. However, our error analysis reveals that generative models still struggle with understanding the semantic relations between entities, and they also tend to generate text with hallucinations or irrelevant information. As a part of error analysis, we utilize BERT to detect machine-generated text and achieve high macro-F1 scores. We have made the text generated by generative models publicly available.[1]

1 Introduction

Graph-to-text generation is a subtask of data-to-text generation and Natural Language Generation (NLG) (Gatt and Krahmer, 2018). Its purpose is to generate fluent descriptive text based on the structure of a given graph (see Figure 1). With the widespread use of graph structured data, this technique plays a crucial role in various Natural Language Processing applications, including question answering, dialogue systems, and data augmentation (He et al., 2017; Zhao et al., 2020; Josifoski et al., 2023). Previous research on model architectures has achieved significant performance on graph-to-text generation benchmarks (Koncel-Kedziorski et al., 2019; Ribeiro et al., 2020; Zhao et al., 2020; Li et al., 2021; Ribeiro et al., 2021b). In particular, Ribeiro et al. (2021a) achieved state-of-the-art performance by employing large pretrained language models and sufficient training data. However, the zero-shot setting for graph-to-text generation remains challenging due to the inconsistent input format (unstructured text vs. preformatted text) between pretraining and fine-tuning stages for large language models.

Recently, generative models such as GPT-3 (Brown et al., 2020), InstructGPT (Ouyang et al., 2022), and ChatGPT have gained tremendous attention in both the NLP research community and the general public. Researchers have evaluated these models on various NLP benchmarks in the zero-shot setting (Bang et al., 2023; Jiao et al., 2023; Ahuja et al., 2023). However, their ability to process structured data, and in particular graph data, such as knowledge graphs, is understudied and worth being explored (Bang et al., 2023). Given the significant resources and annotations required for training graph-to-text generation models (Li et al., 2021), utilizing a zero-shot setting could save training resources and prove advantageous for both economic and ecological reasons.

Previous approaches has come up with a neural pipeline to enable zero-shot for graph-to-text generation but didn't use generative models (Kasner and Dusek, 2022). In contrast, our approach adopts the zero-shot setting by using prompts as instructions for generative models, specifically GPT-3 and ChatGPT (Brown et al., 2020; Ouyang et al., 2022). We evaluate the models' ability to translate graph data into fluent text using the test sets from two widely used graph-to-text generation datasets: WebNLG (Gardent et al., 2017) and AGENDA (Koncel-Kedziorski et al., 2019). Following the method of Ribeiro et al. (2021a), we represent the

Figure 1: Examples of graph structures, prompts and linearized graphs of (a) AGENDA and (b) WebNLG.

graph as a linearized sequence of text for input to the models (see Figure 1).

To assess the performance of the generative models, we conduct a comprehensive evaluation on each dataset. Employing machine translation metrics such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and ROUGE (Lin, 2004) to the generated texts, we reveal that the generative models fall short of matching the quality achieved by state-of-the-art approaches. To identify patterns of mistakes made by the generative models, we perform error analysis by comparing the generated texts with the reference texts. Additionally, we fine-tune a BERT model to detect the machine-generated text. We make the texts generated by the models available on GitHub to facilitate future research on the analysis of machine-generated text and trustworthy AI.

In summary, our study aims to assess the performance of generative models in the zero-shot setting for graph-to-text generation using two distinct benchmarks. Our contribution lies in conducting a rigorous quantitative analysis of the results, shedding light on the effectiveness of generative models in this domain.

2 Related Work

Graph-to-text generation. Various efforts have been made to enhance graph-to-text generation using neural network models. They can be categorized into two main types: Graph Neural Network (GNN) based models and Language Model (LM) based models. GNN-based models typically employ a graph encoder to encode the graph structure (Beck et al., 2018; Marcheggiani and Perez-Beltrachini, 2018; Damonte and Cohen, 2019; Koncel-Kedziorski et al., 2019; Ribeiro et al., 2019; Li et al., 2021). In contrast, LM-based models do not rely on the graph structure but purely on the sequence of tokens in the text. As such, graphs have first been transformed into a linearized representation before being fed into LMs to generate coherent text (Harkous et al., 2020; Ribeiro et al., 2021a,b). Besides GNN and LM, previous works have also explored the use of Recurrent Neural Networks (RNNs) such as LSTM and GRU for graph-to-text generation (Song et al., 2018; Zhao et al., 2020; Guo et al., 2020). We follow the approach of Konstas et al. (2017) and other prior works by using a linearized graph as input for generative models.

Generative Models. Generative language models, such as GPT-3 (Brown et al., 2020), InstructGPT (Ouyang et al., 2022), and ChatGPT, have been designed to learn and generate natural language text. These models are based on the transformer decoder architecture (Vaswani et al., 2017), which enables them to handle large amounts of training data and perform zero-shot applications. While GPT-3 has made a significant breakthrough in text completion, InstructGPT and ChatGPT possess unique characteristics that align user intent with a conversational style. These models are trained using supervised fine-tuning and reward modeling, allowing them to generate high-quality responses that accurately reflect the user's needs and preferences. InstructGPT and ChatGPT are first fine-tuned on the GPT-3 model through supervised learning and then further trained using reinforcement learning based on human feedback.

	AGENDA	WebNLG
Number of Instance	1,000	1,862
Average Input Tokens	169	66

Table 1: Statistics of test sets from AGENDA and WebNLG.

As demonstrated by Ouyang et al. (2022), this approach substantially improves the model's performance on NLP benchmarks. Although there have been numerous reports and research evaluating the performance of generative models in various NLP applications such as summarization (Bang et al., 2023), machine translation (Jiao et al., 2023), and multilingual evaluation (Ahuja et al., 2023), our work focuses on the generative models' capability to handle structured data.

3 Dataset

We evaluate generative models using the AGENDA and WebNLG datasets, as they are widely used in recent research on graph-to-text generation (Koncel-Kedziorski et al., 2019; Ribeiro et al., 2021a; Li et al., 2021) and as they represent different domains: scholarly domain and general domain (e.g., as given in Wikipedia). We focus on the test sets of AGENDA and WebNLG for our experiments, as the models do not require further training. In the following, we briefly describe the used datasets.

AGENDA. Abstract GENeration DAtaset (AGENDA) is a dataset that pairs knowledge graphs with paper abstracts from scientific domains (Koncel-Kedziorski et al., 2019). The graphs in AGENDA were automatically extracted from the SciIE information extraction system (Luan et al., 2018). Each instance in AGENDA includes the title, entities, graph, and abstract of a paper. We use the title, entities, and graph as input for the models.

WebNLG. This dataset is a benchmark for mapping sets of RDF triples to text (Gardent et al., 2017). The RDF triples are subgraphs of the knowledge graph DBpedia (Auer et al., 2007), while the texts describe the graphs in one or a few sentences. The WebNLG challenge[2] has released several versions of this dataset since 2017. In order to compare with previous work, we take the test data of WebNLG challenge 2017 for our experiments.

4 Experiments

Data Preprocessing. Since GPT-3 and ChatGPT require a sequence of text as input, we convert the graph structure into a linearized representation following Ribeiro et al. (2021a). To assist the models in identifying the head, relation, and tail entities, we prepend `<H>`, `<R>`, and `<T>` tokens before the entities, as done in previous work (Harkous et al., 2020). In the AGENDA dataset, each sample also includes a title and entities. Thus, we additionally add `<title>`, `<entities>`, and `<graph>` tokens (see Figure 1).

Model Settings. We use the GPT-3 model variant `text-davinci-003` and the ChatGPT model variant `gpt-3.5-turbo-0301` for our experiments. Each instance is treated as a single request, and the first response from the model is taken as the generated text. The prompt used for the models plays a significant role as it serves as the task description and directly influences the content of the generated text. Previous work designed prompts by asking ChatGPT (Jiao et al., 2023). Following their approach, we ask ChatGPT to provide prompts: "Please provide prompts or templates for graph-to-text generation:". Since AGENDA and WebNLG have different data structures, we use the prompt "Generate paper abstract from title, entities, and graph:" for AGENDA. For WebNLG, we use the prompt "Generate text from graph:". We expect that in this way the generated text fits the format of a scientific paper abstract better for AGENDA, while the models generate texts in open domain for WebNLG.

Baseline. Similar to our experimental methodology, Ribeiro et al. (2021a) finetuned T5 and BART using linearized graphs as input and generated descriptive texts. Therefore, we consider their findings as the baseline for comparison with our own experiments.

Evaluation. Following related work, we implement a thorough evaluation with metrics BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), RougeL (Lin, 2004) and Chrf++ (Popović, 2017). Additionally, to assess the semantic meaning and coherence of the generated text, we employ BLEURT (Sellam et al., 2020), a metric that evaluates not only the surface match of n-grams but also the semantic representation extracted from a pretrained BERT (Devlin et al., 2019) model.

Model	BLEU↑	METEOR↑	RougeL↑	Chrf++↑	BLEURT↑
$T5_{large}$ (Ribeiro et al., 2021a)	22.15	23.73	-	-	-13.96
$BART_{large}$ (Ribeiro et al., 2021a)	**23.65**	**25.19**	-	-	**-10.93**
GPT-3	8.34	14.88	24.99	41.42	-32.54
ChatGPT	10.57	17.02	**25.22**	**45.86**	-28.05

Table 2: Results on AGENDA.

Dataset	BLEU↑	METEOR↑	RougeL↑	Chrf++↑	BLEURT↑
$T5_{large}$(Ribeiro et al., 2021a)	**59.70**	**44.18**	-	**75.40**	-
$BART_{large}$(Ribeiro et al., 2021a)	54.72	42.23	-	72.29	-
GPT-3	20.36	26.95	**45.64**	57.95	**13.39**
ChatGPT	11.08	23.89	35.87	48.75	-10.99

Table 3: Results on WebNLG.

4.1 Results

Our results are summarized in Table 2 and 3. As comparison, we take the results from Ribeiro et al. (2021a), which are achieved by finetuned BART and T5.

The results obtained from AGENDA demonstrate that finetuned BART and T5 models outperform generative models in terms of state-of-the-art performance. Both T5 and BART achieve BLEU scores exceeding 20, while GPT-3 only attains a BLEU score of 8.34 and ChatGPT achieves 10.57. Consistently, other evaluation metrics align with the BLEU scores, further highlighting the limited performance of generative models without finetuning. Notably, ChatGPT exhibits a slightly improved performance compared to GPT-3 on the AGENDA benchmark. Analysis of the results reveals that ChatGPT consistently outperforms GPT-3 across all metrics, showcasing a 2.23 higher BLEU score, a 2.14 higher METEOR score, a 0.23 higher RougeL score, a 4.44 higher Chrf++ score, and a 4.49 higher BLEURT score.

Examining the results from WebNLG, it becomes evident that fine-tuned T5 and BART models consistently outperform generative models without fine-tuning. Notably, both T5 and BART achieve BLEU scores exceeding 50, whereas generative models only attain a BLEU score of 11.08 for ChatGPT and 20.36 for GPT-3. Surprisingly, GPT-3 outperforms ChatGPT on the WebNLG benchmark with a BLEU score that is 9.28 higher, a METEOR score that is 3.06 higher, a RougeL score that is 9.77 higher, and a Chrf++ score that is 9.20 higher. The primary reason for this difference is that ChatGPT tends to produce hallucinations easily and generates longer text. We provide further elaboration on two examples in Section 5.

5 Error Analysis

We observe that the texts generated by generative models contain errors following similar patterns. In Table 4 and Table 5, we show two examples from AGENDA and WebNLG.

As shown in the example of Table 4, generative models are capable of generating fluent paper abstracts based on the provided input, but they contain errors that contradict the facts represented by the graph structure. For instance, the triple "accuracy <R> EVALUATE-FOR <T> correlation analysis" in the example graph is wrongly generated by GPT-3 as "which (correlation analysis) is then used to evaluate the estimation accuracies". Also, ChatGPT describes it as "(The authors) apply clustering and correlation analysis to evaluate the accuracy". In both cases, the models reverse the relationship between "accuracy" and "correlation analysis".

Furthermore, ChatGPT ignores the relations "PART-OF" and "USED-FOR" in the input. This suggests that generative models still face challenges in comprehending the semantic relations between entities, which can result in the generation of inaccurate text.

While generating paper abstracts is complex and challenging, generating short descriptive text from a knowledge graph is relatively more straightforward. As LLMs, GPT-3 and ChatGPT are trained on large corpora and thus already contain world knowledge. In the example provided in Table 5,

AGENDA	Example
Input	Generate paper abstract from title, entities and graph: <title> Estimation of semantic case of Japanese dialogue by use of distance derived from statistics of dependency . <entities> statistics of dependent noun-particle-verb triples atr dialogue corpus measure of distance semantic cases noun-particle-verb triples consistency rates single-case clusters clustering analysis correlation analysis estimation accuracies accuracy <graph> <H> statistics of dependent noun-particle-verb triples <R> USED-FOR <T> measure of distance <H> noun-particle-verb triples <R> PART-OF <T> atr dialogue corpus <H> semantic cases <R> PART-OF <T> atr dialogue corpus <H> accuracy <R> EVALUATE-FOR <T> correlation analysis
Reference	In an attempt to estimate the semantic cases for noun-particle-verb triples in the atr dialogue corpus, the authors propose a measure of distance based on statistics of dependent noun-particle-verb triples. A clustering analysis of all the triples in the corpus was conducted using the measure of distance. Competence of the proposed measure of distance is verified by examination of the distribution of the single-case clusters. By use of the score derived from the measure of distance of the training corpus, the authors conducted the estimation of the correct semantic case for a given noun-particle-verb triples in the test corpus. The result remarkably differentiates the particles with respect to the estimation accuracies. For instance, particle 'wo' has accuracies over 80 %, while 'de' has accuracies less than 40%. The correlation analysis between the accuracy and the consistency rates indicates that the particles of higher consistency have also tendencies to higher accuracies.
GPT-3	This paper aims to estimate semantic cases of Japanese dialogue using a measure of distance derived from statistics of dependent noun-particle-verb triples from the ATR dialogue corpus. Clustering analysis and correlation analysis are employed to examine the consistency rates of single-case clusters, which is then used to evaluate the estimation accuracies of the distance measure.
ChatGPT	This paper proposes a method to estimate the semantic case of Japanese dialogue using a measure of distance derived from the statistics of dependent noun-particle-verb triples. The authors use the ATR dialogue corpus and apply clustering and correlation analysis to evaluate the accuracy of their method. They report consistent rates for single-case clusters and show that their method achieves high estimation accuracies. The study demonstrates the potential of using statistics of dependency for analyzing Japanese dialogue.

Table 4: Paper abstract generated by GPT-3 and ChatGPT, incorrect texts are marked with red.

generative models generate descriptive text fluently based on the structured input. However, GPT-3 produces text with incorrect facts. For instance, "Abner W. Sibal" is the name of a person, but it is recognized as the name of a battle by GPT-3. While GPT-3 produces text with incorrect facts, it is worth noting that ChatGPT-generated text not only covers the input information, but also contains redundant messages from its internal knowledge (hallucinations). Furthermore, the sentence "Abner W. Sibal was a prominent figure who faced great challenges" generated by ChatGPT has made a subjective judgement about the character and may cause unnecessary bias to potential users.

To investigate the difference between model-generated texts and human-written reference texts, we create datasets containing both types of text and finetune a pretrained BERT model for a binary text classification task. The statistics of our datasets are presented in Table 6.

WebNLG	Example
Input	Generate text from graph: <H> Abner W. Sibal <R> battles <T> World War II <H> World War II <R> commander <T> Joseph Stalin
Reference	Joseph Stalin was a commander in World War II in which Abner W Sibal also fought.
GPT-3	Joseph Stalin was the commander of World War II and Abner W. Sibal was one of the battles fought during the war.
ChatGPT	Abner W. Sibal was a prominent figure who faced great challenges during his time as a soldier in World War II. He fought bravely as a commander, leading his troops with dedication and determination. His efforts were critical to the success of the war effort and his name became synonymous with bravery and patriotism. During World War II, the world was gripped in the fight against tyranny and oppression. Abner W. Sibal was one of the many who answered the call to serve his country. Through his leadership skills and strategic thinking, he was able to navigate the treacherous waters of war and emerge victorious. However, the fight against the Axis powers was not just a battle against military might. It was a battle against the ideologies that fueled the enemy's aggression. As a commander, Sibal had to navigate these complexities and ensure that his troops remained committed to the cause of freedom. Throughout the war, Sibal faced many challenges and obstacles. But he remained steadfast and only grew more determined to see the war through to its ultimate conclusion. His efforts were recognized and honored, not just by his own country but also by leaders around the world. Even the likes of Joseph Stalin, renowned commander and leader of the Soviet Union, recognized the critical role Sibal played in the victory against fascism. Today, Abner W. Sibal's name remains a testament to the bravery and dedication of those who fought in World War II. His legacy serves as an inspiration to future generations, reminding them of the importance of standing up against tyranny and oppression wherever it may arise.

Table 5: Descriptive text generated by GPT-3 and ChatGPT, incorrect texts are marked with red, hallucinations are marked with blue.

Dataset	Machine-generated instance	Human-written instance
AGENDA	1000	1000
WebNLG	1862	4894
All	2862	5894

Table 6: Statistics of ChatGPT generated datasets

We create several datasets for AGENDA, WebNLG, and a combined dataset containing both AGENDA and WebNLG examples. The training and test sets are split in an 80:20 ratio. We fine-tune BERT for five epochs using the AdamW optimizer (Loshchilov and Hutter, 2019). As shown in Table 7, BERT achieves high scores across all datasets. This demonstrates that generative models generate text that follows similar patterns, and a state-of-the-art text classifier can easily distinguish between them.

6 Conclusion

In this paper, we explored the capabilities of generative models in generating coherent text from structured data, focusing on two benchmarks: AGENDA and WebNLG. To achieve this, we adopted the linearized graph representation approach employed in prior work. Leveraging the zero-shot ability of language models, we prepended the prompt to the

Model	**Accuracy**	**Macro F1**
GPT-3$_{\text{AGENDA}}$	98.00	98.00
ChatGPT$_{\text{AGENDA}}$	100	100
GPT-3$_{\text{WebNLG}}$	91.64	89.25
ChatGPT$_{\text{WebNLG}}$	96.82	95.75
GPT-3$_{\text{All}}$	93.55	92.38
ChatGPT$_{\text{All}}$	96.40	95.82

Table 7: Results of BERT to detect GPT-3 and ChatGPT generated text.

input text as an instruction for both GPT-3 and ChatGPT. We conducted a comprehensive evaluation using various metrics. Our findings reveal that generative models fall short of surpassing previous models that have been trained and finetuned on large volumes of training data. These results highlight the limitations of generative models in achieving state-of-the-art performance in graph-to-text generation tasks.

Furthermore, we conducted an error analysis of the text generated by the models. The generative models struggle in capturing the relationships between entities and often produce unrelated information, leading to hallucinations. To further investigate the machine generated text, we employ finetuned BERT to conduct a text classification task. BERT achieves high F1 scores in distinguishing between machine-generated text and human-written text. Our study provides extensive evaluation of generative models for graph-to-text generation. Future work should focus on refining machine-generated text and reducing hallucinations for graph-to-text generation by using generative models.

7 Ethical Consideration and Limitation

We observe that generative models may generate text containing fake facts or offensive content. And the datasets we collected may also contain incorrect or offensive statements. We do not support the views expressed in the machine generated text, we merely venture to analyze the machine generated text and provide an useful resource for future research.

As the limitation of this work, we found out that the reproducibility of GPT-3 and ChatGPT is questionable. The models often return different response from same request, which makes our results hard to reproduce and the brings randomness to the evaluation scores.

Acknowledgements

We thank the anonymous reviewers for their helpful comments. We also would like to thank Nicholas Popovic for his feedback on this work.

Microsyntactic Unit Detection using Word Embedding Models: Experiments on Slavic Languages

Iuliia Zaitova, Irina Stenger, Tania Avgustinova
Department of Language Science and Technology, Saarland University, Germany
izaitova@lsv.uni-saarland.de
ira.stenger@mx.uni-saarland.de
avgustinova@coli.uni-saarland.de

Abstract

Microsyntactic units have been defined as language-specific transitional entities between lexicon and grammar, whose idiomatic properties are closely tied to syntax. These units are typically described based on individual constructions, making it difficult to understand them comprehensively as a class. This study proposes a novel approach to detect microsyntactic units using Word Embedding Models (WEMs) trained on six Slavic languages, namely Belarusian, Bulgarian, Czech, Polish, Russian, and Ukrainian, and evaluates how well these models capture the nuances of syntactic non-compositionality.

To evaluate the models, we develop a cross-lingual inventory of microsyntactic units using the lists of microsyntantic units available at the Russian National Corpus. Our results demonstrate the effectiveness of WEMs in capturing microsyntactic units across all six Slavic languages under analysis. Additionally, we find that WEMs tailored for syntax-based tasks consistently outperform other WEMs at the task. Our findings contribute to the theory of microsyntax by providing insights into the detection of microsyntactic units and their cross-linguistic properties.

1 Introduction

Microsyntactic units, which include syntactic idioms and non-standard syntactic constructions, have been defined as language-specific transitional entities between the lexicon and the grammar, idiomatic properties of which are closely tied to syntax (Iomdin, 2017). These units include all the syntactic units that have very specific and even syntactic properties and do not fit into the standard syntax (Iomdin, 2015). Recent research efforts have resulted in the development of several linguistic resources for microsyntactic analysis, such as a microsyntactic dictionary of Russian, a microsyntactically annotated corpus of Russian texts, and a typology of relevant phenomena (Marakasova and Iomdin, 2016; Iomdin, 2016, 2017; Avgustinova and Iomdin, 2019).

Given the vast number and diverse nature of microsyntactic phenomena, it is not surprising that they are often described on the basis of individual constructions or small classes of syntactic phrases. In order to gain a more comprehensive and systematic understanding of these phenomena, it is crucial to attempt an analysis of microsyntactic phenomena at scale, rather than in isolation. In this study, we add to the line of research on microsyntax by adapting quantitative and computational methods used in idiom recognition for identification of microsyntactic units in large corpora of texts and across different languages. We apply different types of Word Embedding Models (WEMs) to the task of microsyntactic unit detection, and test their performance on five functional categories of microsyntactic unit (prepositions, adverbials and predicatives, parenthetical expressions, conjunctions, and particles) in six Slavic languages (Belarusian, Bulgarian, Czech, Polish, Russian, Ukrainian).

Concretely, the contributions of this paper are as follows:

1. We demonstrate that the methods used for idiom recognition can be applied for microsyntactic unit recognition.

2. We find that embedding models adapted for syntactic tasks outperform other WEMs at the task of microsyntactic unit detection.

3. We show that the behavior of embedding models across different types of microsyntactic units has similarities across all six Slavic languages under analysis and is readily generalizable.

Proceedings of Recent Advances in Natural Language Processing, pages 1265–1273
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_134

Our study not only contributes to the theory of microsyntax but also has practical applications in Natural Language Processing, Machine Translation, and other areas of Computational Linguistics where effective handling of non-standard syntactic structures is required.

After presenting the relevant background in Section 2, we introduce the used methods, data and models in Section 3. The obtained results are discussed in Section 4, and finally, the conclusions are drawn in Section 5. The code used for our experiments is available at github.com/IuliiaZaitova/Microsyntactic-Unit-Detection-using-Word-Embedding-Models-Slavic-Languages.

2 Background

2.1 Cross-lingual Comparison of Microsyntactic Units

The cross-linguistic comparability of microsyntactic phenomena has been demonstrated for both closely related and distant languages.

Apresjan (2014) conducts a corpus study to assess the translatability of Russian syntactic idioms, which are a sub-type of microsyntactic units, into English. The study concludes that syntactic idioms are language-specific, but acknowledges the borderline situations in which a syntactic idiom in a first language and its correlate in a second language have partially different properties, implying that it is still possible to compare microsyntactic phenomena cross-linguistically, albeit indirectly.

The study by Avgustinova and Iomdin (2019) provides further evidence for the cross-linguistic comparability of microsyntactic units. The authors investigate the typology of microsyntactic units in four Slavic languages – Bulgarian, Czech, Polish, and Russian – and find that many of the peculiarities of microsyntactic units in one language can be partially reproduced in cognate languages. They propose an approach that uses an existing database of microsyntactic units in Russian available at the Russian Natonal Corpus (rus, 2003–2023) as the pivot source and present a method for parallel examination of microsyntactic units, which could be utilized to create multilingual resources for dealing with non-standard syntactic phenomena.

Even though direct cross-linguistic comparison of microsyntactic units may not always be possible, the use of partial correlates for comparative analysis can provide valuable insights into the nature of microsyntactic phenomena across different languages.

2.2 Word Embedding Models

While current research lacks a specific focus on computational at-scale analysis of microsyntactic units, previous studies suggest that the non-compositionality of idioms and microsyntactic units are closely intertwined. As such, Apresjan (2014) claims that possibly all or the majority of idioms also possess certain compositional properties either on a syntax level or a semantic level or both. We assume that research on semantic compositionality, and in particular, the computational methods and techniques utilized in idiomatic unit recognition, could provide valuable insights for addressing the problem of syntactic idiomaticity.

Despite recent advancements in transformer-based architectures, WEMs remain a popular choice in tackling non-compositionality detection tasks (Salehi et al., 2015; Cordeiro and Candito, 2019; Nandakumar et al., 2019; Hashempour and Villavicencio, 2020). WEMs use context information and represent the meaning of lexical units as vectors based on the idea that words occurring in similar contexts tend to have a similar meaning. At present, research does not agree on a definitive metric to measure the modeling capabilities of WEMs as applied to the non-compositionality detection task. Consequently, different studies have also produced different results when comparing the performance of different WEMs.

Among the WEMs available, research on idiom detection highlights the effectiveness of the Word2Vec CBOW model (Mikolov et al., 2013). As such, in their large-scale evaluation of 816 WEMs Cordeiro et al. (2016) show that Word2Vec CBOW-based architectures produce the best results in detection of semantic non-compositionality in nominal compounds. Additionally, Nandakumar et al. (2019), in their study on how well seven different embedding methods capture the nuances of non-compositional data, also find that the Word2Vec model (the default configuration of Word2Vec is CBOW) performs the best. Moreover, they show that recently-proposed contextualized word embeddings (CWEs) such as BERT (Devlin et al., 2019) and ELMo (Peters et al., 2018) are not adept at handling non-compositionality.

In defense of CWEs, Hashempour and Villavicencio (2020) find that the Context2Vec model prep – prepositions, adv & pred – adverbial and predicative, parenth – parenthetical, conj – conjunctions, part – particles.

Table 1: Microsyntactic units in six Slavic languages.

(Melamud et al., 2016) outperforms the Word2Vec and BERT models due to its ability to place potentially idiomatic expressions into distinct regions of the embedding space (idiomatic/literal) depending on the particular sense of the expression in context.

3 Methodology

3.1 Slavic Languages

We focus on six Slavic languages that belong to the three main sub-groups of the Slavic language family: Belarusian, Ukrainian, and Russian (East Slavic); Bulgarian (South Slavic); and Polish and Czech (West Slavic). This language selection was made to ensure the inclusion of diverse typological variations across the Slavic languages. Each of the chosen languages has publicly-available large-scale corpora, as well as parallel multilingual data, providing a rich resource for our analysis. By including languages from different sub-groups, we aim to capture a broad range of syntactic and semantic phenomena within the Slavic language family. This allows us to conduct a comprehensive analysis of microsyntactic units from a typological perspective.

3.2 Inventory of Microsyntactic Units

To develop a cross-lingual inventory of microsyntactic units, we adopted the methods proposed by Avgustinova and Iomdin (2019) and utilized the Russian National Corpus (RNC) and its parallel sub-corpora (rus, 2003–2023) as the primary linguistic resource. The microsyntactic dictionary[1] provided by the RNC, which includes prepositions, adverbials and predicatives, parenthetical expressions, conjunctions, and particles, served as our pivot database for the development of a multilingual comparative resource of microsyntactic phenomena. Although on the website the dictionary is called 'corpus dictionary of multi-word lexical units', for the purpose of this work we use the name 'microsyntactic dictionary' to emphasize the syntactic idiomaticity of given expressions. For each Russian expression, the database also provides its frequency score in the RNC sub-corpora and the syntactic function that the expression has.

We sorted the available expressions by their frequency scores and selected the 50 most frequent microsyntactic units from each syntactic category except for particles, for which only 27 distinct expressions are available. This yielded a total of 227 microsyntactic units in Russian for further analysis. For each expression, we used the search function of the RNC to extract translational correlates together with two parallel bilingual context sentences from the parallel sub-corpora. We acknowledge that direct correlates of microsyntactic units in different languages are not always available. Thus, we opt for using partial correspondence whenever required, which we believe, despite its limitations, allows us to compare microsyntactic units at scale. In a similar way, we used the search function of the Czech National Corpus (Machálek, 2020). We obtained six parallel sets of 227 microsyntactic units with parallel bilingual context sentences for each unit in all of the six Slavic languages under analysis. The bilingual sentences can be used for future research on microsyntactic units in context. It is important to mention that in contrast to Avgustinova and Iomdin (2019), we had to choose only one equivalent for each of the microsyntactic units in Russian to enable quantitative and computational analysis. Each of the translated expressions and sentences was proofread and, when required, corrected by professional linguists who are also native speakers of the target language.

Our multilingual database of microsyntactic phe-

[1] https://ruscorpora.ru/page/obgrams/

nomena enables us to compare these phenomena across different languages and can be later used for further research on microsyntactic units and syntactic idiomaticity. To the best of our knowledge, this is the first database of its kind that allows for quantitative and computational analysis of microsyntactic units across different languages. Further examples of the obtained data for each type of microsyntactic unit are provided in Table 1, which showcases the microsyntactic units in Russian along with their corresponding translations to other languages under analysis. Our custom dataset is fully open-sourced and is available at huggingface.co/datasets/izaitova/slavic_fixed_expressions.

3.3 Inventory of Syntactically Compositional Counterparts

For each target microsyntactic unit, we have drawn compositional (non-idiomatic) constructions from the training data as counterparts using random sampling. For the purpose of normalization, we ensured that they have the same number of constituent tokens and share at least one word with the counterpart microsyntactic unit. For instance, for the microsyntactic unit *ne jednou* in Czech, the compositional counterpart should be two words in length and contain either the word *ne* or *jednou*. To refine the selection of the non-microsyntactic counterparts, we manually removed any non-compositional units from the initially sampled list and conducted further random sampling until we obtained the full set of compositional counterparts.

3.4 Training Data

The training data for our experiments is sourced from the Leipzig Corpora Collection (LCC) (Goldhahn et al., 2012), which is a publicly available corpus containing text data generated from newspapers and web resources in 293 languages. For each language under analysis, we utilized 500,000 sentences sourced from language-specific news corpora of LCC.

3.5 Word2Vec CBOW

We chose to use the CBOW architecture of the Word2Vec model due to its demonstrated effectiveness in semantic non-compositionality detection, as highlighted in previous research (Section 2.2). Word2Vec CBOW predicts the center word given a representation of the surrounding words, whereas its counterpart Word2Vec Skip-gram predicts contextual words given the representation of the center word[2]. To train the Word2Vec CBOW model, we use Gensim's implementation of the CBOW algorithm (Řehůřek and Sojka, 2010). We ignore all words that occur less than five times in the training corpus, and use a window size of five.

3.6 Context2Vec

Following Hashempour and Villavicencio (2020), we decided to use Context2Vec (Melamud et al., 2016) due to its ability to capture variable-length sentential contexts using a bidirectional LSTM recurrent neural network. We use an optimized implementation of Context2Vec by Aoki (2018) with the original parameters of the model. It is important to note that Hashempour and Villavicencio (2020) show a superior performance of this model when applied to different senses of a token. Although in our experiments we use a single embedding for each token for better comparison with other models, we anticipate that Context2Vec's improved representation of context will contribute to the detection of syntactic compositionality.

3.7 Structured Skip-gram Word2Vec and Word2Vec CWindow

To enhance the quality of word embeddings for syntax-based tasks, we included Structured Skip-gram Word2Vec[3] and Word2Vec CWindow models (Ling et al., 2015) in our methodology. These modified versions of the Word2Vec Skip-gram and Word2Vec CWindow algorithms take into account the relative positions of context words and have been shown to improve parsing accuracy for part-of-speech tagging and dependency parsing tasks. We anticipate these models will offer valuable insights into the detection of syntactic non-compositionality due to their enhanced understanding of token relationships. For both models, we ignore all words that occur less than five times in the training corpus, and use a window size of five.

3.8 Graph-based Syntactic Word Embeddings with Node2Vec

Incorporating a graph-based approach, we utilize the Node2Vec algorithm (Grover and Leskovec,

[2] Due to existing evidence for better performance of CBOW as compared to Skip-gram in compositionality detection, we use only the CBOW configuration

[3] The Structured Skip-gram model is different from Word2Vec Skip-gram

2016) which learns syntactic embeddings based on information derived from dependency parse trees. Previous research by Al-Ghezi and Kurimo (2020) has demonstrated competitive performance of Node2Vec embeddings in part-of-speech tagging tasks compared to other WEMs. By employing dependency parse trees generated by DiaParser (Zhang and Attardi, 2020), we aim to explore the dependencies between tokens in a sentence and leverage Node2Vec's ability to preserve network neighborhoods of nodes for syntactic non-compositionality detection. To train the Node2Vec models, we use PecanPy (Liu and Krishnan, 2021), an accelerated implementation of the Node2Vec algorithm, with default parameters.

3.9 Experimental Setup

For each of the six Slavic languages under analysis, we construct word embeddings using five models: Word2Vec CBOW, Context2Vec, Structured Skip-gram Word2Vec, Word2Vec CWindow, and Node2Vec. Additionally, we generate these word embeddings for two different dataset sizes, one consisting of 100,000 sentences and another of 500,000 sentences.

To pre-process the datasets, we 1) lower-cased the texts; 2) removed punctuation and non-alphanumerical tokens; 3) randomly selected from 5 to 100 sentences containing occurrences of each of the target expressions, including both microsyntactic and compositional phrases; 4) supplemented the data with additional sentences from the corpus up to either 100,000 or 500,000 sentences, depending on the type of experiment being conducted; 5) following Cordeiro et al. (2016), retokenized all target expressions as a single token with a separator (underscore) between the phrase constituents (e.g. *so far* → *so_far*) to represent target expressions as one unit both in training and testing.

3.10 Non-compositionality Prediction

To predict the non-compositionality of an expression, we use cosine similarity between the expression vector representation $v(w1w2)$ and the sum of the vector representations of the component words $v(w1 + w2)$. This method has been extensively used in previous research on non-compositionality prediction (Mitchell and Lapata, 2010; Salehi et al., 2015; Cordeiro et al., 2016; Loukachevitch and Gerasimova, 2017; Nandakumar et al., 2018, 2019), formally:

$$cos(v(w1w2), v(w1 + w2))$$

where for $v(w1 + w2)$ we use the normalized sum

$$v(w1 + w2) = \frac{v(w1)}{||v(w1)||} + \frac{v(w2)}{||v(w2)||}$$

Intuitively, an expression appearing in different contexts from its components is likely to be non-compositional. In this framework, a phrase is compositional if its representation is close to the sum of its component representations (cosine similarity is close to 1), and it is idiomatic otherwise.

In order to compare the results and analyze the variations in performance, all expressions are arranged in ascending order based on their similarity scores. The aim is to examine whether the compositional phrases would have higher similarity values compared to non-compositional phrases. To evaluate the ordering quality, the measure of mean average precision (MAP) is employed – this way, MAP = 1 would correspond to all microsyntactic units ordered lower than compositional expressions, and MAP = 0 would mean that all microsyntactic units are ordered higher than compositional ones.

4 Results and Discussion

The experimental findings for the five models trained on 100,000 and 500,000 sentences are summarized in Tables 2 and 3, respectively. Table 2 shows the MAP scores on 100,000 sentences and Table 3 shows the MAP scores on 500,000 sentences. The best scores per language are presented in bold.

On the datasets of 100,000 sentences (Table 2), Node2Vec achieves the highest score for four out of six languages, while Word2Vec CWindow performs best on Belarusian and Russian for a dataset size of 100,000 sentences. On a larger dataset size of 500,000 sentences (Table 3), the models' performance generally improves, but with less uniform results, which suggests that some of the studied models might require more data to make meaningful generalizations. Overall, the results show that syntax-adapted models (except for Word2Vec Structured Skip-gram) tend to perform better in identifying microsyntactic units, which aligns with our expectations related to the nature of these units. Surprisingly, Node2Vec, which is based on dependency-parsed graphs, does not consistently

Table 3: MAP results on 500,000 sentences.

outperform other syntax-based WEMs that only account for word order. For most languages, it also produces similar or worse results when trained on larger sets of sentences. The Context2Vec model performs poorly on all languages even compared with Word2Vec CBOW, indicating that variable-length sentential context generated by a bidirectional LSTM recurrent neural network is not beneficial for syntactic non-compositionality detection. As for Word2Vec Structured Skip-gram, we know that similarly to the Word2Vec Skip-gram architecture (Section 3.5), it predicts the context tokens given the center token. In the case of syntactic compositionality prediction, where the relationships between words within a phrase are crucial, it could be more advantageous to predict the center token and capture information from its sentential context, which helps in understanding the sentence's structure.

To better interpret why Word2Vec Structured Skip-gram, despite its generally low performance, significantly outperforms other models in the case of the Russian language (500,000 sentences), it is helpful to compare the results by category of microsyntactic units. Figures 1 and 2 depict violin plots of cosine similarity scores by category for the two best performing models trained on the 500,000 sentence dataset in Russian. A clear difference is observable between the distributions of microsyntactic units and compositional units on both plots. Moreover, we can see that the distribution of cosine similarity scores for microsyntactic units is wider for the Structured Skip-gram model, while there is an opposite tendency in the CWindow plots, where compositional units seem to have a wider range of scores. The wider distribution of cosine similarity scores, which influences the quality of ordering, could be one of the factors that contributed to the observed outlier in the MAP score.

From the violin plots, we can also see that some unit types show a higher difference from compositional units. One explanation for that is that some types, such as adverbial and predicative constructions, additionally possess a lower degree of semantic non-compositionality, to which our models are sensitive.

Figure 3 represents the average MAP scores for models trained on 500,000 sentences, grouped by category and averaged across languages. This figure further supports the observation of varying model performance across different linguistic categories. Certain categories (adverbial and predicative, particles) consistently exhibit higher scores across all models, indicating that their non-compositionality is easier for the models to predict. Similarly, prepositions consistently yield lower scores.

4.1 Cross-Lingual Comparison

Cross-lingual comparison of microsyntactic unit recognition is essential for assessing the behavior and scalability of the non-compositionality detection techniques. To get a better representation of the results on microsyntactic unit recognition across languages, we generated heatmaps of MAP scores by category produced by Word2Vec CWindow and Node2Vec models trained on 500,000 sentences (Figure 4). The heatmaps show the performance of each unit type for each language, with darker colors indicating better performance.

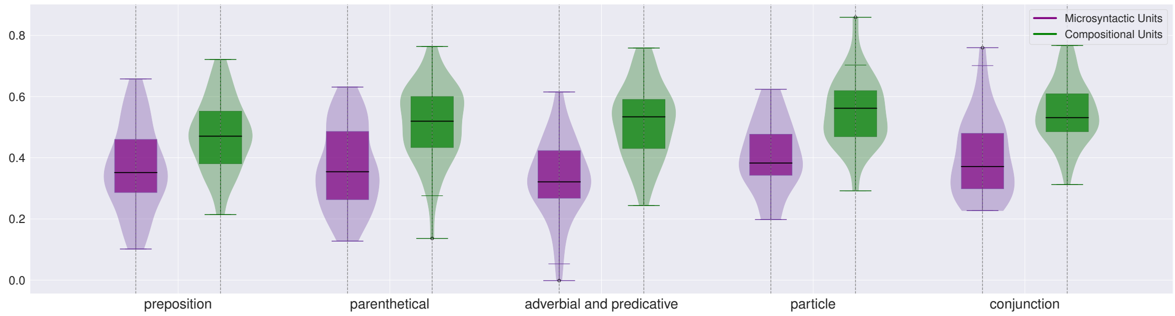

Figure 1: Cosine similarity by type of unit – Word2Vec CWindow trained on 500,000 sentences in Russian.

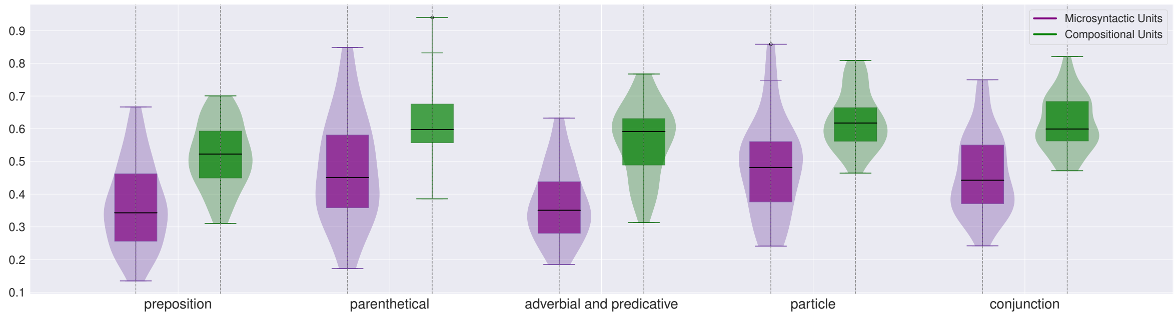

Figure 2: Cosine similarity by type of unit – Word2Vec Structured Skip-gram trained on 500,000 sentences in Russian.

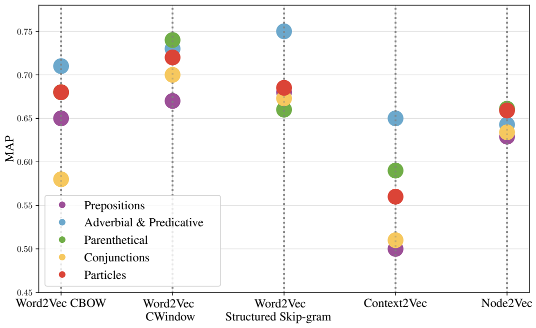


Results are averaged across languages

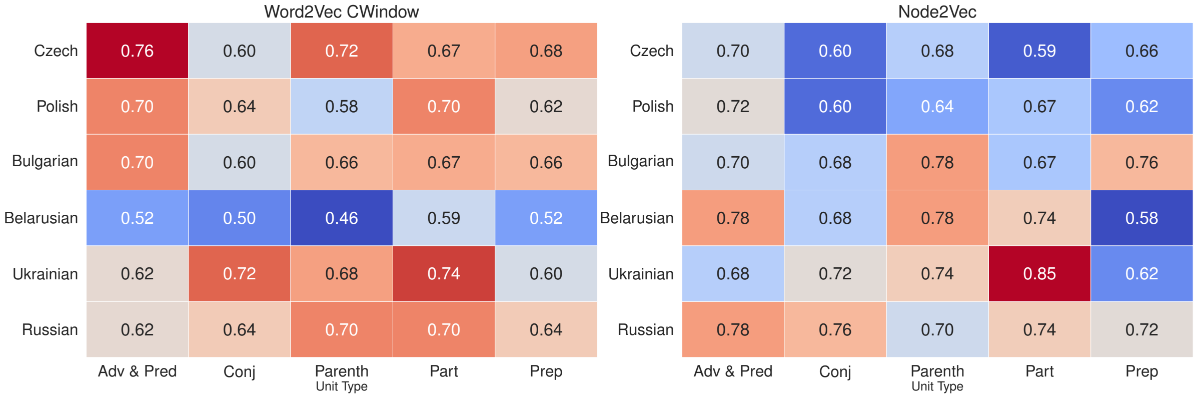
Figure 3: MAP by category for 500,000 sentences.

Across the heatmaps, we observe similarities in performance scores among different languages. For instance, adverbial and predicative constructions, as well as particles, exhibit higher MAP scores compared to other categories. These patterns suggest the presence of shared structural and/or semantic features in types of microsyntactic constructions across different languages.

5 Conclusion and Future Work

In this paper, we presented a novel approach for using WEMs for microsyntactic unit recognition in six Slavic languages. We have built a multilingual comparative database of microsyntactic units in six Slavic languages, each with six sets of parallel bilingual context sentences. Our comparative evaluation of Word2Vec CBOW, Word2Vec CWindow, Word2Vec Structured Skip-gram, Context2Vec and Node2Vec models suggests that WEMs can be effective for non-compositionality prediction, and that WEMs adapted to syntax-based tasks outperform other types of WEMs. The analysis of results shows that there are some differences in the performance of microsyntactic unit recognition across types of these units. In this vein, we have observed that different languages tend to produce similar results across different types of microsyntactic units.

In our future work, we are interested in improving the results for microsyntactic unit recognition. This includes investigating the use of additional features or data sources to improve model performance, as well as exploring different modeling architectures, such as large language models. Additionally, the inconsistent results of microsyntactic unit recognition when split by category also highlight the importance of evaluating models on different types of syntactic non-compositionality. Finally, we plan to explore the use of our database in practical applications, such as improving machine translation systems and using our models as



prep – prepositions, adv & pred – adverbials and predicatives, parenth – parentheticals, conj – conjunctions, part – particles.

Figure 4: Heatmaps of MAP scores by language for Word2Vec models trained on 500,000 sentences.

predictors for intercomprehension experiments.

Abstract

With the ever-growing amount of textual data, extractive summarization has become increasingly crucial for efficiently processing information. The TextRank algorithm, a popular unsupervised method, offers excellent potential for this task. In this paper, we aim to optimize the performance of TextRank by systematically exploring and verifying the best preprocessing and fine-tuning techniques. We extensively evaluate text preprocessing methods, such as tokenization, stemming, and stopword removal, to identify the most effective combination with TextRank. Additionally, we examine fine-tuning strategies, including parameter optimization and incorporation of domain-specific knowledge, to achieve superior summarization quality.

1 Introduction

In the modern era, the sheer volume of data generated daily poses a significant challenge for decision-makers to stay informed about the latest trends and developments. Text summarization addresses this issue by extracting only the most salient information from a text. This study investigates the effectiveness of TextRank, an extractive text summarization algorithm, compared to other common approaches, such as abstractive and hybrid summarizations.

Automatic text summarization can be classified based on the input size, algorithm, content, domain, language, type, and approach (Bounab et al., 2019). One approach is extractive summarization, which selects essential sentences from the input document(s) and concatenates them to form the summary. Another approach is abstractive summarization, which creates an intermediate representation of the input document(s) and generates a summary. Lastly, hybrid summarization combines extractive and abstractive approaches (Ansary, 2021).

Extractive Text Summarization is a widely-used approach in Natural Language Processing (NLP) that aims to condense large volumes of text into shorter, more manageable versions. This method involves selecting the most relevant sentences or phrases from the source text and combining them to create a summary that accurately conveys the essential information and main ideas of the source material (Narayan et al., 2018).

Abstractive Text Summarization is an advanced text summarization approach that employs NLP techniques to generate concise sentences that accurately convey the main ideas of the original text. This technique can benefit various domains where decision-makers require a rapid understanding of a document's primary points. Abstractive summarization can produce more coherent and efficient documents by eliminating redundancy and repetition. Unlike extractive text summarization, which selects and combines existing sentences or phrases, abstractive text summarization generates new and concise sentences, making it more versatile and flexible (Gupta and Gupta, 2019).

Hybrid Text Summarization combines extractive and abstractive text summarization strengths, resulting in a robust approach for condensing large volumes of text into shorter, more understandable versions. This technique minimizes word repetition and enhances the model's accuracy, necessitating ongoing refinement and experimentation to fine-tune the system and optimize its performance (Yadav et al., 2022).

2 Related Work

A recent study presented an NLP-based approach to generate business meeting summaries (Jha, Aryan et al., 2022). This research proposed a methodology employing various NLP techniques, such as Named Entity Recognition (NER), to identify crit-

ical entities. Moreover, the authors utilized the "TextRank" algorithm, based on "PageRank", to rank meaningful sentences and generate summaries according to the sentence rankings. This proposed methodology belongs to the extractive text summarization category. The approach demonstrated promising results in extracting vital information from business meetings and generating summaries that capture the meetings' main ideas.

The application of NLP techniques for summarizing text data, including a transcribed speech from meetings or extracting critical details from articles, has increased interest. Another recent study (Agrawal et al., EasyChair, 2021) explores the topic of summarizing meeting transcripts from Google Meet. This study investigates the effectiveness of various NLP models for summarizing transcripts and compares several models using metrics such as ROUGE. The study offers insights into the performance of different NLP models for extractive and abstractive summarization tasks.

Building upon the insights from these studies, our proposed methodology introduces an enhanced TextRank approach using Cosine similarity for n-grams and fine-tuning hyperparameters. By addressing various pre-processing states, fine-tuning of TextRank, an intended combination of NLP summarization models into a hybrid model, and calculating the evaluation metrics using ROUGE scores widely used in previous research, to ensure a fair comparison with existing methods. We aim to improve extractive summarization's overall performance and accuracy by taking these steps. The reviewed literature provides a solid foundation for our proposed methodology, as it leverages state-of-the-art NLP techniques and insights gained from previous research, such as using TextRank to achieve the highest accuracy.

3 Methodology

Our methodology employs a TextRank algorithm enhanced with Cosine similarity for n-grams and fine-tuned hyperparameters to achieve optimal performance. This approach consists of four critical stages: preprocessing, fine-tuning TextRank, generating the summary, and evaluating the results using ROUGE scores, as shown in Figure 1.

3.1 TextRank Algorithm

TextRank is an unsupervised, graph-based algorithm for extractive summarization (Mihalcea and Tarau, 2004). Inspired by Googpreprocessing, it constructs a graph of sentences and calculates their importance based on connections to other sentences.

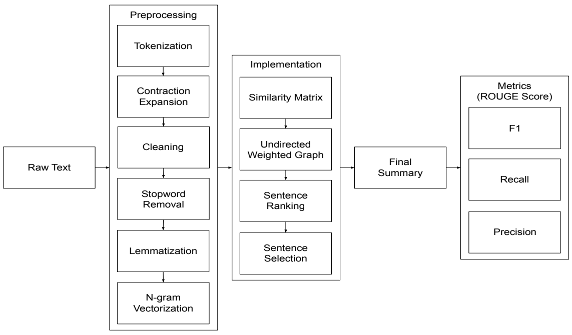

Figure 1: Methodology Flowchart

3.1.1 Cosine Similarity

Cosine similarity is a vector-based similarity measure that calculates the cosine of the angle between two vectors (Li and Han, 2013). In our implementation, we compute the cosine similarity between pairs of n-grams vectors. This similarity measure accounts for the frequency or importance of elements in the sets, making it more robust and flexible and allowing for a more accurate sentence comparison. The mathematical equation for the cosine similarity is represented as follows:

$$\text{Cosine Similarity}(A, B) = \frac{A \cdot B}{\|A\| \|B\|} \quad (1)$$

3.1.2 Jaccard Similarity

The Jaccard similarity is a statistical used for comparing the similarity and diversity of sample sets. In the context of text summarization, we compute the Jaccard similarity between pairs of word sets derived from sentences. This set-based measure effectively captures semantic similarity by considering the shared vocabulary between sentences. It doesn't account for the frequency of words, emphasizing the unique shared and total elements. The mathematical equation for Jaccard similarity is represented as follows:

$$\text{Jaccard Similarity}(A, B) = \frac{|A \cap B|}{|A \cup B|} \quad (2)$$

Where:

- $|A \cap B|$ is the size of the intersection of sets A and B.
- $|A \cup B|$ is the size of the union of sets A and B.

3.1.3 Dice Similarity

Dice similarity is a statistical measure used for evaluating the similarity between two sets. It is particularly used in text analysis, where sets of words derived from sentences are compared. The Dice coefficient is calculated as twice the size of the intersection of sets, divided by the total size of both sets. This measure is similar to the Jaccard index but emphasizes sets' intersection. The mathematical equation for the Dice similarity is represented as follows:

$$\text{Dice Similarity}(A, B) = \frac{2|A \cap B|}{|A|+|B|} \quad (3)$$

Where:

- $|A \cap B|$ is the size of the intersection of sets A and B.
- $|A|$ and $|B|$ are the sizes of set A and set B, respectively.

3.2 Undirected Weighted Graph

In this section, we discuss the formulation of an undirected weighted graph, a pivotal step in the TextRank algorithm. Each sentence in the text under consideration is represented as a node in this graph. The edges that link these nodes carry a weight representing the similarity between sentences, as determined by a chosen similarity measurement function (Mihalcea, 2004).

The Cosine similarity is a measure based on the cosine of the angle between two vectors, in this context, the term-frequency vectors of two sentences. Jaccard similarity quantifies the proportion of shared terms to the total unique terms in both sentences. Dice similarity also considers shared terms but calculates the ratio to the average size of both sentences.

The graph construction involves each pair of sentences contributing an edge, the weight of which is determined by their similarity score according to the chosen metric. Consequently, more similar sentences will have a stronger connection in the graph, as reflected by higher edge weights.

The resulting undirected weighted graph forms the basis for applying the PageRank algorithm.

The concept is illustrated in Figure 2, where nodes (S_1, S_2, S_3, and S_4) correspond to sentences, and edges connecting them depict the relationship between these sentences. The weight labels $w_{i,j}$ represent the similarity scores between sentences i and j according to the chosen similarity metric.

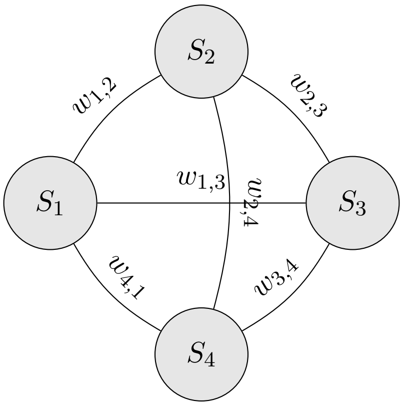

Figure 2: Undirected Weighted Graph

This graph-based text representation supports exploring inter-sentence relationships, which lies at the heart of the TextRank approach for extractive text summarization. Our experimental course with different similarity metrics aims to optimize this relationship exploration further and subsequently improve the summarization quality.

3.3 PageRank Algorithm

PageRank algorithm is a highly influential method developed by Page et al. (Page et al., 1999). The primary function of the PageRank algorithm is to compute the relative importance of nodes within a graph. It achieves this by incorporating an adjustable damping factor, which modulates the likelihood of arbitrary node transitions. This, in effect, mimics the actions of a web surfer arbitrarily transitioning between different web pages.

To achieve practical and efficient implementation of the PageRank algorithm, we utilized the NetworkX library. NetworkX is a comprehensive Python library that creates, manipulates, and investigates complex networks. Notably, it extends beyond the mere creation of networks to facilitate the computation of various network properties, such as the PageRank scores. In this study, NetworkX enabled us to transform our sentences into an interconnected network and apply the PageRank algorithm to the resultant web.

We calculated the PageRank scores of sentences using an iterative equation as provided by the NetworkX library:

$$PR^{(k+1)}(p_i) = \frac{1-d}{N} + d \sum_{p_j \in M(p_i)} \frac{PR^{(k)}(p_j)}{L(p_j)} \quad (4)$$

In this equation, $PR^{(k+1)}(p_i)$ represents the PageRank of sentence p_i at iteration $k+1$, and d denotes the damping factor, an adjustable parameter that controls the probability of random jumps between nodes. N is the total number of sentences, and $M(p_i)$ signifies the set of sentences linking to p_i. Lastly, $L(p_j)$ represents the count of outbound links from sentence p_j. It is noteworthy that higher PageRank scores indicate more significant sentences, which are then included in the resultant summary. Using NetworkX in our approach allowed us to exploit the power of network analysis in the domain of extractive text summarization, making this study a multi-disciplinary endeavor.

3.3.1 Sentence Selection

Based on their PageRank scores, sentences are ranked (Goldstein et al., 1999), and then the top k penalties to include in the summary are selected. The number of sentences (k) is determined by a predefined percentage of the total sentences in the input text. Using a threshold-based sentence selection strategy, the method generates more accurate summaries that include only the most important sentences.

3.4 Summary Construction

Final summaries are formed by concatenating the selected sentences, ensuring the output is contextually relevant.

3.5 ROUGE Score

ROUGE (Recall-Oriented Understudy for Gisting Evaluation) is an important metric because it evaluates text summarization techniques' effectiveness (Lin, 2004). It measures the similarity between the machine-generated and reference summaries based on the number of overlapping n-grams. We tested our resumes with the most common use n-gram lengths 1 (unigrams), 2 (bigrams), and L (longest common subsequence).

3.5.1 Recall

The recall is the proportion of overlapping n-grams in the reference summary that is also present in the machine-generated summary. It is defined as:

$$Recall = \frac{Number\ of\ overlapping\ n-grams}{n-grams\ in\ reference\ summary} \tag{5}$$

3.5.2 Precision

Precision is the proportion of overlapping n-grams in the machine-generated summary also present in the reference summary. It is defined as:

$$Precision = \frac{overlapping\ n-grams}{n-grams\ in\ final\ summary} \tag{6}$$

3.5.3 F1-score

The F1-score is the harmonic mean of precision and recall. It balances the trade-off between precision and recall, providing a single metric for comparing summaries. The F1-score is defined as:

$$F1-score = 2 * \frac{Precision * Recall}{Precision + Recall} \tag{7}$$

4 Experimental Framework

Our overall goal in this experiment is to gather critical key points from data. Therefore, we choose an extractive approach over abstractive and hybrid models. Extractive summarization methods identify and select the most important sentences from the source text, ensuring the critical information is preserved in the summary. This is particularly useful in professional settings where maintaining the accuracy and relevance of communication is crucial.

4.1 Dataset

In our research, we utilized the comprehensive BBC News Summary dataset. This dataset incorporates 2,225 documents, divided into five categories: Business, Entertainment, Politics, Sports, and Tech. The Business category contributes 510 articles, Entertainment presents 386 articles, Politics offers 417 articles, Sports provides 511 articles, and Tech supplies 401 articles. The diversity of these categories facilitates testing our model's performance across various subjects, certifying that our summarization method is adaptable and relevant in numerous contexts.

The dataset also provides fascinating insights into the average number of sentences across categories: Business features an average of 15.66 sentences, Entertainment averages 16.35 corrections, Politics comes in at 20.90 sentences, Sports averages 17.07 sentences, while Tech leads with an average of 24.05 penalties.

The balanced distribution of the dataset and its real-world applicability ensure the model's versatility in managing different content types. With an extensive compilation of documents accompanied by their human-generated summaries, the dataset offers a fitting framework for comprehensive evaluation and benchmarking.

4.2 Similarity Matrices

In this study, we employed the top three similarity measures - Cosine, Jaccard, and Dice - to evaluate the performance of the TextRank algorithm in the context of extractive summarization. We aimed to investigate which similarity measure leads to the most accurate summaries according to the ROUGE metrics (Recall, Precision, and F1 score). After implementing TextRank using each similarity measure, we observed that Cosine similarity outperformed both Jaccard and Dice regarding ROUGE scores.

Since cosine normalizes the vectors by their magnitude, it is less sensitive to the difference in lengths of the vectors (i.e., the number of words or tokens in the sentences). This property allows the Cosine similarity measure to assess the similarity between sentences better, even when they differ in length or word count.

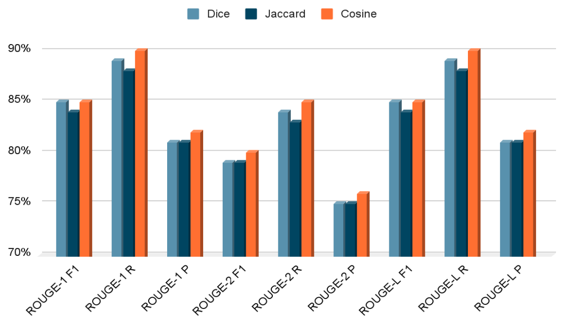

Figure 3: Mean ROUGE Scores by Similarity

On the other hand, Jaccard and Dice similarity measures are based on the ratio of the size of the intersection of the sets to their union or the average of their sizes, respectively. These measures can be more sensitive to differences in sentence lengths and word counts, which might lead to less accurate comparisons between sentences. Consequently, they may not be as effective as Cosine similarity in capturing the semantic similarity between sentences.

The superior performance of Cosine similarity can be attributed to its ability to capture the underlying semantic relationship between sentences more effectively than Jaccard and Dice similarity measures, as shown in Figure 3. This is particularly important in extractive summarization, where the goal is identifying and selecting the most relevant and informative sentences from the original text. By leveraging the strengths of Cosine similarity, the TextRank algorithm can better identify and rank sentences that capture the essence of the source document, leading to more accurate and coherent summaries.

4.3 Tuning Hyperparameters

Our method allows us to customize the percentage of sentences to include in the summary, the rates of sentences, the n-gram range vectorization, and the dampening factor. This flexibility enables the algorithm to adapt to different documents and use cases, ensuring the generated summaries are relevant and valuable.

4.3.1 Percentages of Sentences

We experimented with different values for the summary percentage. As you can see in Figure 4 when using higher rates than 50%, we observed that the precision scores decreased while recall increased. This is because as more sentences are included in the summary, it becomes more likely that non-relevant information will be introduced, leading to a drop in precision. Conversely, recall improves as more content from the original text is covered. On the other hand, when lowering the percentage, the opposite occurs.

Our optimal scores were between 45% and 50%. When calculating the average reference summaries in the entire BBC News Summary data set, we found it to be 45%. However, we stuck with 50% since it was the optimal F_1 score and maintained an over better recall score, which is important in maintaining the key details in data collection.

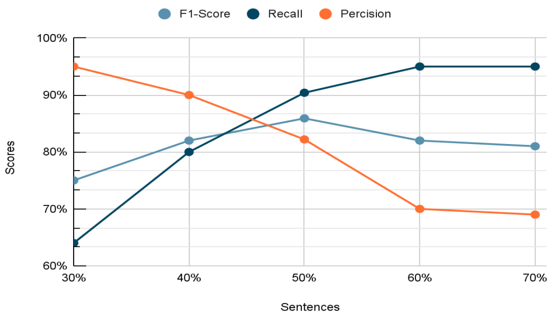

Figure 4: ROUGE-1 Scores by Percentage of Sentences

4.3.2 N-Gram

We tested various n-grams to determine the best configuration for our TextRank-based summarization model. We conducted experiments with n-grams ranging from unigrams (1-1) to 8-grams (1-8). We stopped at 8-grams because the results stayed the same. Our primary goal was to find the optimal n-gram configuration that would yield the highest summarization performance.

Our results indicate that unigrams outperformed all tested n-grams. Increasing the n-gram range resulted in a consistent decrease in performance, suggesting that higher n-grams could not capture the necessary information for accurate summarization. Therefore, our findings indicate that unigrams are the optimal n-gram configuration for our TextRank-based summarization model, allowing it to capture the most relevant information and produce more accurate summaries.

Our findings concluded that unigrams were the optimal n-gram configuration for our TextRank-based summarization model. Using unigrams allowed the model to capture the most relevant information from the text, leading to more accurate summaries.

4.3.3 Dampening Factor

For each dampening factor, the F_1 scores of the generated summaries were measured using the Rouge-1 metric. The F_1 scores increased consistently as the dampening factor increased, indicating that the outlines became more accurate and aligned with the reference summaries. The improvement in F_1 scores continued until the dampening factor reached 0.95, where the optimal performance was achieved.

After the dampening factor reached 0.95, there were no further improvements in the F_1 scores, suggesting that the optimal setting for the dampening factor in this experiment is 0.95. Using this optimal setting, the algorithm could effectively generate high-quality extractive summaries, balancing precision and recall.

Fine-tuning the TextRank algorithm with dampening factors significantly enhanced the quality of the generated summaries. By carefully selecting the optimal dampening element, n-gram range, and similarity measure, the algorithm became more efficient in capturing the most relevant and essential information from the source text. This fine-tuning allowed for a better balance between precision and recall, resulting in summaries that closely matched the reference summaries. These adjustments led to a more accurate and coherent extractive summarization that effectively condensed the main ideas from the original content.

5 Results Analysis and Discussion

TextRank - Extractive

	ROUGE-1	ROUGE-2	ROUGE-L
Precision	0.70	-	-
Recall	0.8581	-	-
F_1 Score	0.7594	-	-

NLTK - Extractive

	ROUGE-1	ROUGE-2	ROUGE-L
Precision	0.731	0.759	0.710
Recall	0.767	0.701	0.769
F_1 Score	0.713	0.651	0.732

Enhanced TextRank - Extractive

	ROUGE-1	ROUGE-2	ROUGE-L
Precision	0.822	0.767	0.820
Recall	0.904	0.859	0.903
F_1 Score	0.859	0.808	0.858

Table 1: Comparison of extractive models

5.1 Evaluating Extractive Models: Our Approach vs. Conventional TextRank

The principal extractive summarization model adopted in our study is TextRank, inspired by the PageRank algorithm (Jha, Aryan et al., 2022). Our approach enhances TextRank's effectiveness by incorporating advanced preprocessing methods, a refined similarity measure, and optimizing the damping factor.

1. **Advanced Preprocessing:** Our approach uses a combination of sophisticated natural language processing libraries, including NLTK and Spacy, for sentence tokenization and lemmatization, which are critical for maintaining sentence-level semantics. Using a predefined contractions dictionary and regular expressions facilitates consistent text formatting through contractions expansion. In addition, noise reduction in the textual data is achieved by removing stopwords and filtering sentences based on length.

2. **Refined Similarity Measure:** Using Scikit-learn's feature extraction tools for n-gram vec-

torization, and the computation of cosine similarity, we create an adjacency matrix that more accurately reflects sentence connections. This enhanced similarity measure, which accounts for the frequency and importance of elements in the sets, improves sentence comparison and the subsequent construction of the sentence graph.

3. **Damping Factor Optimization:** The application of the NetworkX library allows for fine-tuning the damping factor in the PageRank algorithm, a key parameter that controls the probability of random jumps between nodes. These optimization steps better balance precision and recalls in the summarization process.

Our approach achieves superior performance metrics through these refinements over the conventional TextRank model. With a ROUGE-1 F_1 score of 0.859, our model outperforms the traditional TextRank score of 0.7594. Moreover, it records a ROUGE-2 F_1 score of 0.808 and a ROUGE-L score of 0.858, testifying its ability to generate more coherent, structured, and contextually preserved summaries. The higher F_1 scores across all ROUGE metrics reflect the model's strength in producing accurate and informative summaries, marking its broad applicability in various scenarios.

5.1.1 Comparison with EasyChair NLTK Model

The NLTK model is an extractive text summarization method that leverages the Natural Language Toolkit (NLTK), a powerful Python library for computational linguistics. This approach to summarization focuses on selecting top-ranked sentences from the original text to generate the summary. The methodology involves several steps: data preprocessing, tokenization, generating a word frequency table, and sentence scoring based on word frequencies (Agrawal et al., EasyChair, 2021).

The preprocessing phase aims to clean the input text from redundant information and remove stop words. Following this, the reader is tokenized into words and sentences. The word frequency table is then generated to identify the most critical comments in the text, which will be used to calculate sentence scores. The NLTK model selects sentences with the highest scores to form the final summary. While this approach is straightforward, it often falls short in capturing complex relationships between words and maintaining the overall coherence and context of the original text.

The improvements and optimizations in our research approach to TextRank allow it to achieve a ROUGE-1 F_1 score of 0.859 compared to the existing NLTK model's 0.651. The higher F_1 score highlights our model's ability to balance precision and recall, generating informative and accurate summaries essential for various applications.

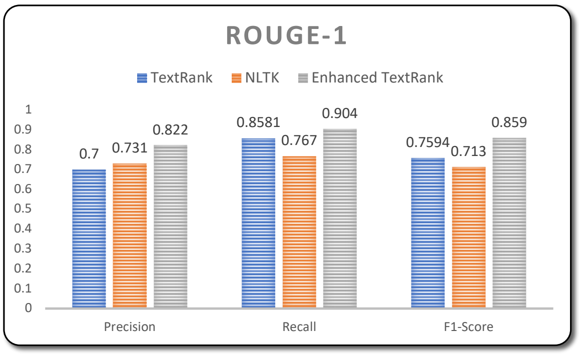

Figure 5: Comparison of ROUGE-1 scores

Our research approach to TextRank outperforms the NLTK extractive method. The superiority of our research approach to TextRank can be attributed to the advanced preprocessing techniques, tokenization, word embeddings, and similarity measures we employ. By incorporating these features, our system can produce high-quality summaries that effectively represent the main ideas and structure of the original text, making it a more suitable choice for various applications that demand accurate and informative summaries.

In conclusion, our research approach to TextRank significantly improves the existing NLTK model and offers competitive performance. The enhancements in preprocessing, tokenization, word embeddings, and similarity measures enable our model to generate high-quality summaries that accurately represent the main ideas and structure of the original text. As a result, our approach is a more viable option for various applications requiring coherent and contextually accurate summaries.

6 Conclusions

This study proposes a refined approach to the TextRank model for extractive text summarization. Our methodology outperforms the existing TextRank method (Jha, Aryan et al., 2022) and the NLTK extractive model (Agrawal et al., EasyChair, 2021) on various ROUGE metrics.
