Preface

The international RANLP conference is a well-established biennial forum for computational linguists and Natural Language Processing (NLP) practitioners which continues to report important trends in the field. In 2023 the programme was dominated by research on developing or exploiting pre-trained large language models (LLMs) and the deep learning technology which was the reason to assign the subtitle ‘LLMs for NLP’ to the volume. The highlights of this year included the urgent and challenging topics such as responsible and explainable machine learning, quality of the existing datasets, multimodality and multilinguality.

The conferences attracted 165 submissions and accepted 31 regular papers, 59 short papers, 41 posters, and 4 demos (excluding workshops). The event was attended by over 170 participants from over 35 countries.

The conference in 2023 features six keynote speakers:

- Eduard Hovy (University of Melbourne, Australia and Carnegie Mellon University, USA),
- Tharindu Ranasinghe (Aston University, UK),
- Sandra Kübler (Indiana University Bloomington, USA),
- Lucas Beyer (Google Brain, Switzerland),
- Isabelle Augenstein (University of Copenhagen, Denmark),
- Efstathios Stamatatos (University of the Aegean, Greece).

The proceedings cover a wide variety of NLP topics, including training, adaptation, evaluation and explanation of language models, multimodal studies, language resources, machine translation, NLP for social sciences and literary studies, simplification and summarisation, topic modelling, opinion-mining and sentiment analysis, fake news, bias and hate speech detection.

In 2023 RANLP was preceded by the summer school ‘Deep Learning for NLP’ and pre-conference tutorials, and hosted a record number of post-conference workshops on popular NLP topics:

- LT-EDI 2023 – Third Workshop on Language Technology for Equality, Diversity and Inclusion
- DravidianLangTech 2023 – Third Workshop on Speech and Language Technologies for Dravidian languages
- TSAR 2023 – Workshop on Text Simplification, Accessibility and Readability
- ALP 2023 – Workshop on Ancient Language Processing
- HumEval 2023 – Third Workshop on Human Evaluation of NLP Systems
- BUCC 2023 – 16th Workshop on Building and Using Comparable Corpora
- CASE 2023 – 6th Workshop on Challenges and Applications of Automated Extraction of Socio-political Events from Text
- ConTeNTS 2023 – Computational Terminology in NLP and Translation Studies
- NLP4TIA 2023 – NLP tools and resources for translation and interpreting applications

In addition to thanking the keynote speakers and workshop organisers who accepted our invitation, we would like to thank the lecturers and tutors of the Summers school and tutorials.

We are grateful to the members of the Programme Committee and all additional reviewers. They ensured that the best papers were included in the Proceedings and provided invaluable comments to the authors.

We would like to use this paragraph to acknowledge the members of the Organising Committee, who worked very hard during the last few months and whose dedication and efforts made the organisation of this event possible. The members of the Organising Committee (listed in alphabetical order below) carried out numerous organisational tasks and were eager to step in and support the organisation of the conference whenever needed: Khadija Ait ElFqih, Elena Blagoeva, Marie Escribe, Emma Franklin, Amal Haddad Haddad, Jessica López Espejel, Teodora Mihajlov and Nikolai Nikolov.

A big THANK YOU to all of you, this conference could not have taken place so smoothly without you!

Finally, many thanks go to Lancaster University and the Institute of Information and Communication Technologies at the Bulgarian Academy of Sciences for their unreserved support of RANLP. Our gratitude goes also to our generous sponsors as well: Bulgarian National Research Fund, Ontotext, Iris.AI, Senso, Cambridge University Press and ELDA.

Caution: This paper contains examples, from datasets, of what some may consider as stereotypes or offensive text.

Abstract

We investigate five English NLP benchmark datasets (on the superGLUE leaderboard) and two Swedish datasets for bias, along multiple axes. The datasets are the following: Boolean Question (Boolq), CommitmentBank (CB), Winograd Schema Challenge (WSC), Winogender diagnostic (AXg), Recognising Textual Entailment (RTE), Swedish CB, and SWEDN. Bias can be harmful and it is known to be common in data, which ML models learn from. In order to mitigate bias in data, it is crucial to be able to estimate it objectively. We use bipol, a novel multi-axes bias metric with explainability, to estimate and explain how much bias exists in these datasets. Multilingual, multi-axes bias evaluation is not very common. Hence, we also contribute a new, large Swedish bias-labeled dataset (of 2 million samples), translated from the English version and train the SotA mT5 model on it. In addition, we contribute new multi-axes lexica for bias detection in Swedish. We make the codes, model, and new dataset publicly available.

1 Introduction

Recent advances in artificial intelligence (AI), large language models (LLM), and chatbots have raised concerns about their potential risks to humanity (Bender et al., 2021; Adewumi et al., 2022; Yudkowsky et al., 2008).[1] One major concern is the issue of social bias, particularly with the data AI models are trained on. Bias, which can be harmful, is the unfair prejudice in favor of or against a thing, person or group (Maddox, 2004; Dhamala et al., 2021; Mehrabi et al., 2021; Antoniak and Mimno, 2021). Measuring bias in text data can be challenging because of the axes that may be involved (e.g. religious or gender bias).

In this work, our motivation is to determine whether social bias exists in NLP benchmark datasets and estimate it. After reviewing some potential bias methods, as discussed in Section 2, we settled for the recent bipol (Alkhaled et al., 2023) because of its advantages. It is a metric that estimates bias along multiple axes in text data and provides an explanation for its scores, unlike other metrics. We investigate social bias in benchmark datasets that are available on the English SuperGLUE leaderboard and two Swedish datasets. The SuperGLUE was introduced by Wang et al. (2019) and provides benchmark datasets for different NLP tasks. Benchmark datasets are datasets for comparing the performance of algorithms for specific use-cases (Dhar and Shamir, 2021; Paullada et al., 2021). Such datasets have been the foundation for some of the significant advancements in the field (Paullada et al., 2021). We investigate the following English datasets: Boolq (Clark et al., 2019), CB (De Marneffe et al., 2019), WSC (Levesque et al., 2012), AXg (Rudinger et al., 2018a), and RTE (Wang et al., 2019). The Swedish datasets are the Overlim *CB* and SWEDN. We discuss more about the datasets in Section 3.2.

Our contributions Firstly, we show quantitatively and through explainability that bias exists in the datasets. The findings correlate with characteristics of bias, such as heavy lopsidedness (Zhao et al., 2018). This work will provide researchers with insight into how to mitigate bias in text data and possibly add impetus to the conversation on whether it is even ethical to remove these social biases from data, because they represent the real world. Secondly, we create and release, possibly, the largest labeled dataset and lexica for bias de-

Proceedings of Recent Advances in Natural Language Processing, pages 1–10
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_001

tection in Swedish (multi-axes bias dataset (MAB)-Swedish) and train a model based on the state-of-the-art (SotA) multilingual T5 (mT5) (Xue et al., 2021). We release our codes, dataset and artefacts publicly. [2]

The rest of this paper is structured as follows. Section 2 discusses some of the previous related work. Section 3 describes the methodology, including details of the characteristics of bipol and the new MAB-Swedish dataset. Section 4 presents the results and discusses some of the qualitative results. In Section 5, we give concluding remarks.

2 Related Work

There have been considerable effort in identifying and measuring the level of bias in datasets (Cryan et al., 2020; Dhamala et al., 2021; Stanley, 1977; Chandrabose et al., 2021). These are usually targeted at gender bias in a binary form (Zhao et al., 2018; Rudinger et al., 2018a). However, studies have shown that the biases in language models for the intersection of gender and race can be greater than those for gender and race individually and that addressing bias along only one axis can lead to more issues (Tan and Celis, 2019; Subramanian et al., 2021). To determine the level of bias in NLP datasets along multiple axes can be a significant challenge, more so that many of these methods admit their approaches may demonstrate the presence of bias but not prove its absence (Zhao et al., 2018; Rudinger et al., 2018a). Table 1 compares some of the methods that have been introduced.

Metric/Evaluator	Axis	Terms
WinoBias (Zhao et al., 2018)	1	40
Winogender (Rudinger et al., 2018a)	1	60
StereoSet (Nadeem et al., 2021)	4	321
Hurtlex (Nozza et al., 2021)	6	1,072
CrowS-Pairs Nangia et al. (2020)	9	3,016
Bipol (Alkhaled et al., 2023)	>2, 13*<	>45, 466*<

Table 1: Comparison of some bias evaluation methods. (*The upper bounds are not limited by the bipol algorithm but the dataset & lexica.)

Furthermore, Bassignana et al. (2018) proposed a multi-language approach using HurtLex to target misogyny because addressing bias in only the English language is not sufficient for addressing the potential harm to society. In the English language, there are common biases that associate female terms with subjects such as liberal arts and family while associating male terms with subjects such as science (Nosek et al., 2002). There are also more words that sexualize females more than males (Stanley, 1977). Other languages have their own peculiarities (Nozza et al., 2021).

In addition to the various methods identified in Table 1 for quantifying the extent of discrimination or bias, there is also odds ratio (OR), which compares the chance of a specific outcome happening, with a certain exposure, to the likelihood of that outcome happening without the exposure (Szumilas, 2010). Another method is the impact ratio (IR), which calculates the ratio of positive outcomes for a protected group to the general group. In Cryan et al. (2020), they compare lexicon method to model classification for gender bias in English language only. Our approach combines the strengths of both approaches and evaluates on English and Swedish data across multiple axes.

3 Methodology

3.1 Bipol

There are two stages in the implementation of bipol (see 1a) before it gives a final score between 0.0 (zero or undetected bias) and 1.0 (extreme bias). The first stage involves the classification of the data samples (into biased and unbiased categories) using a trained model (see 1b). Ideally, it is the ratio of the number of true positives (tp) to the total samples (true positives (tp), false positives (fp), true negatives (tn), and false negatives (fn)), where fp is preferably zero. However, since the trained models will be evaluated on unseen data, the predicted biased samples are likely to have fp in the numerator as expressed in the equation. The evaluations thus come with positive error rate ($\frac{fp}{fp+tp}$) to establish the lower bound of error for the predictions. A good classifier should minimize the number of fp and maximize the number of tp but there's hardly any perfect classifier, even in other tasks such as spam detection or hate speech (Heron, 2009; Feng et al., 2018).

$$b = \begin{cases} b_c . b_s, & \text{if } b_s > 0 \\ b_c, & \text{otherwise} \end{cases} \tag{1a}$$

$$b_c = \frac{tp + fp}{tp + fp + tn + fn} \tag{1b}$$

$$b_s = \frac{1}{r} \sum_{t=1}^{r} \left(\frac{1}{q} \sum_{x=1}^{q} \left(\frac{|\sum_{s=1}^{n} a_s - \sum_{s=1}^{m} c_s|}{\sum_{s=1}^{p} d_s} \right)_x \right)_t \tag{1c}$$

The second stage evaluates the biased samples for sensitive terms listed in the multi-axes lexica

[2] github.com/LTU-Machine-Learning/bipolswedish.git

(see 1c). It involves finding the difference between the two maximum summed frequencies in the types (e.g. female) of an axis (e.g. gender) $(|\sum_{s=1}^{n} a_s - \sum_{s=1}^{m} c_s|)$, which is then divided by the summed frequencies of all the terms in that axis $(\sum_{s=1}^{p} d_s)$. The average over all the axes $(\frac{1}{q} \sum_{x=1}^{q})$ is then averaged over all the biased samples $(\frac{1}{r} \sum_{t=1}^{r}$). Table 2 provides the Swedish lexica sizes. The lexica are derived from Adewumi et al. (2020a,b) and Wikipedia[3] and may be expanded as needed. They include terms that may be stereotypically associated with certain groups and specific gender (Cryan et al., 2020; Zhao et al., 2018). The English lexica contain more and are also derived from public sources (Alkhaled et al., 2023).

Axis	Axis type 1	Axis type 2
Gender	17 (female)	19 (male)
Racial	10 (black)	10 (white)

Table 2: Swedish lexica sizes. These may be expanded.

The rationale for using bipol is because of the strengths of the metric. These include 1) the relative simplicity of calculating a score, 2) it is straight-forward to implement since it is based on existing concepts like lexica and classifiers, 3) it captures semantic and term frequency (TF) aspects of data, 4) it has explainability built in, 5) it's possible to determine the error rate of predictions, and 6) it is not limited in the total number of axes that may be used. We acknowledge, however, that it has limitations that are based on the limitations of the tools that may be used to calculate it.

3.2 Datasets

3.2.1 The New MAB-Swedish Dataset

The dataset was machine-translated (from MAB (Alkhaled et al., 2023)) using the Helsinki-NLP model (Tiedemann and Thottingal, 2020), which was mostly trained with guided alignment. The automatic translation took over 48 hours on one GPU. It has 1,946,975 samples, as given in Table 3. Quality control (QC) for the MAB-Swedish involved translation verification by back-translating some random samples using Google NMT before a review by a Swedish speaker. The English version was constructed from two datasets: Jigsaw[4] and the Social Bias Inference Corpus v2 (SBICv2) by (Sap et al., 2020). Personal identifiable information (PII) were removed from the dataset. More details about the annotation of the base datasets for the MAB can be found in Alkhaled et al. (2023). Some examples in the MAB-Swedish are given in Table 4.

Machine-Translation concerns Bias is a universal concern, though there can be culture-specific biases. A stereotype or degrading comment can be considered of universal concern if it is relevant across cultures. For instance, the first example in Table 4 is of universal concern because women should be respected, regardless of nationality or culture. This also applies to the other biased examples in the table. Hence, MAB-Swedish is relevant for bias detection in Swedish, though it was translated. A limitation of the dataset, however, is that it may not contain examples that are specific to the Swedish culture since the original dataset is from English, with specific references to the USA and Canada.

Set	Biased	Unbiased	Total
Training	533,544	1,209,433	1,742,977
Validation	32338	69649	101987
Test	33470	68541	102011
	599,352	1,347,623	1,946,975

Table 3: MAB-Swedish dataset split.

comment_text	label	old_id	id
Den här slynan är galen som skulle läsa en bok av en kvinna. *(This b*tch is nuts. Who would read a book by a woman.)*	biased	239612	1212584
9 av 10 människor njuter av mobbning. Jag kommer alltid att vara den 10: e *(9 out of 10 people enjoy bullying. I will always be the 10th.)*	biased	none	1517517

Table 4: Examples from the MAB-Swedish (The English in the original is in italics.)

[3] en.wikipedia.org/wiki/Swedish_profanity

[4] medium.com/jigsaw/creating-labeled-datasets-and-exploring-the-role-of-human-raters-56367b6db298

3.2.2 Boolq

It is a question-answering (QA) task where each example has a short passage and a yes/no question about the passage (Clark et al., 2019) . These questions were provided anonymously by Google search users and afterwards paired with a paragraph from a Wikipedia article that has the answer. We evaluated the passage column of the dataset.

3.2.3 CB

This contains short texts in which, at least, one sentence has an embedded clause (De Marneffe et al., 2019). The resulting task is framed as three-class textual entailment on examples that are drawn from the following datasets: Wall Street Journal, fiction from the British National Corpus, and Switchboard. We evaluated the premise column of the dataset.

3.2.4 WSC

This is a coreference resolution dataset (Levesque et al., 2012). Examples consist of a sentence with a pronoun and a list of noun phrases from the sentence. We evaluated the text column of the dataset.

3.2.5 AXg

It is designed to measure gender bias in coreference resolution systems (Rudinger et al., 2018b). Each example consists of a premise sentence having a male or female pronoun and a hypothesis giving a possible antecedent of the pronoun. We evaluated the premise column of the dataset.

3.2.6 RTE

The datasets come from a series of annual competitions on textual entailment (Wang et al., 2019). Data from several sources were merged and converted to two-class classification: entailment and not_entailment. We evaluated the premise column of the dataset.

3.2.7 Swedish CB

This is part of the OverLim dataset by the National Library of Sweden. It contains some of the GLUE and SuperGLUE tasks automatically translated to Swedish, Danish, and Norwegian, using the OpusMT models for MarianMT[5]. We evaluated its training set.

3.2.8 SWEDN

This is a text summarization corpus based on 1,963,576 news articles from the Swedish newspaper Dagens Nyheter (DN) during the years 2000 to 2020.[6] There are five categories of articles in the dataset: domestic news, economy, sports, culture, and others (Monsen and Jönsson, 2021). The training set consists of the first three categories and we evaluate the first 1,000 samples because of the computation cost of evaluation.

3.3 Experiments

The experiments were conducted on two shared Nvidia DGX-1 clusters running Ubuntu 18.04 and 20.04 with 8 × 32GB V100 and 8 x 40GB A100 GPUs, respectively. Average results are reported after running each experiment twice. To evaluate the benchmark datasets, we utilize bias-detection models (Alkhaled et al., 2023) based on RoBERTa (Liu et al., 2019), Electra (Clark et al., 2020), and DeBERTa (He et al., 2021). We train a small mT5 model with batch size of 16, due to memory constraints, on the MAB-Swedish. Wandb (Biewald, 2020), an experiment tracking tool, is run for 5 counts with bayesian optimization to suggest the best hyper-parameter combination for the learning rate (1e-3 - 2e-5) and epochs (6 - 10) before final training of the model. We use the pretrained model from the HuggingFace hub (Wolf et al., 2020). Average training time was 15 hours. Average evaluation time ranges from about 30 minutes to over 24 hours.[7]

4 Results and Discussion

From Table 5 we observe that all the datasets have bias, though little, given that they are smaller than a *bipol* score of 1. The dataset with the least amount of bias is Boolq, which is confirmed by all the three models. This is despite the dataset having the highest number of unique samples. CB has the largest amount of bias and this is also confirmed by the three models. This is also the case for the Swedish CB, when compared with SWEDN.

The average macro F1 score on the validation set of MAB-Swedish is 0.7623 with standard deviation (s.d.) of 0.0075. The resulting error rate is 0.2893. This is relatively reasonable though a bit higher than the error rate for the English RoBERTa, Electra, and DeBERTa, which are 0.198, 0.196, and 0.2, respectively (Alkhaled et al., 2023).

Table 5: Results of average bipol scores. All the datasets have bias, though little.

4.1 Error Analysis

Figure 1 presents the confusion matrix for the mT5 on the MAB-Swedish. The tn, fp, fn, tp are 61,689, 7,960, 12,781, and 19,557, respectively, which are relevant for Eq. 1b. We observe that the model is better at predicting unbiased samples. This is expected since the training data contains more examples of unbiased samples. Table 6 presents some qualitative examples of apparently correct and incorrect predictions in two of the datasets. The first correct example in the English CB appears to have a clear stereotype that *men are naturally right and it is the role of women to follow their lead*. The second correct example, in both the English and Swedish data, may have been perceived as biased by the two different models because of the offensive term *fool* or the overgeneralization that *folk will always take advantage of weakness* or both. Overgeneralization is a characteristic of bias (Rudinger et al., 2018a; Nadeem et al., 2021).

Explaining bias type

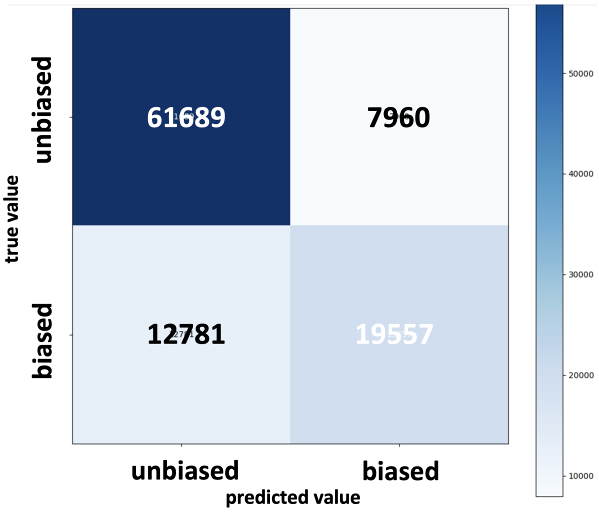

Figure 1: Confusion matrix for mT5.

The type of overall bias (for the gender axis) in many of the datasets is explained by the dictionary of lists produced by bipol (see Appendix .1) and represented in ”top-5 frequent terms” bar graphs of Figures 2 to 13. As expected, we observed that AXg is limited to only gender, unlike Boolq, which also reflects religious bias, as explained in their bipol dictionaries of lists. We observe from Figures 2, 3, and 4 that Boolq is male-biased. Figures 5, 6, and 7 show that CB is also male-biased. This is the case also for RTE, as revealed by Figures 8, 9, and 10. On the other hand, we observe that the case of WSC is not clear-cut because Figure 11 shows only a marginal lead for female bias, Figure 12 shows the difference among the top-5 is zero and Figure 13 shows a slight overall male bias.

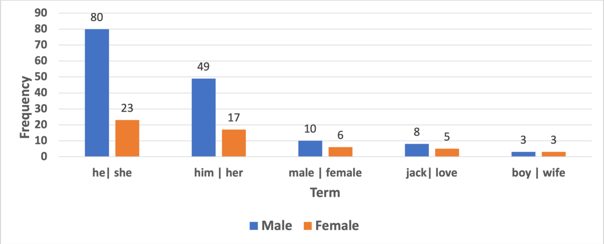

Figure 2: Top-5 gender frequent terms in Boolq by RoBERTa.

5 Conclusion

We show that all benchmark datasets we evaluated, including the Swedish datasets, contain bias to different degrees. This is likely the first time these datasets are evaluated in such a way that estimates the amount of bias and the type. We believe these evaluations will motivate research on how to more effectively mitigate bias along multiple axes in datasets. This work may encourage dis-

cussions on whether the biased samples from the benchmark datasets should be disregarded entirely or if they should be utilized in a different manner than previously done. Our public release of the new MAB-Swedish dataset, lexica and model will also facilitate future work in multilingual bias detection.

Ethics Statement

The authors made the effort to obscure offensive terms in examples that were used in this paper. We note that the models for estimating the biases in the datasets are limited in scope, as they only cover certain number of axes (12). Therefore, a result of 0 on any dataset does not necessarily indicate a bias-free dataset.

Abstract

This paper presents a method for generating Wikipedia articles in the Hindi language automatically, using Wikidata as a knowledge base. Our method extracts structured information from Wikidata, such as the names of entities, their properties, and their relationships, and then uses this information to generate natural language text that conforms to a set of templates designed for the domain of interest. We evaluate our method by generating articles about scientists, and we compare the resulting articles to machine-translated articles. Our results show that more than 70% of the generated articles using our method are better in terms of coherence, structure, and readability. Our approach has the potential to significantly reduce the time and effort required to create Wikipedia articles in Hindi and could be extended to other languages and domains as well.

1 Introduction

Being one of the largest collections of Human Knowledge, Wikipedia is a widely-used, multilingual online encyclopedia that relies on volunteer contributors and an open collaboration model using a wiki-based editing system. While research has shown success in the multilingual aspect of Wikipedia, its local language pages, particularly in Hindi, are lacking. There are only **149,464** Hindi Wikipedia pages, with an average length of fewer than 500 words, compared to **54,121,996** pages in English Wikipedia.

The interlinking of language versions on Wikipedia has undergone a significant overhaul with the introduction of **Wikidata**, a unified scheme that utilizes unique numbers to identify entities and their properties. Wikidata is a collaboratively edited knowledge base hosted by the Wikimedia Foundation, offering a common source of open data under a public domain license that can be used by Wikimedia projects and others. The data in Wikidata is stored in the form of specific IDs that serve as the base for the platform. Each entity has a unique entity ID, which is a number prefixed by a letter. Items are prefixed with Q (e.g., Albert Einstein (Q937)), properties are prefixed by P (e.g., an instance of (P31)), and lexemes are prefixed by L (e.g., L1). This can be seen in [1]. The platform also includes a query service called **WDQS**[1], which allows users to run queries on Wikidata's extensive database using an RDF triple store for SPARQL[2] queries against the current data version.

A knowledge graph, also known as a semantic network, is a visual representation of connections among real-world entities, such as objects, concepts, events, or situations. The fundamental components of a knowledge graph are nodes, edges, and labels. Nodes represent any entity, whether it be a person, place, or thing. Edges, on the other hand, indicate the association between two nodes. Knowledge graphs are essential tools for effective knowledge management, and Wikidata is a prime example of a knowledge graph. In Wikidata, scientists (in our case) are the nodes, with information on the scientist as another node and the property as the edge.

Generating coherent and discourse-related sentence-length natural language text in different languages is now possible due to improved computing power and model capacity. However, generating multiple sentences that display coherence and relevance to a topic remains a challenge, especially in Scientific domains, with minimal research done in

https://doi.org/10.26615/978-954-452-092-2_002

Indian languages like Hindi. Our approach focuses on generating such human-like Hindi Wikipedia pages in the Scientist domain with a minimum length of 500 words. This project aims to surpass existing projects like LSJbot[3] by generating longer documents that encompass all relevant information.

This paper describes a model that generates template sentences using a dataset specifically created from scratch. This dataset incorporates data points from the Scientist domain sourced from Wikidata. The template sentences are manually crafted with key-value placeholders filled using the dataset's specific data points. Following that, the sentences undergo rearrangement based on a rule-based system to generate an article. The paper also introduces this dataset created in Hindi and provides detailed insights into the nuances of the template sentences model along with the dataset construction process. This dataset is comprehensive, containing Hindi key-value pairs for 17,000 scientists who do not yet have a Hindi Wikipedia page. We also believe that our approach can be extended to other domains provided relevant translations and data are scraped for processing.

2 Related Work

Existing methods from Sauper and Barzilay (2009) use the high-level structure of human-authored texts to automatically induce a domain-specific template for the topic structure of a new overview. While Song et al. (2018), Ribeiro et al. (2019), and Guo et al. (2019) focus on generating sentences, a more challenging and interesting scenario emerges when the goal is to generate multi-sentence texts. Banerjee and Mitra (2016) introduces WikiWrite, a system to author new articles on Wikipedia automatically by obtaining vector representations of the red-linked entities using a paragraph vector model (Le and Mikolov, 2014) that computes continuous distributed vector representations of varying-length texts. The representations are then used to identify similar articles that currently exist on Wikipedia. Rapp et al. (2012) used Wikipedia articles in nine languages to identify word translations through keywords and a word alignment algorithm. Schamoni et al. (2014) proposed to use links to retrieve Wikipedia articles in English, similar to an article in German.

To the best of our knowledge, the research conducted by Ribeiro et al. (2020) shows the latest work that introduces a unified graph attention network structure for investigating graph-to-text models that combine global and local graph encoders in order to improve text generation. An extensive evaluation of their models demonstrated that the global and local contexts are empirically complementary, and a combination can achieve state-of-the-art results on two datasets. These models substantially help in providing and enriching Wikipedia Pages. Although these works carry out some kind of matching across languages and improve English Wikipedia, we could not find references on creating Wikipedia Pages for the Hindi Language. To the best of our knowledge, we are the first to propose a dataset and evaluate a method in this field.

3 Method

Our paper aims to make a Hindi Wikipedia page citing all vital information important for any domain-specific data point. We assumed that relevant information on the particular data point requested is available on the Internet but scattered among several pages.

A specific domain (Scientists) is selected, and a search for entities within that domain is conducted in the desired language (Hindi) using WDQS. This search yields a list of data points related to scientists in the specified domain, which can be downloaded in various formats, such as JSON (in this case). To make the data more easily readable, the Python libraries JSON and QWikidata are utilized. Upon decoding the data, each entity consists of two main components: the child and the child name. The child part contains the Wikidata link associated with the entity, while the child name corresponds to the name of the entity as documented in Wikidata. To extract the relevant details, the QID is separated from the child and subjected to further processing.

We have followed a four-tier process to generate the article: **Collecting Domain Specific Key-Value pairs from Wikidata**, **Preprocessing**, **Template Sentence Generation with Data Retrieval Techniques**, **Features Addition & Final Wikipedia Page Generation**. Let us look into each of

[3] https://en.wikipedia.org/wiki/Lsjbot

these in detail.

3.1 Collecting Domain Specific(Biological Sciences) Key-Value Pairs from Wikidata

Before we understand how we collected the domain-specific data, it's important to understand the intricacies of choosing the domain. Initially, we chose monuments as our domain due to the low number of Hindi Wikipedia articles in this category, with only **284** Hindi Wikipedia Pages compared to **11,524** English Wikipedia Pages. However, as we reviewed the available data points, we discovered that the content was inconsistent, lacking coherence and detail, and there were too few data points to establish a reliable template.

After conducting research on various domains, such as animals, films, birds, and trees, we ultimately selected the Scientific Person domain. This domain was ideal because it contained English Wikipedia pages for prominent scientists, botanists, zoologists, and other scientific personalities but no corresponding Hindi Wikipedia pages. Additionally, this domain had a wealth of existing Hindi Wikipedia data compared to the Monuments domain. Once we finalized the domain, we used Wikidata's query service called WDQS to form a preliminary dataset. Querying data using WDQS and its SPARQL technology requires unique identification of domain properties and items, making query writing a task that requires careful attention to syntax dependencies.

The query service provided us with a JSON file containing data on nearly 30,000 Wikipedia pages, of which 13,000 already had existing Hindi Wikipedia pages. An image showing how an actual Wikidata page looks can be seen in Figure 1 in the Appendix. This allowed us to focus on creating Hindi Wikipedia pages for the remaining 17,000 entities within the Scientific Person domain.

3.2 Preprocessing

To obtain the key-value pairs for each scientist, we had to understand how data is stored in Wikidata and find the correct approach to retrieve it. We found that for each scientist, the pairs were embedded so deeply that it required 6-7 nested iterations to obtain the values. An example can be seen in Figure 2 in the Appendix. Although this process was time-consuming, we successfully obtained all the pairs for the 17,000 scientists. We then used various libraries like QWikidata to convert these key-value pairs into a human-readable format. We created a main dictionary for each scientist, with their name as the key and their key-value pairs as a nested dictionary. Some of these nested dictionaries contained English key-value pairs, which were translated manually and combined with the pre-existing Hindi pairs.

To ensure greater accuracy in translation, a Hindi Domain Expert was consulted to translate the English Key-Value pairs, as relying solely on Google/Bing Translate would have resulted in an approximate accuracy of 85% (Dhariya et al., 2017), leading to inconsistent translations in the final dataset. Since these English Key-Value pairs were intermingled with the Hindi and English Pairs, a separate dictionary was created to store the pairs that required translation. Translations were recorded in an Excel file with the corresponding sentence context, allowing for accurate contextual translation.

An interesting example where the sentence context played an important role would be. ***Given Word: "leaves"***. Now, this word, if given no context, could be translated as "पत्तियां" whereas if the context is given saying ***"He leaves for work"***, the Hindi translation for the same word comes out to be completely different i.e. "निकल जाता है" , and hence sentence context was used. The task of back-propagating the translated English Key-Value pairs from the Excel Sheet to the original Hindi Key-Value pairs was anticipated to be tedious and involved mapping and clear demarcations for each entity. Despite incorporating these demarcations, some errors were encountered while using the pandas module. After extensive coding, we were ultimately successful in placing the translated English Key-Value pairs with the existing Hindi Key-Value pairs in Wikidata and were able to complete the dataset.

3.3 Template Sentence Generation with Data Retrieval Techniques

Next, we focused on generating template sentences, but first, we identified the crucial Key-Value pairs for the Scientist Domain. Key attributes such as Doctoral Advisor, Student, Doctoral Student, Awards Won, and Field of Work were considered essential. To extract these pairs, we utilized two highly effective relevance algorithms: TF-IDF and frequency filtering. We'll examine these techniques in depth, detailing each of their contributions toward identifying the most significant Key-Value pairs for each scientist.

3.3.1 TF-IDF

TF-IDF is a statistical approach that measures the relevance of a word to a document in a collection of documents. It calculates the score by multiplying two metrics: the frequency of the word in a document and the inverse document frequency of the word across the entire document set. A higher score indicates greater relevance of the word in the document. As our data had binary values (0 or 1) for the presence or absence of a key-value pair for a scientist, we shifted our focus to document frequency. To determine the relevance of each key-value pair for a given scientist, we calculated the frequency of each key-value pair across all 17,000 scientists, dividing each frequency by the total frequency of all keys in the data. We then sorted these values in decreasing order to identify the key-value pairs with the highest frequency. This approach allowed us to gain a better understanding of the significance of each key-value pair, given the low likelihood of two scientists sharing the same number of keys.

To prioritize the importance of least occurring keys, we reviewed approximately 200 Hindi Wikipedia pages of scientists and compiled a list of keys that were not frequently mentioned across all pages but were crucial for a complete scientist profile. Examples of such keys include: "नामांकित किया गया"[4] or "छात्र"[5] were important, and we decided to use the IDF concept to include such keys as well. To get rid of the other keys which did not affect the quality of the page and also those for which the frequency was extremely low, we used Frequency Filtering, which we will discuss next.

3.3.2 Frequency Filtering

Frequency filtering is a technique used to eliminate stopwords, which are commonly used words that do not provide much meaning in a text. The objective is to avoid diluting the importance of less frequent but more meaningful words. It is indirectly employed by TF-IDF to determine the significance of a word in a document.

We applied the concept of frequency filtering to our data by examining the list of relevant keys sorted by frequency using TF-IDF. To utilize frequency filtering, we established a threshold by analyzing 200 Hindi Wikipedia pages, similar to our earlier approach. Following a comprehensive analysis, we determined a limit for the number of keys to include in our dataset. We set the threshold for the maximum number of keys to 25, aligning with our primary goal of ensuring that each scientist's profile comprised at least 500 words (provided there was sufficient information available on Wikidata). Any keys exceeding the limit were excluded from our dataset.

Upon completion of the aforementioned procedures, we successfully compiled a list of the top 20-25 most relevant and essential Key-Value pairs for each scientist. However, for some scientists, due to limited information available on Wikidata, only 10-15 pairs could be extracted. Nevertheless, we ensured that all available information on Wikidata for such scientists was incorporated into their Wikipedia page. We now proceed to the Template Sentence Generation section.

3.3.3 Template Sentence Generation

With the top 20-25 most significant key-value pairs in hand, we proceeded to generate template sentences. This selection made the process of constructing template sentences more straightforward, as we only had to focus on these keys to create the sentences. The placeholders in these sentences would then be substituted with the unique values of the keys for each scientist. To generate the template sentences, we adopted a unique approach, starting with the most complicated sentences, followed by less complicated ones, and so on. The upcoming paragraph elaborates on this method.

To ensure that the Wikipedia page was as informative and linguistically sound as possible, we opted to merge some of the related keys and create a sentence out of them. For instance, keys such as:

[4] Nominated for

[5] Student

{{व्यवसाय}}[6], {{जन्म तिथि}}[7] and {{जन्म स्थान}}[8]

when used separately would result in 3 different sentences like

1. वह एक प्रसिद्ध {{व्यवसाय}} थे |,[9]
2. वह {{जन्म तिथि}} को पैदा हुई थे |, [10] and
3. उनका जन्म {{जन्म स्थान}} देश में हुआ था |[11]

where {{व्यवसाय}}, {{जन्म तिथि}} and {{जन्म स्थान}} are placeholders for the respective scientist key-value pairs, but if we employ our technique, we will get one sentence that is able to tell us the same information as mentioned in the above sentences:

वह एक प्रसिद्ध {{व्यवसाय}} थे जिनका जन्म {{जन्म तिथि}} को {{जन्म स्थान}} देश में हुआ था | [12]

Recognizing the advantages of utilizing complex sentences, we embarked on identifying pairs of keys that could be combined to form coherent and meaningful sentences. Through our analysis, we discovered several pairs that aligned well together. Here are a few examples:

1. {{नागरिकता}}[13], {{Scientist}}, {{मातृसंस्था}}[14], and {{शैक्षिक दर्जा/उपाधि}}[15],
2. {{Scientist}}, {{कार्य स्थल}}[16], {{नियोक्ता}}[17], and {{पद पर आसीन}}[18]

Based on the above keys, below are the sentences using these keys:

1. {{नागरिकता}} में पैदा {हुए/हुई} {{Scientist}} {{मातृसंस्था}} {के/की} पूर्व छात्र {alivestatus/wgop} और आगे चलके उन्होंने {{शैक्षिक दर्जा/उपाधि}} की डिग्री भी प्राप्त की | [19]
2. {{Scientist}} का कार्यस्थल {{कार्य स्थल}} {alivestatus}, और वह {{नियोक्ता}} में एक {{पद पर आसीन}} के रूप में भी कार्यरत {alivestatus/wgop} | [20]

An important thing to note here is that while making the above template sentences, we had to take care of various Hindi Syntactic Rules. For example, just to compare, in English, the translation for Sentence 1 would be **"Born in {Place}, {Scientist} was an alumnus of the {Alma-Mater} and went on to earn a {Academic Degree}"** where the placeholders **{Place}**, **{Scientist}**, **{Alma-mater}** and **{Academic Degree}** are the English translations of the main four keys in Sentence 1.

Here, we see an interesting difference; in the case of the English Sentence, the gender of the Scientist will not play any role whatsoever in the formation of the sentence. Be it a male or a female scientist; the sentence remains the same. However, the same sentence in Hindi changes drastically with the gender as {थे/थी}(This is represented by {alivestatus} in our case), {हुए/हुई} and {के/की} placeholders also need to be added and changed according to the gender of the scientist. While it is important to consider these nuances, for the purpose of this explanation, we will temporarily set them aside and address them in a later section. For now, let us focus on the four major keys, namely: {{नागरिकता}}, {{Scientist}}, {{मातृसंस्था}}, and {{शैक्षिक दर्जा/उपाधि}} which have been embedded in Sentence 1 within double curly brackets ({{}}).

These two sentences in a Hindi Wikipedia page offer a deeper understanding of the language's complexity by conveying multiple points of information. We used this approach for all 20-25 keys and generated 11 coherent sentences that combined multiple keys. Additionally, we applied P&C concepts to create sentences with fewer complexities but multiple keys. Sentence 1 above contains three keys, and using P&C concepts, we could create three sentences by using any two of the three keys. Therefore, we obtained the following three sentences with every two out of the three keys:({{नागरिकता}}, {{मातृसंस्था}},

[6] Occupation

[7] Birth Date

[8] Birth Place

[9] He/She was a famous {Occupation}

[10] He/She was born on {Birth Date}

[11] He/She was born in {Birth Place}

[12] He/She was a famous {Occupation} who was born on {Birth Date} in {Birth Place}

[13] citizenship

[14] Alma mater

[15] Academic Degree

[16] Work Place

[17] Employed

[18] Position of Employment

[19] {Scientist}, born in {citizenship}, was an alumnus of {Alma Mater} and went on to receive a degree in {Academic Degree}

[20] {Scientist}'s place of work was {Work Place} and she was employed at {Employer} as a {Position of Employment}

and {{शैक्षिक दर्जा/उपाधि}}) :

1. वह {{नागरिकता}} के नागरिक {alivestatus/wgop} और वह {{मातृसंस्था}} {के/की} पूर्व छात्र भी {alivestatus/wgop} | [21]
2. उन्होंने {{शैक्षिक दर्जा/उपाधि}} की डिग्री भी प्राप्त की {alivestatus/gen} और वह {{मातृसंस्था}} {के/की} पूर्व छात्र भी {alivestatus/wgop} |[22]
3. वह {{नागरिकता}} {के/की} नागरिक {alivestatus/wgop} और उन्होंने {{शैक्षिक दर्जा/उपाधि}} की डिग्री भी प्राप्त की {alivestatus/gen} | [23]

Since these sentences sounded naturally coherent and were linguistically sound, they were deemed suitable for use on the Hindi Wikipedia page. To replicate this success, we created multiple variations of the original 11 sentences. For example, If a sentence had three keys originally, we made three sentences with two out of those three keys, or if one of the 11 sentences had five keys, we made ten sentences ($5_{C_2} = 10$ sentences), and so on. After this process, we generated 80 template sentences created through P&C of the original 11 sentences.

Upon reviewing the dataset, we realized that certain scientists did not possess even two out of the three keys. Consequently, if we failed to create a sentence using the one key they did have, we would lose valuable information about those individuals. Therefore, we concluded that in addition to the 11 triple-key and 80 double-key sentences we had generated, we needed to develop additional sentences that accounted for such scenarios. To minimize the level of risk, we opted to create single key sentences based on the 11 sentences we initially developed, resulting in nearly 60 additional sentences. In total, we ended up with 160 template sentences. An image, for another example, showing the three types of sentences created can be seen in Figure 3 in the Appendix.

We now needed to consider the nuances of gender we talked about previously before creating the Wikipedia pages. We examined the Wikidata pages and found the "लिंग" [24] key for each scientist, which we used to determine whether a scientist was male or female. Based on this, we created placeholders for words that varied with gender, such as 'थे/थी' (represented by alivestatus in our case), 'हुए/हुई', and 'के/की' . We then filled these placeholders with the appropriate gender-based choice for each scientist. The following examples illustrate this process. For instance, we took two scientists from our dataset, **Frank Malina** and **Rosina M. Bierbaum**. Frank Malina's country of citizenship/place is the **USA**; alma mater is **Texas A&M University**, and academic degree is **Doctor of Philosophy**, while Rosina M. Bierbaum's country of citizenship/place is the **USA**, alma mater is **Stony Brook University**, and academic degree is **Doctor of Philosophy**. After filling in this information, we obtained the following sentences:

1. USA में पैदा हुए "फ्रैंक मलीना" "टेक्सास A&M यूनिवर्सिटी" के पूर्व छात्र थे और आगे चलके उन्होंने "डॉक्टर ऑफ़ फलसफा" की डिग्री भी प्राप्त की |,[25]
2. USA में पैदा हुई "रोसिना म बैरभौम" "सटोनी ब्रूक यूनिवर्सिटी" की पूर्व छात्र थी और आगे चलके उन्होंने "डॉक्टर ऑफ़ फलसफा" की डिग्री भी प्राप्त की | [26]

As one can notice, there are stark differences in the way Hindi handles gender, with the placeholders like 'हुई', 'हुए', 'के', 'की' changing according to if the Scientist is a male or female. We coded the same for all 17000 Scientists and identified all the Gender information for the same. Thus, finally, after all such nuances were dealt with, we had 160 template sentences in our hands, and we now moved on and were ready for the Feature Addition and Final Template Pages Generation Step.

3.4 Features Addition & Final Wikipedia Page Generation

This section is divided into two parts: Feature Addition, which covers the additional features added to complete the template sentences, and Final Wikipedia Page Generation, which explains the rule-based system used to determine

[21] He/She was a citizen of {Citizenship} and he/she was an alumnus of {Alma Mater}

[22] He/She obtained a degree in {Academic Degree} and he/she was an alumnus of {Alma Mater}

[23] He/She was a citizen of {Citizenship} and he/she obtained a degree in {Academic Degree}

[24] gender

[25] Born in USA, "Frank Malina" was an alumnus of "Texas A&M university" and later went on to obtain a degree in "Doctor of Philosophy"

[26] Born in USA, "Rosini M Bierbaum" was an alumnus of "Brook University" and later went on to obtain a degree in "Doctor of Philosophy"

the order of the template sentences and how the page was ultimately created.

3.4.1 Feature Addition

We reviewed existing Hindi Wikipedia pages of scientists and compared them to our template sentences. We also searched Wikidata to find additional information to make our pages more informative. We discovered that certain keys, such as **”Award Received”** or **”Date of Birth and Date of Death”**, had values and references that linked to other Wikidata pages with valuable information. For instance, the Wikidata page for Nobel Prize was linked to the Wikidata page for the **Award Received** key and provided details on why and for what reason the award was given. Though accessing information through Wikidata’s complex format was challenging, we persevered to access these Wikidata pages.

We also decided to add the ”Alive Status” key to our data, as the Hindi language encodes a person’s living or deceased status, which affects sentence endings like 'है', 'था', 'थे' or 'थी'. Building on this information, we can also see that if we talk about a person who is no longer living, there are three types of the ending of a sentence, namely 'था' or 'थे' or 'थी' which further encodes gender and respect as well. For Females, we take 'थी' . For Males, we use 'था' . Even further, Hindi also has a respect honorific it uses to give respect to either a reputed personality or a great scientist. We use the third type to display respect: 'थे.' To address this, we added Date of Death and Birth information to our template sentences to detect appropriate sentence endings for each scientist automatically. Since we had already obtained this information, we only needed to check if the Date of Death key existed for each scientist. If not, we assumed they were still alive. Using this information, we added the final feature to the template sentences, successfully completing the task.

3.4.2 Final Hindi Wikipedia Page Generation

Before creating the final Hindi Wikipedia page from our template sentences, we developed a rule-based system to determine the order and type of sentences to use. We used the different kinds of sentences we created to help us achieve this (Section 3.3.3).

We decided to start the Wikipedia page with a complex, multi-key sentence to showcase our natural language understanding. To account for situations where a scientist did not have all the keys required for the multi-key sentence, we had two-pair and single-pair sentences as backups. If the scientist did not have the key at all, we excluded that information from the sentences. This ensured that all available information was used to create sentences for the Wikipedia page.

To determine the order of the sentences, we used a weighted metric that assigned higher points to important keys such as Award Received, Date of Birth and Death, Doctoral Advisor, Student, and Academic Degree. Keys like Spouses and Children were given lower points. Additionally, the natural flow of information was taken into consideration, starting with introducing the scientist’s profession, then providing their Date of Birth and Death, followed by their academic qualifications and awards. If the scientist had received any awards or nominations, the reasons behind them were explained next. Finally, their family and eventual death were discussed, with rules in place to correlate the two.

When this was mathematically ascertained, we came up with an order of sentences that we felt justified our observations and gave a deeper natural understanding of the Hindi Language. We also followed the system to go for the double pair sentences and single if needed. An interesting case describes our process:

In the sentence order, we determined that the first sentence for a scientist would include Date of Birth, Place of Birth, and Occupation. The second sentence would contain Academic Degree, Country of Citizenship, and Alma Mater. However, if the scientist doesn’t have the Place of Birth key, we prioritize the double pair sentence that combines Profession and Country of Citizenship, writing it as the first sentence instead. The second sentence remains the same. Similarly, if the Date of Birth key is also missing, we select the single pair sentence that includes Occupation as the starting sentence, followed by the second most complex sentence. If none of these three keys exist for the scientist, we choose the second most complex sentence as the starting sentence. This process continues until all 11 triple-pair sentences are utilized.

Finally, we utilized these sentences to generate the final automatic Hindi Wikipedia page using a program. By inputting a scientist's name from our dataset, the program would automatically create a file that filled in all the relevant information for that scientist. This page can be further enriched by the Wikipedian community.

4 Results

We successfully generated Hindi Wikipedia pages for scientists who did not have one, despite having pages in other languages. The sample template Hindi Wikipedia page is publicly available at this link[27]. We compiled all available information on each scientist and incorporated it into their respective Hindi Wikipedia pages.

We have also created a valuable resource in the form of a dataset consisting of 17,000 entities. The dataset is divided into 1,700 files, each containing information on 10 scientists presented as key-value pairs under their respective names. The dataset and the corresponding code can be found at this link. In the next section, we demonstrate how we evaluated our work by comparing it to existing machine translation outputs from English to Hindi.

5 Human Evaluation

To evaluate our work, we enlisted 20 English-Hindi bilinguals and provided them with 2 sets of 50 articles each of 50 scientists. One set is machine-translated using Wikipedia's in-built translator, while the second set was created using our template approach. Each Scientist has been vetted by 3 different workers. We then did a comparative analysis by creating a survey that hinged on 4 key points on a scale of 1-5. These points were based on the word level, sentence level, discourse level, and overall level of the articles, and the results were tabulated. The following link [28] shows the questionnaire for the research survey conducted.

Out of the 50 articles given, 40 articles that were generated using our method received more points on the scale compared to the machine-translated articles. The following link displays some of these Scientists, with the last column displaying the better output between Template Driven Output & Machine Translation Output. Based on the questionnaire that details the intricacies on word, sentence and overall context level, the scores are compared and the results show that our method has indeed produced better results in terms of readability, coherence, and structure of the articles.

6 Future Work

We recognize that there is a significant lack of Wikipedia pages in other Indian languages, such as Tamil, Telugu, and Gujarati, among others. We believe that our methodology can be extended to these languages if the appropriate data is available, pre-processed in accordance with our code requirements, and, if necessary, the template sentences are written or transliterated from Hindi to the target language.

We also anticipate that a Table-To-Text machine learning model can be applied to the dataset to generate articles in the required language, which would speed up the process even further. This would eliminate the need to create template sentences as the model would automatically generate the article based on the information in the dataset. However, these generated articles would still require manual vetting due to learning bias. In addition to creating Wikipedia pages, we believe that our dataset can be utilized for various linguistic tasks, such as enhancing current machine translation tasks and improving natural language generation models since we provide pre-processed data for 17,000 entities.

Abstract

Utilisation of multilingual language models such as mBERT and XLM-RoBERTa has increasingly gained attention in recent work by exploiting the multilingualism of such models in different downstream tasks across different languages. However, performance degradation is expected in transfer learning across languages compared to monolingual performance although it is an acceptable trade-off considering the sparsity of resources and lack of available training data in low-resource languages. In this work, we study the effect of machine translation on the cross-lingual transfer learning in a crisis event classification task. Our experiments include measuring the effect of machine-translating the test data into the source language and vice versa [1]. We evaluated and compared the performance in terms of accuracy and F1-Score. The results show that translating the source data into the target language improves the prediction accuracy by 14.8% and the Weighted Average F1-Score by 19.2% when compared to zero-shot transfer to an unseen language.

1 Introduction

We are interested in discovering methods to enhance the detection of emerging crises in social media and the transferability of a classification model fine-tuned on a specific language to other languages. Crisis event detection typically relies on two aspects: (1) the detection of *burstiness* of certain keywords or trends in the timeline, and (2) the classification of the detected *bursts* and whether they indicate the occurrence of a disaster or not. The former aspect can be obtained using unsupervised learning to cluster posts that have certain commonalities such as common keywords, time, and location. However, the latter usually depends on the use of supervised learning algorithms to filter out non-relevant posts since bursts can occur for non-crisis related events such as concerts and media events, political events, and other trends that can interfere with the task of responding to emergencies. It is especially important to develop methods to increase the accuracy of classifying relevant posts to support multilingual settings and therefore help provide better response to emergencies. Although the use of machine translation for cross-lingual transfer learning has shown promising results, there are several drawbacks to the existing work including quality of machine translation, limited parallel data, and structural differences which affect the overall performance of the final model.

In this work, we conducted several experiments to assess the effect of machine translation in bridging language gaps for zero-shot cross-lingual classification of crisis-related tweets. Additionally, we investigated potential limitations on the final predictions. Our study focused on transfer learning between English and Arabic languages by fine-tuning a multilingual pre-trained language model like XLM-R for disaster type classification. Despite the inherent heterogeneity of the two languages, our results surpassed existing benchmarks for more linguistically homogeneous languages such as English and Spanish. Our experiments specifically targeted factors that could influence the performance of existing benchmarks, thereby enabling researchers to address these limitations in future studies. Although our focus is on the crisis events, the approaches can be expanded to other types of events.

The structure of the rest of this paper is as follows. A background about the classification task and relevant knowledge about the different language models is discussed in Section 2. Descrip-

[1] We refer to Arabic as the target language (i.e., language of testing data) and to English as the source language (i.e., language of training data).

https://doi.org/10.26615/978-954-452-092-2_003

tion of chosen datasets and the required handling process for our task is shown in Section 3 and 3 respectively. Section 4 explains the experimentation settings to achieve our objective of measuring the effect of machine-translation on the cross-lingual transfer. We discuss our results in details in Section 5 along with an investigation of the possible factors that might have affected the transfer using the machine-translation. We also demonstrate the challenges of cross-lingual transfer learning of the data level and task level in Section 6. While in Section 7 we showcase and compare relevant work, we finally suggest future directions for research in Section 8.

2 Background

Classification tasks have gained a significant amount of attention recently. In the domain of event classification, different directions have been pursued including binary classification (i.e., whether the text indicates an event or not), multi-class classification, and multi-label classification. Multi-class classification ranges in granularity from event type to fine-grained aspects of the text content.

We look specifically into cross-lingual classification of social media content for recent contributions in the area. Deep learning models can accommodate the complexity associated with social media data including noise and a lack of structure compared to traditional machine learning algorithms such as SVM, Naïve Bayes, and Random Forests which may suffer from a decline in performance with the increasing complexity of the data (Wang et al., 2021).

Social media posts, especially Tweets, have been very useful in recent years for many tasks and goals including event detection and classification. Among other types of events (e.g., sports, music, political, .etc), disaster detection and classification has a special characteristic: urgency and need of rapid response. Taking advantage of crowd sourced information posted by people in real-time may play a large role to provide timely and proper response. Considering that a specific event can be reported in multiple languages emphasises the need for multilingual and cross-lingual tools that do not discard helpful information just because it is in a different language. Unlike traditional Neural Networks, the introduction of the transformer-based language models such as Generative Pre-trained Transformer (GPT) (Radford et al., 2018) and its successors, and Bidirectional Encoder Representations from Transformers (BERT) and the models built upon it have transformed the area of Natural Language Processing. Following BERT, which is pre-trained on English Wikipedia (2,500M words) and BooksCorpus (800M words), emerged other BERT-based models such RoBERTa (Liu et al., 2019) and XLNet (Yang et al., 2019) introducing an improvement over BERT's performance since they are pre-trained on more data than the original BERT (Conneau et al., 2020). Particularly, RoBERTa has been pre-trained on 144 GB of data in addition to the 16GB that BERT is pre-trained on while XLNet was trained with over 130GB of textual data including the original 16GB of BERT's.

Following the release of multilingual BERT (mBERT) which is a BERT model trained on Wikipedia text in 104 different languages, other multilingual models such as XLM (Conneau and Lample, 2019) and XLM-RoBERTa (Conneau et al., 2020) have been released as well. Cross-lingual Language Modeling (XLM), like other transformer-based language models, was trained with a masked language modeling (MLM) objective. Additionally, it is trained with a Translation Language Modeling (TLM) which relies on the availability of a dataset with parallel sentences. However, XLM-RoBERTa only uses the MLM objective and trained on a huge corpus of text in 100 languages acquired from the CommonCrawl datasets in a RoBERTa fashion.

Arabic is a widely spoken language, with over 400 million people around the world, according to (UNESCO, 2022). However, there is a scarcity of resources when working on machine learning, especially for domain-specific tasks such as crisis event classification which ignites the need for automated solutions to fill this gap. To address the issue of limited training data for low-resource languages, researchers have employed techniques such as transfer learning (Shi et al., 2022; Yu et al., 2019; Zhang, 2017; Sarioglu Kayi et al., 2021), unsupervised learning (Chauhan et al., 2022; Shi et al., 2022; Sun et al., 2021; Bari et al., 2021), and data augmentation (Maimaiti et al., 2022; Zhou et al., 2022; Şahin and Steedman, 2018). Additionally, initiatives like the Masakhane project (Nekoto et al., 2020) have aimed to build machine translation systems for African languages using collaborative and community-driven approaches. These efforts strive to make machine learning accessible for low-resource languages. While significant progress has been made, further research and collaboration are essential to enhance the quality and availability of machine translation for low-resource languages.

3 Data

We used CrisisNLP[2] (Imran et al., 2016) as an English benchmark dataset for our experiments. CrisisNLP is a widely used hand-labelled Twitter dataset and consists of Tweets collected during ten different disasters including earthquakes, floods, epidemics and other types detailed in Table 1. We grouped similar disasters into a common class, i.e., (*Cyclone, Flood, Hurricane* and *Storm*) were grouped into one broader class called "*Storm*." The total number of samples in the dataset is 20,514 Tweets covering three main types of disasters. On the other hand, we choose Kawarith (Alharbi and Lee, 2021) to be our Arabic dataset used for evaluating the transfer learning of our model. Kawarith contains 12,446 Tweets covering seven different disasters detailed in Table 2. Similar to CrisisNLP, we grouped the classes (*Flood, Rain Storm* and *Storm*) into a broader class called "*Storm*." Since our target is to transfer the model trained on one language to another, we need to keep only common classes existing in both datasets (i.e., *Storm, Epidemic* and *Irrelevant*).

Pre-Processing

As mentioned in Section 3, we grouped data related to different storm classes into one broader class called "*Storm*." The reasons are: (1) not to confuse the classifier since hurricanes, cyclones and typhoons are all storms that share similar characteristics, they only differ in wind speed and location where they originated (Clements and Casani, 2016), and (2) considering them as different events will cause a loss of data because of the lack of tropical storms in the Arabic dataset. After we refine the two datasets (English and Arabic) to have common classes, we started cleaning the data. Data cleaning included removing non-ASCII and special characters such as (ÛÏ) and (&), removing the URLs, user mentions, retweets, Unicode punctuation, and extra white spaces. We also cleaned the text resulted from removing the hashtags by removing the underscores and separating the words by white space (e.g. under_score becomes under score) and camelCase with (camel case) except if the word is in all uppercase to avoid separating a word into single characters (e.g. UPPERCASE to U P P E R C A S E).

4 Experiments

We examine the effectiveness of multilingual BERT-based models, specifically the XLM-RoBERTa model, in the cross-lingual transfer learning of a model fine-tuned on a source language and evaluated on an unseen target language for the disaster events classification task. XLM-R has shown considerable improvement over mBERT on many benchmarks (Hu et al., 2020; Ding et al., 2022). Our intention is to measure the machine-translation effect on the prediction performance by translating the target data into the source language (and vice versa) before testing the model. We are aware that the translation of social media text will not be as accurate as translated formal text due to its informality, misspelled words, noise, slangs and dialects. However, translation might provide a working solution for the scarcity of training data in different languages exploiting the abundance of available English data.

Our experiment consists of three parts. In the first part, we fine-tune a multilingual model (XLM-R) on classifying English disaster events and evaluate it on a labeled dataset consisting of original Arabic Tweets (non-translated). The results of this part will give us a benchmark to compare the second part results with and answer our question (i.e., does translation improve the prediction performance when transferring a model to another language?). The second part involves translating the test set into English before evaluating the fine-tuned model. Finally, we translate the source data into the target language and test on the target data (i.e., Arabic). For machine translation, we use Facebook's M2M-100 model (Fan et al., 2021) which translates between a hundred different languages in any direction. Those results will also be compared to monolingual performance of the model on both languages.

5 Results

The first set of results found in Table 3 shows the performance of the fine-tuned multilingual model

Table 2: Description of Kawarith Arabic disaster dataset.

in a monolingual setting (English to English and Arabic to Arabic). In the English setting, the Accuracy and F1-Scores (Average and Micro) are relatively high (96%, 96.2%, and 96% respectively) while they are (91.13%, 91%, and 91.1% respectively) in the Arabic setting. The possible reasons for this 5% decrease might be the number of training samples since the size of the English data was 17K in total while the Arabic was about 5K after cleaning and balancing. The other reason might be that XLM-Roberta was originally pre-trained on more English data than Arabic (Conneau et al., 2020). The motivation of performing a monolingual examination of the model is to set a benchmark for our model after data pre-processing and class manipulation. The original data is labelled for Tweet content whether it is (caution and advice, infrastructure and utilities damage, casualties, etc.). Most of the existing work uses these classes (with minor modifications) for testing their models. However, we use the disaster type labels (Storm, Epidemic, etc.) to classify the Tweets into the type of event. The main purpose is because the two datasets are labelled differently for content, more details about the labelling are found in Section 6. Disaster type labels allow us to first determine whether a Tweet is about a disaster event (relevance), and second to determine what type of disaster is the Tweet talking about. Finer granularity can be adopted later for classifying the type of information provided by the Tweets.

The second set of results can be divided into three parts: (1) the result of evaluating a model fine-tuned on English data and tested on original Arabic data (zero-shot) and (2) the result of evaluating the model on the same Arabic dataset after translating it to English (target-translation). The latter experiment shows an improvement in F1-Score by 8.2% when testing on a translated dataset as compared to the former while (3) the third score is when we translated the training data into the target language (source-translation) which has shown a substantial increase of 19.2% in F1-Score over the zero-shot setting.

Although translating the test set to the source language has increased the accuracy of the classification, however, the result is still not close to the monolingual performance. To explore this limitation, we investigated the potential reasons behind it as follows:

Setting	Source	Target	Accuracy	M Avg	W Avg
Monolingual	En	En	0.960	0.962	0.960
	Ar	Ar	0.913	0.910	0.911
Zero-shot	En	Ar	0.549	0.529	0.528
Target translation	En	Ar*	0.618	0.610	0.610
Source translation	En**	Ar	**0.697**	**0.645**	**0.720**
Target dev data	En	Ar	0.616	0.473	0.628

* machine-translated to En ** machine-translated to Ar

Table 3: Results of mono-lingual and cross-lingual performance of XLM-Roberta model fine-tuned on English disaster data and evaluated on Arabic data. The Arabic data is translated in English before the test in the second set of results. **En** indicates the use of CrisisNLP dataset while **Ar** indicates the use of Kawarith dataset for Arabic Tweets.

Quality of translation (Machine Translation Vs. Human Translation):

Assuming that poor machine-translation might led to loss of accuracy, we employed a human translator to translate a fraction of the test set to English (i.e. 500 samples). If the result is improved, it means that the machine translation does not produce quality data that escalates to the source language data, therefore, the classification will not result in comparable accuracy to the original data.

The result of this check is shown in the first set of scores in Table 4. Although the human translation improved the accuracy by around 5% and the weighted average f1-score has increased by around 4% the difference is still insignificant. We should also note that the size of the test data in this run (i.e., 500) is less than the first experiment (i.e., 5000) which decreased the accuracy score from 0.618 to 0.394 which might imply that if we translate the whole 5000 samples by human the accuracy should improve further as compared to the machine translation. We also noticed a better classification of the event type (floods) since mis-translating it by machine led to poor classification of that class. Figure 1 shows how this class was poorly classified when data was translated by machine.

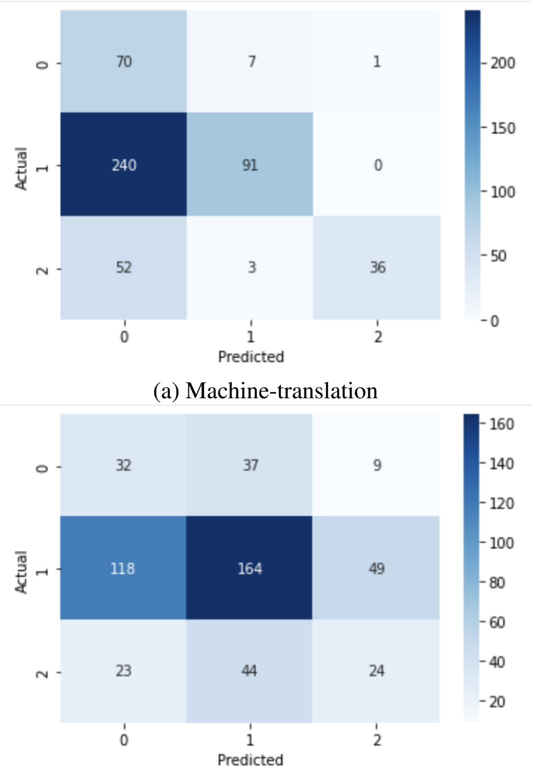
We run a monolingual setting to ensure that the 500 samples of the Arabic data were fairly selected bearing the imbalance of the classes to represent real-world scenarios. The monolingual performance of the model when trained on 80/20 fashion is 0.94, 0.91, and 0.94 for accuracy, macro and weighted average f1-scores respectively as shown in Table 4.

Human Translation as a Reference

The BLEU score is a widely used metric for measuring translation quality by comparing a machine-translated text to a reference translation (Papineni et al., 2002). It ranges between 0 and 1, with 1 representing a perfect match to the reference translation. In our case, we calculated the BLEU score of the machine translation using human-translated data as a reference to gain insights into the overall performance of the chosen machine translation model. The resulting score was 0.127, which is relatively low but expected, as BLEU primarily focuses on n-gram precision and does not consider semantic or grammatical correctness (Reiter, 2018). A low BLEU score indicates differences in n-grams between the machine translation and the reference translation (i.e., human translation). Similarly, (Ramesh et al., 2020) achieved a notably low BLEU score for English-to-Tamil translation. They argued that the nature of the language contributes to the increased number of n-gram mismatches with the reference translation, despite the translation itself being of good quality. It is important to note that our goal is not to achieve a perfect match with human translation, as that is not the aim of our task. The machine-translated text is not the output of our system; rather, we are using it as a parallel language to train the model.

Quality of data being translated (normalised data Vs. as-is data):

On this note, we also employ a linguistic professional to normalise the Arabic Tweets to Modern Standard Arabic (MSA) before translating them by machine. This should give us an idea whether the reason is the poor quality of data found on social media making it hard for the model to generalise



(a) Machine-translation

(b) Human-translation

Figure 1: Confusion Matrix of machine- and human-translated data showing poor classification of class 1 (i.e., storm) when data was translated by machine. 0, 1, and 2 correspond to irrelevant, storm, and epidemic/pandemic, respectively.

to other languages. In other words, the quality of writing and use of various Arabic dialects on social media may affect the model performance.

The second set of results in Table 4 shows a comparison between the two cases with a slight improvement of MSA over the informal Arabic text. Again, there was a drop from 0.549 to 0.398 in accuracy when the test data has decreased from 5K to 500.

Faults in translators (sequence translation Vs. tokenised data):

This was an assumption made when we observed that the machine is translating some tweets as a sequence of repeated words such as those samples found in Figure 2 and sometimes when it encounters some characters it stops translating the sequence and moves to the next sequence. Also some words are mistranslated when found in context such as (سيول), Arabic for “floods” is translated to “Seoul” since the Arabic words for floods and Seoul are written in the same way. The machine translates it to “Seoul” whenever it encounters it with a country or city name which is usually the case. Therefore, we wanted to check if the translation quality is affected by the sequence and context. To do so, we tokenised the sequence before translating it to English to check if the translation improves.

The last result in Table 4 shows that lack of context has led to a drop of performance showing the worst scores of all cases.

Overall, drop of performance when transferring the model from English to Arabic as compared to monolingual performance is expected in such scenarios as in the relevant work (Pelicon et al., 2020; Ahmad et al., 2021; Piscitelli et al., 2021; Caselli and Üstün, 2019; Keung et al., 2020) where the accuracy drops when a model is transferred to other languages. In an attempt to improve the performance further, we adopted (Keung et al., 2020)’s approach of using the target language development set instead of the source language data (i.e., English). This led to a very similar effect as the target translation. The last row in Table 3 shows the result of using the target language dev set as an alternative to using the source language dev set.

6 Challenges

One of the challenges of cross-lingual transfer learning is the heterogeneity of the source and target data. Even when we acquire disaster datasets in two languages, the way they were labelled can affect the quality of transfer. For instance, CrisisNLP was labelled for information conveyed in the tweet text as discrete labels (e.g., Infrastructure damage, Injured people, etc.) while Kawarith is using multi-label classification where one tweet can have more than one label (e.g., Infrastructure damage AND Injured people). Also, additional labels are found in Kawarith that are not in CrisisNLP such as Opinion and Criticism. Such issues can impose challenges in mapping the labels to the closest possible ones and sometimes discarding some samples. Types of disasters covered in each dataset is also a challenge for disaster type classification. While CrisisNLP contains English data about earthquakes, floods, hurricanes, cyclones and diseases, only two types are in common with the Arabic data which results in discarding the uncommon types when classifying disaster types.

Data Manipulation	Accuracy	Macro Avg F1-Score	Weighted Avg F1-Score
MT	0.394	**0.434**	0.431
HT	**0.440**	0.367	**0.467**
MSA	**0.416**	**0.317**	**0.435**
As-is	0.398	0.307	0.415
Tokenised	0.318	0.321	0.324
Monolingual	0.94	0.91	0.94

7 Related Work

With the limited work in cross-lingual transfer learning between English and Arabic for the classification task, we needed to set our own benchmark by training the same model on monolingual settings for both languages and also by comparing the transfer to original vs. translated Arabic data. Although the literature lacks comparative work for crosslingual classification between the two particular languages that we are experimenting on, we surveyed the most relevant ones that are either for different languages or different task.

Zero-shot transfer learning from English to Italian has been examined by (Piscitelli et al., 2021) using a Convolutional Neural Network (CNN) exploiting the shared embeddings provided by MUSE (Multilingual Unsupervised and Supervised Embeddings), a Python library. Although the training data was relatively large (45K English Tweets), they achieved a micro-averaged F1-score of 0.52 for Italian when training the model on the English data only. Similarly, (Caselli and Üstün, 2019) investigated the generalisation abilities of mBERT for event detection and classification for Italian and English. Two scenarios were tested: Event detection (i.e. binary classification) and Event detection and classification (i.e. multiclass classification). They experimented with zero-shot learning by training/fine-tuning the model on one language and evaluating it on the other language that it has never been seen in the training. For the zero-shot multiclass scenario, the F1-score was 42.86 when tested on Italian which was improved to 55.38 when the model was fine-tuned with a mixture of data in both English and Italian. A summary of the most relevant work in zero-shot transfer learning is shown in Table 5.

For transferring to Arabic language, (Ahmad et al., 2021) and (Keung et al., 2020) have studied the transfer of mBERT to Arabic language for XNLI task with very close Accuracy in both works. The former has explicitly provided the language syntax to the model to address the challenge of cross-lingual transfer of typologically different languages. Latter work supported the approach of using the target language Dev set for model selection to increase the accuracy and compared the results of both using English dev and target dev. Indeed, using target language Dev set showed improvement over using source language for model selection.

Table 5: Performance scores of relevant work in cross-lingual transfer learning.

A cross-lingual sentiment classification of news documents has been done by (Pelicon et al., 2020) to transfer an mBERT fine-tuned on Slovenian and tested on Croatian without any prior training data in the latter language and achieved an average result of 51.72 F1-Score.

8 Conclusions and Future Work

Our study aimed at investigating the impact of using machine translation to leverage the cross-lingual capabilities of multilingual transformer-based models such as XLM-RoBERTa. Specifically, we tested both training data translation and test data translation, in order to mitigate the potential performance loss that can occur when testing on an unseen language. Our findings revealed a considerable improvement in performance, which can be particularly useful for transferring a classifier trained on a resource-rich language to a resource-poor language by translating the same training data into a set of target languages providing an acceptable performance when lacking task data in the target language. However, further research is needed to explore additional approaches that can enhance cross-lingual transfer learning and achieve comparable performance to monolingual models, such as the use of ensemble methods to boost the classification of individual learners. Future work will also include a comparison of different machine-translation models for the same task. Overall, our study highlights the potential of machine translation as a powerful tool for cross-lingual transfer learning, and provides a foundation for future research to further improve the performance of multilingual models on text classification tasks across different languages.

Lexicon-driven automatic sentence generation for the skills section in a job posting

Abstract

This paper presents a sentence generation pipeline as implemented on the online job board Stepstone. The goal is to automatically create a set of sentences for the candidate profile and the task description sections in a job ad, related to a given input skill. They must cover two different "tone of voice" variants in German (Du, Sie), three experience levels (junior, mid, senior), and two optionality values (skill is mandatory or optional/nice to have). The generation process considers the difference between soft skills, natural language competencies and hard skills, as well as more specific sub-categories such as IT skills, programming languages and similar. To create grammatically consistent text, morphosyntactic features from the proprietary skill ontology and lexicon are consulted. The approach is a lexicon-driven generation process that compares all lexical features of the new input skills with the ones already added to the sentence database and creates new sentences according to the corresponding templates.

1 Introduction

Writing and posting a job ad can be time-consuming and expensive, especially for small businesses without a human resources department and with a limited budget. The aim of the Stepstone Recruit project is to accompany the entire recruitment process from the creation and publishing of a new job ad to the matching between the job and the CV database and proposing the best candidates for the vacancy. The process is entirely automated and enables the job publisher / recruiter (hereafter referred to as the user) to create a new job ad within a few minutes, without the need to write any text.

As a smaller but crucial part of this large project, the Linguistic Services team has created a pipeline for the automatic generation of sentences for given input skills to be embedded into the job ad text.

The creation of a job ad starts with the selection of a job title (job descriptor, also referred to as JD). From an auto-suggested list the user can select one of ca. 0.5 million German or English JDs (lemmas) organized in ca. 137.000 concepts (synonym groups) from the proprietary ontology. In the next step, a list of the best matching skills is automatically proposed, to be selected by the user for the given job. The JD-skill matching is powered by an AI model trained and developed in the data science department of the company.

For each chosen skill, a set of pre-generated sentences is provided. The user can either accept the first suggestion or select an alternative, while also being able to edit the wording, as well as to add their own text. The generation of the sentences for ALC (automatic listing creation) is the subject of the current paper.

2 Related work

Researchers are actively exploring methods and techniques to automate and enhance text generation tasks. Recent methods, especially machine learning and AI techniques, have advanced significantly, enabling the development of sophisticated approaches for automatic text generation. Notably, the emergence of models like Generative Pre-trained Transformer, GPT and ChatGPT (OpenAI, 2023) has had a transformative impact on the field of text generation, including

Proceedings of Recent Advances in Natural Language Processing, pages 32–40
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_004

applications in the recruitment domain, such as creating job posting descriptions or cover letters.

In our task, we have adopted a template-based, lexicon-driven approach to sentence creation, carefully designed to accommodate diverse input parameters. To the best of our knowledge, there have been no similar research papers specifically focused on automated generation in the recruitment domain. However, there is a long history of research that combines text mining techniques to extract information from the existing corpus with rule-based NLG methods to generate new text based on specific requirements. Other fields, such as weather forecasting (Saliby, 2019), the financial sector (Pejic Bach et al., 2019), and the medical domain (Hueske-Kraus, 2003) are examples that have received more extensive research and application attention than HR and recruitment. A recent systematic survey (Goyal et al., 2023) provides a comprehensive overview of the history of text generation tools and techniques, shedding light on the evolution of this field and its applications.

3 Corpus analysis and Extraction of text building blocks

To achieve the goal of developing an accurate and domain-relevant system, a corpus of 3.8 million text lines specifying the requirements for the candidate profile (hereafter referred to as the profile section) and 4.8 million text lines containing the job description (hereafter referred to as the task section) was analysed. The corpus was extracted from the job ads in German language published on Stepstone's German board in the past two years.

The profile section usually describes skills, competencies, education, and experience that the candidate needs to have (you have knowledge of <skill>; you have experience in <skill>). The task section describes the tasks and the responsibilities of the role (your tasks will include <skill>, your responsibilities will be <skill>). Both sections were processed separately to analyse the behaviour of different skills in different contexts, as well as to extract relevant patterns per section.

The objective was to generate a collection of phrases and text fragments around a placeholder skill, that could be assembled into complete sentences based on various criteria and parameters outlined below. The second main objective was to generate a set of rules and constraints for the replacement of the skill placeholder with the real input skill. Refer to section 4 for more information. The first version of the system is developed for the German language.

3.1 Skill ontology

To ensure syntactically and morphologically accurate replacement of the skill placeholder, all relevant information about the skill must be coded in a lexicon. This includes information such as the base form of the skill, its inflected forms, and any additional semantic or classification codes.

A rich domain ontology representing occupations, skills, industries, education qualifications and other key concepts in the recruitment domain has been the core of all relevant processes in the semantic search, classification, normalization, matching, recommendation, and analytics in the organisation. In the beginning of the project, the skill sub-ontology contained about 80.000 concepts (semantic clusters) with almost 215.000 lemmas (synonyms and translations in a few languages), of which around 62.000 lemmas in German. In addition to the semantic and ontological information, each lemma is stored with its inflected forms and corresponding morphosyntactic features. Minimum required information is part of speech, gender, and number. The corresponding linguistic rules are maintained in an inflection module. All this information serves as input parameters to the sentence generation pipeline. If insufficient, the ontology allows the feature sets to be extended with additional semantic or pragmatic codes at the concept or lemma level. The coding/tagging functionality was extensively used to iteratively optimise the lexicon for the purposes of the project. In the following sections, more details will be given.

While one part of the improvements and annotations remains project-related and language-specific (German), another key by-product of the tagging process is the development of a more generic language-independent skill classification schema, applied to all skills at the concept level.

3.2 Skills in context and concordances

In the previously mentioned corpus, all German skills from the ontology were identified within the text, and concordances were generated to show their surrounding context. For this, the tool Unitex (Paumier, 2008) was used. As the user manual of the tool says: "Syntactic graphs, often called local

grammars, allow you to describe syntactic patterns that can then be searched in the texts. Of all kinds of graphs these have the greatest expressive power because they allow you to refer to information in dictionaries." (Paumier, 2008).
In compliance with the requirements of the tool, the skills were exported into the DELA (Dictionnaires Electroniques du LADL) format (Courtois, 1990) containing inflected forms and semantic codes (Figure 1).

Figure 1: DELA dictionary, compiled for this project

The following semantic codes were established for the initial analysis of the corpus:

- **soft skill** with the subcategories: *personal* (self-confident), *social* (team-oriented), *methodological* (attention to detail)

- **hard skill** with these two special sub-categories: *IT skill* (computer skills and tools such as Java, Cloud Security, UX design), *tool* (tools used in production, skilled trades, logistics etc.: Abrasive wheels, Truck cranes, Blueprint machines)

- **language skill** (knowledge of natural languages: German, English)

The codes were added to the skills at the concept level. Skills that were not tagged in the ontology are considered hard skills without any additional classification.

In Unitex, a simple local grammar (Figure 2) was created containing a single skill box without specifying any surrounding context. To further refine the analysis process, the grammar was divided into individual sub-graphs, with each sub-graph dedicated to a specific skill class as defined in the ontology and in the DELA dictionary.

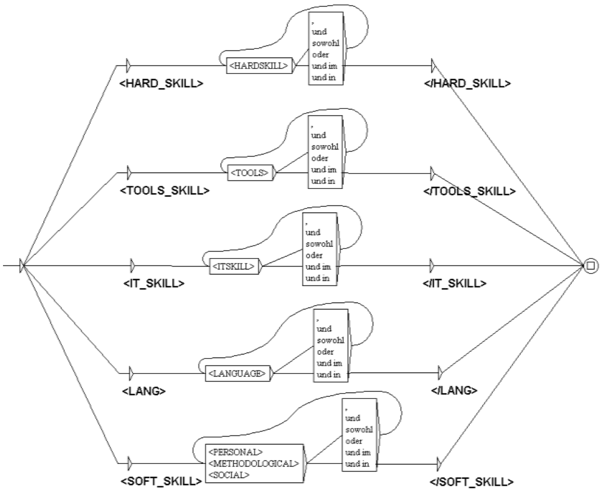

Figure 2: Syntax Graph

The skill boxes in the syntax graph as presented in Figure 2 match any form of any lemma as defined in the lexicon. When multiple skills are concatenated with a comma or a coordinating conjunction, they are grouped within a single <skill> tag to better distinguish the boundaries between the central skill position and its preceding and following context within the concordance.

In Unitex, the chosen length for the left and right context in the concordance view was set to 60 characters each, so the lines in the result file were not equal to sentences. Using a sentence splitting approach for German as described by Thurmair (2012), the potential beginning of a sentence in the left context and the potential ending of a sentence in the right context were detected, and anything outside of this scope was deleted to produce cleaner text for further processing.
Lines that were clearly wrong in the profile or in the task section were deleted. The same went for the lines without any useful content and, of course, for lines without recognised skills in them. The result of this task was a list of approx. 1 million lines.

3.3 Properties of the profile section and the task section

First tests and analyses confirmed the difference between the text structure in the profile section and task section.

In the profile section, the original general distinction between IT skills, tools and other hard skills was not fully mirrored in the found patterns. For some of the analysis tasks, it was sufficient to operate on a generic <skill> placeholder, instead of the tagged skill blocks as in the concordances (hard_skill, tools_skill, it_skill) since most of them followed the same patterns and were embedded into similar contexts. On the other hand, it was discovered that for certain groups of skills a distinction on the lemma level, rather than the class or concept level, would be necessary. For example, instead of only ‘IT skill’, programming languages need to be classified separately (experience in developing in <Python>); also IT tools follow other patterns (experience in working with <Adobe Framemaker>); in cases when the skill lemma already contains the activity (developing, programming), it needs to be embedded into different patterns (<Programmieren in Java>, <Umgang mit MS Office>) (“<programming in Java>, <working with MS Office>”).

Languages and soft skills have clearly shown that they behave differently in the context. Here as well, it was discovered that additional classification is needed according to the lemma form and its morphology rather than according to the class or concept. The following three lemmas belong to the same language skill, but follow different patterns depending on the part of speech and the noun form (for illustration, we will use comparable English examples):

- You speak the <German language> very well.
- You have very good <German skills>.
- You have a very good knowledge of <German>.

Some examples of the classification/annotation codes at the lemma level will be listed further below in section 5.6.

One notable finding from the analysis is the scarcity of soft skills within the task section. They are observed to be rarely mentioned or represented in this section. While the portion of soft skills in the profile section was 26,1%, in the task section it was only 12,8%. Some of the skills were short, semantically incomplete, and very generic (coordination, presentation) and sometimes false positives as soft skills. During the project many such skills were extended or replaced in the ontology by more appropriate skills, extracted from the relevant context found in the concordances (good presentation skills; coordination of manufacturing processes).

Furthermore, it was observed that in the task section, descriptions involving language skills often include multiple skills. For example, phrases such as "your job will include translation from German into English" imply the need for proficiency in both German and English. However, the current project was initially designed to process only one skill as input. As a result, the handling of multiple input skills was deferred to future development stages.

3.4 Application input parameters

The final selection of patterns and preparation of text building blocks was also determined by the following business requirements:

- The input parameter that is referred to as "**tone-of-voice**" should allow the user to choose how to address the job seeker, either by using the polite address in German (Sie), the informal address (Du), or to rather use an impersonal form (n/a).

- Another input parameter is the required **level of experience** for a particular skill, which the user can select to be junior, mid, or senior. If the level of experience is not applicable (e.g., for the soft skills) the input value for the text generation will be n/a. For languages, the value “native” also exists.

- The third parameter is the **optionality** of the given skill, which can be selected as either mandatory (true) or optional/nice to have (false)

  - To ensure diversity and an optimal exposure of various alternatives to the user, the main pragmatic business requirement for each skill is to generate a **minimum of three distinct sentences for each legal combination of tone-of-voice, experience, and optionality**.

The analysis revealed that certain skills may not be compatible with all combinations of the three input parameters. Consequently, the following restrictions were applied to the different types of skills in the profile and in the task sections:

- In the profile section, hard skills and language skills have no restrictions on tone-of-voice, level of experience, or optionality. This means that text with all possible combinations of these three parameters can be generated.

- Soft skills occur frequently in the profile section but have no level of experience.

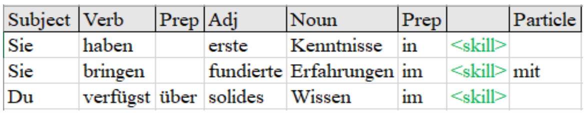
- Soft skills are typically not used in the task section at all.

- Language skills in the task section will be omitted for now, as described above.

- Consequently, in the task section, only text containing hard skills needs to be generated. Hard skills in the task section are always mandatory.

4 Selection of syntactic components, compilation of lexical resources, and development of government rules

The frequent pre-context and post-context blocks around the <skill> position were divided into smaller chunks (Figure 5) according to their part of speech and their role in the sentence (Rothstein, 2008).



Subject	Verb	Prep	Adj	Noun	Prep		Particle
Sie	haben		erste	Kenntnisse	in	<skill>	
Sie	bringen		fundierte	Erfahrungen	im	<skill>	mit
Du	verfügst	über	solides	Wissen	im	<skill>	

Figure 5: Fine-grained sentence chunks

This was the basis not only for the extraction of the syntactic patterns, but also for the collection of the most frequent lexical resources to fill the subject/predicate/object positions, including the corresponding adjectives, adverbs, prepositions, and conjunctions.

4.1 Seed sentences and iterative improvements

By identifying and selecting a first set of reliable patterns and corresponding lexical fillers, it was possible to generate a corpus of seed sentences. Examples were compiled for each semantic and syntactic category, with skill positions being filled by lexicon entries that matched the slot constraints. Through manual evaluation of approximately 11.000 sentences across three iterations, a set of generation rules was developed and iteratively refined. In addition, new semantic and syntactic codes were introduced and applied to existing lexicon entries, and standardised processes were established for tagging all new and future entries in the ontology.

4.2 Syntactic components and word order

A set of fundamental syntactic structures was selected to be used as templates for the text generation Here are some basic examples:

SVO (subject-verb-object) word order:

1. Du sprichst gut <Deutsch>
   “You speak <German> well”
2. Du bist ein <Team Player>
   “You are a <team player>”
3. <Englisch> ist Deine Muttersprache
   “<English> is your mother tongue”
4. Du bringst [Wissen über <Java>] mit
   “You bring [knowledge of <Java>] with you]”
5. Du hast [Erfahrungen in <Java>]
   “You have [experience in <Java>]”
6. [Erfahrungen in <Java>] wären ein Plus
   “[Experience in <Java>]) would be a plus”
7. [Dass Du <Deutsch> sprichst], ist ein Plus
   “[Speaking <German>] is a plus”
8. Was Dich auszeichnet ist, [dass Du <Deutsch> sprichst]
   „What sets you apart is [that you speak <German>]”

VSO (verb-subject-object) word order:

9. Vorzugsweise sprichst Du <Deutsch>
   “You preferably speak <German>”
10. Idealerweise bist Du ein <Team Player>
    „Ideally you are a <team player>”

Depending on the verb and its syntactic valency, and on the word order, the role of the <skill> in the clause can be: **direct object** (after transitive verb, like in examples 1, 9); **subject complement** (after copula verb like in examples 2, 10); **subject** (example 3); **prepositional phrase complement** in a noun phrase with heads such as “experience” or “knowledge”, which function either as a direct object (examples 4, 5) or a subject (example 6); **object in a subordinate clause**, which can function as the subject of the main clause (example 7) or as the subject complement of the main clause (example 8).
To accurately populate the skill slot, its nominative form is selected for the subject, the accusative case for the direct object, and in prepositional phrases the choice between the dative or accusative is governed by the preposition.

4.3 Syntactic government rules

To guide the assembly of the single components into text, a set of syntactic government rules was derived and manually enhanced. Also, further rules were established to ensure the correct morphological agreement between the skill and its associated syntactic structures, including verb conjugation, article usage, declension of adjectives, and word order. Here are some rules:

- Main word order is SVO. The order will change to VSO if the optionality adverb takes the first position in the sentence. The finite verb in German remains in its default second position, since all generated sentences are declarative.
- The choice of a tone-of-voice value must be considered when the personal pronoun (**Du, Sie**) ("you") is the subject of the clause, or its accusative form is the object of the clause (**Dich**, **Sie**) ("you"), also if a possessive pronoun is a part of the pattern (**Dein** Profil, **Ihr** Profil) ("your profile"), and for the correct generation of the subject-verb agreement (Du **verfügst**, Sie **verfügen**) ("you have").

  The particle of a separable verb is placed at the end of the main clause (Sie bringen Erfahrungen in Machine Learning **mit**) ("You bring experience in machine learning").
- In subordinate clauses, the particle is not separated (Was Sie **mit**bringen, sind Erfahrungen in Machine Learning) ("What you bring is machine learning experience").
- In general, subordinating conjunctions move the final verb to the end of the clause (Was Sie vorweisen **können**, sind Erfahrungen in Machine Learning) ("What you can show is experience in machine learning").
- The number of the input skill governs the number of the verb (Java **gehört** (sg) zu Ihren Stärken. Java-Kenntnisse **gehören** (pl) zu Ihren Stärken) („Java belongs (sg) to your strengths. Java skills belong (pl) to your strengths").
- Articles are declined depending on the gender and number of the input skill, and of the case required by the preposition (Erfahrung **im** Management. Erfahrung **in der** Programmierung) ("Experience in management / in programming“).
- If the skill is the subject complement with a copula verb, it needs an indefinite article (Sie sind **ein** Team Player) ("You are a team player").
- Some soft skills (but not all) require an indefinite article if they are subject to the verb "have". Those skills are tagged in the ontology (**ein** Organisationstalent) ("a talent in organisation").

4.4 Casing

Another set of rules is used to adapt the casing in the sentence. In the ontology, all lemmas are capitalised, independently of their part of speech. In the text, adjectives and verbs must be lowercased. For better readability, skills in an apposition are enclosed in double quotes, and remain capitalised (You have experience in the field of "**T**echnical acoustics"). Nominalised verbs remain capitalised in the sentence.

4.5 Lexical resources

For each of the sentence components a list of alternative expressions was created, as for example:

- The predicate position is filled with different verbs (have, posses, bring along, master etc.), or with the copula verb "be". Some of them need a tag in the lexicon.
- Experience levels can be expressed in many ways, such as with adjectives (junior: basic, mid: solid, senior: extensive), with the length of experience (many years), or by using idiomatic expressions (You are a true master in Java).
- If the skill is mandatory for the position, this can be expressed either by the present indicative form of the verb in the main sentence (you have, you bring along), or by idiomatic phrases (Java knowledge is a must). Optional skills can be expressed

by adverbs (ideally, optionally), or by idiomatic phrases (is a plus).

- To avoid string repetition, some patterns are excluded from the choice if the skill itself contains the same (sub)string. (**Kenntnisse** in <Java-**Kenntnissen>,** im **Bereich** <Finanz**bereich>**) („knowledge in <knowledge of Java>, in the domain of <finance domain>“).

The lists of alternative words and phrases include the most frequently occurring expressions extracted from the corpus, ensuring comprehensive coverage of commonly used language variants.

4.6 Ontology annotations

In some cases, the information created in the lexicon by the standard inflection and annotation modules is not sufficient to meet all requirements for the sentence generation process. Several new codes were introduced at the lemma level. In the table below are some examples of tag assignments pertaining to syntactical as well as to semantic properties:

Tag	**Example skill**	**(English)**
indef_art	Auge fürs Detail	Eye for detail
base_lang	Afrikaans	Afrikaans
lang_knowledge	Igbo-Kenntnisse	Knowledge of Igbo
adj_lang	Arabische Sprache	Arabic language
verb_lang	Deutsch sprechen	To speak German
adj_substlang	Südliches Sotho	Southern Sotho
subst_substlang	Khmer-Sprache	Khmer langauge
be	Team Player	Team player
prog_lang	C++	C++
work_with	SAP	SAP
show	Eigeninitiative	Initiative
have	Ausdauer	Endurance
neg_connotation	Bankbetrug	Bank fraud

Table 1: Examples of lemma tags

Tags are used to for example dictate the usage of indefinite articles (indef_art) or the usage of certain verbs as predicates (be, have, show). Semantic tags such as neg_connotation prevent generation of phrases that require experience in illnesses, fraud, terror acts or similar. Instead of “you have experience in money laundering” other formulations are taken, to rather indicate experience as a specialist in this domain. Language skills have many different tags used to select the correct predicate in the clause (speak, know, have (knowledge)).

5 Automatic process in production

Subsequently, the final collection of rules and resources was automatically applied to all the skills featured in the ontology, resulting in the creation of almost 30 million unique sentences for approximately 62.000 skills.

To streamline the regular production process, a pipeline was established to generate sentences for newly added skills in the ontology. The infrastructure incorporates the databases for the ontology maintenance and storage of the sentence data, a Python pipeline for the generation of new sentences, and a serverless process for automatic export of new data to the production system.

5.1 Generation pipeline

The sentence generation pipeline comprises the following sequential steps:

- The pipeline begins by examining the ontology for any newly added skills. A temporary dictionary is created.
- The features of the new skills, such as concept tags, lemma tags, number, and gender, are compared against previously processed skills.
- In the case of multiword phrases, the head positions are compared, and the pipeline searches for the longest common ending of the head tokens. If a common length of at least 3 characters is found, the skill is immediately selected as an example for the new skill.
- If not all requirements are met, the rules are relaxed. This includes accepting shorter common endings and allowing a fewer number of matching tags. These relaxations are logged for further manual checks and analysis.
- The pipeline selects the best matching example skill based on the previous comparisons.
- Corresponding example sentences are retrieved from the database, serving as templates for generating new sentences.

5.2 Quality assurance

The formal automatic quality assurance task encompasses the evaluation of the following aspects: number of patterns per skill, number of sentences per pattern, deletion of skills from the ontology (it checks if any skills were removed from the ontology, to delete the corresponding data sets in the sentence DB).

In addition to the formal automatic evaluation, a qualitative evaluation is conducted through manual checks of the logs. This evaluation aims to identify the reasons for missing example skills or insufficient coverage. Potential reasons could include missing tags, a wrongly assigned head position for the lemma, incorrectly inflected forms, or wrong features. Typically, improvements in the ontology are required to address these issues and enhance the quality of sentence generation.

6 First results

In the pilot phase of the project, 20 stakeholders were asked to test the system, to use it to publish their job ads, and to give their explicit feedback.

In total, 465 listings (job ads) were published. Quantitatively, the published listings contained a total of 2031 sentences in the profile sections. 1289 of them were taken from the auto-suggest without any modification. The task section contained 1580 sentences in total. 1229 of them were taken from the auto-suggest without any changes.

All other sentences were added by the job publisher during the job ad creation. In both sections, it was observed that most of the lines that did not come from the auto-suggestion option were rather simple enumeration, either single skills (mostly free-text, so out-of-vocabulary skills) or skill lists, where similar skills were grouped together in one bullet point.

Qualitatively, the stakeholders' descriptive feedback was positive. They appreciated that the job ad could be created in very short time. In the first test round, the sentences were sometimes perceived as schematic and uniform, with similar structure and same sentence beginnings. To overcome that, an external module was developed to select sentences with the longest lexical distance.

The following qualitative feedback provided by stakeholders and internal testers significantly influenced the further development of the generation module:

SVO sentences with personal pronouns “Du” or “Sie” as the subject, were perceived as dominant and monotonous. Instead, neutral sentences where the skill itself served as the subject (Several years of experience in the field of "Virtual Design" are a must) or sentences with as subordinate clause as the subject (What you have already acquired is basic experience in output management) were considered more natural and appealing. As a result, the number of such sentences was increased.

Sentences expressing that the skill is optional were found to be richer and more varied compared to sentences with mandatory skills. This is because many of the “nice to have” patterns follow the VSO order, with the optionality adverb typically taking the first position in the sentence, and as such they offer an opportunity to enhance the diversity of the sentence beginnings by expanding the vocabulary for the given slot (e.g. ideally, desirable, optional, advantageous).

Since the selection of the formal, informal, or neutral tone as well as the specification of optionality are essential input parameters, the freedom in selecting slot fillers is limited. To introduce more variety, strategies such as sentence order inversion and the use of idiomatic fillers (e.g. <skill> is a must; a must is <skill>) were employed.

7 Summary and Outlook

The paper describes a method for automatic creation of content using pre-established rules and templates, without any reliance an artificial intelligence or machine learning algorithms. The process enables to quickly create high-quality and contextually appropriate content. It offers numerous advantages including efficiency, consistency, customisability, and accuracy. It can serve as both the primary approach for sentence creation and as fallback option for AI methods.

The qualitative improvements will concentrate on allowing multiple skills as the input to the generation.

Lastly, user feedback will be integrated into the development loops (free-text skills that are not in the ontology yet, modified sentences, patterns that never were selected or were discarded by the user).

Abstract

The rise of social media eases the spread of hateful content, especially racist content with severe consequences. In this paper, we analyze the tweets targeting the death of George Floyd in May 2020 as the event accelerated debates on racism globally. We focus on the tweets published in French for a period of one month since the death of Floyd. Using the Yandex Toloka platform, we annotate the tweets into categories as hate, offensive or normal. Tweets that are offensive or hateful are further annotated as racial or non-racial. We build French hate speech detection models based on the multilingual BERT and CamemBERT and apply transfer learning by fine-tuning the HateXplain model. We compare different approaches to resolve annotation ties and find that the detection model based on CamemBERT yields the best results in our experiments.

1 Introduction

The rapid advancements of social media platforms like Facebook, Twitter, and YouTube during the last couple of years have enabled users to express and distribute their sentiments on events and ideas freely and conveniently. This eases the usage of hateful messages that can imply threats or harassment against minorities (Chiril et al., 2020). Since there are variations in defining hate speech globally, we took the following explanations as working definitions in this research. Therefore, hate speech is defined as a public communication consisting of messages that may express threats, harassment, intimidation, or disparagement of a person or a group on the basis of some characteristic such as race, color, ethnicity, gender, sexual orientation, nationality, religion, culture or other characteristic (Nockleyby, 2000). Besides, offensive speech is also hurtful speech that is directed against another person. Compared with hate speech, offensive speech has fewer legal implications since it does not attack people based on their group identity, rather it hurts individuals based on personal characteristics and makes them offended. More specifically, racism is a type of discrimination that makes up a large portion of hate speech and is usually directed against the perceived ethnicity, appearance, religion, or culture (Rzepnikowska, 2019).

Figure 1: French language test example presented for performers

After the killing of George Floyd on May 25th, 2020, the number of racist comments on social media platforms, especially on Twitter, has increased substantially (Carvalho et al., 2022). Social media platforms use mainly content moderation systems, which are human-machine collaborative systems to detect and handle hate speech as an automatic detection system in spite of the limitations that such systems have to control the problem (Horta Ribeiro et al., 2021). These days, the task of automatic hate speech detection in general and racial hate speech, in particular, has attracted the attention of many natural language processing researchers.

To advance the development of hate speech detection algorithms in multiple languages, we extend the English hate speech detection model from HateXplain (Mathew et al., 2021) to the French language by employing our own annotated dataset. Despite there are various types of discrimination and intersections among them, we limit the scope

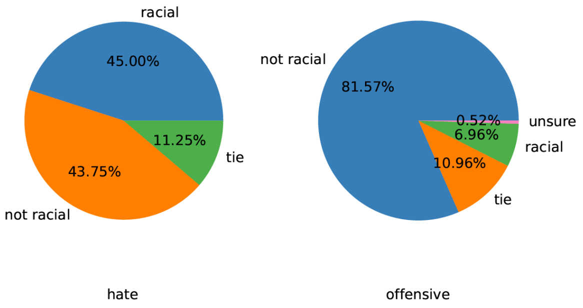

Figure 2: Class distributions of our French racial dataset

of our research to racial discrimination which is one of the most critical problems in society (Vanetik and Mimoun, 2022).

The study addresses the following research questions:

- Can BERT and HateXplain models be efficiently adapted to other languages or cultures, specifically to racial hate speech detection tasks in French?
- What are the main challenges of racial hate speech data annotation on the Toloka crowdsourcing platform?

In this paper, we employ a crowdsourcing-based racial hate speech data annotation using the Yandex Toloka platform[1]. Moreover, we fine-tuned HateXplain (Mathew et al., 2021), which is a BERT-based classification model for tweets in the French language.

The main contributions of this research include the following:

1. Collecting racial hate speech dataset in French,
2. Exploring the annotation challenges of racial hate speech annotation on the Yandex Toloka crowdsourcing platform, and
3. Adaptation of a racial hate speech detection model for the French Twitter dataset.

The remainder of the paper is organized as follows. The paper provides the related works in Section 2. While the data collection procedures and strategies are presented in Section 3, the data annotation strategies are briefly discussed in Section 4. We present our experiments including the baseline models, the results, and the error analysis in Section 5. Finally, the conclusion and future work are presented in Section 6, and the limitations of the research are indicated in Section 7.

2 Related Works

In academia, there is a strong interest in detecting hate speech and exploring the challenges facing the task. To address the issue, many researchers attempted hate speech studies by creating their own datasets and building classification models that can detect and classify hateful content from texts on social media platforms. In this regard Mozafari et al. (2020); Mathew et al. (2021); Ousidhoum et al. (2019); Davidson et al. (2017); Wang et al. (2021); Waseem and Hovy (2016); Vidgen and Derczynski (2020); Matamoros-Fernández and Farkas (2021); Vanetik and Mimoun (2022) and many other researchers investigated hate speech and developed classification models.

Most of the studies use Twitter data (Mathew et al., 2021; Vidgen and Derczynski, 2020). According to the work by Matamoros-Fernández and Farkas (2021), Twitter data is the most widely used source of data for computational social science such as hate speech and sentiment analysis tasks. Some researchers use lexical methods to retrieve social media texts based on the entries in a lexicon and build datasets for social computing (Njagi et al., 2015). The work by Davidson et al. (2017) analyzed the quality of lexical methods and proved that it is more effective to detect offensive language than hate speech. They also identified racism and homophobia more often as hate speech while sexism is more often offensive. Hate speech, racism, and racial profiling are less studied in French when compared with English (Vanetik and Mimoun, 2022). As indicated in Table 1 the study by Vanetik and Mimoun (2022) collected 2,856 French tweets and labeled them into racist and non-racist speech, and fine-tuned the BERT models for both multilingual with English dataset and monolingual models for French and English. Despite the dataset employed to build the models being a bit small in size, Vanetik and Mimoun (2022) achieved an F1-score of 67.4% for the monolingual French dataset and 64.7% for the multilingual dataset respectively as shown in Table 1. Table 1 also presented datasets and models focused on racial hate speech. The other tasks on racial hate speech presented by Waseem and Hovy (2016); Waseem (2016); Sanoussi et al. (2022) achieved F1-scores of 95.4%, 76%, and 65% class label per-

[1] Yandex Toloka: https://toloka.yandex.com

formance results respectively in different datasets.

There are fewer annotated datasets that deal with racist speech than for general hate speech, in particular for the French language (Vanetik and Mimoun, 2022). A few studies were conducted on racial hate speech in French. Chiril et al. (2020) created a French corpus of the sexist dataset by collecting tweets using keywords and becomes the first dataset to detect sexism and multi-target hate speech. Models developed for other languages such as English can not be properly adopted for racial hate speech classification in French due to contexts variations in culture and differences in linguistic features.

Mathew et al. (2021) presented a hate speech dataset annotated in three different perspectives such as:

1. the basic 3-class classification (hate, offensive or normal)
2. indicating the target community who are victims of hate/offensive speech and
3. the rationales behind the labeling decisions.

Mathew et al. (2021) adapted the CNN-GRU (Zhang et al., 2018), BiRNN (Schuster and Paliwal, 1997), BiRNN-Attention (Liu and Lane, 2016) and BERT (Devlin et al., 2019) models by modifying the original architectures.

For example, Mathew et al. (2021) fine-tuned the BERT model of Devlin et al. (2019) by adding a fully connected layer with the output corresponding to the classification tokens in the input where the token output usually holds the representation of the sentence to add attention supervision that matches the attention values corresponding to the token in the final layer.

3 Data Collection

Most of the existing hate speech datasets in French and other languages do not focus on racial hate speech. The dataset used in this research is collected from Twitter focusing on tweets that are published for one month following the death of George Floyd[2]. The death of George Floyd accelerated debates and demonstrations globally. Following the death, social media platforms such as Twitter, Facebook, and YouTube have become places for hate and offensive speeches in general and racial hate speech in particular.

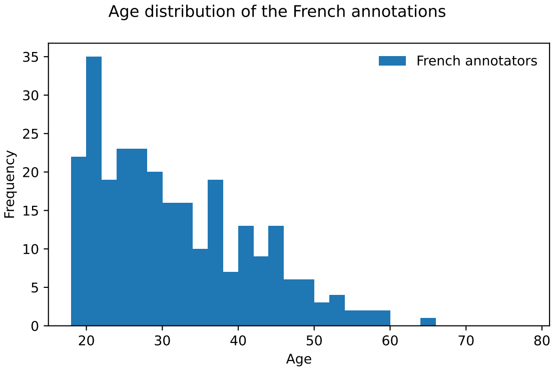

Figure 3: The age distribution of the annotators.

We employed 3,473 French hate speech lexicon entries adapted from the work of Stamou et al. (2022); Chiril et al. (2020) to filter the tweets that might contain racial hate speech content from the total 200m tweet corpus. We used the Python language detection[3] tool to filter tweets that are only written in French. We also removed truncated tweets since such tweets lack complete information and may confuse the annotators during annotation, and the model during experimentation. We removed retweets and kept only unique tweets that are not duplicated. Moreover, usernames and URLs are anonymized and replaced with <USER> and <URL> respectively. A total of 5k tweets are annotated using three independent annotators on Yandex Toloka crowdsourcing platform.

4 Annotation

Annotation by itself is a very complex task and becomes more challenging for hate speech annotations due to the lack of complete background contexts behind the texts scrapped from social media platforms (Davidson et al., 2017; Ayele et al., 2022a). We annotated 5k tweets on Toloka crowdsourcing platform and each tweet is annotated by three independent Toloka performers. We annotated 50 random tweets and evaluated the annotations by experts for the correctness of the corresponding labels. These control tweets were used to control malicious annotators engaging in the annotation task. Each task presented to performers contains 15 tweets and one of the tweets is a control question. Users are asked to classify tweets into **hate**, **offensive**, **normal** and **unsure**, and further classify hateful tweets into **racial**, **non-racial**

Author	Language	Size	Labels	Best F1-Score
Vanetik and Mimoun (2022)	French	2,856	racist, not racist	67.4%
Sanoussi et al. (2022)	Chadian mixed French-Arabic	14,000	hate, insult, neutral, offensive	95.4%
Waseem and Hovy (2016)	English	16,914	racism, sexism, neither	76.0%
Waseem (2016)	English	6,909	racism, sexism, racism &sexism, neither	65.0%

Table 1: Status of racial hate speech studies (data size, labels, method, and best score and resource availability)

and **unsure**. If **hate** is chosen by an annotator, the targets **racial**, **non-racial**, and **unsure** will pop up immediately for the performer. The **unsure** label is provided to give performers the opportunity to indicate that a tweet is very hard to classify.

According to the work by Ross et al. (2017), providing the basic definitions and task descriptions of the annotation project beforehand improves the alignment of the opinions of the annotators on the class labels. We presented the annotation guideline to provide a complete description of the annotation task. Two training task pools structured in the same way as the actual task were presented to be completed by Toloka performers before joining the main annotation task. Such procedures can help Toloka performers to have sufficient knowledge and understanding of the annotation task.

One of the main challenges of crowdsourcing data annotation is the prevalence of malicious data annotators who merely participate in the annotation task to gain financial rewards (Öhman, 2020; Ayele et al., 2022b). In order to prevent potential malicious performers from engaging in the annotation task, we prepared a French language test and presented it to each performer as indicated in Figure 1. Toloka performers needed to pass the French language test in order to participate in the main French racial hate speech annotation task. We also limited the location of performers and allowed those performers who lived in France or Belgium. The performers who successfully completed the two training task pools, lived in France or Belgium, and passed the French language test were qualified and provided the privilege to access the main annotation task pools. A Fleiss kappa of 0.3 inter-annotator agreement, which indicated a fair agreement, is achieved. Each tweet was annotated by three annotators and the final gold label was aggregated from these three annotations with a majority voting scheme. As indicated in Figure 2, 45% of the tweets annotated as hate contained racial content and 11.25% had also ties. Hateful tweets had more probability to contain racial content and ties than offensive tweets. Figure 3 showed that the majority of Toloka performers who participated in the French racial hate speech annotation were young adults below 40 years. The summary of the overall annotation information is presented in Table 2. Moreover, the sample annotation task presented to Toloka performers for annotation is depicted in Figure 4, and the completed French racial Toloka project indicating the overview of the French racial hate speech annotation project is also provided in Figure 5. Each annotator earned $0.1 per task.

Fleiss Kappa score	0.3
Total number of Annotated tweets	5002
Number of annotators participated in the task	275
Mean age of annotators in years	31.11
Country distribution of annotators	265 Fr, 8 Be, 3 O
Accuracy for 50 random tweets	0.24
F1 score for 50 random tweets	0.24
Racial accuracy for 50 random tweets	0.12
Average time for 15 tweets	2 min 10 sec
Number of collected keywords	3473

Table 2: Basic annotation information (Fr= French, Be = Belgium, O = Others)

5 Experiments

5.1 Baseline Models

The BERT language model facilitates a lot of natural language processing tasks. It consists of transformer encoder layers with a self-attention mechanism (Devlin et al., 2019). The model has grown into a family of language models for a wide range of languages. The multilingual BERT and CamenBERT models are examples of such extensions. The works like HateXplain (Mathew et al., 2021),

further fine-tuned the models with hate speech dataset collected from posts on Twitter[4] and Gab[5], which were filtered with keyword lists. The dataset was constructed for English and accommodated rationales to better explain the decisions of the crowd workers who annotated the posts. The HateXplain (Mathew et al., 2021) model achieved an accuracy of 70% and an F1-score of 69% on this dataset.

For this research, we employed the baseline BERT and other extended BERT models. The HateXplain dataset was used for fine-tuning the BERT models which are pre-trained for a wide range of language processing tasks. It was further preprocessed and applied for fine-tuning the multilingual BERT model. Additionally, the dataset was translated with Google Translate to French and trained on the French language model camemBERT[6]. CamemBERT is a pre-trained transformers language model developed for the French language on the original BERT (Martin et al., 2020).

We conducted different experiments by fine-tuning the HateXplain model with the multilingual BERT (ML BERT) and CamemBERT models on different datasets and class label generations. As indicated in Table 3, the first four experiments focused on the ML BERT and HateXplain model combinations (i.e., 1.0, 1.1, 1.2, and 1.3) while the next four experiments focused on the CamemBERT and HateXplain model combinations (i.e., 2.0, 2.1, 2.2, and 2.3). We analyzed the influence of different kinds of datasets and label aggregations on the performance of the models as shown in Table 3. One of them is the automatic aggregation of the three annotations for each tweet based on the Dawid-Skene aggregation method[7]. Opposed to automatic aggregation, some studies were conducted with a custom aggregation method that combines the votes in the following way: the classifications with at least two votes were considered the ground truth for each tweet. When there are three different classifications, the tweet is either removed (Experiment 1.1 and 2.1) or if there is at least one hateful label, it is considered hateful and otherwise offensive (Experiment 1.3 and 2.3) as shown in Table 3.

Table 4: Further experimental results based on Experiment 2.1 of Table 3

5.2 Results

For both of the BERT-based models, the datasets performed nearly similar results, as shown in Table 3. Hence, the model based on the Dawid Skene aggregation gained a better accuracy and F1-score than the aggregation based on the ones with a majority voting for both the multilingual BERT and camemBERT. The removal of the votes with ties has led to the best results for both base models. This implied that adding ties does not lead to better results. Experiments on the multilingual BERT such as Experiment 1.1 in Table 3 performed worse than the corresponding camemBERT (Experiment 2.1). This indicated that augmenting target datasets with translated English datasets like the HateXplain can improve the performance of the BERT modes.

The offensive tweets were predicted well but some normal tweets were also classified as offensive. There were remarkable differences between the performance of the models based on the multilingual BERT and the French camemBERT. Whilst the multilingual BERT always predicted *normal* as the class label with nearly the same score for every tweet, the camemBERT labeled the tweets appropriately. The multilingual experiments achieved a lower score than the camemBERT models. A random sample of 50 tweets that were incorrectly classified by the model was analyzed together with the reasons for the incorrect classification.

Despite all the three annotators agreed with 100% on the labels of some tweets, there were variations in the classification model where some were wrongly classified. For example, no tweet in the test set was classified as hate even though there were examples from annotators who all agreed that the corresponding tweet was hateful. This can be explained due to the class imbalance problem in the original dataset. Through further fine-tuning, the best performing model was chosen and hyperparameters like the number of epochs and the learning rate were varied as shown in Table 4. As the dataset has unbalanced classes, a stratified splitting of both the train and the test set was chosen as another experiment and showed improvements in the performance of the models.

6 Conclusion

This paper presented the collection of racial hate speech datasets from Twitter. The dataset was collected for a period of one month following the death of George Floyd in May 2020 as his murder was associated with racism. The debate regarding racism escalated during that time and racist speeches and expressions on almost all social media platforms were also aggravated. A total of 5k tweets are annotated as hate, offensive, normal, and unsure using Toloka. Furthermore, hate and offensive tweets were labeled as racial, non-racial, and unsure classes. This dataset can be used as a benchmark dataset for French racial hate speech research. The BERT model is successfully fine-tuned with the dataset together with the translated HateXplain dataset. Our experiment achieved an accuracy of 88% and an F1-score of 86% which are improving over the baseline HateXplain model.

In future work, we plan to work on further filtering the lexicon entries in order to reduce the class imbalance problem. Extending the dataset to include the racial targets and the rationales of the label decisions can also be future work. We published the resources in GitHUb[8].

7 Limitations

Due to the resources and time constraints, the annotators were not necessarily experts, which might have influenced the quality of the dataset. Since the task of racial hate speech is complex, distinguishing between hate and offensive content is even very difficult for the annotators. There are many cases where the annotators choose "unsure" as well as totally disagreed on the label's tweets during annotation. In addition to the low quality, the size of the dataset is also small and has a data imbalance problem that can be associated with the limitations of this research.

Abstract

In this paper, we present a study of efficient data selection and annotation strategies for Amharic hate speech. We also build various classification models and investigate the challenges of hate speech data selection, annotation, and classification for the Amharic language. From a total of over 18 million tweets in our Twitter corpus, 15.1k tweets are annotated by two independent native speakers, and a Cohen's kappa score of 0.48 is achieved. A third annotator, a curator, is also employed to decide on the final gold labels. We employ both classical machine learning and deep learning approaches, which include fine-tuning AmFLAIR and AmRoBERTa contextual embedding models. Among all the models, AmFLAIR achieves the best performance with an F1-score of 72%. We publicly release the annotation guidelines, keywords/lexicon entries, datasets, models, and associated scripts with a permissive license[1].

1 Introduction

In this digital era, social media platforms have become an important part of everyday life for people globally. The 2023 Global Digital Report disclosed that nearly 5.16 billion people use the internet and the number of social media users exceeded 4.76 billion worldwide. Over 64.4% of the world's population is already online, and nearly 60% of the people are active users of different social media platforms (Kemp, 2023).

Hateful content targeting minorities is rapidly spreading across social media platforms and becoming a major socio-political and cultural challenge in the world (Williams et al., 2020). To tackle the problem, many countries, like Ethiopia, crafted hate speech regulation laws even though the regulations have limitations for implementation (Ayalew, 2020). Moreover, there has been a rising interest among researchers in hate speech detection to expose and regulate this phenomenon with technological solutions. In this regard, researchers like Mathew et al. (2021); Ousidhoum et al. (2019); Poletto et al. (2017); Davidson et al. (2017); Waseem and Hovy (2016) have proposed several hate speech classification models and datasets for the development of automatic hate speech detection systems. Despite many researchers claiming state-of-the-art performance on their own datasets, the models can not be generalized for all languages and datasets (Gröndahl et al., 2018).

Ethiopia's legal regulations that were designed to counteract hate speech are not very well implemented. This is due to the complex nature of the online community, which is difficult to control by local laws, and the anonymity of online users who spread hateful messages while hiding behind their screens. Moreover, the available hate speech classification models built for high-resource languages such as English could not be used for low-resource languages like Amharic since such tasks incorporate cultural, social, and political variations in addition to language-specific differences. We have compiled Amharic hate speech datasets from Twitter and built classification models using different machine-learning approaches.

In this paper, we addressed the following research questions, which are formulated for Amharic, but also apply to other low-resource languages:

1. How to identify appropriate data collection and selection approaches for constructing hate and offensive speech datasets for Amharic?

2. What are the main challenges in the annotation and classification tasks of Amharic hate speech?

[1] https://github.com/uhh-lt/AmharicHateSpeech

Proceedings of Recent Advances in Natural Language Processing, pages 49–59
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_006

The paper presented benchmark hate speech data selection approaches, a dataset consisting of over 15.1k annotated tweets, and various classification models. This work has the following main contributions:

1. A well-defined hate speech data selection and preprocessing pipeline for hate speech annotation,
2. The collection of benchmark hate and offensive speech lexicon entries,
3. The development of hate speech annotation guidelines and strategies for quality data annotations, and
4. Releasing benchmark dataset and classification models for Amharic hate speech task.

We organized the remainder of the paper as follows. The study provides introductory information about the Amharic language in Section 2. Related works are presented in Section 3. Data collection and preprocessing details are discussed in Section 4. Data annotation strategies are described in Section 5. We present classification models in Section 6 and the results and discussion part of the paper in Section 7. An error analysis of model results is described in Section 8. Section 9 concludes and shortly discusses future avenues, limitations are indicated in Section 10.

2 Amharic Language

Amharic is the second-largest widely spoken Semitic language next to Arabic. It is written from left to right with its own unique 'Fidäl' scripts. Fidäl is a syllable-based writing system where the consonants and vowels co-exist within each graphic symbol. Amharic is the working language of the Federal government in Ethiopia and many regional states in the country (Salawu and Aseres, 2015). In Amharic, there are 34 core characters each having seven different variations to represent vowels. Besides, it has 51 labeled characters, 20 numerals, and 8 punctuation marks. Amharic uses more than 310 unique characters and is a morphologically complex and highly inflected language (Gezmu et al., 2018).

3 Related Work

Hate speech refers to language content that targets identity such as ethnicity, gender, disability, or political and religious ideology, which indirectly or directly focuses on their group identity and has the potential to incite violence (Casanovas and Oboler, 2018). In contrast, offensive speech is a speech that usually targets individuals to be offended but not based on their group identity (Casanovas and Oboler, 2018).

Hate speech has been addressed by many researchers using data scraped from online messages on social media. Among the various studies, Waseem and Hovy (2016); Davidson et al. (2017); Founta et al. (2018); ElSherief et al. (2018); Ousidhoum et al. (2019); Founta et al. (2019); Winter and Kern (2019); Mathew et al. (2021); Röttger et al. (2022b); Demus et al. (2022); Röttger et al. (2022a) conducted hate speech research in languages such as English, German, French, Arabic, Spanish, Portuguese and Hindi and published their datasets and models to advance further research.

As indicated in Table 1, among a few studies conducted for Amharic, the work by Mossie and Wang (2018); Tesfaye and Kakeba (2020) and Abebaw et al. (2021) used binary classification (hate or non-hate) labels on Facebook comments using different machine learning algorithms, while Mossie and Wang (2020) further tried to identify vulnerable communities to hate speech among the major ethnic groups in Ethiopia. The studies by Abebaw et al. (2021); Mossie and Wang (2018, 2020) have collected their datasets from the Facebook pages of some media organizations for a few months and from limited users. Ayele et al. (2022b) presented a crowd-sourced Amharic hate speech dataset from Twitter with a kappa score of 0.34 and a model performance of 50% for the F1-score with AmRoBERTa which is fine-tuned for the Amharic. The dataset presented by Ayele et al. (2022b) is a low-quality dataset since it is collected using a crowdsourcing annotation approach in a low-resource language context and its lower performance score may also be associated with the dataset quality. Even though most of the authors have reported state-of-the-art performance results, we can not reproduce the results since neither the datasets nor the models are published publicly except the one described in Ayele et al. (2022b).

4 Data Collection and Preprocessing

We have been collecting and storing Amharic tweets every day since 2014 and built a Twitter dataset in a relational database using the Twitter API. Our algorithm scrapes large numbers of tweets

Author	Size	Labels	Best Method	Best Score	Resources Available
Mossie and Wang (2018)	6,120	hate, not hate	Naïve Bayes	79.8%: acc	No
Mossie and Wang (2020)	14,266	hate, not hate	CNN-GRU	92.6%: acc	No
Tesfaye and Kakeba (2020)	30,000	hate, free	LSTM	97.9%:acc	No
Abebaw et al. (2021)	2,000	hate, not hate	SVM	92.5% :F1	Dataset only
Abebaw et al. (2022)	2,000	hate, not hate	MC-CNN	68.5% :F1	Same Dataset
Ayele et al. (2022b)	5,267	hate, normal, offensive	RoBERTa	50.0%: F1	Yes

Table 1: Amharic hate speech studies (data size, labels, method, and best score and resource availability)

that are written in Amharic, Awgni, Guragigna, Ge'ez, Tigrinya, or other Semitic languages that use the Fidäl script. Currently, we have collected and stored more than 18 million tweets. As indicated in Figure 1, the number of tweets stored in our repository showed a substantial increase since 2020 due to the evolving economic, social, and political dynamics in Ethiopia. Particularly, in the years 2020, 2021, 2022, and 2023 until April showed a significant increase in the number of tweets collected every day, which might be due to the following reasons:

1. The prevalence of the Covid-19 pandemic and its global impacts,
2. Ethiopia's Tigray region holds a regional election in defiance of the federal government,
3. The escalations of various national socio-political problems in Ethiopia,
4. The conflict between the federal government and the Tigray People's Liberation Front (TPLF) in the Tigray region,
5. The 6th Ethiopian national election,
6. The assassination of artist Hachalu Hundessa and the imprisonment of opposition political party leaders in Oromia region due to the mass demonstrations and violence in the region following the death of the artist, and
7. The Grand Ethiopian Renaissance Dam (GERD) dispute between Ethiopia and Egypt reached a high peak. The GERD case was even taken to the UN security council despite Ethiopia's complaints that it was not a security issue at all.

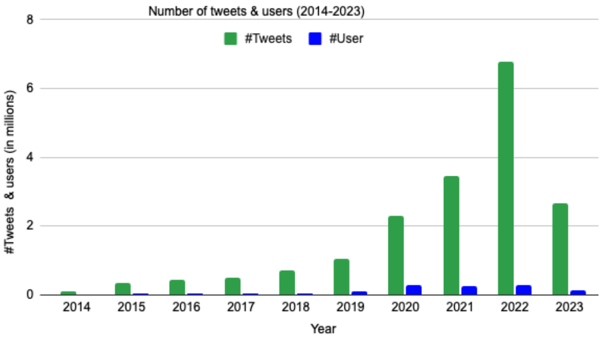

Figure 1: Number of tweets and users scraped per year

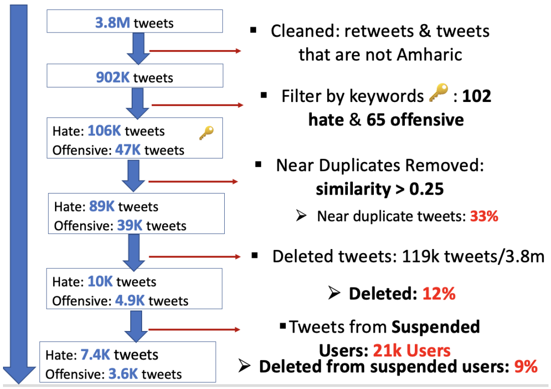
For this research, we collected 3.8 million tweets from October 2020 to November 2021 for 14 consecutive months, mainly focusing on tweets that are written during the socio-political dynamics in Ethiopia, mainly related to the reasons mentioned above (#2, #3, #4, #5, and #7).

4.1 Data Sampling

Figure 2 presented the various data collection, preprocessing, and sampling strategies employed in the paper. We removed retweets and filtered out non-Amharic tweets using the Python language detection tool[2] resulting in 902k tweets out of 3.8 million tweets. Through employing hate and offensive lexicon entries, we further filtered the tweets

[2] https://pypi.org/project/langdetect/

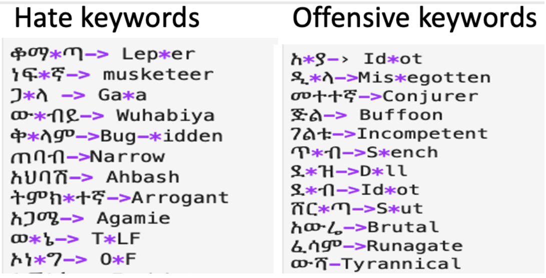
and reduced the target dataset to 153k tweets. Figure 3, shows a sample of some hate and offensive keywords that are used to filter the dataset. The keywords were collected from volunteer communities through Google Forms shared via social media platforms. We have also used the keywords listed in Yimam et al. (2019) as an initial query.



3.8M tweets
902K tweets
Hate: 106K tweets
Offensive: 47K tweets
Hate: 89K tweets
Offensive: 39K tweets
Hate: 10K tweets
Offensive: 4.9K tweets
Hate: 7.4K tweets
Offensive: 3.6K tweets
Cleaned: retweets & tweets that are not Amharic
Filter by keywords : 102 hate & 65 offensive
Near Duplicates Removed: similarity > 0.25
Near duplicate tweets: 33%
Deleted tweets: 119k tweets/3.8m
Deleted: 12%
Tweets from Suspended Users: 21k Users
Deleted from suspended users: 9%

Figure 2: Data selection and preprocessing pipeline

We further examined the filtered tweets for a random number of samples and find out that there are tweets with unique IDs but are duplicates or near-duplicates of each other. This might be due to some users who copy and post others' tweets with some minor modifications. We explored different mechanisms and employed shingling methods to filter the near duplicate tweets using the Jaccard similarity index. The Jaccard similarity measure of all the pairs of tweets was calculated and the near duplicate tweets were obtained. We considered a 25% similarity score as the maximum tolerable threshold value and achieved 130k unique clean tweets by removing all the tweets that have a Jaccard index greater than the threshold value (i.e. with less than 25% similarity). It is indicated that 33% of the tweets are near duplicates in the corpus, and therefore are excluded from being sampled for this study.



Hate keywords

ቆማ*ጣ-> Lep*er
ነፍ*ኛ-> musketeer
ጋ*ላ -> Ga*a
ው*ብይ-> Wuhabiya
ቅ*ላም->Bug-*idden
ጠባብ->Narrow

ትምክ*ተኛ->Arrogant
አጋሜ-> Agamie
ወ*ኔ-> T*LF
ኦነ*ግ-> O*F

Offensive keywords

አ*ያ-› Id*ot
ዲ*ላ->Mis*egotten
መተተኛ->Conjurer
ጅል-> Buffoon
ገልቱ->Incompetent
ጥ*ብ->S*ench
ደ*ዝ->D*ll
ደ*ብ->Id*ot
ሸር*ጣ->S*ut
አውሬ->Brutal
ፈሳም->Runagate
ውሻ-Tyrannical

Figure 3: Sample hate and offensive keywords

4.2 Dealing with Deleted Tweets

Twitter deletes some tweets that are reported as inappropriate and even suspends some users due to various reasons. We explored many deleted tweets and found out that 12% of the tweets in our repository are deleted from Twitter and are no more available. Among the deleted tweets, around 9% are from suspended users alone. We have annotated some samples of deleted tweets from both active and suspended users for pilot investigations if they contain more hateful content than the accessible tweets.

We have finally created two large pools of unlabelled tweets, one containing keywords and the other without keywords. The keyword-based unlabelled pool consisted of around 113k accessible tweets containing hate and offensive keywords. The second unlabelled pool, which is without keywords, is comprised of accessible tweets that do not contain hate and offensive keywords. The tweets are anonymized by replacing usernames with <USER> tokens and removing URLs from the tweets.

5 Data Annotation

Previous studies on Amharic hate speech classification such as Mossie and Wang (2018, 2020); Abebaw et al. (2021) identified two classification categories (i.e. hate vs non-hate) while studies in English and other languages (Davidson et al., 2017; Mulki et al., 2019) used Hateful, Offensive, and Normal class categories. Recently, the study by Mathew et al. (2021) introduced the "unsure" category and employed four class categories, which are hate, offensive, normal, and unsure. We used the WebAnno[3] annotation tool, which is a web-based annotation framework for all annotations.

5.1 Pilot Annotation

As the first round of pilot annotation, we annotated 3k tweets containing hate and offensive keywords. As indicated in Table 2, the pilot data annotation covered mainly tweets from 3 different categories such as accessible tweets, deleted tweets from suspended users, and deleted tweets from active users.

Each tweet is annotated by three annotators. While the first two annotators labeled each tweet independently, the third annotator who served as

[3] https://www.inf.uni-hamburg.de/en/inst/ab/lt/resources/software/webanno.html

Category	Hate	offensive	Normal	Unsure	# Total
Accessible tweets with keywords	498	198	252	8	959
Deleted tweets from suspended with keywords	490	254	244	14	1000
Deleted tweets from active users with keywords	488	173	387	6	1055
Total number of annotated Tweets	**1,477**	**623**	**885**	**28**	**3013**

Table 2: Pilot annotated tweets by category

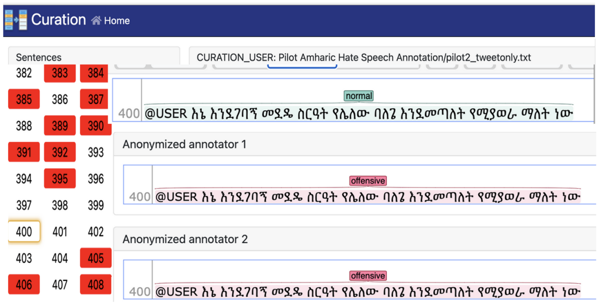
a curator or an adjudicator made the decisions on the final gold labels. A total of 5 annotators were involved in the pilot annotation task and each annotator earned 0.5 ETB or $0.01 cents per tweet. The annotators can label 150 tweets per hour and earn 75 ETB or $1.5, which is nearly equivalent to the hourly wage of BSc holders in Ethiopia. We prepare training manuals and annotation guidelines and deliver intensive training to make the task clear for the annotators and the curator.

The pilot annotation result consisted of 1487, 892, 627, and 28 tweets labeled as hate, offensive, normal, and unsure class labels respectively. We employed Cohen's kappa coefficient to compute the inter-annotator agreement (IAA) and achieved a 0.44 agreement score for the pilot annotation. Other related studies, for example, Del Vigna et al. (2017) reported a 0.26 inter-annotator agreement score on the Italian dataset while Ousidhoum et al. (2019) reported 0.153, 0.202, and 0.244 IAA scores of kappa coefficient on English, Arabic, and French datasets respectively. Besides, Mathew et al. (2021) reported a 0.46 inter-annotator agreement score on the English data set, which indicated a moderate agreement among annotators. Therefore, our 0.44 inter-annotator agreement score fell under the moderate category which encouraged us to pursue the main annotation task.

As shown in Table 2, hateful tweets seemed more dominating in the dataset since the pilot annotations in all categories used tweets consisting of keywords only. The deleted tweets were examined and compared with the accessible tweets if they contained more hateful content. No significant differences were found in the distributions of hateful tweets across the three categories (accessible tweets, deleted tweets from suspended users, and deleted tweets from active users). The deleted tweets are excluded from being sampled in the final dataset since they are no more available on Twitter.

5.2 Error Analysis of Pilot Annotations

Hate speech annotation is highly subjective and challenging even for human annotators (Fortuna et al., 2022; Ayele et al., 2022a). During the pilot study, we observed disagreements between annotators on their annotation labels due to the subjective nature of hate speech annotation. In some cases, the curator also deviated from both annotators and selected a different annotation label. Such annotation errors were analyzed with examples as presented in Figure 4. Despite hate speech annotation is a very subjective task, we tried to understand the different views of annotators using expert judgments. Three experts, a lawyer (Assistant professor in Law), a political science expert (Ph.D. student), and a journalism expert (Associate professor of media and communications) were engaged in a focus group discussion to analyze the potential sources of annotation disagreements between the annotators as well as the adjudicator. The experts evaluate the annotation deviations and suggest possible justifications for the source of the disagreements on the labels of those tweets. In general, we observed that hate speech annotation is a highly context-sensitive and challenging task (Ayele et al., 2022a), which usually resulted in lower inter-annotator agreements.



CURATION_USER: Pilot Amharic Hate Speech Annotation/pilot2_tweetonly.txt

normal
400 @USER እኔ እንደገባኝ መደዴ ስርዓት የሌለው ባለጌ እንደመጣለት የሚያወራ ማለት ነው

Anonymized annotator 1

offensive
400 @USER እኔ እንደገባኝ መደዴ ስርዓት የሌለው ባለጌ እንደመጣለት የሚያወራ ማለት ነው

Anonymized annotator 2

offensive
400 @USER እኔ እንደገባኝ መደዴ ስርዓት የሌለው ባለጌ እንደመጣለት የሚያወራ ማለት ነው

Figure 4: Sample deviations between annotators and the adjudicator taken from WebAnno (Yimam et al., 2013)

As shown in Figure 4, the two annotators agreed that the tweet (translated in English here) "as I understood it, 'Medede' means a crazy, naughty and disrespectful person who talks randomly" is offensive. The reason was that the annotators might have thought that the tweet targeted the user indicated in the tweet ('@USER') while the curator labeled the tweet as normal since the curator thought that the author of the tweet was defining the word 'Medede' rather than targeting an individual. The red colored numbers (the left side) in Figure 4 showed that the two annotators disagreed on that item label while the tweets shaded with light red and light cyan colors (right side) represented the annotator's and curator's decisions respectively. In most cases, where annotators faced tweets with mixed languages other than Amharic, they usually annotated the tweet as "Unsure".

5.3 Main Annotation Task

The pilot annotation indicated that the selection from the lexicon-based unlabelled pool suffered from data imbalance problems. Therefore, we mixed the lexicon-based unlabelled pool with the non-lexicon-based pool on a 70/30 proportion. Each batch of annotations comprised 70% from the keyword-based unlabelled pool and 30% from the unlabelled pool with no keywords respectively. The annotation of the dataset including the pilot study took over a year. We performed the pilot annotations in 6 batches and the main annotations in 22 batches, where we analyzed each batch before pursuing the next batch. The annotators were nominated from different cultural, religious, gender, and age categories, and each user annotated from 3,800-4500 tweets. A kappa score of 0.48 is achieved on a dataset of over 15.1k tweets on the main annotation task which is better than the pilot task. The dataset consisted of 6,664, 5,554, 2,283, and 86 hate, normal, offensive, and unsure class label distributions respectively. The 86 tweets annotated as "unsure" were further examined with expert consultations to explore the sources of annotation decisions. Since the majority of the tweets labeled "unsure" contained mixed languages of non-Amharic words that confused annotators, they were excluded from being used in the experiment.

6 Classification Models

Texts on social media platforms are usually unstructured, written in mixed scripts, and lack uniformity in writing styles than texts in the normal context. Moreover, social media texts do not follow spelling/grammar rules as well as other language standards that make hate speech detection tasks a complex problem. Hate speech is linguistically, culturally, and historically dependent on the context of the speech and requires developing classifiers that capture these dependencies (Albadi et al., 2018).

6.1 Classical Machine Learning Approaches

These days, most hate and offensive speech classification studies mainly employ deep learning approaches despite they require large amounts of labeled datasets. In this study, we apply both the classical machine learning and deep learning approaches. We have also employed two contextual embedding approaches from the Amharic Semantic resource repository (Yimam et al., 2021).

The classical machine learning algorithms learned to make predictions through varieties of iterative learning processes from data without being explicitly programmed but only based on patterns and inference on the data (Mueller and Massaron, 2021). Among these algorithms, we have applied logistic regression (LR), support vector machine (SVM), and Naïve Bayes (NB) classification algorithms with bag-of-words (BOW) and n-gram feature extraction methods.

6.2 Deep Learning Models

Most of the current research studies on hate speech detection and classification tasks are based on deep learning approaches with contextual embedding rather than statistical approaches. Deep Learning is a machine learning technique that can be trained to predict outputs from a given set of inputs in a supervised learning approach. It has networks capable of learning in hierarchical layers to understand representations and features from data in increasing levels of complexity and uses these multiple layers to progressively extract higher-level features from the raw inputs (Young et al., 2018).

In this study, we employed recurrent neural networks (RNN), long short-term memory (LSTM), bidirectional long short-term memory (BiLSTM), and convolutional neural networks (CNN). The LSTM network addresses the long-term dependency problem by introducing a memory into the network. RNN is well known in natural language processing applications despite its suffering from vanishing gradient problems. Particularly, the LSTM solves the vanishing gradient problem (Oshikawa et al., 2018). The relative insensitivity to gap length is an advantage of LSTM over RNNs (Glasmachers, 2017; Miedema, 2018), and other sequence learning methods in numerous tasks and

Classifier	Precision	Recall	Accuracy	F1-score
Logistic Regression (LR)	0.68	0.68	0.68	0.67
Linear Support Vector Machine (LSVM)	0.68	0.67	0.67	0.67
Naïve Bayes (NB)	0.68	0.65	0.65	0.63
Recurrent Neural Network (RNN)	0.61	0.62	0.62	0.62
Long Short-Term Memory (LSTM)	0.61	0.62	0.62	0.61
Bidirectional Long Short-Term Memory (BiLSTM)	0.61	0.62	0.62	0.61
Convolutional Neural Network (CNN)	0.62	0.63	0.63	0.62
Framework for state-of-the-art NLP (FLAIR)	**0.72**	**0.72**	**0.72**	**0.72**
Robustly Optimized BERT (RoBERTa)	0.70	0.70	0.70	0.70

Table 3: Performance of the models

applications. The Bi-LSTM neural network learns long-term dependencies without retaining duplicate context information and operates in both directions to incorporate past and future context information through its LSTM units.

We also employed two contextual embedding models, the RoBERTa (A Robustly Optimized BERT Pre-training Approach) and the FLAIR (a very simple framework for state-of-the-art NLP) that are fine-tuned with the Amharic dataset, namely Am-FLAIR and Am-RoBERTa (Yimam et al., 2021). RoBERTa is a replication of the BERT model, which is developed by Facebook (Liu et al., 2019). Unlike BERT, RoBERTa allows training on longer sequences and dynamically changes the masking patterns. FLAIR is a very powerful framework that is developed by Zalando and built on top of PyTorch (Akbik et al., 2019).

7 Results and Discussion

We employed the 80:10:10 data split mechanism for creating the train, development, and test instances. We have used the development dataset to optimize the learning algorithms. All the results reported in the remaining sections are based on the test dataset instances. Deep learning algorithms are computed using the following hyper-parameters, *embedding dimension = 100, epochs = 10, batch_size = 64, activation = softmax, and optimizer = adam.*

F1-score (F1), Precision (P), Recall (R), and Accuracy (Acc) are used to compare the performance of the models. We conducted experiments with the classical machine learning models such as LR, LSVM, and NB; deep learning models like RNN, LSTM, BiLSTM; and CNN, and the fine-tuned Amharic transformer models such as AmFLAIR and AmRoBERTa.

As presented in Table 3, logistic regression (LR) achieved 67% F1-score and 68% performance for precision, recall, and accuracy. LSVM achieved a 68% precision score, and 67% recall, accuracy, and F1-scores. The Naïve Bayes obtained the least F1-score which is 63% from all classical methods. LR and LSVM outperformed the Naïve Bayes in all measures except for precision. LSTM, BiLSTM, RNN, and CNN achieved lower and nearly similar results in all measures of precision, recall, accuracy, and F1 scores. We attribute this to the size of the dataset; while it is common sense that deep learning approaches can achieve higher results by better modeling the properties of large training data, it seems that our dataset was not large enough to leverage their power. The Am-FLAIR contextual embedding model achieved 72% scores for all measures such as precision, recall, accuracy, and F1-scores, which is the overall best result in our experiments. AmRoBERTa also achieved 70% precision, recall, accuracy, and F1 scores, which are the second-best scores. In general, the contextual embedding models such as AmFLAIR and AmRoBERTa outperformed both the deep learning and the classical machine learning methods in all performance measures on the dataset. This confirms the general trend of well-performing transformer-based language models also for the case of Amharic.

8 Error Analysis from Model Outputs

We examined model-predicted tweets against their corresponding gold labels to observe discrepancies. As indicated in Table 5, the model correctly classified 1,034 tweets out of 1,501 test examples. We randomly took 25% of the incorrectly classified instances and conducted extensive investigations in a focus group discussion with three domain experts to explore the potential reasons for the errors.

#	Tweet	English translation	Gold	Predicted
1	እውነትም በእድሜ ትንሹ መሪ?	Oh, truly the youngest leader?	offensive	normal
2	የ *_*ስ ዘ*_ናዬ አያት በቅ_ኝ በኩል የቆመ_ው ባንዳ	M*l** Z*****'s grandfather, the betrayer, standing on right side	hate	normal
3	በኦሮሚያ ክልል የተደረገው የድጋፍ ሰልፍ የኦሮሞ ብልፅግና እና ኦነግ ሸኔን አንድነት ያሳየ ነው ተባለ	The rally in Oromia showed the unity of PP and OLF-Shene parties.	hate	normal
4	@ USER ለወራሪ ጋር ሽምግልና የለም። እምሽክ ነው	No mediation with the invaders, just destroy them.	hate	normal

Table 4: Model errors: wrongly predicted tweets against the gold labels

		PREDICTION			
		Hate	Offen.	Normal	Total
GOLD	Hate	**516**	85	101	702
	Offen.	63	**154**	47	264
	Normal	104	67	**364**	535
	Total	683	306	512	**1501**

Table 5: Confusion matrix from FLAIR

63.6% of the errors are mistakes by the model while 28.8% of errors are due to annotator mistakes. The experts found that the remaining 7.6% errors are difficult to judge due to a lack of background contexts. We found out that the main reasons for the errors are annotation bias, association with some keywords, lack of background contexts, informal writing styles in social media, mixed language use, the presence of sarcasm, and idiomatic expressions. Annotation bias, presence of sarcasm, association with some keywords, and the lack of background contexts constituted 29.7%, 13.6%, 11%, and 8.5% of the causes for the errors, respectively. There were also cases where even the experts could not come up with justifications for some errors due lack of background contexts to label some tweets. To showcase the possible justifications for the errors, we to took 5 tweets as presented in Table 4. Tweets with ironic/sarcastic expressions even confused human annotators. For example, **Tweet 1** in Table 4 with the gold label 'offensive', targeted an individual with sarcasm expression and is wrongly predicted as 'normal' by the model. **Tweet 2** annotated as 'hate' is wrongly predicted as 'normal' by the model. This is due to typographic errors in the tweet such as missing characters and unnecessary spaces between characters that we indicated with the '-' symbol. The '*' symbols are used to hide sensitive words from the tweets. Despite **Tweet 3** looking positive news, it contained ironic expressions that the model did not predict correctly. But annotators knew the additional background contexts to understand and label the tweet. **Tweet 4** with gold label 'hate' is wrongly predicted as 'normal' by the model due to the inclusion of informal terms that are not used in the standard Amharic writing system that could confuse the model.

9 Conclusion and Future Work

The paper presented data selection and annotation strategies, and classification models for the Amharic Twitter dataset. A total of 15.1k tweets were annotated into hate, offensive, normal, and unsure classes. We proposed data selection and sampling strategies, a list of hate and offensive lexicon entries, and an annotated dataset for Amharic hate speech research. We also presented both classical and deep learning models trained on a new dataset. The study explored hate speech annotation challenges and revealed that annotation of social media texts for hate speech classification is highly context-dependent. Models that have used contextual embedding models such as Am-FLAIR and Am-RoBERTa outperformed all the models, where Am-FLAIR achieved the best scores of all.

In future work, we plan to use semi-supervised active learning to select hateful tweets employing the human-in-the-loop annotation approach. Exploring the targets of hateful content can also be another future work to deal with. To advance hate speech classification research in Amharic and other low-resource languages; the dataset, hate and offensive keyword lexicons, the best-performing models, annotation guidelines, data selection pipelines, and associated source codes are publicly released with a permissive license [4].

10 Limitations

The research study encountered the following limitations. Firstly, the small dataset size could limit the robustness and applicability of the results to be generalized in various contexts. Secondly, the scarcity of the offensive class instances within the dataset might impact the model's ability to accurately detect offensive content. Additionally, the lack of diversity among annotators might have introduced biases in the labeled data, affecting the model's ability to handle inputs from various cultural or linguistic backgrounds. Moreover, the study explored only a few models and embedding approaches and might potentially overlook more effective alternatives. Lastly, the hyperparameters of the models were not extensively fine-tuned to explore opportunities for optimizing performances. These limitations collectively highlight the need for further investigations with larger datasets, diverse annotators, and a broader exploration of models and fine-tuning techniques.

Acknowledgment

The dataset collection of this project is supported by the **Lacuna Fund**. In recognition of this support, we extend our acknowledgments to Lacuna Fund on behalf of the **ICT4D Research Center** at Bahir Dar Institute of Technology, Bahir Dar University, Bahir Dar, Ethiopia.

Bhojpuri WordNet: Problems in Translating Hindi Synsets into Bhojpuri

Abstract

Today, artificial intelligence systems are incredibly intelligent, however, they lack the human-like capacity for understanding. In this context, sense-based lexical resources become a requirement to develop artificial intelligent machines. Lexical resources like Wordnets have received scholarly attention because they are considered crucial sense-based resources in the field of natural language understanding. They can help the machines in knowing the intended meaning of the communicated texts, as they are focused on the concept rather than the words. Wordnets are available only for 18 Indian languages. Keeping this in mind, we have initiated the development of a comprehensive wordnet for Bhojpuri. The present paper describes the creation of the synsets of Bhojpuri and discusses the problems that we faced while translating Hindi synsets into Bhojpuri. Some of the challenges are lexical anomalies, lexical mismatch words, synthesized forms, lack of technical words, etc. Nearly 4000 Hindi synsets were mapped for their equivalent synsets in Bhojpuri by following the expansion approach. We have also worked on the language-specific synsets, which are unique to Bhojpuri. This resource is useful in machine translation, sentiment analysis, word sense disambiguation, cross-lingual references among Indian languages, and Bhojpuri language teaching and learning.

1 Introduction

Today's era is one of science and technology. People have been communicating using the Internet and social media and enjoying different forms of media and entertainment. For this, they require accessible resources in their own languages; however, we Indians are forced to depend on the tools that are available, either in English or only in a few major Indian languages. The creation of linguistic resources in a language, particularly in a low-resourced language, is a very challenging task. To understand the intended meaning of a communicated text, one needs knowledge of the world along with competency in the language, which cannot be captured with any traditional resources as meaning resides not in the words but in the minds of the people using them (Nida, 1979). We need a very comprehensive and intelligent tool to understand a text like a human. In recent years, wordnets have been considered a very crucial tool in the field of natural language processing. WordNet is an online lexical resource and a semantic network (Bhattacharyya, 2010). It is constituted of synsets. Each synset expresses a distinct concept. So synsets are the basic building blocks of WordNet (Bhattacharyya et al., 2006). WordNet's design is inspired by the current psycholinguistic theories of human lexical memory (Miller, 1998). WordNet stores lexical items in ontological that are used to represent IS-A-KIND-OF, IS-A-PART-OF and other relations such as the hypernymy-hyponymy and holonymy-meronymy. Wordnets have been developed for more than 200 languages (Rebele et al., 2016) because wordnets are considered to be the most important lexical resource available for natural language processing tasks like word sense disambiguation, information retrieval, machine translation, sentiment analysis, and as well as for language learning and teaching. Wordnets have been developed for 18 Indian languages (Bhattacharyya, 2010). Except Hindi, all Indian language wordnets have been developed following the expansion approach, and Hindi has been considered as their source language (Bhattacharyya, 2010). Bhojpuri is a spoken by millions of people in India, as well as in several countries such as Mauritius, Nepal, and others throughout the world. There are fewer efforts have been made in the realm of digitization and the development of lexical resources for this language. This is the motivation behind the creation of Bhojpuri WordNet. The main goal of this paper is to create synsets for Bhojpuri. We have discussed the creation of Bhojpuri Synsets, considering Hindi Synsets as its source language. We followed the expansion approach to create Bhojpuri synsets.

Proceedings of Recent Advances in Natural Language Processing, pages 60–68
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_007

The paper is divided into six sections. Section 2 discusses the related research on wordnets, particularly in the Indian context. Section 3 briefly explains the Bhojpuri WordNet, its methodology, and the statistics of the Bhojpuri Synsets. Section 4 covers the problems and difficulties encountered while translating Hindi synsets into Bhojpuri. Section 5 explores Bhojpuri language-specific synsets, and we conclude the paper in the last section.

2 Review of literature

The first WordNet was developed for the English language at Princeton University in 1985 by G. A. Miller. It contains only content words. It doesn't give pronunciation, etymology, usage notes, or pictorial illustrations. The current structure of WordNet was inspired by Levin's works English Verb Classes and Alternations (Miller, 1995). Levin tried to organize more than 3,000 English verbs into categories based on their common behavior and meaning (Levin, 1993). WordNet is structured in lexical hierarchies in the form of synsets. Synsets are a set of synonyms. Minimality, coverage, and replaceability (MCR) principles govern the creation of the synsets (Bhattacharyya, 2010). Minimality means the synonyms must have minimal differences from other synonyms, coverage is that the synonyms must cover the concept, and replaceability is the synonyms that could be substituted in most cases without changing the meaning of a concept. Here, in WordNet, the focus shifts from words to concepts (Dash et al., 2017). Later wordnets for European languages were developed under an umbrella project for 8 European languages like Dutch, Spanish, Italian, German, French, Czech, and Estonian (Vossen, 2002). It was named Euro WordNet and developed under the headship of P. Vossen from 1996 to 1999 (Vossen, 2002). Each concept was linked to the closest synset in Princeton‘s WordNet. So it allows cross-language information retrieval from one language to another. In recent, there were efforts to develop lexical resources for low resource languages like KangleiWordnet. It was developed at IIIT, Manipur. For its development, both the linkage approach and the expansion approach were applied to (Nongmeikapam, 2023). It is an integrated wordnet of 5 major local languages of Manipur, viz., Manipuri, Tankhul, Thadou, Mao, and Kabui wordnets. For KhagleiWordNet, the linked language is Manipuri instead of Hindi and English is used as the secondary language. Apart from it, (M, 2017) worked for Tirukkural WordNet. He used the expansion approach, but Tamil as the pivot language.

2.1 Indian Language WordNets

Hindi WordNet was the first wordnet and was started in 2000 and developed in 2006 at IIT Bombay. Since then, wordnets for a number of Indian languages have been developed, in parallel with Hindi WordNet (Narayan et al., 2002). Hindi WordNet is a system for bringing together different lexical and semantic relations between Hindi words. The design of the Hindi WordNet is inspired by the famous English WordNet. It was developed using the merge approach and further linked with English WordNet for cross-lingual references. No attempt was made for compound and conjunct verbs. Each synset was mapped onto some places in the ontological structure of wordnet with a specific synset ID number. Linkages between nominal and verbal, adjectival and adverbial concepts like ability link, capability link, and functional, or derived from, modified nouns have been additionally added (Narayan et al., 2002).

IndoWordNet: IndoWordNet is a project similar to EuroWordNet. It is a linked lexical resource for 18 Indian languages' wordnets (Dash et al., 2017). However, Hindi has been their pivot language, and they followed the expansion approach (Bhattacharyya, 2010). In the expansion approach, the lexicographers translate the source synsets in the target language. It allows to add or drop synonyms in the synset depending upon the language richness. Unlike Hindi WordNet, it covers typical complex Indian language phenomena like complex predicates and causative verbs (Dash et al., 2017). Due to the morphological richness and different cultural traits of Indian languages, a linkage approach was also adopted (Dash et al., 2017).

Assamese WordNet (AWN): Assamese WordNet was developed at Guwahati University. (Moromi, 2019) dealt with the design and development of the AWN. She followed the expansion approach. Problems, challenges, and complexities faced in the development of the AWN have been briefly discussed in her Ph.D dissertation. This work also classifies Assamese text by utilizing AWN.

Bangla WordNet: Dash, N.S., and his team worked for the development of Bangla WordNet at ISI Kolkata, IIT Kharagpur, and Jadavpur University (Dash, 2017b). They followed the expansion approach and used Hindi as a source language. The encountered challenges are paradigmatic lexical gaps in wage terms, reordering of phrases, differences in flora and fauna, lexical mismatches, and false cognates during the synset creation for Bengali.

Gujarati WordNet: DDU Gujarat worked for Gujarati WordNet. According to Bhattacharyya (Bhatt et al., 2017), synsets of Hindi were translated into Gujarati following the expansion approach. Sources of translation were Bhagvat and Mandal (Patel, 1958) and the Gujarati Lexicon (Chandariya, 2005). Till 2017, 108 Gujarati language-specific synsets have been recorded.

Kashmiri WordNet: The University of Kashmir developed Kashmiri WordNet and compiled 29469 synsets for Kashmiri (CFILT, 2023). It also used Hindi as a pivot language and followed the expansion approach (Kak et al., 2017). The authors talk about language-specific synsets (LSS) for Kashmiri.

Konkani WordNet: Amrita University started working for Konkani in 2009, and till 2023, approximately 32370 synsets (CFILT, 2023) have been developed following the expansion approach. (Desai et al., 2017) classifies two types of challenges. They are discrepancies and issues in the source language, and challenges due to differences in the source and target languages.

Marathi WordNet: Bhattacharya and his team at IIT Bombay worked on the Marathi WordNet, which was created utilizing the expansion approach from the Hindi WordNet (HWN) (Popale and Bhattacharyya, 2017). The lexicographer's experience is that Hindi and Marathi are close members of the same family, as many Hindi words have the same meaning in Marathi. However, they also find it difficult to find a single word to express the concepts of HWN, lack color concepts, and have borrowed some words from Hindi. The developers think that there is a need for LSS for Marathi.

Odia WordNet: The University of Hyderabad has worked for Odia WordNet by following the expansion method. It is an interlingual WordNet in Odia (Mohanty et al., 2017). The authors identify some gaps that were encountered in kinds of wages, derivation of nouns from nouns or adjectives, complex kinship in Hindi, and the absence of some Hindi concepts in Odia. They think that there is a need to create an LSS for some new or unique expression of Odia.

Punjabi WordNet: Thapar University and Punjabi University worked for Punjabi WordNet. Rattan (2011) used the expansion approach and used Hindi as a source language for Punjabi. The author developed a web application for the Punjabi-Hindi bilingual and Punjabi-Hindi-English trilingual dictionaries. The IL-MultiDict tool has been used for the creation of Punjabi WordNet (Rattan and Bhatia, 2011). The authors observe a lower number of synonyms in Punjabi in comparison with the Hindi.

Sanskrit WordNet: Kulkarni and his team worked for Sanskrit WordNet at IIT Bombay. Sanskrit WordNet was developed using the Synskarta tool (Kulkarni et al., 2010). It is an online interface for synset creation following the expansion approach specific to Sanskrit. However, it has additional information like etymology, references, and expectancy for the words. (Nair, 2011) worked for the most celebrated thesaurus in Sanskrit. This work is a web application for the Sanskrit ontological representation of each word in Amarakosha named 'Amarakośajñānajālam'.

Tamil WordNet: Tamil University worked for the Tamil WordNet. 25419 Tamil synsets (CFILT, 2023) have been made using the Hindi synsets (Dash et al., 2017). (Rajendran et al., 2002) claim that the majority of co-synonyms listed under a synset in Hindi are deceptive since they group terms together with diverse meanings. They advised that it would be better if an independent wordnet was made for Tamil.

Telugu WordNet: Dravidian University worked for Telugu WordNet, and 21091 synsets (CFILT, 2023)have been developed using the expansion approach. (Arulmozi and Kesava Murty, 2017) have discussed the problems, challenges, and complexities faced in the development of the Telugu WordNet. For many kinship terms, particularly in gender terms and younger-elder issues, it is a problem to have their equivalent in Hindi.

Urdu WordNet: Urdu WordNet was developed at Jawaharlal Nehru University, New Delhi. (Rahman et al., 2017) list technical difficulties, cultural inadequacy, and synset linking issues while creating the synsets of Urdu from Hindi by following the expansion approach. They suggested translation, transliteration, derivation, neologism, multi-words, and explanation to tackle the issues.

In our survey, we find no work has been done towards the synsets creation in favor of Bhojpuri till 2021. We assume that there is also a need for lexical resources in Bhojpuri, as wordnets have emerged as a crucial resource developed for NLP applications. So we started working on the development of synsets for Bhojpuri.

3 The Bhojpuri WordNet (BWN)

The Bhojpuri WordNet is a sense-based lexical resource for the Bhojpuri. It has been developed following the expansion approach and has used Hindi as its source language. Bhojpuri WordNet interface enlists synset ID, synonyms, gloss, examples, and word categories and represents the concepts in MCR principles of WordNet. Since the Bhojpuri WordNet uses Hindi as its pivot language, many indigenous concepts practiced by the Bhojpuri community are not listed in the Hindi WordNet. So this WordNet also includes the Bhojpuri Language-specific synsets (BLSS) for total inclusion of the indigenous knowledge of the community on the technical front.

3.1 Methodology of Bhojpuri WordNet

Many a time, the source language and the target language have a strong kinship relationship. In such a case, the expansion approach becomes all the more attractive since the distracting influences of cultural and region-specific concepts are minimal (Sharma and Kumar, 2017). 17 Indian languages' wordnets were developed following the expansion approach and used Hindi as a source language (Dash et al., 2017). Since Bhojpuri is closely related to Hindi, we used Hindi synsets as a source resource and developed the BWN using the expansion approach. We are using the IL-MultiDict synset creation tool to record equivalent Bhojpuri synsets in parallel to Hindi synsets.

First, we look at the Hindi synsets that appear in the IL-MultiDict synset creation tool, and then we look for concepts in Bhojpuri; if the concept is available in Bhojpuri, we find out equivalent synonyms. Translated synsets are validated based on a bilingual **Bhojpuri-Hindi Shabdkosh**[1] and a multilingual **Bhojpuri-Hindi-English Shabdkosh**[2] offline dictionaries. We also used online dictionaries like **Glosbe**[3] and **Jogira**[4]. We checked words' frequency in the Bhojpuri Language Technological Resources (BHLTR) corpus (Ojha, 2019). At last, we got validations of the concepts and their frequency to maintain the MCR principles via 5 native speakers and 2 experts in Bhojpuri. After the validation, we add or include synonyms available in Bhojpuri, save them into the database, and proceed to the next synset. So far, out of 4000 Hindi synsets, we could find only 3267 equivalent Bhojpuri synsets. Figure 1 shows the IL-MultiDict tool used for the development of Bhojpuri synsets. The tool's left panel shows Hindi synsets (source language), and the right panel shows Bhojpuri synsets (target language). The given concept ***nīmana***: {nīmana, āchā, baḍhiṃyā, baḍhiṃmā, bhālā, nika, nimana, sajjanagood} of Bhojpuri is equivalent to 'good' in English. The figure 2 depicts the complete architecture of the Bhojpuri synset creation methods.

3.2 The Bhojpuri WordNet and Synset Statistics

The Bhojpuri WordNet consists of 3267 synsets following the expansion approach, nearly 4000 Hindi synsets were taken into account and mapped for their equivalent translation or for their near counterparts in Bhojpuri. It lowered the quantity of concepts because of the linguistic lacunarity. Only 3267 Hindi synsets could be translated into Bhojpuri, 311 Hindi synsets could not be identified in Bhojpuri; 190 proper names were ignored; and there are still synsets that need to be resolved. To ensure the reliability and consistency of the synonyms of the language, they were cross checked against the Bhojpuri-Hindi bilingual online or offline dictionaries, the **BHLTR corpus** [5] (Ojha, 2019), and other resources like an online website **Jogira**[6]. The POS statistics of the study are as follows: 2720 nouns, 119 adjectives, 385 verbs, and 43 adverbs.

4 Issues and Challenges

Since we are using Hindi synsets to create Bhojpuri synsets following the expansion approach, we have to translate the Hindi synsets into Bhojpuri. While translating from one language to another, we encountered many lexical and semantic gaps due to the socio-cultural differences, morphological richness of the languages, and so on. Therefore, we also faced many difficulties while creating synsets for Bhojpuri. In this section, we are going to dis-

cuss some of the challenges and their solutions in order to fill in the gaps.

4.1 Lexical Anomalies: Equivalent Concept is Not Found

Because of its own cultural practices and distinguishing features, a linguistic community usually differs from its adjacent community. Therefore, there is a potential that a Language A may not have a concept that a Language B does; in this instance, the concept of language A will not have any equivalents in the target language B. In Hindi WordNet, the concept of Hindi does not find any equivalence in Bhojpuri. For example: Consider the Table 1.

Synset ID	Synset	Gloss
19913	mallārī	‘A kind of rāgīnī’
19945	saurāṭī	‘A kind of rāga’
19958	puṃgariyā	‘An ornament’

Table 1: Non-availability of Bhojpuri equivalents for Hindi synsets

4.2 Lexical Mismatch: False Cognate

Many concepts enlisted in the Hindi synsets look identical to Bhojpuri concepts but they differ in sense denotation. These types of words are called false cognates because learners might be confused by looking at them at the first sight. They might entertain as the equivalent concept. Some of the examples are given in the Table 2.

Syn. Id	Synset	Gloss HIN	Gloss BHOJ
4741	maidāna	‘field’	‘going to toilet’
7171	bādāma	‘peanut’	‘Almond’

Table 2: Semantic mismatches between Hindi-Bhojpuri

4.3 Synthesized Form or Direct Borrowings

Today, the world has become a global village because of the modern developments. As a result, these contemporary concepts have given rise to numerous words. Due to the lack of the sound or sound patterns, the majority of modern words in Bhojpuri have either been directly borrowed or synthesized by the community. Native speakers typically simplify the consonant clusters by the insertion of epenthetic vowel like ’a’ or ’i’ between or before clusters. This process breaks the syllable so that it can aid up in pronunciation. For Example, let’s consider the Table 3.

Synset ID	Synset	Gloss	BHOJ Syns
260	svara	Vowel	sovara
7512	voṭa	vote	bhoṭa
2000	pradhāna	Prime	paradhāna

Table 3: Nativized or simplified Bhojpuri equivalents for Hindi Synsets

4.4 Lack of Technical /Scientific Word

Hindi has been the medium of instruction in formal education in Bhojpuri region. So Bhojpuri has not developed technical jargon for scientific and technical concepts. Even though these concepts are there in the language but no word has been coined yet so users continue practicing Hindi terms. Some examples have been listed in the Table 4.

Synset Id	Synset	Gloss
112	ubhayacara	‘Amphibian’
4035	saṃpreṣaṇa	‘Communication’
338	kaśerukī	’Vertebrate’

Table 4: Direct borrowed or transliterated Bhojpuri equivalents for Hindi synsets

To overcome the problem, we follow with some strategies either we should use the transliterated version or go with the direct borrowings of the expression in Bhojpuri. Otherwise we have to coin new equivalent terms in Bhojpuri. However, Bhojpuri speakers either go with the explanatory expression or direct borrowings.

4.5 Concept is Available, but with a Reduced Number of Synonyms

The most essential aspect of the Expansion approach is that it allows us to add or drop synonyms based on the available synonyms in the language. We have also noticed that whereas Bhojpuri has fewer synonyms for a notion, Hindi has a greater number of them. For instance, consider the synset ID 2186; Sun, given in Table 5, the concept of the sun has 102 synonyms in Hindi but Bhojpuri hardly enlists a dozen synonymous words for the sun. Likewise, the concept of *śiva* has up to 53 synonyms in Hindi but Bhojpuri enlists only 12 to 15 synonymous words.

Hindi Synsets	BHOJ Synsets
sūrya, sūraja, bhānu, divākara, bhāskara, prabhākara, dinakara, ravi, āditya, dineśa, āphatāba, aphatāba **And so on.**	suruja, sūraja, aragadeva, adita deva, dēva, adita, dinakara, bhāskara, ravi, dineśa, divākara, aruna

Table 5: Bhojpuri synset with a reduced number of synonyms

4.6 Lexical Gaps

The lexical gap in a language is when the meaning of a word of a particular language does not fit into the meaning of the other language which exhibits a difference in the meaning (Dash, 2017a). Likewise, in certain contexts, Bhojpuri speakers practice more concepts however Hindi enlists less numbers of terms for that kind of concept. The concept of *cāvala* ’rice’ is used for both cooked and uncooked rice in Hindi, Where as two different words *cāura* for uncooked rice and *bhāta* for cooked rice are used.

5 Bhojpuri Language-specific Synsets

Language specific synsets refers to unique concepts which are available only in the particular language and no conceptual match is find in other languages (Buitelaar and Sacaleanu, 2001). Every language has some concepts or ideas which are unique to only that language. Since Bhojpuri WordNet is being developed by using Hindi Synsets so here, there is potential that many indigenous concepts specific to Bhojpuri might have not been listed in the Hindi synsets. So there is a need of language specific synsets for Bhojpuri. These language specific words are called *thethee* (desee). Sometimes, it is better to call it regional specific synsets instead of Language specific synsets (Dash, 2017a).

To create Bhojpuri language-specific synsets, we first collect and assemble a list of LSS for Bhojpuri and provide a complete description of the LSS and examples of its usage in sentences, with a pictorial depiction if possible. We do comparison and validation across languages. We study these LSSs carefully to determine whether they are really monolingual in nature, or originated in the language, and fit the LSS principles (Dash, 2017a). If the concept appears unique to Bhojpuri, we consider it as Bhojpuri Language-specific Synsets (BLSS) otherwise the LSS is dropped. Following confirmations, we approve and augment them in the Bhojpuri LSS database (in blss.accdb). Till now, we have recorded 100 language specific synsets for Bhojpuri. Some of those have been listed in the table 6 and 7.

ID	**18**
CAT	NOUN
CONCEPT	khānā khilā ke bāda javana kucha baratana meṃ baca ke sukhā jālā
GLOSS	What is left after eating meal and after drying up it hardens
EXAMPLE	“baratana meṃ kharakaṭala jama gila ha ”
SYNSET	kharakaṭala, kharakaṭa

Table 6: Language specific synsets of Bhojpuri -1

ID	**6**
CAT	ADJ
CONCEPT	u ādamī je jarūrata se jādā bolata hokhe ā bākī oke kuchahu jānakārī na bā basa khālī ṭara ṭara bakavāsa kare lā
GLOSS	The man or boy who talks too much even though he doesn’t know anything just talks nonsense
EXAMPLE	“dīpā māṃjhī tejasvī yādava ke labarā kaha dehanī”
SYNSET	labarā, labariyāha, labarīyāha

Table 7: Language specific synsets of Bhojpuri -2

6 Conclusion

In this paper, we have tried to delve into the issues and challenges that have occurred during the creation of Bhojpuri synsets. As Bhojpuri is considered closely related to Hindi. So Hindi has been made the source synset for its development. The Bhojpuri WordNet follows the expansion approach and MCR principles of WordNet. What we have experienced during this research that there are several issues like no equivalents found, less derived abstract nouns and adjectives, reduced number of synonyms in comparison to Hindi, and lack of modern scientific technical words. These challenges look for serious involvement at the time of synset creation for Bhojpuri. Synthesized forms, direct borrowings with some sort of simplification, and nativization processes are ways to sort out the complexities. We have presented only some sample cases to explicit the problems and challenges that we faced in the development. Since our work depends on the Hindi synsets and IL-MultiDict offline tool for the Bhojpuri synsets, we found many indigenous concepts or ideas have not been incorporated into the Hindi synsets. This gap requires the creation of BLSS as a part of the Bhojpuri WordNet. We find Bhojpuri is more synthetic than Hindi. However, the Bhojpuri community simplifies the consonant clusters and nativizes some of the borrowed sounds while pronouncing. The Bhojpuri WordNet as a lexical resource could contribute to machine translation, sentiment analysis, word sense disambiguation, and cross-lingual references among Indian languages. The future scope of Bhojpuri WordNet (BWN), a lexical database for the Bhojpuri language, holds immense potential for further development and application. Here are some potential areas where BWN can be expanded and utilized; Education and Language Learning, Visual WordNet, a bilingual Hindi-Bhojpuri dictionary, and in Hindi-Bhojpuri translation applications. These advancements would enable BWN to play a vital role in various applications in the field of natural language processing.

Acknowledgement: We acknowledge NLP team, IIT Bombay for providing the IL-MultiDict tool. We also acknowledge Prof. R.B. Misra and Prof. S. Shahi for their help in the discussion of the creation of Bhojpuri synsets.

Abstract

Definitions are a fundamental building block in lexicography, linguistics and computational semantics. In NLP, they have been used for retrofitting word embeddings or augmenting contextual representations in language models. However, lexical resources containing definitions exhibit a wide range of properties, which has implications in the behaviour of models trained and evaluated on them. In this paper, we introduce 3D-EX, a dataset that aims to fill this gap by combining well-known English resources into one centralized knowledge repository in the form of <term, definition, example> triples. 3D-EX is a unified evaluation framework with carefully pre-computed train/validation/test splits to prevent memorization. We report experimental results that suggest that this dataset could be effectively leveraged in downstream NLP tasks. Code and data are available at https://github.com/F-Almeman/3D-EX.

1 Introduction

Lexicographic definitions have played an important role in NLP. For example, definitions, and more specifically, term-hypernym pairs occurring in them, constitute a core component in applications such as taxonomy learning (Navigli et al., 2011; Velardi et al., 2013; Espinosa-Anke et al., 2016), knowledge base construction (Delli Bovi et al., 2015), or for augmenting language models (LMs) (Joshi et al., 2020; Chen et al., 2022). For this reason, numerous works have proposed methods to extract definitions from corpora (definition extraction, or DE) (Navigli and Velardi, 2010; Espinosa-Anke and Schockaert, 2018; Spala et al., 2020). However, DE, traditionally framed as a sentence classsification problem, plateaus quickly in terms of its applicability to real-world settings for a number of reasons, namely: (1) it is tied to a reference corpus; (2) it does not handle flexible contexts (e.g., definitional information appearing across several sentences); and (3) incorporating monolithic sentence-level definitional knowledge into LMs during pretraining is not straightforward. A complementary task to the above is definition modeling (DM), a promising direction both from resource creation and NLP standpoints. DM is the task of automatically generating human-readable lexicographic definitions or glosses given some input. From its inception, where Noraset et al. (2017) trained a bidirectional LSTM on $\langle t, d \rangle$ pairs, where t is an input term, and d is its corresponding definition, more recent contributions in this area have leveraged contextualized representations by augmenting t with some context c (Ni and Wang, 2017; Gadetsky et al., 2018; Ishiwatari et al., 2019; Reid et al., 2020; Bevilacqua et al., 2020).

A crucial prerequisite for enabling, among others, successful DM systems is having access to datasets that combine terms, definitions, and *good dictionary examples* (Kilgarriff et al., 2008; Kosem et al., 2019; Frankenberg-Garcia et al., 2019). In lexicographic resources, these good dictionary examples are written by professional lexicographers or domain experts, and often adhere to some style guidelines. This makes these sentences a valuable contextual resource for understanding the meaning of words, sometimes complementing knowledge gaps that may still exist even after reading a concept's definition.

DM is, arguably, one of the most recent direct NLP application of lexical resources. We therefore argue for the need of a centralized repository that could be used to train and test DM systems, explore out-of-domain generalization, and most importantly, act as a unified test bed for lexical semantics tasks. In this paper, we fill this gap by introducing 3D-EX, a dataset that unifies a diverse set of English dictionaries and encyclopedias. Our results suggest that, indeed, 3D-EX is a valuable

Proceedings of Recent Advances in Natural Language Processing, pages 69–79
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_008

resource for testing generative models in lexicographic contexts due to its varied sources, which makes it hard to memorize, and is also helpful for augmenting competitive baselines in downstream tasks.

2 Related work

Lexical resources have a long-standing tradition in lexical semantics (Camacho-Collados et al., 2018). Given the breadth of the area, we will review some of the most prominent existing resources, and then focus on how these resources have been leveraged in NLP tasks.

2.1 Lexical resources

Arguably, the best known lexical resource in NLP is WordNet (WN) (Miller, 1995), and as Hovy et al. (2013) described it, "the list papers using WN seems endless". Other resources which have complemented or augmented WN in the NLP space include knowledge bases such as Yago (Suchanek et al., 2008), DBPedia (Auer et al., 2007), BabelNet (Navigli and Ponzetto, 2012) or WikiData (Vrandečić and Krötzsch, 2014)[1]. Traditional dictionaries have also played an important role in NLP, we review these in Section 3, as they constitute the backbone of 3D-Ex.

2.2 Applications in NLP

Lexical resources in general, and dictionaries in particular, have played a critical role in recent years for improving (knowledge-rich and organic) NLP systems. For instance Faruqui et al. (2014) retrofitted word embeddings using semantic relations; Joshi et al. (2020) and Chen et al. (2022) used definitional information to augment pretrained LMs; and Delli Bovi et al. (2015), Espinosa-Anke et al. (2016) and Xu et al. (2022) used definitions for generating knowledge bases. In parallel, a generative avenue mostly revolving around DM has garnered substantial interest, where earlier works used LSTMs (Noraset et al., 2017; Gadetsky et al., 2018; Ishiwatari et al., 2019), and later contributions shifted to LMs (Bevilacqua et al., 2020; Huang et al., 2021; August et al., 2022). These works used DM models for downstream tasks like word sense disambiguation (WSD) (Navigli, 2009), word-in-context classification (Pilehvar and Camacho-Collados, 2019) or specificity-controlled glossary writing. Other works have explored complementary spaces, e.g., exemplification modeling (i.e., generating suitable dictionary examples given a word-definition pair) or full-fledged dictionary writing (Barba et al., 2021; de Schryver and Joffe, 2023; Sierra et al., 2023).

2.3 Datasets

Let us review the datasets we integrate into 3D-EX and how they have been applied either in lexicography or downstream NLP tasks.

WordNet: WN is an electronic lexical database for English that organises words in groups of synonyms called *synsets* (Miller, 1995; Fellbaum, 2013). Each synset is described by its definition, surface forms (lemmas), examples of usage (where available), and the relations between synsets, e.g., hypernymy (is-a), meronymy (is-part) or troponymy (manner-of). WN's primary use in NLP is as a sense inventory (Agirre and Edmonds, 2007; Zhang et al., 2022; Pu et al., 2023).

CHA: CHA (Chang and Chen, 2019) is an online dataset of words, definitions and dictionary examples from the Oxford Dictionary. It can be considered as a corpus of "traditional" dictionary definitions, and has been leveraged for DM by Bevilacqua et al. (2020) and for benchmarking the quality of WN's examples (Almeman and Espinosa-Anke, 2022).

Wikipedia: Wikipedia is an online encyclopedia that is created by various contributors on the web (Yano and Kang, 2016). In this work we used a dataset that is built by Ishiwatari et al. (2019) from Wikipedia and Wikidata and each entry consists of a phrase, description, and example. This dataset is used to evaluate DM approaches that combine distributional and lexical semantics using continuous latent variables (Reid et al., 2020).

Urban: Urban Dictionary is a crowd-sourced dictionary for terms that are not typically captured by traditional dictionaries (Wilson et al., 2020). In this work we used URBAN dataset that was created from Urban dictionary by Reid et al. (2020) as a corpus of uncommon and slang words.

Wiktionary: Wiktionary is a freely available web-based dictionary that provides detailed information on lexical entries such as definitions, examples of usage, pronunciation, translations, etc.

[1] Note that all these resources include definitions, unlike other resources designed for different purposes such as commonsense reasoning (e.g., ConceptNet (Speer et al., 2012)).

(Bajčetić and Declerck, 2022). It has been used as a resource for WSD (Meyer and Gurevych, 2011; Matuschek and Gurevych, 2013), especially for retrieving WSD examples which augment labeled data for rare senses (Blevins et al., 2021) and for non-English tasks (Henrich et al., 2012; Segonne et al., 2019).

Webster's Unabridged: Webster's Unabridged is a version of Webster's dictionary (Webster, 1900) served by the Project Gutenberg initiative (Various, 2009). It describes English words by providing definitions and notes (where needed).

Hei++: Hei++ is a dataset that associates human-made definitions with adjective-noun phrases. Since there is no publicly available dataset to evaluate the quality of definition generation models on free phrases, Hei++ is built by Bevilacqua et al. using the test split of the HeiPLAS dataset (Hartung, 2015).

MultiRD: The MultiRD dataset was created by (Zhang et al., 2019) to evaluate a multi-channel reverse dictionary model that has multiple predictors to predict attributes of target words from given input queries. This dataset uses the English dictionary definition dataset created by Hill et al. (2016) as the training set and three test sets: a *seen* definition set, an *unseen* definition set, and a description set that includes pairs of words and human-written descriptions. For each entry, it also includes morphemes, lexical names and sememes.

CODWOE: The CODWOE (Comparing Dictionaries and Word embeddings) SemEval 2022 shared task (Mickus et al., 2022) aimed to compare two types of semantic descriptions, namely dictionary glosses and word embedding representations. This task was applied to multiple languages, and one dataset per language was provided. Each dataset contains a list of examples and, subsequently, each example contains the following key fields: identifier (includes the word), gloss, and embedding-related information.

Sci-definition: Sci-definition is a dataset constructed for the task of generating definitions of scientific terms with controllable complexity (August et al., 2022). The definitions are drawn from MedQuAD (Abacha and Demner-Fushman, 2019) and Wikipedia Science Glossaries[2]. For each term, 10 journal abstracts are provided from S2ORC (Lo et al., 2020) to allow models to incorporate related scientific knowledge (Fan et al., 2019; Clark et al., 2018).

3 Building 3D-EX: Data Cleaning

A prerequisite for unifying the above resources into 3D-EX, is to perform a number of preprocessing steps. This process includes: lower-casing; removing special tokens and any noisy characters such as the `tab` sign; removing entries where their definitions have more than 10% of non alphanumeric characters; removing entries that have null values either in words or definitions; removing entries where examples are the same as defined terms, and removing duplicate entries within each dataset or split.

3.1 Dataset-specific cleaning

While the above steps are applied to all datasets, each individual resource in 3D-EX undergoes a specific preprocessing set of steps:

Urban: since Urban dictionary is built by end-users who are not trained lexicographers, we found that it has number of noisy definitions (typically, too short, or containing a high proportion of emoticons, exclamation marks, and so forth). To handle them, we built a binary classifier based on RoBERTa-base (Liu et al., 2019) where 4,000 positive examples are randomly sampled from Wiktionary, CHA and WN, and 2,000 negative examples are randomly sampled from Urban. This classifier, which obtains almost perfect accuracy, is then applied to the entirety of the Urban dataset, leaving 3D-EX only with Urban entries that are similar to those in more traditional resources, both in content and, more importantly, in style. Table 1 lists examples of this filtering process, where we can see Urban-specific properties such as colloquialisms (phrasal verbs, personal pronouns, lack of punctuation marks or high proportion of slang/unknown words).

Wiktionary: Since some definitions in Wiktionary include the time where words were coined (e.g., “first attested in the late 16th century” or “from 16 c”), we deleted them using regular expressions.

MultiRD: we removed (again, using regular expressions) uninformative definitions such as ”see synonyms at” and ”often used in the plural”.

Term	Definition	Example	F.
baby bentley	a way to describe a beat up old car you wish was a Bentley	Dave calls his beat-up Neon his baby Bentley	1
pang	pangers pingerz pang pangs pangs MDMA ecstasy	Hi Marissa, it's Frank Recard calling. I'll be in the neighborhood later on, and I was wondering if maybe you wanted to get some pang pangs	1
suckafish	the correct term for one who you think is a sucker, loser, or anything else	Wow, that guy is being a total suckafish	1
farblegarb	a lot of random garbage	The signal was disrupted, producing a lot of farblegarb	0
citrixify	the process of modifying or altering a computer application for the purpose of publishing the application using Citrix Presentation Server	In order to properly publish that Java-based application, I had to citrixify it so it would run in a seamless window	0
axcellent	when something rocks and is excellent	Dude, that new haircut is axcellent	0

Table 1: Examples of Urban entries that were removed vs. retained (labels 1 vs. 0 in column **F.**).

Sci-definition: in order to construct the **Sci-definition** dataset as `<term, definition, example>` triples, we took the following steps: from each abstract, we extracted sentences that include the target term, which would act as examples. From these examples, we excluded sentences only containing lists of keywords (typically found in abstracts), and also any example with more than 10% non alphanumeric characters (similarly to our approach to cleaning definitions in Section 3).

3.2 Unification and splitting

Tables 2 and 3 show summary statistics for each dataset. It is desirable to keep a reference to the original source (dictionary or glossary) for each entry, however, we noticed that there are `<term, definition, example>` duplicates across datasets. This is why the final 3D-EX resource contains the SOURCE field as an array containing the sources where that entry was found. Furthermore, in terms of splitting 3D-EX for experimentation, it is well known that an issue in word/phrase classification datasets can occur due to a phenomenon known as "lexical memorization" (Levy et al., 2015), where supervised models tend to associate prototypical features to word types. This has been typically been addressed by releasing two splits, one random, and one known as "the lexical split", where all instances of a given term do not appear across splits (Vulić et al., 2017; Apidianaki and Soler, 2021; Espinosa-Anke et al., 2022). We follow this practice and release 3D-EX with a Random and a Lexical split. Tables 4 and 5 show examples of entries in 3D-EX and dataset statistics after unification in terms of unique instances across both splits, respectively.

Finally, to shed some light on how similarities are distributed across datasets, we investigate cosine similarities of their SBERT embeddings, and compute similarities between terms and definitions, and between definitions and examples (see Figure 1). An immediate finding by inspecting these similarities is that Hei++, a carefully curated dataset used to evaluate multiword DM systems, is the one showing the highest similarity between terms and definitions (Figure 1a), this is likely because, first, entries in Hei++ are rather specific, and do not include generic and frequently used terms. This, along with, also, a rather detailed definition, makes their similarity rather high. On the opposite end of the spectrum we unsurprisingly find Urban dictionary, although it remains for future work to explore whether Urban Dictionary's definitions are indeed dissimilar to their corresponding terms, or because they are so rare that their embeddings are of lower quality. Interestingly, we also find that Sci-definition also exhibits high similarity between terms and definitions. Concerning definitions and examples (Figure 1b), Sci-definition is again the one with the highest similarity scores, and interestingly, Wiktionary is the dictionary with the lowest aggregate similarity, which suggests that examples in Wiktionary could be purposefully written to cover different topics than their definitions. As with the case of Urban Dictionary, a careful semantic analysis of these dictionaries remains for future work.

4 Experiments and Results

In order to test the usefulness of 3D-EX, we perform an intrinsic set of experiments where we "stress test" the dataset for artifacts, indirect data leakage (near-synonyms), potential for memorization, etc. This, we argue, is an important step to guarantee 3D-EX can be used for testing lexical semantics models based on it.

4.1 Source classification

In the task of *source classification*, the goal is to, given a <term,definition> instance, predict its original source. We posit that this is an important experiment to determine which sources are more unique (i.e., easier to classify), and which seem to conflate different lexicographic features (e.g., writing style, coverage or any other artifact). To this end, we fine-tune `roberta-base` (Liu et al., 2019) for 3 epochs on the training set of 3D-EX. Note that this is a 9-way multilabel classification problem, since for a given <term,definition> tuple, there may be more than one associated source.

We report the results of this experiment in Table 6. We can see how the lexical split is substantially harder than the random split.

4.2 Reverse dictionary

Reverse dictionary (or concept finder) is a helpful application for copywriters, novelists, translators seeking to find words or ideas that might be "on the tip of their tongue" (Hill et al., 2016). It is also reflection of the interactions between a speaker and the mental lexicon (Zock, 2004; Zock et al., 2010). More relevant to NLP, however, reverse dictionary datasets can be seen as benchmarks for evaluating representation learning methods, as there are works that have used definitions as, e.g., the sole source for learning word embeddings (Bosc and Vincent, 2017) or for debiasing them (Kaneko and Bollegala, 2021).

This task is a ranking problem in which, given a definition, the task is to retrieve a ranked list of the most relevant words, and it has a long-standing tradition in computational semantics (Bila et al., 2004; Dutoit and Nugues, 2002; El-kahlout and Oflazer, 2004; Glassman et al., 1992; Thorat and Choudhari, 2016) . To establish a set of baseline results on this task, we report results from several embedding models on the random and lexical test sets. Note that while these baselines are unsupervised, we only report results on the test sets to accommodate future experiments by supervised systems. In terms of evaluation, we report *Mean Reciprocal Rank* (MRR), which rewards the position of the first correct result in a ranked list of outcomes:

$$\mathrm{MRR} = \frac{1}{|Q|} \sum_{i=1}^{|Q|} \frac{1}{rank_i}$$

where Q is a sample of experiment runs and $rank_i$

Term	Definition	Example	source
emergent	coming into existence	an emergent republic	WordNet
word	an (order; a request or instruction); an expression of will	he sent word that we should strike camp before winter	Wiktionary
central london	innermost part of london , england	westminster is an area of central london within the city of westminster , part of the west end , on the north bank of the river thames	Wikipedia
ejac-flashback	when a picture or video is familiar to you	dude I've just had a ejac-flashback that chick was last nights wank material	Urban
notice	a displayed sheet or placard giving news or information	look out for the notice of the samaritans information evening in the end of september	CHA
worship	to participate in religious ceremonies	we worship at the church down the road	CODWOE
accessory navicular bone	an accessory navicular bone is a small bone located in the middle of the foot	the accessory navicular bone is one of the most common accessory ossicles, which sometimes become symptomatic	Sci-definition
able	having sufficient power, strength, force, skill, means, or resources of any kind to accomplish the object	-	Webster's Unabridged
abbreviation	an abbreviation is a shorter way to write a word or phrase	-	MultiRD
skew picture	an inaccurate or partial representation of a situation	-	Hei++

refers to the rank position of the *first* relevant outcome for the *i*th run. MRR is commonly used in Information Retrieval and Question Answering, but has also shown to be well suited for lexical semantics tasks such as collocation discovery (Wu et al., 2010; Rodríguez-Fernández et al., 2016).

We evaluate the performance of traditional sentence encoding SBERT (Reimers and Gurevych, 2019) models, namely `all-MiniLM-L6-v2` , `all-distilroberta-v1` and `all-mpnet-base-v2`. We also evaluate Instructor (Su et al., 2022), an instruction-based encoder that can generate text embeddings tailored to any task given the appropriate prompt. Instructor works by optionally providing the type of the target text (e.g., "a Wikipedia sentence") and the task (e.g., "document retrieval"), to ultimately build a prompt such as "Represent this Wikipedia sentence for

	Random Split			Lexical Split

Average	0.77	0.62	0.68	0.71	0.54	0.60

Table 6: Results in the source classification experiment, reported both for the Random and Lexical splits of 3D-EX.

Model	Random	Lexical
all-distilroberta-v1	8.41	11.38
all-MiniLM-L6-v2	9.40	13.75
all-mpnet-base-v2	10.98	15.34

Table 7: Reverse Dictionary results of the SBERT models on the reverse dictionary task in the two 3D-EX test sets.

retrieving relevant documents". For our use case, we test three variants of Instructor for encoding both words and definitions: (1) no instruction; (2) providing a generic description of the target text (i.e., "the sentence" and "the word"); and (3) providing a domain-specific description of the target texts (i.e., "the dictionary definition" and "the dictionary entry").

We show the results of the SBERT models in Table 7, and the Instructor results in Table 8. We can see that even without any instruction prepended to the embedder, the Instructor model outperforms vanilla SBERT models, and that, interestingly, the best results overall in both splits (random and lexical) are obtained by providing a generic description of target words, and in the random split it is better to not include instructions for the definitions, while in the lexical split the best performing configuration involves providing detailed instructions for embedding the 3D-EX definitions.

As a final piece of analysis, we perform experiments on both test sets with the best performing model (based on the split type) to see which sources are harder to solve in the task of reverse dictionary. From Table 9, it can be seen that Wikipedia and Urban are the most challenging resources for this task, which could be attributed to either or both dataset size and large number of very similar definitions and terms, as opposed to for instance Hei++ or Sci-definition, which are meant to capture unique terms. These are, by nature, more unique when compared to the rest of the lexicon, an insight we revealed when exploring dataset-specifc similarities in Figure 1.

Random		word		
		no	gen.	dict.
definition	no	14.18	**14.71**	14.56

5 Conclusions and future work

In this paper we have introduced 3D-EX, a dataset that unifies different encyclopedias and dictionaries into one single resource. We have conducted an in-depth analysis of the dataset across several splits (random vs lexical), as well as dictionary source classification and reverse dictionary experiments. Our results suggest that this dataset is both challenging for representation learning methods and promising as a resource for augmenting lexical semantics systems. It has also helped us unveil semantic properties in the different dictionaries and encyclopedias we have integrated into 3D-EX.

For the future, we would like to further explore the potential of 3D-EX for downstream NLP tasks, incorporating more resources, and exploring multilingual variants. An additional avenue would be to explore the interaction of unorthodox dictionaries like Urban with traditional lexicographic resources in the context of controlled technical/jargon DM. Finally, leveraging 3D-EX as a resource for pretraining LMs, similarly to the DictBERT approach (Chen et al., 2022), could help inform LMs with new, domain-specific and/or colloquial terms.

Ethics and Broader Impact Statement

This paper is concerned with the automatic building of a dataset by combining publicly available information in the web. As a result, there could be potential for the presence of incorrect or harmful information in this derived dataset, especially if crowdsourced; however, we encourage collaborative efforts from the community to help address these risks. Specifically, vulgar, colloquial, or potentially harmful information in Urban Dictionary, which the authors of this paper do not endorse.

Abstract

Metaphors use words from one domain of knowledge to describe another, which can make the meaning less clear and require human interpretation to understand. This makes it difficult for automated models to detect metaphorical usage. The objective of the experiments in the paper is to enhance the ability of deep learning models to detect metaphors automatically. This is achieved by using two elements of semantic richness, sensory experience, and body-object interaction, as the main lexical features, combined with the contextual information present in the metaphorical sentences. The tests were conducted using classification and sequence labeling models for metaphor detection on the three metaphorical corpora VUAMC, MOH-X, and TroFi. The sensory experience led to significant improvements in the classification and sequence labelling models across all datasets. The highest gains were seen on the VUAMC dataset: recall increased by 20.9%, F1 by 7.5% for the classification model, and Recall increased by 11.66% and F1 by 3.69% for the sequence labelling model. Body-object interaction also showed positive impact on the three datasets.

1 Introduction

Metaphors are an important and widespread form of language construction. A metaphorical sentence's meaning is not a direct, literal translation of its parts, but rather an overall collection of meanings in a specific context. For example, the phrase "*weigh my options*" refers to the situation in which the advantages and disadvantages of an option are examined for a decision. It is a CONSIDERATION, not a literal WEIGHING. This form of notation refers to the Conceptual Metaphor Theory (Lakoff and Johnson, 1980), where the source domain WEIGHING provides the words used to describe the target domain CONSIDERATION. Another example that discusses LOVE while addressing the concept of HEAT: "*I bumped into an old flame at the library*". Such examples demonstrate that understanding and interpreting metaphors are complex tasks for the field of NLP. Many fields, such as Information Extraction (Do Dinh et al., 2018; Le et al., 2020) and sentiment analysis (Rentoumi et al., 2012; Karanasou et al., 2015; Biddle et al., 2020) benefit from metaphor detection. Many experiments are being undertaken to improve the detection task using machine learning and deep learning models.

The term "sensorimotor knowledge" describes knowledge learned through the body's interactions with its surroundings. This knowledge could aid in comprehending metaphors, understanding how they are constructed, and consequently, enhance the performance of automated metaphor detection. By incorporating sensorimotor knowledge as a feature in neural network models, this improvement could become feasible. While some research has been conducted on sensory experience and conceptual norms for automated metaphor detection, as of the writing of this paper, no study on the impact of adding body-object interaction to neural network models as a feature for metaphor detection has been published.

The paper makes the following contributions:

1. The study aims to enhance the word/context representations provided by GloVe and ELMo vectors by incorporating scores from two datasets related to sensory experience and body-object interaction. These additional scores will serve as lexical features to improve the models' understanding of metaphors.

2. The study will conduct metaphor detection experiments using two different deep learning models. One model is designed for sentence-level metaphors and is based on the BiLSTM

Proceedings of Recent Advances in Natural Language Processing, pages 80–89
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_009

classification model proposed by (Gao et al., 2018). The other model is for word-level metaphors and relies on the sequence labeling model (RNN_HG) proposed by (Mao et al., 2019).

3. The performance of the two deep learning models will be evaluated on three corpora: VUAMC, TroFi, and MOH-X. These corpora likely contain diverse and varied examples of metaphors, which will provide insights into how well the models generalise across different datasets.

The paper is structured as follows: Section 2 provides a preview of the existing literature of related works. In Section 3, the theories forming the foundation of this study are introduced. Section 4 introduces the models and datasets used in the experiments, along with the steps to be followed in Section 5 for both models. Section 6 presents the analysis and decisions made during the experiments. Finally, Section 7 provides a conclusion, summarising the paper's findings.

2 Related Work

The concept of semantic richness comes from the theory of semantic representation, stating that information is stored and retrieved through an interconnected network of concepts. This network includes features and information contributing to the meaning of each concept (Pexman et al., 2007; Findlay and Carrol, 2018). Richer concepts have more semantic information, leading to faster activation, improved processing, and better decision-making in the brain (Kounios et al., 2009). Similar concepts may not evoke the same semantic information, showing varying levels of richness. Semantic richness is assessed based on two categories: elements related to the network's strength and elements linked to the perceptual aspect of the network (Findlay and Carrol, 2018). While numerous studies have examined strength-related elements in Natural Language Processing (NLP), like the number of features and neighborhood density (Pexman et al., 2002; Mason, 2004; Wilks et al., 2013; Goldberg, 2017), the elements associated with the perceptual part of the network have received less attention.

Based on shared information from the environment that senses sensory input (such as taste, sight, sound, etc.), language facilitates a common ground for communication. This idea holds true for both literal and figurative languages, as introduced by Tekiroğlu et al. (2015), who attempted to measure the impact of these sensorial elements on metaphor identification using a dependency-parsed corpus of adjective-noun (AN) pairs. Meanwhile, (Wan et al., 2020) tested the conceptual norms as a linguistic enhancement method for metaphor detection of VUAMC verbs. However, as of the date of this publication, the concept of body-object interaction has not been researched in association with automated metaphor detection. For the task of metaphor detection, in the hope of better automated detection, it is essential to understand this complex form of language, and these features could facilitate such understanding.

3 Theories

The mind is capable of forming mental images and evoking various sensations when reading or hearing certain words. This ability to trigger sensory and/or perceptual experiences in the mind is known as a sensory experience (Juhasz and Yap, 2013). For instance, when the word *incense* is encountered, the mind may generate a mental picture, and the word *fragrance* may evoke the actual smell associated with *incense*. Metaphors are a type of language that relies on describing a mental image to represent an abstract concept. They achieve this by using words from a concrete, sensed domain and applying them to another domain. As mentioned in the introduction, Lakoff and Johnson (1980) described the conceptual metaphor mapping where the concept of CONSIDERATION is depicted as a sensed WEIGHING experience. This theory is further developed in Lakoff et al. (1999), which suggests that bodily interactions with the environment are projected onto the new conceptual notions of these metaphors. This developed theory aims to explain how conceptual metaphors can be understood even when the direct experiential connection between the source and target domains is lacking, leading to some mappings being vague. For instance, the metaphor "*he is hungry for recognition*" can be understood by mapping DESIRE is HUNGER because "*food is desired*". This physical reaction of hunger is connected to the abstract idea of seeking recognition.

Based on the discussion above, metaphors create an image-scheme knowledge called the sensory interaction system, where abstract concepts paint mental images of human bodily interactions. Words with a high score on the image scale could be used in metaphors where their score is noticeably higher than that of the context, further associated with some degree of human sensory input.

The body–object interaction rating reflects how easy it is to interact physically with the word's referent (Siakaluk et al., 2008). The high scale score indicates that the body's interaction with this concept is easier. For example, *key* was found to be more concrete and perceivable and linked to high-level sensory, haptic and visual experiences, this is in contrast to the word *mountains*, which scores low on the scale of body–object interaction with a lesser degree of the characteristics previously mentioned. One can see *mountains* but cannot interact with them with everyday human physical actions, while one can see, touch, and turn to unlock with *keys*. Within the cognitive sciences, researchers investigate the influence of body-object interaction measurement on various cognitive activities, including word recognition and information acquisition. The theory of the embodied view of cognition, as presented by (Siakaluk et al., 2008), posits that conceptual knowledge is grounded in perceptual interactions with the environment. This means that learning and understanding new concepts are built upon prior knowledge acquired through interactions with the surrounding environment. This observation could be applied to the idea of metaphors, as Lakoff et al. (1999)'s theory could be extended to the concept of body-object interaction. For instance, in the example '*this movie stinks*", it is clear that the statement expresses a negative remark about the movie, based on the known experience that '*stink is bad*". In other words, such metaphors can be easily comprehended because the tactile and visual experiences associated with them are akin to what the metaphor is referring to. Consequently, body-object interaction measures may aid in translating this knowledge into language that can be used to explain words and concepts. Particularly, abstract ideas could be better understood by employing this measure.

4 Metaphor Detection Experiments Setup

This section provides details about the experiments, which consist of two stages. The first stage is the preprocessing stage, where the SVM model trained on SEN and BOI lists assigns prediction scores to all tokens in the metaphorical corpora. In the second stage, the effect of these added predictions on metaphorical tokens is tested using the BiSTLM and RNN_HG models (Gao et al., 2018; Mao et al., 2019) for both sentence-level and word-level metaphor detection.

4.1 Metaphor Corpora and Other Datasets

Three metaphor corpora will be used; all will undergo the same steps from the preprocessing to the detection experiments. These datasets are the VUAMC, MOH-X and TroFi Gao et al. (2018) and Mao et al. (2019). The use of multiple datasets is essential to evaluate the performance of the models across various contexts and domains, ensuring that the models do not become overfitted to specific datasets and can generalise effectively to new data. Moreover, additional datasets related to sensory experience and body-object interaction will be used to train the SVM, which will be used to predict scores for all words in the mentioned metaphor corpora.

The VUAMC dataset (Tighe, 2010) is a manually annotated corpus containing metaphors from various registers. The MOH-X dataset (Mohammad et al., 2016) consists of simpler and shorter sentences compared to the other datasets, with each sentence having one labelled verb. Similarly, TroFi (Birke and Sarkar, 2006) shares similarities with MOH-X, having simpler sentences. The datasets utilised in the study contain lists of sentences, and the classification datasets (VUAMV, MOH-X, and TroFi) are labeled as 0 for literal and 1 for metaphor, based on the presence of a metaphorical verb. On the other hand, the VUAMC sequence dataset labels each word in the sentence for metaphoricity. The sequence model utilises the MOH-X and TroFi datasets, using 1 for the target verb if it is a metaphor, and 0 for all other words in the sentence.

Juhasz and Yap (2013) published a 5,000-word English word list rated for their sensory experience. The words were rated on a scale of 7, where low numbers indicated a low image/sensory impact. For example, the word *intent* was assigned a sensory experience rating of 2.40, while *balloon* received a rating of 5.45, indicating a richer image/sensory impact. The scoring scale was later reorganized as integers, resulting in rating results ranging from 1 to 6. In their study, Pexman et al. (2019) compiled a word list containing over 9,000 English words rated for their *ease of body interaction* on a scale of 1 to 7. A very low score signifies that it is challenging

Dataset	Total	Meta.	Lit.
VUAMC CL	10,489	2,837	7,652
VUAMV SQ	17,932	4,717	16,064
MOH-X	214	192	195
TroFi	3737	50	50

Table 1: The breakdown of the metaphorical datasets, number of sentence, tokens, metaphor and literal.

for the body to interact with those words physically. For instance, the word *ceiling* has a low score of 2.5 because it is not easy to perform physical actions like jump and touch with the *ceiling*. In contrast, the word *chair* received a higher rating on the scale, 6.88, indicating that it is easy to interact physically with it; one can underlinetouch, move and sit on a *chair* with ease. The scale was later rearranged as integers, ranging from 1 to 6.

Table 1 provides an overall statistics about the metaphorical datasets. The VUAMC CL utilised in the classification experiments contains a total of 10,489 sentences, out of which 2,837 are metaphorical, and 7,652 are literal. In the sequence experiments, the VUAMC SQ comprises 15,820 sentences with 17,932 tokens. Among these, 4,717 tokens are metaphors, and 16,064 tokens are literal. The MOH-X dataset includes 647 sentences with 214 unique target verb tokens, 192 appear in metaphorical sentences, and 195 in literal sentences. Lastly, the TroFi dataset consists of 3,737 sentences with 50 unique verb tokens. Each of these verb tokens is found in both metaphorical and literal sentences. In addition, Table 2 displays the token count for each dataset and indicates how many tokens are covered by the sensory and body-object lists. These lists will be utilised to train the SVM, enabling the assignment of predicted sensory and body-object scores to each token in the metaphorical dataset. The original ratings and the predicted ratings will be evaluated separately during the metaphor detection process.

4.2 Embeddings

In the preprocessing step, the SVM utilises BERT pre-trained as the vector representation for the words in the datasets. GloVe and ELMo are used only in the metaphor detection experiments as the word/context representations for VUAMC, MOH-X and TroFi.

Dataset	Total	SEN	BOI
SEN	5856	_	_
BOI	9349	_	_
VUAMC Cl.	17017	3059	3572
VUAMC Seq.	16979	3156	3701
MOH-X	1677	694	811
TroFi	13738	2771	3216

Table 2: The breakdown of total tokens for each dataset and the number that the sensory experience and body–object interaction list covers.

GloVe is a 300-dimensional word embedding for word meaning derived from statistical techniques used to calculate word–context co-occurrence in a large corpus (Pennington et al., 2014). Embeddings from Language Models (ELMo) (Peters et al., 2018) are deep 1,024-dimensional contextualised embeddings that represent each word's whole sentence input, where the context of a word's surroundings is considered, resulting in a dynamic representation that can change based on the sentence in which it appears. Along with GloVe, they make a 1,324-dimensional vector that represents each word in the sentence for the three metaphor datasets.

The Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) are formed by deep bidirectional representations that capture the contextual information from both the right and left sides of unlabelled text. Each word in the sensory and body-object dataset word list is assigned a BERT representation serving as SVM inputs during training. Similarly, every word in the VUAMC, MOH-X, and TroFi acquires a BERT representation and receives predicted scores from the SVMs. These predicted scores will be tested in the subsequent metaphor detection stage.

4.3 Models

The baseline[1] used to evaluate the sentence-level metaphor detection was built on the BiLSTM proposed by Gao et al. (2018). The word-level metaphors were tested using the RNN_HG sequence labelling model introduced by Mao et al. (2019). Both models rely on GloVe and ELMo embeddings to capture contextual information. The experiments on VUAMC use three splits for training, validation, and testing, whereas the tenfold

[1] The authors wrote in the README file that running the provided script is expected to result in some numbers that are **lower** than the reported numbers because the reported numbers in the paper were achieved with early stopping and additional training with smaller learning rates. These details were not included in the available scripts and were not provided in the paper.

cross-validation technique is applied for MOH-X and TroFi. Table 3 presents the hyperparameters used for these baselines.

4.4 Preprocessing Stage

The main objective of this paper is to assess the impact of enhanced contextual information on the metaphor detection task by incorporating sensory and body-object scores. Additionally, the study aims to gain deeper insights into the relationship between these elements and metaphors. The testing of the effect of sensory and body-object scores on the metaphor detection task involves three steps. Section 5, describes these three steps in detail for VUAMC, MOH-X, and TroFi.

1. Test the metaphor detection models when VUAMC, MOH-X, and TroFi words are present in the sensory and body-object datasets. Out-of-list words are assigned a score of 0. The main aim is to assess the impact of incorporating the current ratings of the sensory and body-object datasets on metaphor detection, without relying on pre-trained tools for prediction.

2. Each word in the sensory and body-object datasets receives a pre-trained BERT embedding, which is then used as input to train two SVMs: one for sensory and another for body-object. Next, each word in VUAMC, MOH-X, and TroFi datasets is assigned a pre-trained BERT embedding, allowing the SVMs to provide single-digit sensory and body-object scores. These obtained scores are then combined with GloVe and ELMo embeddings, creating input for the classification and sequence labelling models used in metaphor detection.

3. Similar to step 2 for training the SVM, however, the SVM assigns the predicted scores as probability distributions with six digits. Each digit represents the probability that the word falls under a specific score. These digits are then concatenated with GloVe-ELMo embeddings to create input for the metaphor detection models. The objective of this step is to evaluate the value of using higher-detail scores as probabilities, in contrast to single-digit scores.

5 Implementation and Results

5.1 SVMs

In steps 2 and 3 of the preprocessing, the SVM is employed to assign sensory and body-object predicted scores to all words in the VUAMC, MOH-X, and TroFi datasets. Initially, the SVM is trained on the sensory and body-object datasets using BERT pre-trained vectors as input to represent each word in these lists. Next, BERT pre-trained vectors are extracted for each word in the metaphorical corpora, and these vectors are then utilized in the SVM to assign a predicted score for each word.

Subsequently, the predicted scores are concatenated with the GloVe-ELMo embeddings to serve as the input for the metaphor detection models. As reported by Alnafesah et al. (2020), integrating a probability distribution for concreteness rating into both the classification and sequence labelling models yielded significant improvements in performance, with the F1 scores increasing by 10.23% and 6.81%, respectively. The probability distribution provided valuable information regarding the scoring of specific words, leading to improved performance in metaphor detection for the models. Table 4 displays the F1 scores obtained from the tenfold cross-validation during the training of the SVMs on the sensory and body-object datasets.

5.2 Classification and Sequence Labelling for Metaphor Detection

The sentence-level metaphor detection baseline is established using the BiSTLM model introduced by Gao et al. (2018). This model classifies sentences as either *metaphor* (assigning 1) or *literal* (assigning 0) based on the target verb and its surrounding context. For word-level metaphor detection, the baseline is built on the RNN_HG model proposed by Mao et al. (2019). This model assigns a label of 1 for *metaphor* or a label of 0 for *literal* to each word in the sentence, based on the word's surrounding context. This section presents the results for each step of testing the sensory experience and body-object interaction using these models for metaphor detection task.

In step 1, only words in VUAMC, MOH-X, and TroFi that are present in the sensory and body-object datasets are given scores. This step aims to evaluate the existing ratings without the intervention of the SVM. Table 5 displays the results of this step, denoted as *SEN_ST1* and *BOI_ST1*, for precision, recall, and F1 in both detection models.

Exp.	**P.**	**R.**	**F1**	**H_size**	**Drop1**	**Drop3**	**B_size**	**Layer**	**Epch**
VUAMC Cl.	56.28%	51.107%	53.57%	128	0.3	0.2	64	1	20
VUAMC Seq.	76.23%	64.45%	71.22%	256	0.5	0.2	2	1	29
MOH-X Cl.	75.44%	77.393%	76%	300	0.2	0.2	10	1	30
MOH-X Seq.	76.408%	81.63%	78.46%	256	0.5	0.1	2	1	20
TroFi Cl.	69.661%	73.04%	71.088%	300	0.2	0	10	1	15
TroFi Seq.	68.98%	74.489%	71.575%	256	0.5	0.1	2	1	20

Table 3: The hyperparameters used to acquire the baselines used for these experiments. The classification experiments are built on Gao et al. (2018), and the sequence labelling experiments are built on Mao et al. (2019). Precision, Recall and F1 for MOH-X and TroFi are the best of the tenfold cross-validation.

SVM	**F1 Mean**	**F1 MAX**	**F1 MIN**
SEN-single	38.678%	43.247%	35.213%
SEN-prob.	40.026%	44.273%	37.606%
BOI-single	38.881%	42.887%	36.791%
BOI-prob	39.03%	41.711%	35.508%

Table 4: The mean, max. and min. F1 scores for each SVM trained on the sensory experience and body–object interaction datasets.

The F1 scores for sensory with the classification model showed an increase in all three datasets, with VUAMC experiencing the highest increase, reaching 57.603% from 53.57%. Similarly, recall for VUAMC increased, reaching 61.839%. However, precision decreased in VUAMC and TroFi, while there was a small increase of 1.67% in MOH-X. As for body-object, precision increased for VUAMC and MOH-X, while recall and F1 for MOH-X and TroFi showed the opposite trend. TroFi's recall showed a greater increase, reaching 76.613%, while MOH-X's F1 showed a better increase, reaching 77.048%. The sequence model with sensory showed improvement in F1 for all three datasets. Recall increased in VUAMC (71.199%) and TroFi (76.471%), but slightly decreased in MOH-X. Similarly, for body-object, F1 increased in all datasets. Recall in VUAMC reached 73.298% and 75.638% for TroFi, while it decreased slightly in MOH-X.

In step 2, the SVMs' single-score assigned predictions are tested. These models assign sensory and body-object scores as a single digit to all words in the three metaphor datasets. The results are shown under *SEN_ST2* and *BOI_ST2* in Table 5. The classification with sensory experiments in VUAMC, there were minimal changes in all three metrics. Recall and F1 of the MOH-X and TroFi datasets increased slightly, while precision decreased slightly. For body-object in the MOH-X dataset, there were increases in all three metrics. On the other hand, in VUAMC's results, precision increased to 58.04%, while recall and F1 decreased. In contrast, recall and F1 increased for TroFi dataset, while precision decreased. The TroFi dataset experiments with sensory showed improvement in all three metrics. F1 for VUAMC and MOH-X increased to 73.85% and 79.033%, up from 71.22% and 78.46%, respectively. Precision decreased in VUAMC and increased in MOH-X, while the opposite was true for recall in both datasets. For the body-object in the sequence experiments, there was an overall increase in almost all metrics for all datasets. However, precision for VUAMC and TroFi showed decreases in the results.

In step 3, the sensory and body-object predictions as a probability distribution are tested for all three datasets. The predictions, in the form of a six-digit score, are added to the vectors for all words. The results are shown in Table 5 under *SEN_ST3* and *BOI_ST3*. The classification model for MOH-X with the sensory experiments showed an increase in results for all three metrics. VUAMC's and TroFi's recall and F1 increased, while precision slightly decreased. VUAMC's F1 reached 56.1%, and recall reached 56.7%. However, for body-object, the model's performance with VUAMC showed a decrease in all metrics. On the other hand, precision and F1 increased in MOH-X, while recall decreased very slightly from 77.393% to 77.358%. As for TroFi, F1 and recall increased to 75.418% and 71.664%, respectively, but Precision decreased to 68.416%. For MOH-X and TroFi, all three metrics increased slightly in the sensory experiments with the sequence model. In contrast, precision decreased in VUAMC, while recall and F1 increased to 71.968% and 73.27%, respectively. Similarly, in body-object, VUAMC's precision decreased to 74.96%, while recall increased to 70.799%, and F1 to 72.82%. However, recall decreased in MOH-X and TroFi, while F1 increased to 79.275% and 71.925%, respectively. Precision also increased in

Table 5: The results of the classification and sequence labelling experiments for both sensory and body-object are presented. The results for MOH-X and TroFi represent the best performance from the tenfold cross-validation. The highest values of recall and F1 for each dataset under each feature are highlighted in bold.

both MOH-X and TroFi to 79.439% and 70.03%, respectively.

6 Analysis and Discussion

When analysing the incorrectly predicted files for the classification model of sensory experience, prepositions frequently appear, and the word *get* is prominent on the list. For instance, in the sentence "*probably need to get Ken's permission!*", all words received a sensory predicted score of 1, except for the word *Ken*, which received a score of 2. Despite the slight shift in ratings, especially for the word *Ken* following the target verb *get*, the model failed to make the correct prediction. This could be attributed to the very low sensory experience ratings for all words in the context, along with the nature of the word *get* as a metaphor. Words like *get* and others in similar situations are frequently used words that have lost their metaphorical meaning and have become literal. Additionally, the misprediction could be due to the lack of a noticeable rating shift, causing the model to overlook the metaphoricity indicators.

In another example, the case of the phrasal verb appears in "*I'll get some tables up with erm*" where the SVM's predicted sensory ratings for "*get some tables up*" were 1, 1, 3, and 2. The words *get* (1) and *up* (2) had slightly shifted ratings. However, it is possible that the model did not detect the phrasal verb due to the distance between its parts. Additionally, the model's decision could be related to the actual meaning of the sentence. In this context, *get* is used as the literal verb *acquire*, and the word *table* represents an *object that can be acquired* in a literal sense. Because there was no significant shift in the sensory ratings with the rating distance, the model classified the sentence literally based on these factors.

The word *produce* in the sensory rating was also misclassified in the sentence "*He chuckled, produced two cardboard cups, and poured me a generous slug of the whiskey.*" A similar situation was observed where the meaning of the target word matched the context, and there were no noticeable rating shifts. As a result, the model incorrectly classified the sentence as literal. In this case, the phrase "*produced two cardboard cups*" could be interpreted as literal since it refers to the actual action of creating the object *cup*. However, the intended meaning of the sentence was likely *bring out two cups* rather than *make two cups*. The phrase *to produce* can also mean *to bring out* or *to make apparent or present to the public*. This alternative meaning is what the sentence is likely trying to convey. The lack of noticeable sensory experience rating shifts (with sensory ratings of 2, 1, 3, and 3) might not have provided enough helpful information for the classification model to correctly understand the intended meaning of the sentence. As a result, it classified the sentence as literal based on the available information.

The analysis of the incorrectly predicted files for body-object with classification reveals that the words *got* (body-object rating of 1), *go* (body-object rating of 2), and *back* (body-object rating of 5) appear at the top of the list. For instance, in the example "*having got some of the plumbing details wrong*" (*having* 2, *got* 1, *some* 1, *of* 1, *the* 1, *plumbing* 3, and *details* 2), it is evident that the rating shift between the words is slight, from 1 to 2 to 3. Furthermore, the words *plumbing* (rating of 3) and *details* (rating of 2) do not indicate strong physical manipulation. These factors combined could explain why the model's performance did not exhibit significant improvements, as observed in the sensory experiments. The same reasoning applies to the sentence "*Well, hang on a minute,*" where the ratings are 1, 1, 2, 1, and 1, with the verb *hang* as the target. The notable shifts in ratings could not provide any additional information beyond what was already known from the GloVe and ELMo embeddings.

The sensory ratings with sequence experiments misclassified the word *plant* in the sentence "*pull all nuclear plant out of the impending sale.*" as a non-metaphor. When examining the sensory ratings (*pull* 3, *all* 1, *nuclear* 3, *plant* 3, *out* 2, *of* 1, *the* 1, *impending* 2, and *sale* 2), the ratings were low, combined with the lack of an apparent shift, which may have led to missing the metaphoricity hints in using the word plant with *nuclear*. The word *down* in "*two dressing rooms and toilets down there.*" could be explained in the same way. The lack of noticeable rating shifts (*two* 1, *dressing* 2, *rooms* 3, *and* 1, *toilets* 3, *down* 2, and *there* 2) and the matching meaning of the word *down* as the direction, with the context being the *position of rooms*, could have pushed the model to misclassify the word *down* as literal.

The words *got* and *go* are also among the incorrectly predicted words for the sequence labelling experiments. The body–object interaction rating for *got* is 1 and for *go* is 2, both of which have low body–object interaction ratings. In the example "*I 've only got until tomorrow.*" the model misclassified the word *got* as literal. The body–object interaction ratings (*I* 2, *'ve* 1, *only* 1, *got* 1, *until* 1, and *tomorrow* 2) show no noticeable shifts between the words. Although the word tomorrow indicates time, and *got* indicates a somewhat physical action, the model should not misclassify the word *got*, because handling time physically is impossible. However, the body–object interaction rating did not reflect that when it gave the word *got* a low body–object interaction rating.

According to Pexman et al. (2019), the ratings reflect the ease of physical interaction with these words. Some of the words, in their sense, are similar; however, their body-object interaction ratings are different. For instance, *he* has a body-object interaction rating of 2.96, *she* has 3.30, *boy* has 4.9, and *girl* has 5.52. These variations in ratings for words that are supposed to be close in meaning space could have affected the metaphor learning with the body-object interaction ratings. Furthermore, Pexman et al. (2019) stated that the ratings were derived from concreteness and imageability ratings, along with other variables, but these specific variables were not specified.

7 Conclusion

This paper examined the impact of adding sensorimotor knowledge (sensory experience and body-object interaction) as external lexical resources to neural network models for the automatic detection of metaphors in text. Sensory relies on an image scheme, where a mental image is evoked along with other sensory activations to convey the intended meaning. On the other hand, body-object is derived from concreteness and imageability, which describe how easy it is to interact with a particular entity. Both concepts have been extensively studied in fields outside of NLP. The ratings from the lists, as well as the ratings obtained from trained SVMs, were tested on three metaphorical datasets using two types of deep learning models: one classifies sentences, and the other classifies words as literals or metaphors based on context. The models' performances demonstrated promising results, showing improvements in recall and F1 for metaphor detection across the three datasets. For future work, a more comprehensive breakdown of the variables could be used to acquire the ratings for sensory and body-object lists. This could include making the type of activated sensory more apparent. Additionally, considering imageability and concreteness in these tests might help bridge the gap in some of the variations in ratings observed, as mentioned previously (he and boy, girl and she).

Abstract

It is neither possible nor fair to compare the performance of question-answering systems for the Holy Quran and Hadith Sharif in Arabic due to both the absence of a golden test dataset on the Hadith Sharif and the small size and easy questions of the newly created golden test dataset on the Holy Quran. This article presents two question–answer datasets: Hadith Question-Answer pairs (HAQA) and Quran Question–Answer pairs (QUQA). HAQA is the first Arabic Hadith question–answer dataset available to the research community, while the QUQA dataset is regarded as the more challenging and the most extensive collection of Arabic question–answer pairs on the Quran. HAQA was designed and its data collected from several expert sources, while QUQA went through several steps in the construction phase; that is, it was designed and then integrated with existing datasets in different formats, after which the datasets were enlarged with the addition of new data from books by experts. The HAQA corpus consists of 1598 question–answer pairs, and that of QUQA contains 3382. They may be useful as gold–standard datasets for the evaluation process, as training datasets for language models with question-answering tasks and for other uses in artificial intelligence.

1 Introduction

Natural language processing and artificial intelligence have been employed to computerize numerous tasks that require an expert in the field. One such task involves analyzing textual material to extract information that can be used to answer questions, including finding answers from Islamic religious texts such as Hadith sharif and the Quran.

The Holy Quran and the Hadith Sharif are the primary sources for millions of Muslims worldwide. Muslims draw from them for legislation, teachings, wisdom, knowledge, and a complete understanding of religion, making them important and fertile resources for answering their questions. Consisting of 30 parts, 114 suras and 6236 verses, the text of the Holy Quran is the word of God in classical Arabic (CA) (Atwell et al., 2010). The Quranic text has several characteristics, such as its series of verses of different lengths; one verse may cover various topics, and the same topic may be covered in many different verses. These characteristics lead to there being many challenges in processing and researching the Quranic text. Hadiths are the sayings and deeds of the Prophet Muhammad, may God bless him, that were handed down through a chain of narrators. They may consist of a short or long sentences about what the Prophet, may God bless him and grant him peace, said, his conversations with someone else or what he narrated to his companions about his actions regarding a particular matter. The significance of the Hadith lies in the Quran's directive for Muslims to follow the teachings of the Prophet Muhammad, since many of the topics that are touched upon in the Quran are mentioned in greater detail in the hadiths. For example, God commanded Muslims to pray according to the Holy Quran, but the method and mechanism for praying are mentioned in the Hadith Sharif. Processing hadiths faces the same challenges as processing the Quranic text. In addition, there are 33,359 hadiths in the Al-Sihah al-Sittah books (Altammami et al., 2020).

Much research effort has been devoted to developing a system that can respond to inquiries related to the Quran (Malhas et al., 2022), while only a few studies have focused on addressing questions from the hadiths. However, the primary difficulty of question-answering (QA) studies concerns the direct and easy questions and small size of the Quranic question–answer collections and the absence of a Hadith question–answer corpus. As a result, each study of building a QA system for hadiths has used its own dataset to evaluate the system, which has led to obstacles in comparing the results (NEAMAH and SAAD, 2017; Abdi et al.,

Proceedings of Recent Advances in Natural Language Processing, pages 90–97
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_010

2020; Maraoui et al., 2021). In addition, the small size of Quranic datasets in the training phase has affected the results of the language models in the Quran QA task (Malhas and Elsayed, 2022).

Therefore, we aim to enrich the Arabic Islamic language resources. The design objectives of our two question–answer datasets are as follows: (1) to use a variety of expert books, (2) to cover various types of questions and topics and different difficulty levels of the questions and (3) to collect as many questions as possible for use in training language models and systems evaluation.

Our contribution is threefold: (1) We present Quran Question–Answer pairs (QUQA), the most extensive reusable Quran question–answer collection, by integrating the existing available datasets and enlarging them using different resources and challenging questions. This dataset covers a large number of questions and more verses, with the questions being in modern standard Arabic (MSA) and the answers from Quran verses in CA. (2) We introduce Hadith Question–Answer pairs (HAQA), the first reusable Arabic hadith question–answer corpus, by collecting the data from different expert resources. (3) We make these two datasets available [1] to the research community, which will reflect positively on research on Islamic QA. They can be used as a golden test collection or as training and testing data in language model research.

In the following section, we discuss the existing related collections. We then outline the methodology for designing, collecting, and building our two datasets. After that, we show the resulting datasets. Finally, we present our conclusion.

2 Related Work

Most of the existing studies of building QA systems for the Holy Quran have involved creating test sets to evaluate their systems, but these datasets are unavailable. For example, datasets containing 263 question–answer pairs have been developed, and a small part of the questions were collected from websites, with the vast majority generated manually from Quranic text. These questions are solely about the 'Al-Baqarah' and 'Al-Fatiha' chapters (Hamdelsayed and Atwell, 2016; Adany et al., 2017). In addition, Hamoud and Atwell (2017) collected 1500 questions and answers from websites.

Alqahtani (2019) constructed the first available corpus of 1224 question–answer pairs called the Annotated Corpus of Arabic Al-Quran Question and Answer (AQQAC) that were gathered from the Islam – Quran & Tafseer website [2]. Studies have not used this dataset to evaluate QA systems for several reasons, such as (1) many of the answers only consist of interpretations and not evidence from the Quran, and (2) some of the questions include complete verses from the Quran written in CA, and the exact required answers are written in MSA by the scholar. Therefore, this dataset cannot be used directly since the exact answers do not use Quranic words (Sleem et al., 2022). Nevertheless, after cleaning this dataset and excluding answers that only contain interpretations, we found that only 1232 verses are used to answer the questions, covering only 19% of the Holy Quran. In addition, the number of questions (611) is small, and they are simple and taken straight from the text.

Malhas and Elsayed (2020) developed a dataset called AyaTEC, and the process of building this collection went through many stages. They began by collecting questions from different sources, then freelancers found the answers to these questions from the Quran. Finally, specialist religious scholars reviewed the datasets. In addition, they developed an extended version of AyaTEC called QRCD, which was intended to be an intensive machine reading comprehension (MRC) task. It has been used in several recent studies to train and test different language models to obtain a system for answering questions that performs well (Malhas et al., 2022).

Nevertheless, the size of this dataset is relatively small, and the number of questions is very limited. After excluding indirect answers, there are 169 questions and 1166 records, since one question may have more than one answer. Only 1247 verses are used to answer the questions, which means that this corpus only covers around 20% of the Quran. Not all correct answers are included (Alnefaie et al., 2022). The use of this collection in measuring the system's performance does not measure the strength of the actual answering system, since the nature of the most questions is direct.

Based on the above, to address the shortage of datasets, we design and create the QUQA by cleaning and integrating the existing datasets, enlarging them with more challenge questions from various

[1] http://github.com/scsaln/HAQA-and-QUQA

[2] http://http://islamqt.com/

sources and covering a more significant number of verses.

On the other hand, other researchers have been interested in finding answers to questions from hadiths and tested their systems by building different test collections. NEAMAH and SAAD (2017) collected hadiths and then asked university students to create questions from them, with the collection size reaching 12 questions. Abdi et al. (2020) built a collection of 3825 question–answer pairs by reading the hadiths and extracting questions manually. Maraoui et al. (2021) constructed a corpus of 33 questions from native Arabic speakers and online forums. Nevertheless, all these datasets are unavailable, and to the best of our knowledge, no Hadith Sharif question–answer datasets are publicly available. Therefore, we introduce the HAQA dataset to the research community to fill this gap.

3 Building QUQA and HAQA

The methodology for creating QUQA and HAQA went through several stages, consisting of designing the two datasets, identifying the data sources, and collecting and cleaning the data. Figure 1 shows the development methodology of these two datasets, which we now go on to discuss in detail.

3.1 QUQA and HAQA Design

As a starting point for building the two datasets, we must define the structure of the collection, its metadata, and the format in which it will be available. We designed the Quran dataset based on the AyaTEC and the AQQAC designs, and the common metadata between the two corpora were adopted. Similar metadata were selected for HAQA to suit the nature of hadiths. Comma- separated values (CSVs) with UTF-8 encoding format were used because many systems can easily use them following their conversion into XML format. Every record in the QUQA CSV file includes the information listed in Table 1. The information in the HAQA records is similar.

3.2 Identifying Data Sources

To create the corpora, we used two sources, namely books and available datasets. Many books include questions and answers about the Quran and the Hadith Sharif, but they did not meet our requirements. For example, the answers in some sources are solely in the words of an expert and do not contain evidence from the Quran or the hadiths. Additionally, we did not have permission to publish the data of some sources in our datasets. The available datasets and books matching our requirements that were used to build QUQA are as follows:

- AQQAC: This was the first Islamic dataset made available to the research community and contains answers from Quranic verses, interpretations of the verses and explanations of them in the words of an expert. This dataset file is available in XLXS and XML formats. Among the topics covered by this dataset are stories of the prophets and previous nations, Islamic legal rulings and knowledge of unseen matters (Alqahtani, 2019).

- AyaTEC: This is a specialized dataset with answers from the Holy Quran. It consists of three XML files that must be linked together. The questions relate to 11 topics, including battles, humans, stories of the prophets and faith in God (Malhas and Elsayed, 2020).

- 900 Questions and Answers in Managing the Verses of the Book: This is a set of questions and answers from the Quran developed by the writer due to his belief that formulating material with questions and answers increases a person's understanding of the subject (AL-muselli, 2020).

- 100 Quranic Questions and Answers: This is a set of questions and answers from the Quran developed by the writer to answer people's questions and make them more aware of their religion (Alakeel, 2018).

The books that were used to create QUQA and HAQA are as follows:

- The Doctrine of Every Muslim in a Question-and-Answer Book and the Abridged Version of the Islamic Belief from the Quran and Sunnah: This is a series of publications by Sheikh Zeno that answers the most important questions in the Muslim faith (Zeno, 2004, 2007).

- Inference on Children's Treasure: This contains a set of questions covering the following topics: the most important matters of religion, the foundations of faith, belief, the principles of jurisprudence, etiquette, dealings between people, the Prophet's biography etc. This

book's questions are related to the basics of religion, the Prop het's life, faith, matters related to the afterlife etc. (Al-Wadi, 2016).

- Prayer (1770) Question and Answer: This contains people's questions related to the topic of prayer, with answers taken from the Quran and the hadiths (Al Alami, 2022). This selection achieved the design goals, since the most significant questions, in terms of their type, topic and source, were included in these corpora.

3.3 Data Collection

This stage consisted of two steps, the first being to integrate the existing datasets and the second to use new sources. As mentioned earlier, there are two corpora in the Quran domain, AQQAC and AyaTEC, while the hadiths have no dataset. We wrote a Python program to convert the existing two datasets into the structure and format of our dataset. In the second step, we used the new sources to enlarge QUQA and create HAQA. The sources of the two collections consist of six books, some of which are available in text format and some not. Therefore, we wrote a Python program using OCR to convert some of the books into text format, which we reviewed manually. After that, we wrote a program that extracted questions and answers from text files and put them in our files. As a final step in this stage, we filled in the metadata using Python, or manually in some cases.

3.4 Cleaning the Data

Cleaning data is the process of detecting and fixing errors and incorrect information. Such errors include misspellings, missing information, unwanted items, and noisy and duplicate data. This cleaning process improves the quality of the resulting data, which reflects positively on the purpose of collecting it. There are two methods for cleaning data: one that is manual and the other automated. We used the manual method to discover spelling errors, missing information and duplicate information, although this approach usually takes time and effort. In addition, we used the automated approach by applying some regular expressions to remove extra spaces and non-Arabic characters. An example of a QUQA final record is shown in Table 2 and Table 3 while a HAQA example is shown in Table 4 and Table 5. We combined the answers of duplicate questions.

Annotation	Description
Record Id	The unique record number.
Question Id	A question number may appear many times in this dataset due to the following: 1.The question has many different answers. 2.The question has one answer, but it is mentioned in many different verses in the Quran.
Question Text	The question text
Quetion Type	The type of question can be a factoid (F), a confirmation (C) or a description (D).
Question Start Word	The question keyword.
Answer ID	The number of unique answers to the same question: 1.If the question has only one answer in a sense that comes totally or partially from different verses with different syntax, the numbering appears as 1.1, 1.2, 1.3 etc. 2.If the question has different answers in the same or different verses, the numbering appears as 1, 2, 3 etc.
Full Answer	The whole answer consists of expert commentary, the Quranic verse and the hadith.
Expert Commentary	An answer uses an expert's words alone.
Answer Instances	The exact part of a verse that answers the question. The verse may contain more than one answer, and each answer considers an answer instance.
Quran Full Verse Answer	A complete verse that considers or contains the answer.
Chapter Name	The chapter name.
Chapter Number	The chapter number.
Verses Number Start	The number of the first verse.
Verses Number End	The number of the last verse.
Source Name	The name of the source.
Source Link	The link to the source.
Credibility	Yes, if an Islamic expert has reviewed the answers; no, if they have not done so.
Question ID in the Original Dataset	The question ID in the original dataset.

Table 1: QUQA annotation.

4 Evaluation of the Corpora

QUQA is an Arabic question-and-answer dataset on the Holy Quran consisting of 3382 records and over 301,000 tokens. Since some questions may have more than one answer, there are 2189 questions. The answers in this corpus are extracted from 2930 verses of the Holy Quran. Accordingly, this dataset covers almost 47% of the Quran. We noticed that the questions in the new dataset are more diverse and challenging than those in the previous datasets, as shown in Table 2 and Table 3. In contrast to the two existing datasets, whose questions are considered to be direct and explicit because they include the words found in the answer, extracting the answer is easy. Table 6 shows the comparison results between our corpus and the two existing corpora. This dataset covers many topics, including worship, the most important matters of religion, the foundations of faith, belief, the principles of jurisprudence, etiquette, matters related to the afterlife, dealings between people, the life of the Prophet, battles, humans, and stories about prophets. There are 199 single-answer and 1990 multiple-answer questions. The single-answer questions are ones that have only one answer found in one or several verses in the Quran, with answers that are repeated in different places in the Quran being semantically and/or syntactically similar. The multiple-answer questions have several different answers to the question.

In addition, when we analyzed the Arabic HAQA dataset of Hadith sharif answers, we found that there are 1598 records and 1359 questions. The hadiths in this collection were taken from various sources of basic hadith books; for example, there are hadiths from Al-Bukhari, Muslim, Al-Tirmidhi, Al-Nasai, Ibn Majah, Imam Ahmad, Ibn Shaybah and others. The most important matters of religion, battles, biographies of men about the Prophet Muhammad, the foundations of faith, belief, the principles of jurisprudence, etiquette, dealings between people, the life of the Prophet, worship and others are the main topics covered by this dataset.

Datasets	AQQAC	AyaTEC	QuQA

# Questions	611	169	2189
#Verses in the answers	1232	1247	2930
% of Quran coverage	19%	20%	47%

Table 6: Comparing QuQA, AQQAC and AyaTEC.

5 Conclusion and Future Work

This paper presents the process of building two Islamic religious corpora in Arabic. QUQA and HAQA are two datasets that contain questions and answers about the Holy Quran and the Hadith Sharif, respectively. Since these corpora include more than 4900 records, they are considered to be the largest Islamic corpora available [3] to the research community.

These two datasets enrich the resources of the Arabic language, which suffers from a shortage of datasets in comparison with English and other languages. They open the door to conduct much more research in the field of artificial intelligence and the task of studying the nature and understanding of classical Arabic texts.

In the future, we plan to enlarge these two corpora to cover a significant number of hadiths and Quranic verses, including a greater variety of question types and challenging questions that will improve the dataset's quality. Different languages, such as English, can be added to them. In addition, a question–answer corpus can be built for other Islamic books using the same methodology, enhancing the state-of-the-art of Islamic QA systems.

Abstract

This study investigates the use of Natural Language Processing (NLP) methods to analyze politics, conflicts and violence in the Middle East using domain-specific pre-trained language models. We introduce Arabic text and present ConfliBERT-Arabic, a pre-trained language models that can efficiently analyze political, conflict and violence-related texts. Our technique hones a pre-trained model using a corpus of Arabic texts about regional politics and conflicts. Performance of our models is compared to baseline BERT models. Our findings show that the performance of NLP models for Middle Eastern politics and conflict analysis are enhanced by the use of domain-specific pre-trained local language models. This study offers political and conflict analysts, including policymakers, scholars, and practitioners new approaches and tools for deciphering the intricate dynamics of local politics and conflicts directly in Arabic.

1 Introduction

In the Middle East, political upheaval and carnage have long been issues (Blankenship, 2020). Deep divisions, geopolitical rivalries, and foreign meddling have historically riven the area, from the Israeli-Palestinian conflict to the ongoing civil war in Syria. Even if the root causes of these conflicts are complex and multidimensional, the role that language and communication play in shaping the narratives that underlay them cannot be ignored. Language is commonly used as a strategy to rally support, defend violence, and discredit opposing viewpoints. Therefore, it is essential to develop effective methods for understanding and analyzing the role that language and texts plays in Middle Eastern politics and conflicts via news reports and other sources. Natural Language Processing (NLP) approaches can evaluate large amounts of text and have shown great promise in identifying patterns and insights that would otherwise be difficult to spot. Recent, pre-trained language models (PLM), like BERT (Devlin et al., 2018), have improved in efficiency for a range of NLP tasks, including sentiment analysis, text categorization, and language synthesis. PLMs have received a lot of attention in the literature, but most of it has focused on English or other widely spoken languages; very few studies have examined how well they apply to Arabic. The Arabic language has a rich and complicated morphology, which has increased the requirement for highly advanced NLP tools that can meet the language's expanding needs across a variety of fields and applications (Ameur et al., 2020).

This research fills this vacuum in the literature by investigating the application of Arabic-specific PLMs for politics, conflicts and violence in the Middle East. We reference a variety of pertinent academic works, such as investigations into the nature of political violence (Asal et al., 2020), the function of language in conflicts (Webber et al., 2020), and the creation and use of PLMs (Jawahar et al., 2019; Devlin et al., 2018) such as ConfliBERT (Hu et al., 2022).

The performance of two PLMs, BERT and ConfliBERT-Arabic, focuses on the analysis of Arabic text about politics, conflict, and violence in the Middle East. BERT is a more general-purpose PLM that has been used to tackle a variety of NLP problems, whereas ConfliBERT-Arabic is a domain-specific PLM optimized on a corpus gathering texts relevant to regional politics, conflicts and violence. We contrast their effectiveness with a different PLM, AraBERT (Antoun et al., 2020).

This work has implications for multiple users such as policymakers, researchers, and conflict analysts. By providing cutting-edge tools and methods for investigating politics and conflicts in the Middle East, our study develops data for more effective conflict prevention and resolution programs. By

Proceedings of Recent Advances in Natural Language Processing, pages 98–108
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_011

examining the role that language and communication play in affecting the politics and conflicts in the region, we can provide a more nuanced understanding and prediction of the underlying causes of these conflicts and cooperation in the Middle East.

Our experiments show that domain-specific pretraining significantly improves model performance, particularly for identifying information about political conflict. We examine in detail each model's applications and their benefits and drawbacks.

2 Challenges

2.1 The Arabic Language

The Arabic language possesses distinctive characteristics that set it apart from English. A single Arabic character can take up to three different forms, each corresponding to a specific position within a word (beginning, middle or end). Moreover, Arabic lacks capital letters, which poses a considerable challenge for NER tasks, where capitalization plays a crucial role in other languages (Alkhatib et al., 2020). Arabic also has long and short vowels, but short vowels are no longer used in newspapers, leading to high ambiguity in texts as disambiguation using these vowels is impossible. In word disambiguation in Arabic, the diverse pronunciations of a word can give rise to various meanings. These small signs added to letters help readers differentiate between similar words. Nonetheless, omitting diacritics from some words can result in numerous lexical ambiguities (Laatar et al., 2018). Lastly, Arabic is highly inflectional, with a very complex morphology. The general form of an Arabic word comprises Prefix(es) + Stem + Suffix(es), with the number of prefixes and suffixes ranging from 0 or more. Affixes are added to the stem to obtain the required expression. For example, the Arabic word ”manzil” means ”house,” while ”almanzil” means ”the house,” illustrating how an Arabic word can be translated into two words. Another example, ”sayaktoubounaha,” which means ”and they will write it,” when written in the general form introduced above, becomes sa+ya+“ktoub”+ouna+ha. From an NER perspective, this peculiarity of Arabic poses a significant obstacle as it results in data sparseness (Benajiba et al., 2007).

2.2 Corpora Building

When scraping Arabic sites, text encodings must be in UTF-8 for the text to be processed by NLP. This also accounts for the Arabic text direction, from right to left, and proper encoding ensures that this feature is recognized (Meskaldji et al., 2018). Several technical issues are that, 1) Arabic sites store limited data due to high database costs; 2) Security features on many Arabic sites can hinder scraping efforts. Thus trial, and error runs are necessary to determine the optimal number of parallel threads and sleep time between consecutive scrapes of the relevant sites. Since some Arabic websites present static news stories on individual pages while others generate dynamic stories, scripts had to be written from scratch, tailored to the structures of individual news websites. Finally, it was essential to ensure that the sites being scraped are written in modern standard Arabic (MSA).

3 Related Work

Recent developments in pre-trained language models have significantly advanced the field of Natural Language Processing. Here, we review three of the most prominent models: BERT, Multilingual BERT, AraBERT, and ConfliBERT.

3.1 BERT

Bidirectional Encoder Representations from Transformers (BERT) is a Google developed PLM (Devlin et al., 2018). BERT is trained on a massive corpus of text using an unsupervised learning method that involves predicting missing words in a sentence. BERT has demonstrated superior performance on various Natural language Processing tasks, including sentiment analysis, question answering, and language translation. To fine-tune BERT for specific tasks, a task-specific layer is added on top of the pre-trained model, and the whole architecture is trained on a labeled dataset. This approach has shown to achieve state-of-the-art results in several Natural Language Processing tasks. However, one of the limitations of BERT is its focus on the English language.

3.2 Multilingual BERT

Multilingual BERT is an improved version of BERT that addresses the language dominance of the original model (Pires et al., 2019). Multilingual BERT outperforms the original BERT in several languages. For tokenization, Multilingual BERT uses a 110k shared WordPiece vocabulary file that spans 102 languages. Similar to the English BERT, lower casing+accent removal, punctuation splitting, and whitespace tokenization were applied. However, the Arabic language's complex concatenative (Al-Sallab et al., 2017) system poses a challenge for BERT-compatible tokenization, as words can have different forms but the same meaning. Therefore, when using BERT-compatible tokenization, tokens appear twice, once with the Arabic definite article ”ال” (equivalent to ”the” in English) and once without it, leading to unnecessary redundancy (Antoun et al., 2020).

3.3 AraBERT

AraBERT is a PLM specifically designed for Arabic language understanding (Antoun et al., 2020). AraBERT is trained on a large Arabic corpus using the same methodology as BERT, but uses different tokenization. The authors segment words using Farasa (Abdelali et al., 2016) into stems, prefixes, and suffixes, and then train a SentencePiece, an unsupervised text tokenizer and detokenizer, in unigram mode on the segmented pre-training dataset to produce a subword vocabulary of approximately 60k tokens. One of the limitations of AraBERT is that the training corpus is not domain-specific, compiled from Arabic Wikipedia and other public datasets.

3.4 ConfliBERT

ConfliBERT is an English PLM designed for conflict and political violence (Hu et al., 2022). ConfliBERT is trained on a large domain-specific corpus using a multi-task learning method to perform several related tasks simultaneously. ConfliBERT has demonstrated superior performance on several political violence detection tasks with external validation (Häffner et al., 2023). ConfliBERT is finetuned with a task-specific layer added on top of the PLM, and the entire architecture is trained on a labeled dataset for the downstream task. ConfliBERT has been expanded to Spanish with the introduction of ConfliBERT-Spanish (Yang et al., 2023)

Overall, each model has its strengths and limitations. While BERT and its variants have proven to be effective in several NLP tasks, they have a limited focus on the Arabic language. In contrast, AraBERT is specifically designed for Arabic language understanding, but its training corpus is not domain-specific. Our work aims to build upon the strengths of previous language models to create a specialized model that is tailored to the Arabic language and the domain of political violence. By combining the features and methodologies of BERT, AraBERT, and ConfliBERT, we aim to develop a model capable of accurately detecting and analyzing instances of political conflicts and violence in Arabic texts.

4 Approach

To develop ConfliBERT-Arabic, we implemented a series of steps, namely corpora collection, pretraining strategies, and evaluation tasks. The first step involves the creation of a domain-specific corpus for pre-training. Publicly available Arabic datasets focusing on politics and conflict domains are limited, and thus we conducted our own data collecting to extract political text from Arabic sources, thus enabling us to achieve better results on political tasks. After building the corpus, we developed our domain-specific model based on BERT, a powerful language model that has been successfully validated in multiple domains in both English and Arabic languages (Lee et al., 2019; Beltagy et al., 2019; Chalkidis et al., 2020; Gu et al., 2021; AL-Qurishi et al., 2022; Bayrak and Issifu, 2022; Boudjellal et al., 2021). Our Masked-Language Modeling (MLM)-based BERT model shows improved performance compared to other transformer models that use different self-supervision tasks. The final step involves evaluating the performance of ConfliBERT-Arabic on downstream tasks related to political and conflict analysis to measure its effectiveness in real-world applications.

4.1 Corpora Building

During our data collection process, we scraped a total of 84 sources from various Arabic language speaking countries. A total of 19 countries were covered in the corpus building. These sources consisted of newspaper sites, mainstream media, and government sources such as national news agencies. The list of sources were curated and scraped by native Arabic speakers to ensure all sources were in Modern Standard Arabic (MSA). Our focus during scraping was on news from the Political, International, and Local sections of the sources, as we determined that these categories provided a greater proportion of political, conflict and violence-based articles. To ensure the highest quality of data, we ignored sections focusing on Culture, Entertainment, Economy, Business, and Sports. In total, we were able to extract 11.5GB of data from these sources. To construct the corpora, we followed these steps:

1. For several Arab countries, we curated a list of official national news agencies. We also included national news agencies of countries with Arabic as a second language such as Mauritania, Kyrgyzstan and Tajikistan.

2. We curated a list of newspapers that are widely circulated and considered reliable sources for news. We focused on highly political countries in the region which are Palestine, Saudi Arabia, Lebanon, Syria, and Iraq.

3. We curated a list of well known Mainstream Media Sources in the region such as BBC Arabia and Aljazeera. A few of these resources were run by non-arab countries, but targeted the region with arabic sites, such as Russia Today Arabia by Russia and Adnki by Italy.

4. We created python scripts to extract text from the list of sources using high performance computers (HPC) that have 96 cores with 10 GB memory each.

5. For each source, we processed and cleaned the data. This involved removing duplicate texts, carriage returns, peripheral punctuation marks, extra white space, and pop-up advertisements text.

6. We stored the extracted data in a CSV files using arabic friendly UTF-8 encoding. The CSV includes metadata such as country name, outlet name, article title, link, and date.

After scraping the data, we designed a filtering technique to reduce the possibility of irrelevant news articles. For example, the international section of a newspaper might include a story about an Olympic Games match between two politically rival countries. While this article may have political implications for the countries involved, we consider it more relevant to sports than to our domain. To create our filter, we built a list of relevant and irrelevant keyword. The keywords were created after verbs and actors in the CAMEO dictionary (Gerner et al., 2002) and reviewed by experts in the political science domain. The number of matches with the relevant and irrelevant keywords were compared against each other and the thresholds was tuned to filter the most relevant political, violence and conflict-based news. Table 2 shows statistics of the extracted corpora after filtering.

4.2 Domain-Specific Pretraining

As shown in Figure 1, we employed a continual method (Cont) to adapt BERT to the political, conflict, and violence domain. This method involves initializing the BERT's model vocabulary and checkpoints, then training the model for additional steps on our domain-specific corpus. We used Multilingual BERT and AraBERT as the base BERT models for our Cont method. Since Multilingual BERT and AraBERT have already been pretrained about one million steps on a generic arabic domain, the Cont method will require fewer steps than training from scratch. The Cont method has shown comparable results to training from scratch. According to (Lee et al., 2019), continuous pretraining of BERT on a biomedical dataset for 470K steps results in performance comparable to pretraining for one million steps.

When it comes to casing, although there is no distinction between upper and lowercase letters in Arabic, previous works for English (Beltagy et al., 2019; Gu et al., 2021; Devlin et al., 2018) have shown, in specific domains, uncased models perform slightly better than cased models especially when it comes to NER tasks. Therefore, we decided to evaluate both cased and uncased versions of Multilingual BERT for Arabic to highlight any differences and to be comprehensive in our research.

4.3 Evaluation Tasks

The development of pre-trained language models has been accelerated by the introduction of comprehensive benchmarks in the general NLP domain (Wang et al., 2018, 2019; Rajpurkar et al., 2018; Lai et al., 2017), as well as in biomedical applications (Peng et al., 2019; Gu et al., 2021). To comprehensively evaluate ConfliBERT-Arabic, we collected a diverse set of datasets for Named Entity Recognition (NER) and Binary Classification (BC). However, we faced a challenge as we could not find any comprehensive benchmarks for evaluating Arabic language models specifically in the political, conflict and violence domain.

The focus of Arabic NLP in recent research has mainly been on social media and dialect detection. Luckily, we did find some news-based datasets, but they covered a wide range of news topics which included politics. Therefore, we had to filter these news based datasets to isolate the political, conflict and violence related sections. As for datasets

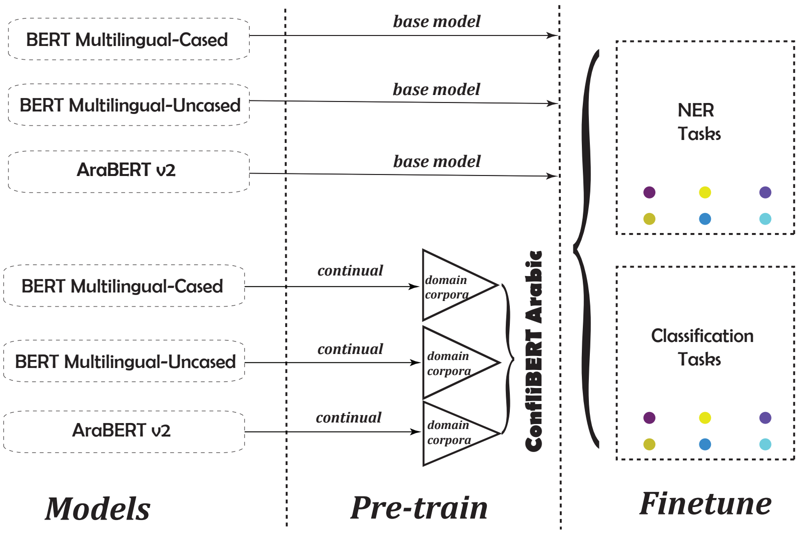

Figure 1: Workflow of our ConfliBERT-Arabic framework.

Table 2: Statistics of the extracted political and conflict-specific dataset

that focused on Wikipedia and social media, although these datasets may not cover the political domain specifically, we decided to evaluate them using our model. The reason is many of these datasets did include political posts from social media and Wikipedia that reference conflicts and violence. Moreover, we noticed social media in the MENA region is highly political and full of conflicts and violence, and we were interested in the results. Below we present the datasets and their corresponding tasks.

4.3.1 Binary Classification (BC)

Political scientists need Binary Classification to identify political and conflict-related documents from large news corpora. We gathered several datasets, including **SANAD** (Einea et al., 2019), **Ultimate Arabic News** (Al-Dulaimi, 2022), **AraFacts**(Ali et al., 2021), **DataSet for Arabic Classification**(mohamed, 2018) and **Arabic Dialects and Topics** (Boujou et al., 2021). SANAD comes from AlArabiya, Akhbarona, and Alanba AlKhaleej newspaper websites. We created two BC tasks here one for AlArabiya and one for Alanba AlKhaleej. Ultimate Arabic News is a collection of single-labeled texts from Arabic news websites and press articles. AraFacts contains claims from five Arabic fact-checking websites, mostly of political nature. DataSet for Arabic Classification consists of 111,728 documents collected from the Arabic online newspapers Assabah, Hespress and Akhbarona. Finally, we acquired Arabic Dialects and Topics, which is a dataset for topic detection for social media posts in different Arabic dialects. These datasets cover a wide range of text types, but we focused on evaluating their performance for Binary Classification tasks.

4.3.2 Named Entity Recognition (NER)

The NER datasets we selected are annotated in CoNLL format and contain entities such as location, organization, person, group, event, and others. The datasets are as follows: **KALIMAT** (El-Haj and Koulali, 2013), which includes documents from the Omani newspaper Alwatan; **AnerCORP** (Benajiba et al., 2007), a publicly available Arabic NER dataset from news sources with 150,286 tokens and 32,114 types; **AQMAR** (Mohit et al., 2012), which is a corpus of 74,000 tokens from 28 annotated Arabic Wikipedia articles; **Wikiann** (Rahimi et al., 2019), a manually annotated dataset covering approximately 3,000 sentences from 31 Wikipedia articles; **LinCE MSA-EGY** (Aguilar et al., 2019), an annotated social media dataset using Twitter, where the tweets were harvested from the timeline of 12 Egyptian politician public figures; **WDC** (Althobaiti et al., 2014), which contains 165,119 sentences from Wikipedia, consisting of around 6 million tokens; and finally, **POLYGLOT-NER** (Al-Rfou et al., 2015), a generated annotated dataset using Wikipedia and Freebase.

5 Experimental Setup

5.1 Pre-training Setup

We implemented ConfliBERT-Arabic using the previously mentioned continual (Cont) techniques. The architecture used is similar to Multilingual BERT-Base with 12 layers, 768 hidden units, 12 attention heads, and a total of 110M parameters. The vocabulary file used is identical to the original Multilingual BERT and AraBERT vocabulary files. We used 2 Nvidia A-100 GPUs with 10 GB memory to train the models. We used an Adam optimizer (Kingma and Ba, 2015) with the learning rate set to a peak value of 5e-5 and then linearly decayed. To accommodate the long paragraphs of new data, we trained the model with a sequence length of 512. The overall training time for each Cont model took about three days.

5.2 Fine-Tuning Setup

For Named Entity Recognition (NER) tasks, we predicted the sequence of BIO tags (a common tagging format for tagging tokens in a chunking task) for each token in the input sentence. We pre-processed the dataset to ensure the correct CoNLL format and used a (70,15,15) split for Train, Test, and Dev for all datasets. For Binary Classification (BC), we required a sequence classification/regression head on top of the pooled output of BERT. We used cross-entropy loss for binary classification. We split our datasets into (70,15,15)

Model		NER F1 Score	BC F1 Score
ConfliBERT Arabic	Multilingual-Uncased-Cont	**77.07**	**90.85**
	Multilingual-Cased-Cont	**77.14**	**90.78**
	AraBERT-Cont	**77.88**	**91.54**
BERT multilingual	Uncased	76.69	89.12
	Cased	76.86	89.10
AraBERT		75.89	90.16

Table 3: Summary F1 results of our evaluation by task

Dataset	Domain	ConfliBERT-Arabic F1 Score			BERT F1 Score		
		AraBERT	Cased	Uncased	AraBERT	Cased	Uncased
AnerCORP	Newswire	**81.17**	77.74	77.75	79.7	75.23	75.46
Kalimat	Newspaper	82.09	**83.72**	82.37	81.53	82.74	82.63
LinCE	Social Media	**79.96**	79.19	79.67	77.47	76.39	76.59
WikiANN	Wikipedia	**92.97**	92.06	92.2	92.88	91.73	91.68
WDC	Wikipedia	72.91	72.85	72.72	71.49	**73.03**	73.27
Polyglot	Wikipedia	**64.61**	62.48	62.35	60.111	62.66	62.03
Aqmar	Wikipedia	71.45	71.95	72.4	68.07	**76.28**	75.23

Table 4: Summary of F1 measure results of NER datasets

for Train, Test, and Dev. We fine-tuned our models on a single Nvidia A-100 GPU for five epochs with a learning rate of 5e-05, batch size of 16, and a maximum sequence length of 128 for NER and 512 for BC. We repeated all experiments ten times with different seeds. We use F1 scores as performance metrics for both tasks.

6 Results and Analysis

Table 3 reports the F1 scores for each model by task with results using the mean of 10 seeds. As shown, ConfliBERT-Arabic outperforms Multilingual BERT and AraBERT, where our models consistently report the best results (in bold) for both tasks. To compare ConfliBERT-Arabic Continual with other models, we evaluated the best results from cased, uncased, and AraBERT versions of BERT. Our findings show that ConfliBERT-Arabic Continual based on AraBERT performs the best overall by achieving the top results in 9 out of the 13 datasets evaluated. Overall, the models fine-tuned on our data had the best results in 11 out of the 13 datasets.

6.1 NER Evaluation Results

In Table 4, we can observe that our models outperformed the competing models on 5 out of the 7 evaluated datasets. Notably, our models demonstrated significant improvements across various types of datasets, including news articles, Wikipedia entries, and social media content, particularly when the datasets involved topics related to politics and international affairs.

In news-based datasets such as AnerCORP and Kalimat, our continual models demonstrated improvements over standard BERT. AnerCORP contained a significant amount of political and international data, with 34.8% of the dataset originating from Aljazeera.net, which primarily featured political articles focusing on conflict and violence. Consequently, our continual models exhibited considerable enhancements compared to standard BERT models. Similarly, for Kalimat, which was collected from the Omani newspaper Al-Watan, our models performed better, as the dataset mainly consisted of local and international news that covered the gulf region's political conflicts.

Regarding LinCE, researchers focused on social media data obtained from Twitter, specifically 12,334 tweets posted by 12 Egyptian political public figures. As the dataset was predominantly political discussing the region conflicts and featured numerous political named entities, our models outperformed standard BERT models.

For Wikipedia-based datasets, our performance varied depending on the specific articles used in each dataset. In the case of Polyglot, our models excelled due to the political and conflict/war oriented Wikipedia articles extracted using Freebase. Similarly, WikiANN, which contained political and conflict-related articles, led to our models performing well.

On the other hand, Aqmar and WDC, which consisted of more general articles unrelated to politics or conflict, we witnessed a better performance from the regular BERT models. For instance, Aqmar included 28 Wikipedia articles covering history, science, sports, and technology, as researchers aimed to adapt named entity analysis to new domains. In the case of WDC, the articles were sourced from Wikipedia's open domain, representing various genres. Here, the baseline cased multilingual BERT marginally outperformed our models. This was expected, as our models were pretrained and specialized for the political and conflicts domain.

For the NER datasets, we used p-values to confirm the statistical significance of the differences. Using AnerCORP, LinCE, and Polyglot, we contrasted our models with AraBERT and Multilingual BERT. All results are statistically significant at $p<0.01$. This makes sense given that all of these datasets have a strong political focus. In contrast, generic datasets such as Aqmar, had a $p>0.1$.

Dataset	Domain	ConfliBERT-Arabic F1 Score			BERT F1 Score		
		AraBERT	Cased	Uncased	AraBERT	Cased	Uncased
Ultimate Arabic News	News	**97.46**	95.85	95.89	95.74	94.27	94.80
DataSet for Arabic Classification	News	**97.47**	97.01	97.21	97.05	96.15	96.18
Arabic Dialects & Topics	Social Media	**67.09**	60.87	60.93	60.01	59.90	60.40
SANAD	AlArabiya News	**98.83**	97.81	98.01	98.42	97.11	97.13
	AlKhaleej News	**99.51**	99.09	99.07	98.93	98.02	98.22
Arafacts	Fact Checking	**75.21**	72.83	72.57	72.02	70.34	67.55

Table 5: Summary of F1 measure results for classification dataset

Given that our models was trained on a corpus of political domain data, it makes sense.

In summary, our models demonstrated superior results when applied to datasets rich in political, international, and conflict-related content, regardless of whether the data was sourced from news outlets, Wikipedia, or social media. For datasets that do not involve these topics, regular BERT models tended to yield better results.

6.2 BC Evaluation Results

Binary classification results are illustrated in Table 5. All datasets exhibited improved performance with our models. These datasets included four from newspapers, one from social media, and one from a fact-checking site. Since the datasets were originally created for topic classification purposes, all articles were annotated and labeled by categories such as Culture, Finance, Medical, Politics, Religion, Sports, and Tech.

To create our binary classification dataset, we sampled articles from the politics category, with emphasis on conflict and violence, alongside non-political data from other topics. The data was then labeled with 0 or 1 to indicate whether the articles were related to political conflict and violence or not.

Our ConfliBERT Arabic Continual model, based on AraBERT, demonstrated the best performance across all datasets except for one, where our uncased version performed better. Additionally, our models performed exceptionally well on political tweets and a fact-checking site, which also featured a significant amount of political content.

Again, we used p-values to confirm the statistical significance of the differences for datasets including Arabic Classification, SANAD Alarabiya, and SANAD AlKhaleej where there were only marginal gains in F measure. We contrasted the best outcomes from our models with the baseline iterations of BERT in each experiment. In all three tasks, our models performed better, with statistical significance set at $p<0.01$.

7 Conclusion and Future Work

In this paper, we introduce ConfliBERT-Arabic, a pre-trained language model for politics, conflict and violence in Arabic-language. ConfliBERT-Arabic's development required the acquisition and curation of a sizable domain-specific corpus for the pre-training stage. We also thoroughly assessed the model's performance across a range of NLP tasks and datasets, showing that ConfliBERT-Arabic regularly outperforms BERT in the politics, conflict and violence domain, especially when working with sparse training data. Researchers and decision-makers interested in tracking, analyzing, and predicting political violence and war in the Middle East will find these findings to be of great interest. ConfliBERT-Arabic is an important advancement that will help a large community of political scientists and decision-makers as a whole.

In future work, we are planning to expand on parameters such as vocabulary size and epochs to better optimize ConfliBERT-Arabic. Additionally, applying ConfliBERT-Arabic to more challenging tasks such as understanding, inference, question answering, and uncertainty qualification is planned

Ethical Impact

To address concerns of bias in machine learning, our research employs several measures. Firstly, we utilize standard social science practices to select corpora and training data (Barberá et al., 2021). Secondly, we gather a corpus with unparalleled global coverage for the pre-training stage, which aims to reduce regional biases. Thirdly, we move beyond biases inherent in dictionary-based methods by utilizing machine learning techniques, as suggested by Wilkerson in (Wilkerson and Casas, 2017). Lastly, we use multiple coders for the training data. However, due to copyright issues, we are unable to share the raw data, which hinders the principles of FAIR data (Wilkinson et al., 2016). The overarching aim of our research is to generate accurate and reliable conflict data to prevent or mitigate harm. These data offer an objective means to comprehend and examine conflict and armed violence. Our research endeavors to produce superior data resources to fulfill this purpose.

Abstract

Generative language models achieve the state of the art in many tasks within natural language processing (NLP). Although these models correctly capture syntactic information, they fail to interpret knowledge (semantics). Moreover, the lack of interpretability of these models promotes the use of other technologies as a replacement or complement to generative language models. This is the case with research focused on incorporating knowledge by resorting to knowledge bases mainly in the form of graphs. The generation of large knowledge graphs is carried out with unsupervised or semi-supervised techniques, which promotes the validation of this knowledge with the same type of techniques due to the size of the generated databases. In this review, we will explain the different techniques used to test and infer knowledge from graph structures with machine learning algorithms. The motivation of validating and inferring knowledge is to use correct knowledge in subsequent tasks with improved embeddings.

1 Introduction

Knowledge bases (KB) are widely used for storage information used in different machine learning tasks. Knowledge bases are generally represented by knowledge graphs (KG), which store information that employ nodes (entities) and edges (relations) creating a network. This way of storing knowledge has been popularized in recent years due to it being a more expressive, versatile and scalable than traditional databases (Hogan et al., 2021).

The efficient use of knowledge stored in a KG with machine learning models is not a trivial task. Traditional machine learning models, including deep neural networks use vectors as input, while the structure of KGs is more complex and can't be simplified in a vector, due to the need for representing nodes, edges, connectivity, global relations inside the graph and features of every element (Sanchez-Lengeling et al., 2021).

Methodologies used for extracting knowledge from KGs focus on creating latent vectors with the graph information (embeddings) or using neural networks specially designed for dealing with the graph structure.

Many KBs are developed using non supervised machine learning techniques, generating massive data in the process. Those methods may cause errors when completing the KB due to false relations between nodes. Large KBs also have problems with not useful information introduced for a specific task which can be considered as noise.

2 Knowledge Graph Structure

KGs are made up of two sets of elements $G = V, E$. Where V is the set of nodes (entities) and E is the set of edges (relations). Where:

$$|V| = N, |E| = R$$

being N and R the number of entities and relations, respectively.

A knowledge graph can be classified as homogeneous or heterogeneous if nodes are of the same class or different classes, cyclic or acyclic if its possible to reach the initial node traveling between edges or no and directed or undirected if nodes are connected in one direction only or both, respectively.

There are variants from conventional graph, this is the case of hypergraphs which contains hyperedges linking more than two nodes or multigraphs which allow more than one edge between two nodes.

Graph Knowledge can be represented in many ways due to the versatility of the graph structure. A

Proceedings of Recent Advances in Natural Language Processing, pages 109–116
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_012

representation of nodes and edges connecting those nodes is necessary. More complex graphs may consider many features inside each node, nodes containing subnodes with their own relations, features for each edge, different types of edges and global features associated with the entire graph (Sanchez-Lengeling et al., 2021).

For representing the information contained in a KB, consider a head entity e_h and a tail entity e_t sharing a relation r. This is represented by a triple (e_h, r, e_t). If the entities are directly connected with the relation we consider this a ”1-hop” relation, otherwise it is called a ”multi-hop” relation. Multi-hop relations are more difficult to detect, mainly for entities with a distance of 3 hops or more. There are many tasks involving constructed KGs in NLP, most of the current research focus on entity linking, question answering (QA) and Fact Checking. The structure of triples is generally utilized for representing graph information in the lowest level. This is the general structure in query languages developed for graph databases as Cypher for databases like Neo4j and sparql for data in the Resource Description Framework (RDF) format.

3 Machine Learning Techniques

ML techniques used on KBs represent the information contained in nodes and edges in a structured format as embeddings, other models act directly over the graph structure, this is the case of Graph Neural Networks (GNNs).

We have considered three different families of models for Entity Linking according to the techniques used to perform the task. There are translational models, which consider that the different relationships between elements can be represented as displacements in space, matrix factorization models represent the relationships between entities as tensors and perform decomposition operations on the tensors to represent each entity and relationship and finally deep neural models are used to obtain the main characteristics of each possible relationship and determine whether they are truthful or encode information from nearby entities.

3.1 Translational models

3.1.1 Euclidean Space Models

Translational models express the existing relation between two entities as a translation in a vector space. Head entity *h* and tail entity *t* have a relation *r* which can translate the first entity to the second, this is the case for the first translational model, TransE (Bordes et al., 2013):

$$h + r \approx t \tag{1}$$

The loss function for creating embeddings with TransE is based on:

$$|h + r - t| \approx 0 \tag{2}$$

TransE does not deal well with complex relations, i.e relations one-to-many (1-N), many-to-one (N-1) or many-to-many (N-N). TransH improves the representation of complex relations creating a unique hyperplane for each relation between two entities (Wang et al., 2014). In this case, the relation is a vector of the hyperplane and entity vectors are translated to the hyperplane by a multiplication with a specific relation matrix(W_r).

TransR considers both entities and relations should be in different spaces. This allow different entity representations according to the relation between them (Lin et al., 2015). In this case, entities *h* and *t* from each triple are proyected in the relation space multiplying with the matrix M_r getting h_r and t_r.

TransD uses less parameters than its predecessor, this can be done using vector multiplications instead of matrices. TransD assumes two vectors for each entity and relation: the first vector (*h, r, t*) represents the meaning of the entity or relation and the second (h_p, r_p, t_p) indicates how the entity must be proyected in the relation space, is utilized to map entities in the relation space (Ji et al., 2015). For each triple there are two matrices M_{rh} (relation-head) and M_{rt} (relation-tail) for proyecting entities in the relation space.

TransD uses the same number of parameters for each specific relation. This may lead to overfitting when using more parameters than necessary (simple relations) or underfitting when there are less parameters (complex relations). In TranSparse(separate) each relation uses a sparse matrix for each entity, with different sparse degrees. This enable the use of more or less parameters depending of the complexity of the relation (Ji et al., 2015).

TransE regularization forces entity embeddings to stay inside a spherical vector space out of the range of the correct triple. The regularization used in TransE is normalization, making the magnitude of each embedding become 1 during each step of learning. This provoke a violation of equation (2), making the sum of head entity and relation not equal to tail entity. This causes major problems, warping the embeddings obtained. To solve this TorusE creates entity and relation embeddings using the same principles as TransE but in a torus space (Ebisu and Ichise, 2017).

PairRE employs paired vectors for representing complex relations. These vectors proyect entities in the euclidean space where distance is minimized if the relation is right. The main advantage of PairRE is that both paired vectors allow more versatility in the loss function, achieving a better representation of complex relations (Chao et al., 2020).

3.1.2 Complex Space Models

Even if Euclidean space models progressively improve state of the art, they still have difficulties dealing with relations of symmetry, anti-symmetry, inversion and composition. RotatE tries to solve this problem with a complex space in order to represent embeddings using Euler's identity. This way the translation from the head entity to the tail entity is a rotation (Sun et al., 2019). RotatE also changes the loss function introducing self adversarial samples, which improves the training process. The score function employed in RotatE is the the same as equation (2), but using Hadamard product instead of vector sum between head entity and relation.

RotatE is improved with more dimension spaces through relation modeling with orthogonal transformations embeddings OTE (Tang et al., 2019). OTE makes orthogonal transformations with the head and relation vectors to the tail vector, and then from the tail and relation vectors to the head vector.

Extending the idea of complex spaces, QuatE uses an hypercomplex space with 3 imaginary components *i*, *j*, *k* with the objective of having more degrees of freedom to the obtained embeddings. In this case, the scoring function utilized rotates head entity using the Hamilton product (Zhang et al., 2019).

Previous models interpret relations using only translations or rotations inside a geometric space, but not both types of movements. Whereas translationals models are not capable of represent fundamental aspects of relations as symmetry, inversion or composition, rotational models fail to deal with hierarchical relations or multiples relations between two entities. However, DualE deals with these problems using dual cuaternions (Cao et al., 2021). Dual cuaternions are built with the sum of two cuaternions ($Q = a + \epsilon b$) where a and b represent the two cuaternions. Using dual cuaternions it is possible to model embeddings with translation and rotation relations.

3.1.3 Other Non-Euclidean Space Models

Other models explore the posibility of using mathematical expresions out of the euclidean space.

ManifoldE is a model that uses non-euclidean space. It considers that translational models are algebraically ill-conceived because they generate more equations than variables to solve, leading to approximate calculations for tasks like entity linking, where there are many entity candidates for one relation. In the case of ManifoldE, it uses a principle based on a ”manifold” function for expressing the relation between two entities (Xiao et al., 2015). With this approach calculation should be exact, retrieving true candidates for each relation. ManifoldE expands the position of golden triples from one point (TransE) to a manifold using a larger dimension sphere, diminishing noise when detecting true relations between all candidates and improving embedding vectors precision. Considering a head entity and a relation, all possible tail entities are inside a manifold of greater dimension (sphere). Scoring function is obtained as the difference in distance between radius of the sphere and equation (2). ManifoldE improves their results using a hyperplane as a manifold instead of a sphere.

Hyperbolic space is ideal for modeling entities with hierarchical information due to its curvature. The problem with hyperbolic space is representing entities with different hierarchies under different relations. MuRP utilizes a *Poincaré Ball* as a hyperbolic space, creating multi-relational embeddings for each entity and relation (Balažević et al., 2019). The key of MuRP is using a hypersphere in hyperbolic space because it grows exponentially compare to euclidean space, having more space to separate each node. MuRP trains relation-specific parameters used for transforming entity embeddings through Möbius matrix-vector multiplication (in order to obtain the hyperbolic entity embeddings) and Möbius addition. The hyperbolic entity embeddings are obtained by Möbius matrix-vector multiplication projecting the original embeddings to the tangent space of the Poincaré ball transformed by the diagonal relation matrix and then projected back to Poincaré ball.

MuRP cannot encode some logical properties of relationships. It uses a fixed curvature for each relation.Although specific curvature for each relation would represent better hierarchies based on the context, it also uses only translations in the hyperbolic space. By contrast, ATTH creates embeddings in hyperbolic space using reflexions and rotations, enabling RotatE patterns to be captured, as well as considering a relation-specific curvature c_r that allows a variety of hierarchies (Chami et al., 2020). Rotations are created with Givens transformations matrices due to this model does not employ complex numbers. ATTH use entity biases in the scoring function which act as margins for triples.

Previous methods are designed for creating entity and relation representations in Euclidean, Hyperbolic or Hyperspherical space, but no one of them compare results in different spaces. Geometry Interaction Knowledge Graph Embeddings (GIE) (Cao et al., 2022) considers vectors in Euclidean (E), Hyperbolic (H) and Hyperspherical (S) spaces for head and tail entities and uses an attention mechanism over each vector in order to prioritize the space which represents better knowledge from the entity. Vectors in Hyperbolic and Hyperspherical space are logarithmically mapped to tangent space before applying attention and then features are extracted. GIE has an attention vector with a specific component for each different space both for head and tail entities inside a triple.

3.2 Tensor factorization models

Using tensors for expressing entities and relations has some advantages over translational models:

· Tensors can represent multiple relations of any order, you just need to increase tensor dimensionality.

· Previous knowledge from the problem structure is not necessary in order to infer knowledge from data.

3.2.1 Euclidean Space Models

RESCAL is the first tensor factorization model created to represent relations between entities. In this model, each matrix is constructed representing the relation between two entities, like a confusion matrix, and each matrix indicates a specific relation. The data is given as a $(n \cdot n \cdot m)$ tensor where *n* is the number of entities and *m* is the number of relations (Nickel et al., 2011). RESCAL employs the following factorization over each slice of tensor X_k:

$$X_k \approx AR_kA^T, \text{for } k = 1, ..., m \tag{3}$$

Where A is a *n* x *r* matrix containing latent-component representation of entities an R_k is an *r* x *r* matrix that models the interactions between latent components for relation *k*.

Matrix R_k is asymmetric, which is useful for considering whether a latent component acts as a subject or object, given that each entity has a unique latent-component representation even if it is a subject or object in a relation. Matrices A and R_k are computed solving the following minimization problem:

$$min\ f(A, R_k) + g(A, R_k) \tag{4}$$

Where:

$$f(A, R_k) = \frac{1}{2}(\sum ||X_k - AR_kA^T||_F^2) \tag{5}$$

and *g* is a regularization term included to avoid overfitting:

$$g(A, R_k) = \frac{1}{2}\lambda(||A||_F^2 + \sum ||R_k||_F^2) \tag{6}$$

In order to reduce training parameters in RESCAL, DistMult uses a diagonal matrix W_r instead of an asymmetric relation matrix (Yang et al., 2014). This leads to a more expressive model than transE with the same number of parameters, being as scalable as previously mentioned models but less expressive than RESCAL.

Holographic embeddings use vector circular correlation to represent entity embeddings. HolE creates holographic embeddings for represent pairs of entities(Nickel et al., 2015). Correlation makes HolE efficient to compute and scalable to large datasets. This operation can be considered as a compression of the tensor product, in circular correlation each component is a sum of a fixed partition of pairwise interactions. HolE can store and retrieve information via circular convolution and circular correlation, respectively and it also learns the embeddings of the data.

SimplE is a tensor factorization method based con *Canonical Polyadic*(CP) decomposition (Kazemi and Poole, 2018). It uses two vectors for each entity (h_e, t_e) and relation $(v_r, v_{r^{-1}})$. SimplE uses a similarity function for each triple which is the average of the CP scores for the current triple and its inverse relation triple.

TuckER is a lineal model for tensor factorization which generalizes previous tensor factorization models like RESCAL, DistMult, ComplEx and SimplE based on *Tucker decomposition*. It makes a decomposition from the binary tensor of triplets. It factorizes a tensor into a core smaller tensor multiplying one matrix for each dimension in the original tensor (Balazevic et al., 2019). In the case of TuckER, the decomposition creates a smaller tensor *W*, and matrices e_h, w_r and e_t for head entity, relation and tail entity, respectively.

3.2.2 Other Non-Euclidean Space Models

As RotatE, ComplEx uses imaginary numbers in the complex space, in this case it performs tensor factorization using Hermitian dot product, which involves the conjugate-transform on one of the two vectors multiplied. With this type of dot product, we obtain a non symmetric matrix being able to represent antisymmetric relations while maintaining linearity and low time complexity (Trouillon et al., 2016).

3.3 Deep Neural Models

Graph neural networks can encode information about neighbours from each specific node, introducing context during processing in the neural network.

3.3.1 Graph Convolutional Networks (GCNs)

The first GCN introduced generates hidden states for each node processed taking into consideration each neighbour and relation. For each GCN layer, the processed node adds information from each neighbour equally as shown in the next equation:

$$h_i^{(l+1)} = \sigma \left(\sum_{m \in M_i} g_m(h_i^{(l)}, h_j^{(l)}) \right) \quad (7)$$

Where h_i^l is the hidden state of node i for the layer l in the GCN. M_i is the set of neighbours considered for node i, g_m is a linear transformation which uses a weight matrix *W* and σ is an element-wise activation function.

The context given by graphs improves many tasks when dealing with relational data, this is the case for R-GCN, an encoder that produces a hidden state for each node considering neighbours but also specific relations (Schlichtkrull et al., 2017), in contrast with original GCN, being suitable for processing heterogeneous graphs.

3.3.2 Graph Attention Networks (GATs)

GCNs make convolutions considering equal importance among all edges in the processed graph, which may be a shallow approach for tasks where specific nodes and edges have more important information than others (Kipf and Welling, 2017). In order to solve this issue, Graph Attention Networks are introduced. GATs make a convolution considering different weights for each edge connected to a specific node and can have multiple weights associated for each edge equal to the number of attention heads (Veličković et al., 2018).

A2N uses attention mechanism with specific queries in order to generate conditioned embeddings taking into account each query with the neighborhood of a source entity (Bansal et al., 2019). A scalar attention score is generated for each neighbour and then their embeddings are aggregated generating a new source embedding $\hat{s}$. Lastly, concatenate the new source embedding with the initial and projecting it to obtain the final source embedding, **s** . In the original paper, DistMult is utilized as an attention scoring function as it allows the projection of neighbors in the same space as target entities.

The use of non-Euclidean spaces has been extended to graph neural networks as in the case of M2GNN (Wang et al., 2021). Previous models using non-Euclidean spaces only considered homogeneous relations, so they lack expressiveness in this respect. M2GNN creates a non-constant heterogeneous curvature space using new parameters in the network called curvature coefficients. The proposed architecture also makes use of attention heads to improve the accuracy obtained.

3.4 Convolutional Neural Networks (CNNs)

CNNs utilized broadly in computer vision have recently been used for entity linking. The main reason is that CNNs can solve entity linking tasks with far less parameters than previous mentioned models like DistMult. CNNs are also considered a very expressive way of representing entities and relations comparing to translational models, due to the number of features extracted with the CNN filters (Kipf and Welling, 2017).

ConvE is the first convolutional model achieving good results with entity linking tasks. It is simple, as it uses only one convolutional layer with 2D convolutions, a proyection layer to the embedding dimension and an inner product to make the entity linking prediction (Dettmers et al., 2017). The convolution is made by first concatenating the 2D vectors from the head entity and relation embeddings. Score function used for training the model is the following:

$$\phi(\mathbf{e_h}, \mathbf{e_t}) = f(vec(f(\overline{e_h}; \overline{r_r}) * w))\mathbf{W})\mathbf{e_t} \quad (8)$$

Where $\overline{e_h}$ and $\overline{r_r}$ are the 2D representations of embeddings $\mathbf{e_h}$ and $\mathbf{r_r}$ respectively. w are filters used in the convolutional layer, $\mathbf{W}$ is the matrix for projecting the data into another dimensional space for matching $\mathbf{e_o}$.

ConvKB uses a convolutional layer with 3-column matrices, where each matrix is made of the concatenation of the triple vectors (e_h, r, e_t). The features obtained after convolution are concatenated and score is obtained performing a multiplication with a weight vector **w** (Nguyen et al., 2018).

Filters used for convolution in previous models are designed arbitrarily, which can lead to a poor performance. In order to solve this problem, HypER uses a hypernetwork for determining the right filter for each relation (ević et al., 2019). A fully connected layer is used for obtaining embeddings representing head entity and relation, then the hypernetwork creates the filters of each relation embedding which will be utilized during convolution of entity embeddings. The hypernetwork proposed is a single fully connected layer. HypER uses a weight matrix that projects the results to another dimensional space in order to make the dot product between head entity and tail entity.

4 Discussion and future directions

The representation of knowledge bases as embedding vectors can be seen as a way to obtain contextualised embeddings of any knowledge base with a graph structure, such as ontologies. Furthermore, contextualized embeddings can be used beyond tasks such as entity linking or knowledge base completion by representing the latent knowledge of the knowledge bases used in the form of vectors.

Contextualised embedding vectors commonly used in natural language processing (NLP) are usually obtained from a corpus with unsupervised techniques such as Word2Vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014), using Long-Short Term Memory neural networks (LSTMs) on the text as in the case of ELMo (Peters et al., 2018) or using language models with Transformers-type architecture as BERT (Devlin et al., 2019).

With the methods explained in this paper, contextual vectors can be created taking into account as context only the graph itself and the relations existing in it without taking into consideration any corpus. This becomes even more important taking into account the current research trends within NLP focused on combining knowledge from ontologies with the latent language of language models, creating synergies with the aim of improving the state of the art in different NLP tasks, achieving explainable models or reaching competitive results with lighter models (Pan et al., 2023). It is expected that the improvement of embeddings obtained from knowledge graphs will be useful to achieve a better integration between language models and knowledge graphs.

5 Conclusions

Both in the case of translational models and in tensor factorization, there is a tendency to represent increasingly complex spaces, to the point of combining different types of spaces into one (euclidean, hyperspherical and hyperbolic) or to represent increasingly complex vector spaces (complex space, quaternions, etc.). However, in some cases it is observed that the state of the art is surpassed without necessarily increasing the complexity of the space represented; this is the case of SimplE (which achieves results similar to ComplEx) or Tucker.

Alternative spaces to the euclidean with positive or negative curvature tend to better represent some properties of entities with a smaller number of features, such as circular relations in hyperspherical spaces and hierarchies in hyperbolic spaces, allowing the creation of embeddings at a lower computational cost.

In the case of deep neural models, tests have also been carried out with positive and negative curvature spaces. In these cases, curvature is a parameter to be trained within the network.

The current state of the art is led by models that combine different vector spaces (GIE, M2GNN).

Abstract

Relationship extraction from unstructured data remains one of the most challenging tasks in the field of Natural Language Processing (NLP). The complexity of relationship extraction arises from the need to comprehend the underlying semantics, syntactic structures, and contextual dependencies within the text. Unstructured data poses challenges with diverse linguistic patterns, implicit relationships, contextual nuances, complicating accurate relationship identification and extraction. The emergence of Large Language Models (LLMs), such as GPT (Generative Pre-trained Transformer), has indeed marked a significant advancement in the field of NLP.In this work, we assess and evaluate the effectiveness of LLMs in relationship extraction in the Holocaust testimonies within the context of the Historical realm. By delving into this domain-specific context, we aim to gain deeper insights into the performance and capabilities of LLMs in accurately capturing and extracting relationships within the Holocaust domain by developing a novel knowledge graph to visualise the relationships of the Holocaust. To the best of our knowledge, there is no existing study which discusses relationship extraction in Holocaust testimonies. The majority of current approaches for Information Extraction (IE) in historic documents are either manual or Optical Character Recognition (OCR) based. Moreover, in this study, we found that the Subject-Object-Verb extraction using GPT3-based relations produced more meaningful results compared to the Semantic Role labeling-based triple extraction.

1 Introduction

Understanding unstructured texts using computational methods is considered a challenging task due to the complexity of the natural language. Holocaust testimonies are firsthand accounts provided by survivors, witnesses, and others who experienced or observed the atrocities of the Holocaust during World War II (Isuri A. Nanomi Arachchige, 2023). Holocaust testimonies also belong to the category of unstructured texts, which presents unique challenges for computational assessment. These testimonies are often emotionally charged and contain highly-sensitive and personal information which is scattered everywhere in the testimony. Moreover, Holocaust testimonies contain a range of linguistic complexities, such as archaic language, regional dialects, and highly specialised terminology related to the Holocaust, which can be challenging to parse using traditional NLP techniques.

Extracting relationships from Holocaust testimonies is essential for historians as these firsthand accounts provide valuable information about the Holocaust. By uncovering hidden connections and associations between entities from the testimonies, historians can gain deeper insights into the historical context, dynamics between individuals and groups, and the broader narrative of the Holocaust. This information helps to enhance the understanding of the events, identify patterns, and shed light on the social, political, and cultural aspects of this tragic period in history. However, existing approaches for IE in historic documents are mainly manual (reference), or a few based on advanced digitalised approaches such as OCR (Bryant et al., 2010). Recently, there have been some efforts made towards IE in historic documents using NLP (Blanke et al., 2012).

Relationship Extraction (RE) plays a crucial role in discovering meaningful connections and associations between entities from Holocaust testimonies to enhance our understanding of the historical context. However, the unstructured nature of these testimonies presents additional challenges when it comes to extracting relationships, making

Proceedings of Recent Advances in Natural Language Processing, pages 117–123
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_013

the task even more difficult for humans. Dependencies between words and phrases, captured by dependency parsing, provide valuable insights into the syntactic and semantic relationships within the text. There are many downstream applications which are based on extracted relations, such as Information Retrieval (Guo et al., 2020), Question Answering (QA) (Lan et al., 2021), and Knowledge Graph Construction (Zhang et al., 2022). A knowledge graph is a type of graph database that is designed to systematically organise and present knowledge in a structured format. In the context of unstructured data, knowledge graphs are used to extract and organise the information into a structured format using different cutting-edge NLP techniques. Further, graphical representations improve the accuracy and relevance of the search and retrieval results of information from unstructured texts. Visualising relationships between entities and events in the Holocaust using a graph enables people to identify all of the personal names, places, and locations mentioned in a collection of testimonies.

However, with recent advancements in large language models (LLMs) such as GPT3, there has been significant progress in uncovering hidden relationships within specific content (Xu et al., 2023; Haddad et al., 2023). These LLMs, trained on vast amounts of textual data, have demonstrated their capability to learn complex patterns and capture nuanced relationships between entities. LLMs have introduced a novel paradigm known as in-context learning (ICL) (Dong et al., 2022). This paradigm, as exemplified by studies such as (Brown et al., 2020), formulates NLP tasks as language generation problems, allowing the models to make predictions based on demonstrations provided within the context. Instead of relying solely on fine-tuning with labelled data, LLMs leverage the power of language generation to produce outputs such as Named Entity Recognition. The objective of this paper is to examine the performance of LLMs by employing ChatGPT on Holocaust testimonies for RE. Following are the contributions of the proposed paper.

- We evaluate the traditional dependency parser-based relation extraction method against the results of the GPT model.

- We conduct systematic analysis to provide valuable insights into the strengths and weaknesses of each traditional dependency extraction and relationships obtained from the GPT.

- We release the code of the experiments as an open-source GitHub project[1]

The rest of this paper is organised as follows. We critically analyse related work in Section 2. We present our methodology in section 3. In Section 4, we describe our experiments and report the results and Section 5 discusses the next steps of this research. Finally, a brief conclusion is provided in Section 6.

2 Related Work

In this section, we critically analyse existing research in the field of NLP for relationship extraction. We will discuss and establish the context of RE within historic documents in particular Historical testimonies. Previous studies have paid little attention to the computational approaches for information extraction in Holocaust testimonies. The valuable information embedded within these testimonies remains largely unexplored, representing a hidden knowledge source within historical data. Leeuw, D. et. al shed light on the existing digital infrastructure for Holocaust studies and underscored the significant limitations inherent in this domain (De Leeuw et al., 2018). They emphasised the pressing need for computational approaches to effectively address these challenges and overcome the limitations. Moreover, some rule-based computational approaches were performed on multi-source Holocaust victim reports to extract biographical information (Sagi et al., 2016).

To date, no study has been conducted specifically focused on identifying the relations and entities present in Holocaust testimonies. This research gap highlights the untapped potential for leveraging computational techniques. Relationship extraction is a common downstream task that is often performed in conjunction with named entity recognition in various domains, including biomedical (He et al., 2023), finance (Wu et al., 2023), and more. The goal of RE is to identify and extract meaningful connections or associations between entities mentioned in the text. According to previous studies, several approaches have been considered in identifying relationships.

[1] https://github.com/isuri97/infoextra

- **Existence of relationship between entities** classify whether a meaningful semantic relationship exists between two entities or if they are mentioned together without a specific named relationship.

- **Extracting predicate verb as relationship type** predicate does not consist of a closed set of possible classes. Any predicate verb that appears in a sentence and indicates a relationship between entities is considered a relationship type. The normalisation of relationship types is deferred for future processing or analysis.

These extracted relationships can then be used to build knowledge graphs (Milošević and Thielemann, 2023), which serve as representations of the extracted information.

The recent advancements in LLMs have led to their widespread adoption in various NLP tasks, including text classification (Sun et al., 2023). These studies have leveraged GPT models to improve the performance of text classification tasks. Furthermore, a recent study (Wan et al., 2023) explored the use of LLMs for relationship extraction. However, their findings indicate that LLMs reveal lower performance than fully-supervised baselines, such as fine-tuned BERT. Despite the application of transformer-based models in relationship extraction across various domains, there is currently a lack of annotated datasets specifically tailored for the Holocaust domain. This poses a challenge in leveraging the power of these models for extracting relationships from Holocaust testimonies and gaining domain-specific insights. Addressing this gap by creating annotated datasets tailored to the Holocaust domain would greatly contribute to the development of more accurate and contextually relevant relationship extraction models.

Despite the promising performance of LLMs in various NLP tasks, the application of In-Context Learning (ICL) for relation extraction (RE) still presents challenges. RE involves identifying the semantic relationship between two entities mentioned in a sentence, which requires a comprehensive understanding of natural language. Recent research by (Carrino et al., 2022) has explored the application of GPT3 ICL for biomedical RE and evaluated the complete dataset, suggesting that there is room for improvement in this area for domain-specific contexts.

3 Methodology

In this section, we describe the proposed pipeline employed for creating the knowledge graph. As shown in Figure 1, our proposed knowledge graph consists of four components: 1) Data processing, 2) Coreference resolution, 3) Triple extraction 4) Visualisation. After the collection of Holocaust testimonies, the coreference resolution component identifies chains of entities and pronouns that refer to the same entity. The triple extraction component extracts relation triples from the text using open information extraction techniques and lastly, extracted relationships are visualised our findings on a graph database. The details of each component are presented below.

3.1 Data Processing

The collection of documents plays a pivotal role in our project, with a specific focus on extracting information from Holocaust testimonial transcripts. Our primary objective is to gather a comprehensive set of English-language testimonies sourced from diverse Holocaust testimonial archives. To accomplish this, we have employed web scraping techniques to gather data specifically from the Wiener Library website. Subsequently, we have undertaken appropriate pre-processing steps to ensure the data is prepared for further analysis and information extraction. Table 1 refers to the list of relations that we have taken into consideration.

As discussed in the introduction, in order to experiment with how RE works with GPT3, we have processed the same set of testimonies with the GPT3 API. Due to the limitation of the GPT3 API for processing long documents, we are required to divide the documents into smaller parts. This allows us to work within the constraints of the API and effectively process the content.

Though individual testimony consists of different types of relationships bonded with the environment, for this experiment only we have chosen the following relationships which describe the survivor experiences.

Relationship Category	Relationship
Biographical	born, die, learn, live, locate
Career	work, employ, travel, return
Holocaust Events	forced, transport, evacuate, arrest, deport, kill

Table 1: List of Relations

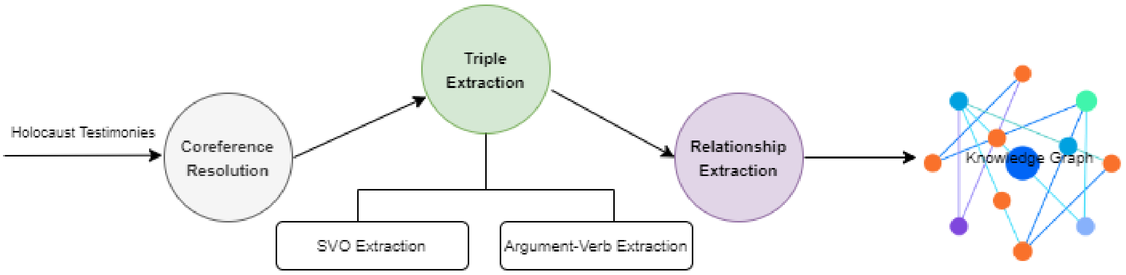

Figure 1: Proposed pipeline

3.2 Coreference Resolution

The coreference resolution component aims to identify and group together entities in natural language text that refer to the same entity. We have employed crosslingual coreference[2] Python library for this.

3.3 Triple Extraction

In this section, we conduct experiments using two methods for triple extraction and provide a detailed discussion of each method.

3.3.1 Method 01: Chunking based Extraction

From Chunking-based Extraction, we extract Subject, Object, and Verb extraction from the Holocaust testimony data. In this approach, we employed the chunking method to identify subject-verb-object (SVO) triplets to locate verb phrases, longer verb phrases and noun phrases. We define part-of-speech patterns, such as *"POS": "AUX"*, which help us identify the relevant components of the triplets. Table 2 refers to examples of method 01.

Subject	Verb	Object
Jews	taken	Auschwitz
Dr. Denes	transport	detention camp
Mrs Milman	employed	SS

Table 2: Examples for SVO Extraction (original text)

3.3.2 Method 02: Semantic Role Labelling based extraction

In this method, we employ the AllenNLP [3] model to determine the latent predicate-argument structure of a sentence and provide representations. After extraction of the Verb, we mapped with the arguments and relations defined in the sentence. To minimise the complexity of the arguments we consider only the First argument with verb either with another argument or else argument modifier. Table 3 refers to examples of method 02.

Argument	Verb	Argument1
Frau Meier	living	In 1936
Frau Morgenstern	escape	to Switzerland
Frau Gerard , a school principal	recommended	a young man

Table 3: Examples for SRL Extraction (original text)

3.4 Relationship Extraction with the GPT3

After applying the same set of testimonies to the GPT3 API, we retrieve the automatically generated relations from the model's output. To obtain these relations, we construct a prompt that describes the desired output, including the named entities specific to each testimony and the relationships observed by the GPT3 API.

3.4.1 Prompt Construction

In our approach, we create a specific prompt for each document, which is then inputted into the GPT model. The prompt is designed based on x, to provide the necessary context and information for the model to generate an appropriate response. It typically includes the following components:

Task Description x_{desc} We offer a concise summary of the task description for relationship extraction (RE) to think as a historian and present a predefined set of instructions to define Name entity tags. The task description is given as follows: *I*dentify the named entities with their named entity tags.

Demonstrations x_{demo} In the demonstration part, we reformulate each example by first showing the input prompt and then asking to generate the relation. The input prompt can be further enriched by asking to include the original

Relationship Type	Original		GPT3	
	Method 01	Method 02	Method 01	Method 02
born	1,090	3	722	0
die	3,625	10	1,504	5
learn	2,715	75	272	17
live	9,513	234	2,998	136
work	7,148	322	3,317	229
travel	3,253	97	985	57
return	2,314	3	1,090	0
transport	1,626	7	1,122	5
find	203	74	66	43
locate	856	6	885	2
employ	985	13	241	6
forced	99	12	2,170	7
evacuate	841	4	353	2
arrested	723	28	2,134	23
deport	2,015	4	1,554	4

Table 4: Frequencies of the occurrences of relations

sentences.

$$(x^1_{demo}, y1^1_{demo}, y2^1_{demo}), .., (x^n_{demo}, y1^n_{demo}, y2^n_{demo})$$

where x^j_{demo}, $1 \leq$ j $\leq$ k denotes the j^{th} input sequence and $y1^j_{demo}$, $y1^j_{demo}$ denotes the text which is remade from the label, e.g., list of named entity tag and the reformulated sentences

Test Input x_{input} Test input is the test text document needed to identify the relations. The prompt x_{prompt} for a Test input is constructed by concatenating the task description x_{desc}, a sequence of demonstrations

3.5 Visualisation in graph database

In this study, Neo4j [4] was utilised as a database management system to store and visualise the extracted relations in the form of a graph. In the triple, the subject/object pair or argument pair act as nodes in the graph and the verb act as the relation. Figure 2 illustrates the knowledge graph created for a set of triples.

4 Results and Comparative Analysis

In this section, we evaluate the results obtained from the methods described above.

We adopted the above-described methods to the original transcripts of testimonies and their GPT-derived relations. Table 4 describes the overall count of individual relationships identified according to the two methods. After obtaining the frequencies related to all relations, we manually access the relations as there is no computational method available to determine which relation is most relevant to the testimony, as a single relation may or may not be important for relationship extraction. We identified that the relations obtained using Subject-Verb-Object extraction (Method 01) have considerable random noises.

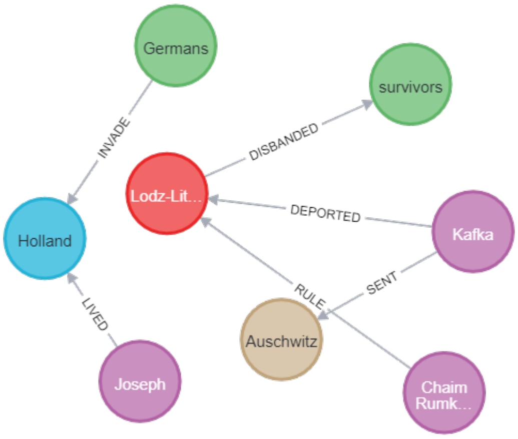

Figure 2: Knowledge graph visualisation of a sample set of triples

After conducting a comparative analysis between GPT3 results and the original testimonies relations, we identified that GPT3 results have less noise and they were properly arranged.

Furthermore, another finding from this research

[4] https://neo4j.com/

is that the Argument-Verb Extraction method (Method 02) also failed to identify many relations in the context of the Holocaust, both in the original data and in the relations generated by the GPT model. This suggests that the Argument-Verb Extraction method may not be suitable for accurately capturing the full range of relations in this specific domain.

5 Discussion and Future Works

The primary contribution of this paper is the identification of relations through dependency-based SVO extraction, semantic role labelling, and GPT prompts in Holocaust testimonial data which describe about the survivor experience. These identified relations are then visualised in a graphical format, providing a clear representation of the relationships within the data. Based on our findings, we observed that the relations generated by the GPT3 API and the triplet extraction method based on subject-verb-object were able to provide the most accurate and effective results when identifying relations in Holocaust data.

Currently, our research primarily focuses on identifying relations from individual Holocaust testimonies. However, our future plans involve expanding this work to link individual testimonies together by establishing additional relations. This broader network of relations will enable a deeper understanding of the collective experiences, interactions, and events within the Holocaust, contributing to a more comprehensive and interconnected understanding of this historical period. Moreover, we plan to extend our experiment with name entity recognition combine with RE and integrate the results got with the SVO extractions as a part of triple integration to construct an *N-to-N* knowledge graph. By integrating the extracted triples from the Holocaust testimonies and mapping the predicates to a common schema, we aim to create a comprehensive and interconnected knowledge graph. This graph will capture the relationships, associations, and connections between entities, events, and concepts related to the Holocaust.

6 Conclusion

This research, evaluates and compares the performance of traditional rule-based dependency methods for relationship extraction with the recent advancements in LLMs. Through our proposed novel knowledge graph relationships can be visualised better than baseline approaches, hence proving the usefulness of the work specifically for the historians for better synthesis and presentation of the hidden information. This study represents the first-ever investigation into the domain-specific analysis of Holocaust text data. It focuses on examining the unique characteristics and challenges presented by this specific domain in the process of relationship extraction.

Acknowledgments

This paper is dedicated to the memory of Dr Vinita Nahar, who passed away while camera-ready version of this paper was being prepared.

Impact of Emojis on Automatic Analysis of Individual Emotion Categories

Ratchakrit Arreerard, Scott Piao
School of Computing and Communications
Lancaster University
UK
{r.arreerard,s.piao}@lancaster.ac.uk

Abstract

Automatic emotion analysis is a highly challenging task for Natural Language Processing, which has so far mainly relied on textual contents to determine the emotion of text. However, words are not the only media that carry emotional information. In social media, people also use emojis to convey their feelings. Recently, researchers have studied emotional aspects of emojis, and use emoji information to improve the emotion detection and classification, but many issues remain to be addressed. In this study, we examine the impact of emoji embedding on emotion classification and intensity prediction on four individual emotion categories, including *anger*, *fear*, *joy*, and *sadness*, in order to investigate how emojis affect the automatic analysis of individual emotion categories and intensity. We conducted a comparative study by testing five machine learning models with and without emoji embeddings involved. Our experiment demonstrates that emojis have varying impact on different emotion categories, and there is potential that emojis can be used to enhance emotion information processing.

1 Introduction

In this study, we investigate the issue of how emojis can impact on the automatic analysis of emotion in social media messages. This topic has been studied over past years, but further research is needed to fully understand the characteristics of the emojis and how they contribute to the conveyance of emotion. Automatic emotion analysis is a process of identifying emotions expressed by people. In social media, the emotions can be conveyed with various media including text, emojis, pictures, or other codes.

Because social media platforms impose little or no restriction on language usage in terms of grammar and formality, social media data contains a wide range of styles and forms, including informal, colloquial, slang, and ungrammatical expressions, mixed with emojis and other images. Such an unconstrained writing styles of social media messages present a tough challenge to the task of automatic emotion processing. As Hasan et al. (2019) pointed out, the casual style and semantic ambiguity of social media messages are the main two challenges in determining emotions in such data. To improve the automatic emotion analysis, researchers started to consider emojis as additional features. For example, word and emoji embedding are combined in the hope to generate better features for emotion classification. Emojis can contain emotion information that can help to identify emotions. However, as Barry et al. (2021) found, emojis are not always a good choice for representing emotion.

In this work, firstly we carried out experiments of emotion classification of four emotion categories and emotion intensity prediction using word embeddings as the sole features based on EmoInt dataset (Mohammad and Bravo-Marquez, 2017), and used the results as a benchmark. Then, we added emoji embeddings to the word embeddings to observe how the emoji information affects the performance of the emotion analysis. Our experiment results show that, overall, adding emoji embedding can marginally improve emotion analysis for some emotion categories. We foresee that emoji embedding can potentially improve the performance of emotion analysis further if we can design better methods of combining word and emoji embeddings.

2 Related Work

Recently, emojis have been used in automatic emotion analysis. For example, Wood and Ruder (2016) grouped commonly used emojis into six emotion categories, including *anger*, *disgust*, *fear*, *happi-*

Proceedings of Recent Advances in Natural Language Processing, pages 124–131
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_014

ness, *sadness*, and *surprise*. These emojis were used as emotion labels of messages for training emotion classification models. They also created a test data by manually annotating data. Their emotion classifiers trained on the emoji-labeled dataset produced a good performance on *joy* and *sadness*, but produced slightly lower performance on the other emotion categories.

Another application of emojis is to use them to train better word embeddings (Shoeb et al., 2019) to achieve a better emotion representation. The authors extracted a new word embedding by using Mikolov et al. (2013)'s *Word2vec* model as an intermediate representation. Firstly, they collected Twitter data to train a word2vec model. Then they created a new embedding model based on cosine similarity between words and emojis. They tested emotion intensity prediction by comparing EmoTag with well-known embedding models as benchmark, such as GloVe, and found EmoTag produced similar performances to that of the benchmark.

Eisner et al. (2016a) developed an emoji embedding model named Emoji2Vec, which was trained on emoji names and keyword phrases from the Unicode emoji list. They used Google News word2vec embeddings to formulate vectors and represent emojis from their describing phrases to train Emoji2Vec. Sentiment analysis task was used to evaluate the capability of Emoji2Vec, and the result showed that Emoji2Vec improves the overall performance of sentiment analysis.

Ahanin and Ismail (2020) proposed another pre-trained emoji embedding named FuzzyMoji2Vec. They compiled a list of commonly used emojis. Then these emojis were classified into one or more emotion classes based on the correlation between emojis and emotion labels. The embedding was trained on emojis and their emotion labels. Because the number of emojis in their dataset was limited, they extended the coverage of emojis using Fuzzy Clustering to classify unseen emojis collected from Twitter. The unseen emojis were clustered based on messages classified into 11 emotions. FuzzyMoji2Vec was reported to outperform Emoji2Vec in emotion classification.

More recently, Barry et al. (2021) developed the pre-trained emoji embedding Emojional. Emojional learned emoji embedding based on keywords representing emojis collected from the online emoji dictionaries of Emojipedia and EmojisWiki. They employed Google News Word2vec to create input vectors. Then they trained the embedding by predicting the corresponding emojis from the given inputs. They evaluated the Emojional in comparison with FuzzyMoji2Vec and Emoji2Vec. They showed Emojional was generally more accurate than state-of-the-art embeddings for the sentiment analysis task.

The past research shows that emoji embedding can improve the performance of emotion analysis. However, the most past works mainly reported on overall performances. It is necessary to gain a deeper understanding of the characteristics of emojis and about how emoji embedding can affect analysis of individual emotion categories. This paper examines the impact of emoji embedding on emotion classification and intensity prediction on four emotion categories *anger*, *fear*, *joy*, and *sadness*, which are included in the EmoInt annotation.

3 Experiment Setup

3.1 Dataset for Experiment

In this study, we used EmoInt as our experiment dataset. It is a collection of tweets in English, in which each tweet is tagged with an emotion label (*anger*, *fear*, *joy*, and *sadness*) and an emotion intensity value from the range of [0, 1]. These tweets are grouped into four sub-datasets of the aforementioned emotion categories.

Table 1 shows the structure of the dataset contents. As shown, there are slightly more *fear* messages than other categories. On the other hand, the average length (number of characters) of messages under different emotion categories are roughly the same, around 95 characters. Approximately 10% of tweets in the EmoInt contain at least one emoji. Also, the messages under each emotion category contain from 61 to 93 unique emojis.

We chose this dataset for our experiment, because it contains emojis, and its generally balanced emotion category structure and manual emotion annotation, which closely match the aim of this study. Particularly, the manual annotation of emotion intensity provides very useful information for our study.

3.2 Machine Learning Model

Because our focus of this study is to assess the impact of emoji embedding on emotion classification and intensity prediction, we selected five commonly used machine learning models, including Support Vector Machine (SVM), Support Vec-

Features	Train data				Test data			
	Anger	Fear	Joy	Sadness	Anger	Fear	Joy	Sadness
Total Sentences	857	1,147	823	786	760	995	714	673
Avg. Sent. Length	91.75	97.47	94.26	96.42	94.82	96.04	93.84	95.61
Sent. with emojis	100	127	91	79	108	122	115	77
Sent. without emojis	757	1020	732	707	652	873	599	596
Total emojis	234	204	190	216	216	220	263	128
Total unique emojis	64	78	78	74	64	80	93	61

Table 1: The statistics of EmoInt dataset contents.

tor Regression (SVR), Linear Regression, Logistic Regression, and Bi-directional Long Short Term Memory (Bi-LSTM).

In further detail, we chose SVM and SVR for emotion classification and intensity prediction respectively. Similarly, we chose Logistic Regression and Linear Regression for the classification and intensity prediction. We also selected Bi-LSTM to perform both tasks.

Figure 1 illustrates the workflow of Bi-LSTM. The left workflow is used when emojis are not considered, and the right workflow is used when emojis are considered. Emoji input will be concatenated with the output from the Bi-LSTM.

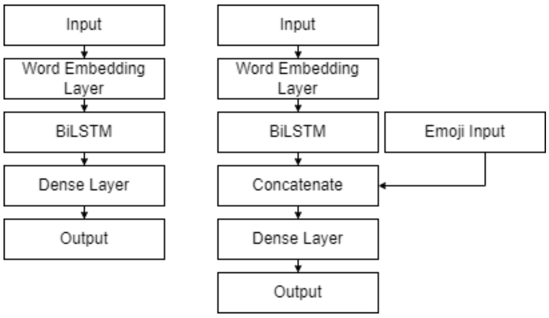

Figure 1: Bi-LSTM model for word embedding only (left) and Bi-LSTM model for word and emoji embedding (right).

We select a linear kernel for SVM and SVR. As for Bi-LSTM, we freeze the embedding layer to prevent it from adjusting weights. The loss functions for emotion classification and emotion intensity prediction are Binary Cross-Entropy and Mean Square Error respectively. As for activation functions, SoftMax and Sigmoid are used in emotion classification and emotion intensity prediction respectively.

For SVM, SVR, and Logistic Regression, *scikit-learn* (Pedregosa et al., 2011) software library was used; for Linear Regression, *statsmodels* library (Seabold and Perktold, 2010) was used; for Bi-LSTM, it was implemented using TensorFlow (Abadi et al., 2015) library.

3.3 Feature Selection

With regrades to embedding, we selected three pre-trained word embeddings: fastText(Mikolov et al., 2018a,b), GloVe(Pennington et al., 2014b,a), and BERT(Devlin et al., 2018b,a). For embedding, we selected Emoji2vec(Eisner et al., 2016b) and Emojional(Barry et al.).

As mentioned in the previous section, we selected five machine learning models with different types of inputs. For SVM, SVR, Logistic Regression, and Linear Regression, we use averaged word embedding vectors as input. Firstly, we sum the embedding vectors of the words in each tweet. Then each element value of the summed vector is divided by the number of words to generate a new vector to represent the whole tweet.

Regarding Bi-LSTM, we create word index vector and use it as input. The word index vector is created by transforming each word in the text of the tweet into an index number according to the embedding model used. This index is mapped to the embedding vector in the second layer of Bi-LSTM as shown in Figure 1.

As for emoji embedding, we use the averaging of emoji embeddings as input. Again, we sum the embedding vectors of individual emojis appear in a tweet. Then each element value of the summed vector is divided by the number of emojis present in the tweet to generate a new emoji embedding vector for the tweet.

When we combine word and emoji embeddings of a tweet for SVM, SVR, Logistic Regression, and Linear Regression, the averaged emoji embedding vector is concatenated to the counterpart averaged word embedding. For Bi-LSTM, the averaged emoji embedding vector is concatenated to the output of the third layer of Bi-LSTM, as illustrated in Figure 1.

3.4 Evaluation

We used Pearson correlation coefficient as the measurement for emotion intensity prediction, while the performance of emotion classifiers was evaluated using precision, recall, and F-measure. In our case, emotion classification is a multi-class classification task with four emotion categories. Therefore, we measured the performance for each individual class as well as the overall performance of the classifiers. However, the numbers of tweets under different emotion categories in EmoInt are not exactly the same. Thus, when calculating the overall performance metrics, we considered the ratios of numbers of the tweets under each emotion category, as shown below:

$$Precision = \sum_{e} Precision_e \times ratio_e \quad (1)$$

$$Recall = \sum_{e} Recall_e \times ratio_e \quad (2)$$

$$F1 = \frac{2(Precision \times Recall)}{(Precision + Recall)} \quad (3)$$

where,

$\sum_e ratio_e = 1$

$Precision_e$ = precision of emotion e

$Recall_e$ = recall of emotion e

4 Experiment

4.1 Emotion Classification

4.1.1 Word Embeddings as Sole Features

In the first phase of this experiment, we used only word embeddings as features for emotion classification, including BERT, fastText and GloVe. With regards to classifiers, we tested SVM, Logistic Regression and Bi-LSTM. This part of experiment aims to test the efficiency of word embeddings for emotion classification and to create a benchmark for comparing the performance of emotion classification when emoji embeddings are added as additional features.

Tables 2, 3 and 4 show precision, recall and F-measure of emotion classification for each emotion obtained with BERT, fastText, and GloVe separately.

Table 2 shows that Bi-LSTM outperformed SVM and Logistic Regression when using BERT as a feature. It achieved 65.23% precision, 64.42% recall, and 0.648 F-measure. The classifiers effectively identified tweets under *joy* with F-measure ranging from 0.597 to 0.746, but struggled to identify tweets under *sadness* with F-measure ranging from 0.477 to 0.557.

Table 3 shows, when fastText was used, Bi-LSTM also outperformed SVM and Logistic Regression. It produced 68.99% precision, 68.91% recall, and 0.69 F-measure. The classifiers performed best when identifying tweets related to *joy*, with F-measures of 0.608-0.745. However, it performed poorly for identifying tweets related to *sadness*, with F-measure ranging 0.464-0.623.

Table 4 shows the results obtained using GloVe as feature. Again, Bi-LSTM outperformed the other two classifiers. It achieved 80.44% precision, 80.30% recall, and 0.804 F-measure. The classifiers were effective in detecting tweets under *joy* category, with F-measure ranging 0.722-0.866. However, it performed poorly when detecting tweets under *sadness* category, with F-measure ranging 0.612-0.768.

The above results reveal that Bi-LSTM is the most effective classifier, and GloVe provides the most effective features. All classifiers performed well in identifying *joy* tweets, but they struggled in recognising *sadness* tweets.

4.1.2 Combining Emoji and Word Embeddings

In the second phase of the experiment, we combined word and emoji embeddings for emotion classification. With respect of emoji embedding, we tested Emoji2Vec and Emojional. Regarding classifiers, we tested three classifiers of SVM, Logistic Regression and Bi-LSTM. This part of experiment aims to test the impact of emoji embeddings on emotion classification by using the results obtained with word embeddings (see Tables 2, 3 and 4) as the benchmark.

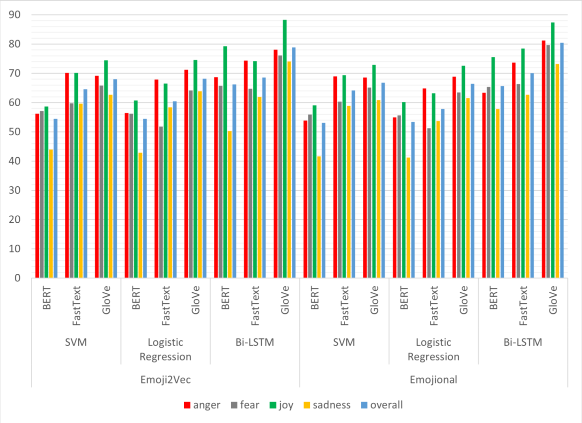

Figure 2: Precision (%) of emotion classification using word and emoji embeddings as features.

In detail, we first created word embedding features and emoji embedding features for each tweet, using the method discussed in Section 3.3. Then we concatenated each of three word embeddings (BERT, fastText and GloVe) with each of two emoji embeddings (Emoji2Vec and Emojional), obtain-

	Classifier	Metric	Anger	Fear	Joy	Sadness	Overall
BERT	SVM	Pre. (%)	58.04	56.85	58.96	44.03	54.87
		Rec. (%)	53.68	52.16	60.36	52.01	54.36
		F1	0.558	0.544	0.597	0.477	0.546
	Logistic Regression	Pre. (%)	56.23	56.09	60.78	43.56	54.51
		Rec. (%)	49.87	50.45	61.20	55.27	53.79
		F1	0.529	0.531	0.610	0.487	0.541
	Bi-LSTM	Pre. (%)	**70.09**	**63.60**	**75.57**	**51.18**	**65.23**
		Rec. (%)	**60.13**	**63.22**	**73.67**	**61.22**	**64.42**
		F1	**0.647**	**0.634**	**0.746**	**0.557**	**0.648**

Table 2: Performance of emotion classification using BERT as feature.

	Classifier	Metric	Anger	Fear	Joy	Sadness	Overall
fastText	SVM	Pre. (%)	**72.28**	60.82	71.86	60.72	66.08
		Rec. (%)	62.11	75.68	67.23	52.60	65.53
		F1	0.668	0.674	0.695	0.564	0.658
	Logistic Regression	Pre. (%)	68.24	51.43	66.56	59.22	60.60
		Rec. (%)	51.45	**79.30**	56.02	38.19	58.47
		F1	0.587	0.624	0.608	0.464	0.595
	Bi-LSTM	Pre. (%)	67.35	**66.25**	**74.58**	**68.95**	**68.99**
		Rec. (%)	**73.55**	69.65	**74.37**	**56.76**	**68.91**
		F1	**0.703**	**0.679**	**0.745**	**0.623**	**0.690**

Table 3: Performance of emotion classification using fastText as feature.

ing six new embedding vectors for each tweet. In this way, for the tweets of EmoInt, we created six sets of feature vectors, which were passed to the classifiers for emotion classification. Figures 2, 3, and 4 show the precision, recall, and F-measure of the emotion classification respectively.

As shown in Figure 2, Bi-LSTM with GloVe+Emojional achieved the best overall precision of 80.43%. In terms of individual emotions, all classifiers except Logistic Regression (with fastText+Emojional and fastText+Emoji2Vec) yielded the best precision for detecting *joy* tweets compared to other emotion categories, and the best precision (88.29%) was produced by Bi-LSTM with GloVe+Emoji2Vec.

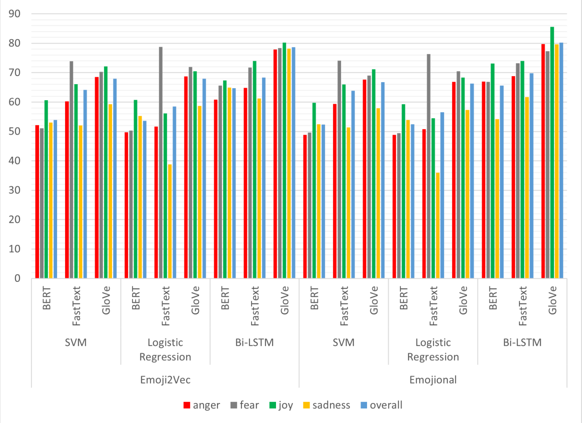

Figure 3: Recall (%) of emotion classification using word and emoji embeddings as features.

Figure 3 reveals that Bi-LSTM with GloVe+Emojional yielded the best overall recall of 80.27%. Regarding individual emotions, twelve and six classifiers produced the best recalls for the *joy* and *fear* categories respectively. Again, Bi-LSTM with GloVe+Emojional achieved the best recall of 85.57% for classifying *joy* tweets.

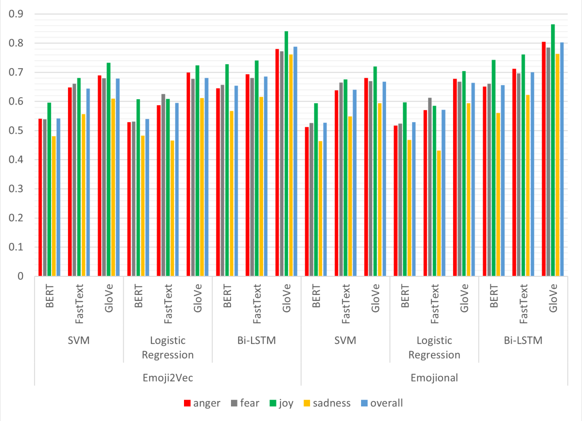

Figure 4: F-measure of emotion classification using word and emoji embeddings as features.

Figure 4 shows that Bi-LSTM with GloVe+Emojional produced the best F-measure of 0.803. As for individual emotions, all classifiers except Logistic Regression (with fastText+Emojional and fastText+Emoji2Vec) achieved the best F-measures for detecting *joy* compared to other emotion categories, and Bi-LSTM with GloVe+Emojional yielded the best F-measure of 0.865.

The experiment results reveal that Bi-LSTM with the combination of Emojional with either BERT or fastText can improve overall F-measure by up to 0.010. The best performance of emotion classification was obtained by using Bi-LSTM with GloVe+Emojional embedding vectors. But emoji embeddings do not always improve emo-

	Classifier	Metric	Anger	Fear	Joy	Sadness	Overall
GloVe	SVM	Pre. (%)	69.36	65.88	74.46	63.03	68.06
		Rec. (%)	68.82	70.05	71.85	60.03	68.01
		F1	0.691	0.679	0.731	0.615	0.680
	Logistic Regression	Pre. (%)	71.16	64.15	75.08	63.77	68.24
		Rec. (%)	68.82	72.46	69.61	58.84	68.01
		F1	0.700	0.680	0.722	0.612	0.681
	Bi-LSTM	Pre. (%)	**79.92**	**76.92**	**88.69**	**77.49**	**80.44**
		Rec. (%)	**78.03**	**81.71**	**84.59**	**76.23**	**80.30**
		F1	**0.790**	**0.792**	**0.866**	**0.768**	**0.804**

Table 4: Performance of emotion classification using GloVe as feature.

tion classification. For example, in our experiment, Emojional slightly degraded the classification result when it was added to GloVe for Bi-LSTM classifier.

4.2 Emotion Intensity Prediction

4.2.1 Intensity Prediction with Word Embedding

As mentioned earlier, one of our main aims of this study is to test how emoji embeddings can impact on emotion intensity prediction. For this purpose, we needed to create a benchmark for comparison, by involving only word embeddings. We followed similar process as that of emotion classification mentioned in section 4.1.1, only using word embeddings for emotion intensity prediction, including BERT, fastText and GloVe. For each of the three embeddings, we tested three prediction models of SVR, Linear Regression and Bi-LSTM. We used Pearson correlation coefficient to compare the automatic emotion intensity prediction results against the manual annotation in the EmoInt as gold standard.

Table 5 presents the evaluation results for BERT, fastText and GloVe. In the table, the codes *SVR*, *LR*, *BI* refer to Support Vector Regression, Linear Regression, and Bi-LSTM respectively. In addition, the codes *A*, *J*, *F* and *S* refer to *anger*, *joy*, *fear*, and *sadness*. An additional code *M* is used to refer to *mean coefficient score*. (Same codes are used for Tables 6 and 7)

As shown in the table, Bi-LSTM with GloVe achieved the highest overall performance, with 0.47 coefficient. In terms of individual emotions, all prediction models were relatively effective in predicting intensity value for *fear* and *sadness*, with coefficients ranging 0.38-0.54 and 0.36-0.58 respectively. On the other hand, all prediction models yielded the lowest performance in predicting *joy* intensity, with coefficients ranging from 0.13 to 0.35.

4.2.2 Intensity Prediction by Combining Emoji and Word Embeddings

Based on the experiment discussed in the previous section, we combined word and emoji embeddings (Emoji2Vec and Emojional) for extended features, following the same twitter embedding vector creation process mentioned in section 4.1.2. Then we applied three prediction models, SVR, Linear Regression, and Bi-LSTM on the feature vectors of tweets in the EmoInt.

This part of experiment aims to test the efficacy of emoji embedding on emotion intensity prediction, with the results obtained with only word embedding (see Table 5) as the benchmark. Tables 6 and 7 show the evaluation results for Emoji2Vec and Emojional respectively.

As shown in Table 6, Bi-LSTM with Emoji2Vec+GloVe yielded the highest overall Pearson correlation coefficient of 0.47. When it comes to individual emotions, all prediction models are relatively effective in predicting *fear* and *sadness* intensity values compared to *anger* and *joy*, with coefficients ranging between 0.38-0.55 and 0.37-0.57 respectively. On the other hand, all prediction models produced the lowest coefficients in predicting *joy* intensity compared to other categories, ranging from 0.10 to 0.36.

Table 7 shows that Bi-LSTM with Emojional+GloVe produced the highest overall coefficient of 0.48. Regarding individual emotions, all prediction models effectively predicted intensity values of *fear* and *sadness* compared to other emotion categories, with coefficients ranging from 0.38-0.56 and 0.38-0.58 respectively. On the other hand, all prediction models produced the lowest performance for *joy*, with coefficients ranging from 0.10 to 0.31.

As shown in our evaluation results, adding emoji embedding has improved the ability to predict intensity level of *anger*, *fear* and *sadness*. Before emoji embeddings are added, the coefficients of emotion intensity prediction range from 0.30-0.47 for *anger*, 0.38-0.54 for *fear*, and 0.36-0.58 for

		A	F	J	S	M

	LR	*0.26*	*0.38*	*0.10*	*0.37*	*0.28*
	Bi	0.40	0.43	0.11	0.38	0.33
GloVe	SVR	0.34	0.45	0.22	0.53	0.39
	LR	0.28	0.42	0.25	0.42	0.35
	Bi	**0.49**	0.52	0.31	**0.57**	**0.47**

Table 6: Evaluation statistics of emotion intensity prediction with combination of word and Emoji2Vec embeddings.

sadness. After adding emoji embedding, the coefficients for these categories are marginally increased by up to 0.03. On the other hand, emoji embedding slightly degraded performance in predicting intensity of *joy*. Such a result indicates that emojis can generally be helpful in conveying intensity level of *anger*, *fear* and *sadness*, but they may be less relevant to intensity level of *joy*.

Our experiment showed that classifiers are less effective for *sadness* compared to other categories. We checked emotion words in each sub-dataset of EmoInt by looking up the NRC Emotion lexicon (Mohammad and Turney, 2013). We found that *anger* words are more likely to appear in *anger* messages, and similar case for *fear* and *joy* words. On the other hand, We found similar numbers of *anger*, *fear*, *joy*, and *sadness* words appear in the *sadness* sub-dataset. We speculate such an even distribution of emotion words in the *sadness* sub-dataset can be the cause of the difficulty of detecting *sadness* messages.

Regarding emotion intensity prediction, we found that the intensity prediction models performed poorly for *joy* compared to other categories. We checked some samples from the *joy* sub-dataset and observed that some emojis with opposite emotions co-occurred within same tweets, such as ”U+1F602” (face with tears of joy) and ”U+1F62D” (loudly crying face). In addition, emojis of *joy* appeared in messages classified under other categories. This may have caused the difficulty of predicting emotion intensity for *joy*.

		Emojional

Table 7: Evaluation statistics of emotion intensity prediction with combination of word and Emojional embeddings.

5 Conclusion

In this paper, we reported our study which aims to study the impact of emoji embeddings on emotion classification and intensity prediction in social media messages, using the EmoInt as our training and test dataset. We examined the performance of five machine learning models with all possible combinations between a set of three word embeddings (fastText, GloVe, BERT) and two emoji embeddings (Emoji2Vec and Emojional). We compared the results obtained with and without emoji embeddings to assess the impact of emoji embedding on analysing individual emotion categories. Because the EmoInt dataset only contains annotation of four emotion categories (*joy*, *anger*, *fear* and *sadness*), our study focused on these categories.

In our experiment, we tested 18 different combinations of $\{$classifier + word_embedding + emoji_embedding$\}$. We observed improvement on emotion classification for *fear* in six cases, for *joy* in five cases, and *anger* and *sadness* in four cases. As for emotion intensity prediction, the improvements was observed for *fear* in eight cases, *sadness* in seven cases, *anger* in four cases, and *joy* in one case. Therefore, it is a mixed picture how emojis can improve the automatic emotion analysis.

We acknowledge our results are not conclusive, as we used simple embedding combination methods, and only a small portion of tweets in EmoInt contain emojis, making it difficult to examine the impact of emoji embeddings in further details. For future work, we aim to explore larger emoji embedding datasets and more embedding combination techniques.

Abstract

This paper examines the effectiveness of different feature representations of audio data in accurately classifying discourse meaning in Spanish. The task involves determining whether an utterance is a declarative sentence, an interrogative, an imperative, etc. We explore how pitch contour can be represented for a discourse-meaning classification task, employing three different audio features: MFCCs, Mel-scale spectrograms, and chromagrams. We also determine if utilizing means is more effective in representing the speech signal, given the large number of coefficients produced during the feature extraction process. Finally, we evaluate whether these feature representation techniques are sensitive to speaker information. Our results show that a recurrent neural network architecture in conjunction with all three feature sets yields the best results for the task.

1 Introduction

The aim of this study is to investigate the efficacy of feature representations of audio data in accurately classifying discourse meaning in Spanish. The task involves determining whether an utterance is a declarative sentence, an interrogative, an imperative, etc. Since there does not seem to be an agreed upon name for this task, we will refer to it as discourse meaning (rather than referring to a broader sense of this term).

In human perception, this process involves the comprehension of the relationship of words, phrases, and clauses used in a sentence, as well as their overall contribution to the intended meaning of the sentence. We focus on the prosodic features of different discourse meanings in Spanish. Pitch, or the perceived highness or lowness of a sound, can play a role in distinguishing between different discourse meanings. For example, declarative sentences typically present a falling pitch contour, indicating that the statement is complete, while interrogatives usually have a rising contour, signaling that a question is being asked.

In contrast to tonal languages such as Mandarin Chinese, Thai, or Punjabi, which mark the phonological contrast of pitch at the lexical level (word level), intonational languages such as Spanish or English mark the phonological contrast of pitch at the utterance level. For Spanish, pitch movements are mainly used to signal discourse meaning or to mark focus. The properties that govern production in intonation are structurally analogous to those that govern lexical tones and morphological paradigms (Ladd, 2008). This means that a declarative statement like *María viene* 'María is coming' and its interrogative counterpart *¿María viene?* 'Is Maria coming?' differ only in the intonational contour with which they are produced, since both are syntactically and lexically identical.

1.1 Research Questions

Our study focuses on three main research questions:

RQ1: How do we represent intonation as features in discourse-meaning classification for Spanish?

RQ2: Do different feature representations convey distinct types of information?

RQ3: Are these feature representation methods sensitive to speaker information, or do they abstract away from this information?

RQ1 addresses the question of how pitch contour information can be represented for a discourse-meaning classification task using speech data of Spanish. We focus on three different audio features widely used in speech recognition and classification tasks such as emotion recognition (Badr et al., 2021; Issa et al., 2020; Zhou et al., 2019): Mel Frequency Cepstral Coefficients (MFCCs), Mel-scale

Proceedings of Recent Advances in Natural Language Processing, pages 132–142
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_015

spectrograms, and chromagrams. We also evaluate the effectiveness of using mean values of each band as opposed to all frequency measures. Utilizing means may be efficient when representing the speech signal for a discourse-meaning classification task, given the large number of coefficients produced during the feature extraction process.

RQ2 is concerned with the differences between the three audio feature representations. If they convey different types of information, we expect to see improvements in classification by using combinations of representations. MFCCs, generally considered one of the most effective type of feature in audio classification tasks (Dave, 2013; Xie and Liu, 2006), discard a significant amount of information by a low-rank linear projection of the Mel spectrum. Thus, Mel spectrograms and chromagrams may provide information that is no longer present in MFCCs.

RQ3 examines potential speaker effects in our data. Specifically, we investigate if there are individual differences in how people produce the intonation curves for distinct discourse meanings, and whether the feature representations are sensitive to those differences; i.e., whether these audio representations can generalize across different discourse meanings, or if there is any overlap that could lead to bias in the classification process.

The remainder of the paper is organized as follows: Section 2 outlines previous research on Spanish intonation and modeling intonation in other languages. Section 3 details the methodology utilized in this study, including information about the corpus, the algorithms, the feature extraction processes, and hyperparameter optimization. Sections 4 – 6 present the results for the three research questions. Finally, Section 7 outlines our conclusions and future work.

2 Related Work

2.1 Spanish Intonation

Spanish sociophonetic research (Face, 2001, 2005, 2008, 2004; Estebas-Vilaplana and Prieto, 2010; Quilis, 1993) describes the pitch contours used by speakers in different dialectal areas. The majority of intonation studies conducted in Spain are descriptive, with a focus on describing the intonational contours of certain regions. Many of these studies have relied on elicited speech to analyze these productions (e.g., Estebas-Vilaplana and Prieto, 2010), while others have adopted a corpus approach (e.g., Torreira and Floyd, 2012). However, it remains to be explored how generalizable these contours are, and whether machine learning techniques can be applied to extract information about intonation and automatically classify discourse meaning.

2.2 Speech Classification

The automatic detection and classification of discourse meaning has been the focus of many recent studies in speech classification. Prosody modeling has been particularly important in English and other languages, with research focused on detecting prominence and phrase boundaries (Levow, 2005). Researchers have explored incorporating context into feature-level recognition of prosodic events (Mishra et al., 2012), as well as normalizing features by immediate context when detecting and classifying prosodic events (Rosenberg, 2009, 2010, 2012). Sequential models have also been used to examine prosodic modeling, with some studies attempting to predict prominence and phrasing at the syllable and word level using models based on normalized segment duration and pauses (Wightman and Ostendorf, 1994; Ananthakrishnan and Narayanan, 2005).

Additionally, modeling F0 contours has been explored; some of them attempted to model F0 contours directly (Bailly and Holm, 2005; Fujisaki, 1983; Hirst and Espesser, 1993; Kochanski and Shih, 2003; Ni et al., 2006; Pierrehumbert, 1981; Taylor, 2000; Van Santen and Möbius, 2000), while others simulated the underlying mechanisms of F0 production (Chodroff and Cole, 2019; Cole et al., 2022). Most recent studies have used deep learning models such as LSTM neural networks (Zeyer et al., 2017; Sundermeyer et al., 2012), and multimodal deep learning approaches that combine audio and text inputs to achieve high performance on speech intention classification tasks (Gu et al., 2017; Agüero and Bonafonte, 2004). However, more research is needed to explore how different machine learning approaches can be used to model intonation in languages such as Spanish.

3 Methodology

3.1 Corpus

For our experiments, we collected a scripted speech corpus[1] that was designed for the analysis of Span-

[1] https://github.com/sarroniz/speech_corpus

ish intonation under laboratory conditions, to exclude factors such as the length of utterances, differences in lexical content, noise in the signal, etc. The reading task included six different types of discourse meaning, each having a total of twenty examples. The elicited discourse meanings (Hualde and Prieto, 2015) are described below, the corresponding schematic representation of the contours are shown in Figure 1.

Broad Focus Declarative Statements are the most common type of discourse meaning. They are used to bring every element in the sentence into focus, so there is no emphatic element in the utterance (e.g., *Juan compra pan* 'Juan buys bread'). The syntactic structure in Spanish is usually subject (S), verb (V), and complements (C).

Narrow Focus Statements selectively focus on one part of the sentence (e.g.: *Juan compra pan* 'Juan buys bread' as the answer to the question *¿Quién compra pan?* 'Who buys bread?', where *Juan* is focused information). The syntactic structure is usually SVC.

Absolute Interrogatives are used to request a yes/no answer from the interlocutor. Spanish yes/no questions have the same syntax as broad focus statements, and require intonation to convey interrogativity in the absence of contextual cues. Unmarked questions may omit the inversion of the subject, but it is often omitted (e.g., *Compran pan* 'They buy bread' vs. *¿Compran pan?* 'Do they buy bread?').

Partial Interrogatives are interrogative sentences that convey interrogativity directly through the presence of a question word, without the need for intonational signaling (e.g.: *¿Quién viene a la fiesta?* 'Who is coming to the party?'). Unmarked partial interrogatives in Spanish can share the same intonation pattern as broad focus statements.

Exclamatives are utterances with an exclamative nuance and show an initial peak in the nuclear accent that aligns within the accented syllable (e.g.; *¡Qué mañana tan bonita!* 'What a lovely morning!').

Imperatives in Spanish are often highly exclamatory, resulting in an expanded pitch range, greater intensity, and longer duration. Their intonation patterns can vary and are not necessarily linked to specific geographic regions. Imperatives are often represented by final pitch accents.

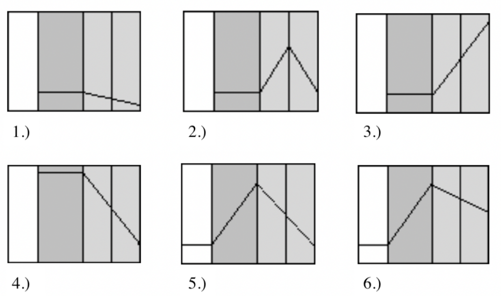

Figure 1: Schematic representations of the contours in Spanish for the six types of discourse meaning (Estebas-Vilaplana and Prieto, 2010).

We collected samples from nine different speakers (seven from southern Spain, and two from the Madrid area). In total, 1 080 different speech productions (9 speakers * 6 types of discourse meanings * 20 examples) were used for our experiments, with an average duration of 1.159 seconds[2]. For all of the audios, the corpus includes information about demographic information of the speakers (such as age, gender, level of education, time spent out of their place of birth, etc.), plus the type of discourse meaning.

3.2 Classifiers

We experiment with different classifiers using the *scikit-learn* library (Pedregosa et al., 2011): support vector machines (SVC), Random Forest, k-nearest-neighbors (kNN), decision trees, and a multilayer Perceptron (MLP). We use grid search cross-validation to optimize hyperparameters.

Additionally, we experiment with Long Short-Term Memory (LSTM) recurrent neural networks, both unidirectional and bidirectional, using *Keras* in TensorFlow[3]. The model takes input in the form of a 1-dimensional sequence, where the length of the sequence is determined by the number of features in the input data. Three convolutional layers are stacked; each layer consists of a convolutional operation followed by batch normalization, activation (using the ELU activation function), max pooling, and dropout. The LSTM layer was added with 64 units. We set the model to return sequences rather than just the last output. We also use a softmax activation function in a fully connected dense layer. We follow the hyperparameter optimization by Zeyer et al. (2017) for acoustic modeling in

[2] Only sonorant segments were included (no occlusives), resulting in a continuous, uninterrupted pitch signal.

speech recognition.

For the optimal hyperparameters used in the experiments, see the Tables in appendix A.

3.3 Feature Extraction

We use three different audio feature representations: *Mel-Frequency Cepstral Coefficients (MFCCs)*, *Mel spectrograms*, and *chromagrams*. MFCCs are commonly used in speech recognition systems (Dave, 2013) and represent the spectral envelope of speech, while Mel spectrograms are a spectral representation of audio signals where the frequency scale is warped to better match human auditory perception. Chromagrams, in contrast, are a type of harmonic feature that capture the pitch content of an audio signal by projecting the frequency content onto a set of pitch classes.

All three feature sets are extracted using *librosa* (McFee et al., 2015), a Python library for audio analysis and feature extraction. We start by extracting the Short-Time Fourier Transform (STFT) of each audio sample. By computing the Fourier transform on each segment, multiple power spectrograms are produced for each audio file. The frame size and hop size are set to default in librosa ('n_fft=2048' and 'hop_length=512'). Figure 2 shows two examples of the STFT power spectrograms.

Mel-Frequency Cepstral Coefficients We use triangular, overlapping window functions (Hanning function) on the STFT power spectra and compute the energy within each window. Then we map the frequencies to the Mel scale. After testing a range of coefficients for MFCCs (10, 20, 40, and 60), we choose 40 since it proved optimal during optimization. Figure 3 shows two examples of the MFC coefficients representations. Positive MFCCs correspond to low-frequency regions of the cepstrum, and negative MFCCs represent high-frequency regions.

Mel Spectrogram Mel spectrograms convert the frequency axis of a spectrogram to a non-linear Mel scale, which is based on the human auditory system's response to frequency[4]. Mel frequencies are logarithmically spaced, and equal distances on the Mel scale correspond to equal perceptual differences in pitch. We generate Mel spectrograms using a filterbank of triangular overlapping filters that sum to 1 over the frequency axis of the spectrogram. The resulting coefficients represent the energy in a particular Mel frequency bin at a specific time. Figure 4 shows two examples of Mel spectrograms.

Chromagrams provide a mapping of the audio signal to pitch classes over time, i.e.; CDEFGAB plus five semitones (Birajdar and Patil, 2020). Chromagrams are computed by grouping the STFT coefficients into 12 frequency bands, resulting in a 12-dimensional feature vector for each time frame. Figure 5 shows two examples of chromagrams.

[4] Mel spectrograms are similar to MFCCs, the difference stems from the use of a nonlinear Mel-scale frequency axis instead of the linear frequency axis of traditional spectrograms.

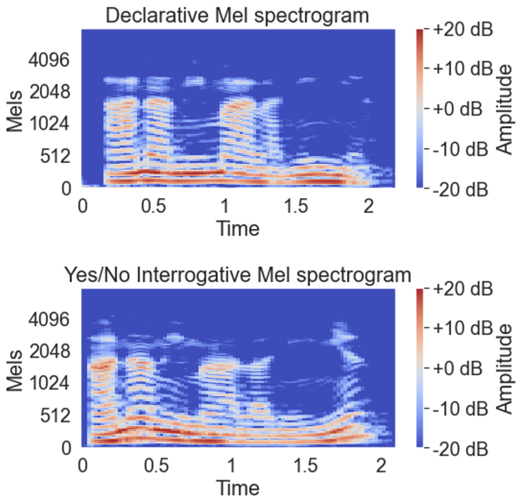

Figure 4: MEL frequency spectrograms, for a broad focus declarative sentence (top) and an absolute yes/no interrogative sentence (bottom).

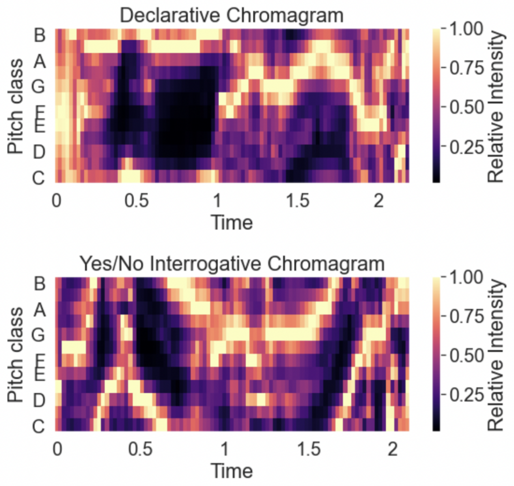

Figure 5: Chromagram examples for a broad focus declarative sentence (top) and for an absolute yes/no interrogative sentence (bottom).

Features	All values (N)	Means (N)
MFCC	7 840	40
Mel Spectrogram	23 936	128
Chromagram	3 812	12

Table 1: Distribution of the number of coefficients for each feature set for each audio sample when using a) all the values provided by STFT, and b) the means of those values for all the frames along the time axis.

3.4 Data Normalization and Scaling

After creating matrices of the three feature sets under consideration, we scale the resulting features, standardizing the different coefficients so that they have zero mean and unit variance (using *StandardScaler* in scikit-learn).

4 RQ 1: Exploring Audio Feature Representations

The first research question (RQ1) investigates the effectiveness of the three representations of the audio signal: MFCCs, Mel-scale spectrograms, and chromagrams. Our goal is twofold: 1) to investigate whether the three audio features are effective in capturing the necessary information to classify pitch based on discourse meaning, and 2) to assess whether the use of mean values, as opposed to all values, is a more efficient method for capturing this information.

Since the number of frames produced by STFT varies based on the length of each audio file, the exact number of all the coefficients for each feature set varied accordingly. Therefore, to ensure uniformity, we padded with zero values such that each file had the same number of coefficients as the longest file. Specifically, we set the number of coefficients to MFCCs=7,840; Mel spectrograms=23,936; chromagrams=3,812 (see Table 1). In the case of means, we generated a matrix back from each extraction process, and computed the mean of those matrices to obtain a single feature array for each speech sample. We obtained a total of 180 features for each array, distributed as follows (see Table 1): MFCCs=40; Mel Spectrograms=128 (number of Mel frequency bands); chromagrams=12 (one per pitch class).

We performed a stratified, randomized 9-fold cross-validation for each of the experiments in order to compare these results with those for RQ3 below (we had 9 speakers in our corpus).

4.1 Results and Discussion

The results for RQ1 are shown in Table 2. Overall, we see that the performance of the algorithms varies significantly depending on the feature type used. Among the algorithms tested, the LSTM models perform the best when using the feature types Mel spectrograms and chromagrams while the MLP outperforms both LSTM models when using MFCC, reaching the highest accuracy of 82.64% (using means).

In terms of feature types, MFCCs and Mel spectrograms outperform chromagram features across all classifiers. MFCCs yield the highest accuracy for every algorithm (ranging from 35.08% to

Classifier	MFCC		Mel		Chrom	
	means	all	means	all	means	all
Random Forest	58.91	36.65	56.95	27.50	42.29	39.06
KNN	69.79	37.75	63.54	22.13	47.01	44.53
SVC (linear)	68.55	38.53	54.49	21.86	39.65	41.80
SVC (RBF kernel)	53.34	37.31	50.35	21.91	43.14	40.36
Decision Tree	53.32	35.08	51.89	23.40	41.15	37.47
MLP	**82.64**	40.10	59.13	34.90	42.25	57.92
LSTM	79.16	54.17	63.14	37.50	50.64	29.17
BiLSTM	80.55	45.83	**68.33**	45.83	**54.72**	41.67

Table 2: Results for the different combination of audio representations for each model.

82.64%), followed by Mel spectrograms (ranging from 21.86% to 68.33%), whereas chromagram features yield the lowest accuracy (ranging from 29.17% to 54.72%). When considering all the features, the LSTM model with MFCCs using means achieved the highest accuracy (82.84%), while the LSTM model with chromagram features using means result in the lowest accuracy (29.17%).

In general, the use of means provides better results than using the individual values extracted from STFT frames, with around 20-30% of improvement in most cases. The only exceptions are the linear SVC and MLP used with chromagrams, which see a slight decrease in their accuracy when using means instead of all the coefficients (e.g., from 41.80 to 39.65 for the linear SVC).

Using the means of the values in MFCCs can be beneficial because it reduces the dimensionality of the feature set, making it less prone to overfitting and noise. Using mean values captures essential information in the audio signal while avoiding noise and irrelevant variations in individual frames. Mean values also provide more global information about the signal. For chromagrams, this approach may be more effective due to their high dimensionality and the need to capture harmonic and inharmonic relationships between musical notes, while also mitigating overfitting and computational complexity issues.

The findings of this experiment indicate that employing means of MFCC features in combination with an MLP yields the most effective classifier for the precise categorization of discourse meaning in Spanish. However, further investigation is required to understand the specific information conveyed by each feature, and whether combining them will lead to an improvement in classification performance.

5 RQ2: Comparing Information Content of Audio Features

RQ2 investigates whether the three audio feature representations convey different types of information. While MFCCs have been shown to be the most effective for the audio classification tasks for RQ1, their reliance on a low-rank linear projection of the Mel spectrum may lead to information loss. Thus, we explore the possibility of enhancing the discriminatory power of MFCCs by incorporating additional representations, such as Mel spectrograms or chromagrams, which may convey complementary information. If the combinations of audio features provides a full set of information, we expect increased classification results.

We focus on means for each feature type since their use resulted in higher accuracy for RQ1. We replicate the methodology of the previous experiment using the same data split as above.

5.1 Results

Table 3 shows the results from this experiment (for ease of comparison, we repeat the 'means' results from Table 2). Overall, the results show that the combination of features has a significant impact on classification accuracy, either positive or negative: When combining MFCCs and Mel spectrograms, all classifiers profit from the addition of Mel spectrograms in comparison to using only MFCCs. In this setting, MLP reaches the highest accuracy of 83.80%. In contrast, adding chromagrams to MFCCs results in a decrease in accuracy for all models, except for the LSTMs, which show an increase in accuracy from 80.55% (MFCC) to 81.94% for the combined-features model (for the biLSTM). However, this is still minimally lower than the MLP's results using this combination of features.

Classifier	MFCC	Mel	Chrom	MFCC+Mel	MFCC+Chrom	Mel+Chrom	All
Random Forest	58.91	56.95	42.29	60.99	58.57	58.80	60.34
KNN	69.79	63.54	47.01	70.70	66.67	66.93	71.70
SVC (linear)	68.55	54.49	39.65	70.77	65.88	58.72	70.90
SVC (RBF)	53.34	50.35	43.14	54.95	51.51	53.30	55.03
Decision Tree	53.32	51.89	41.15	55.05	52.31	53.35	53.97
MLP	**82.64**	59.13	42.25	**83.80**	**82.18**	65.05	**84.61**
LSTM	79.16	63.14	50.64	82.86	79.62	66.20	83.14
BiLSTM	80.55	**68.33**	**54.72**	81.75	81.94	**68.89**	83.05

Table 3: Results for the different combination of audio features per classifier.

When we combine Mel spectrograms with chromagrams, we observe a slight increase in accuracy of around 3-5% for most classifiers over the performance of the individual models. However, even the best model (using the biLSTM, reaching 68.89%) is about 11.5% lower than when combining the biLSTM with MFCCs (80.55%).

The performance of the combination of all three feature types is generally very close to that of the MFCC+Mel combination, thus showing that chromagrams do not add much additional information to the mix. Most classifiers profit minimally from the addition of chromagrams. The only exceptions are the random forest, and the decision tree. The biLSTM reaches the highest performance overall with an accuracy of 84.68%.

The results from this experiment indicate that combining MFCCs and/or Mel spectrograms with chromagram features can enhance the accuracy of our classification tasks. Chromagrams capture distinct information from MFCC and Mel spectrograms, and while they do not have enough discriminative power on their own, they introduce some new information to the other features. However, not all classifiers can profit from the addition of information, we see an intricate interaction of classifier type, feature type, and performance.

6 RQ3: Analyzing Speaker Effects

RQ3 investigates the impact of speaker effects on the classification of discourse meaning. Our objective is to examine whether there exist individual variations in how people generate intonation curves for different types of sentences and whether these differences are captured by the three feature representations.

We replicate the previous experiments while employing a leave-one-out cross-validation approach where each fold corresponds to one speaker. Since the model has not seen any data from the test speaker, a deterioration in this setting will indicate that the features types include speaker specific information.

6.1 Results and Discussion

Results for the experiment with individual features are shown in Table 4, while Table 5 shows the results for the combination of features. Columns labeled ‘Random’ show the results from RQ1 and RQ2 for reference, and columns labeled ‘Speaker’ show the results when we split by speaker.

The results in Table 4 show the expected pattern, the results when leaving out a speaker are generally lower than the corresponding random settings. The only exception is for the MLP using Mel spectrograms, for which the results improve marginally (from 59.13% to 59.26%). The smallest decreases occur when using the MFCC and non-neural methods. The results of the LSTMs decrease by more than 10% absolute with all feature types, even when using MFCCs. For the Mel spectrograms and chromagrams, these losses are more similar to those of the non-neural classifiers, which also suffer significant losses. The highest results are once again obtained when using the MLP with MFCCs, reaching 81.13%, which is only slightly lower than the 82.64% in the corresponding random setting.

The results for the combination of features in Table 5 show the same trend: Splitting the data by speaker causes slight to significant losses across the different classifiers and feature combinations. The same combinations that work well for the random data split also work well for the speaker setting. We obtain the best results using the MLP with all features (84.49%).

Overall, these results show that, as expected, there is speaker dependent information present in the features. If we do not have access to an example

from a speaker, the task is more difficult. However, it is less obvious why this affects the MLP and the non-neural method (using MFCCs) only mildly but the LSTMs and the other features to a much higher degree. This will require a more in-depth analysis.

7 Conclusion and Future Work

In this paper, we investigated the efficacy of various audio input representations for accurately classifying discourse meaning in Spanish. We explored pitch contour representation using three audio features and compared the efficiency of utilizing means with different algorithms. We also evaluated if these features convey different information and their generalizability across speakers. Our findings suggest that using a combination of the three features with a recurrent neural network architecture provides the best results for our discourse-meaning classification task.

We also found that there is speaker specific information represented in the features, and that that combination of MLP and MFCCs is much more robust in a setting where we test on an unknown speaker than the other combinations. We will need to have a closer look to understand better why this is the case.

We are also planning on extending the corpus to include more speakers, and to balance it for dialects.

8 Limitations

It is important to explain the limitations of the current study. The corpus used for the experiment is limited in size and scope, which may have impacted the generalizability of the results. Further experiments with larger corpora that encompass a broader range of discourse meanings and linguistic features are necessary to validate and extend the findings of this research. Nevertheless, the present study provides valuable insights into the interaction between classifier and feature types, which will need to be considered in future experiments.

Abstract

This article presents a work-in-progress project, which aims to build and utilize a corpus of Romanian texts written or spoken by non-native students of different nationalities, who learn Romanian as a foreign language in the one-year, intensive academic program organized by the University of Bucharest. This corpus, called LECOR – Learner Corpus for Romanian – is made up of pairs of texts: a version of the student and a corrected one of the teacher. Each version is automatically annotated with lemma and POS-tag, and the two versions are then compared, and the differences are marked as errors at this stage. The corpus also contains metadata file sets about students and their samples. In this article, the conceptual framework for building and utilization of the corpus is presented, including the acquisition and organization phases of the primary material, the annotation process, and the first attempts to adapt the NoSketch Engine query interface to the project's objectives. The article concludes by outlining the next steps in the development of the corpus aimed at quantitative accumulation and the development of the error correction process and the complex error annotation.

1 Introduction

The LECOR corpus is developed through the project "Learner Corpus of Romanian (LECOR). Collection, Annotation and Applications", funded by the Romanian Government as part of the subprogram dedicated to research projects to stimulate independent young teams (TE). The host institution of the project is the University of Bucharest. In this section we present the core features of the LECOR corpus and the different uses for which it has been designed. The main goal of the project is to build and make accessible the first Romanian electronic learner corpus and, at the same time, to professionalize human resources in this field of research. It will be a corpus in free access, open for searching through the provided interface. LECOR will be downloadable only by request and only for research purposes, which will be in accordance with the informed consent signed by learners.

LECOR is a monolingual general learner corpus, collected over four academic years (2019-2024). The target language is (general, standard) Romanian, learned in a native speaking environment and taught by native teachers. The learners are university students, aged generally between 18 and 25. Their native languages are various (more than 20 mother tongues): Arabic, Chinese, Korean, Albanian, Greek, Armenian, Turkmen, Turkish, Persian, Slavic languages (Bulgarian, Serbian, Ukrainian, Belarusian, Russian, etc.). Among the internationally spoken languages, Arabic and Mandarin Chinese are well represented, in contrast to English, Spanish, and Hindi, which are scarcely or not at all found, just like all Western and Northern European languages. The Romance languages are also weakly represented, especially through their non-standard varieties: Spanish and Portuguese from Latin America, and French from Africa. As a general characteristic, the learners' native languages exhibit typological distance both from Romanian and among themselves. As the corpus processing is not yet complete, an exact proportion of native languages in LECOR cannot be provided at this time.

In its first version, LECOR will contain written (80%) and oral (20%) learners' samples. The corpus is planned to be of large size, including 4,000 samples (of which, 800 audio transcriptions). The 4,000 samples in the corpus have very different sizes (ranging from samples provided by A1-level students, consisting of at least 40-50 words, to samples provided by B2+ level students, containing more than 350 words). Taking an average of 150-170 words per sample, we can approximate

Proceedings of Recent Advances in Natural Language Processing, pages 143–152
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_016

the size of LECOR at the end of the project to be over 600,000 words. At the moment, about 4,500 written productions are collected (from which a selection will be made, prioritizing exam papers and texts produced in class) and about 500 files with audio homework and exam recordings; users of the corpus will have access to original samples (handwritten texts and audio files). All the texts will be automatically annotated with lemma and POS-tag, while a small part will be annotated for errors. The LECOR corpus was designed to be scalable, so the aim is to increase its size and continue the annotation.

In each of the four academic years on the duration of the project, samples are collected, mostly in controlled contexts, from approximately 50-70 students per year, documenting their progress from A1 to B1 or B2 proficiency level. Therefore, the corpus can be used for both synchronic/cross-sectional and diachronic/ longitudinal research.

LECOR is all the more valuable as it encompasses, besides A2, B1 and B2 samples, at least one quarter of A1 samples and as it thoroughly documents the interlanguage development of several dozens of learners, who have produced approximately 60 samples throughout an entire academic year[1].

Regarding the representativeness of proficiency levels, LECOR is a relatively balanced corpus: the number of samples from A2 and B1 learners is comparable, whereas A1 learners contribute slightly fewer samples, and B2 learners produce the least number of samples.

The text types are varied and comply with the minimum proficiency level requirements (e.g. argumentative essays are not required at beginner level). In LECOR there are descriptions (of a city, of a (class)room, a house, a person, etc.), especially at A1 and A2 levels, narratives (*What I did today, What I used to do on holiday as a child, A nightmare trip*, etc.), argumentative essays (Why it's good to learn languages, Online shopping – pros and cons, Protecting the environment, etc.). Several description and story-telling tasks are based on pictures. The text genre are also diverse: e-mail (letter), long WhatsApp message, review, essay, description, procedure (recipe, health instructions), etc.

LECOR is a very well documented resource, learner variables/metadata, as well as text and task variables/metadata being carefully and thoroughly recorded, following the core metadata scheme for learner corpora (see König et al., 2022). Because it is a large annotated corpus with rich metadata and a high degree of representativeness, LECOR will have many possible end-uses.

At first, it will be used in studies about non-native Romanian acquisition and, in general, in second language acquisition research (for testing particular SLA theories, to set up the interlanguage profile at certain stages of SL / FL development, to track individual differences, etc., see also Granger et al. (2015)).

Then, the corpus can be used in language teaching and in natural language processing. Traditionally, learner corpora are used for didactic purposes (for an overview of applications, see at least McEnery et al. (2006); Díaz-Negrillo and Thompson (2013); Granger et al. (2015); Mitchell (2021)). On the one hand, it can be used to inform instructional materials design, such as course books (e.g. *Learning from common mistakes*, Brook-Hart (2009)), learner dictionaries (see, for example, Macmillan English dictionary advanced learner, Rundell (2007)), wordlists (e.g. *Focus on Vocabulary 2: Mastering the academic word list*, Schmitt and Schmitt (2011)), etc.; moreover, the metadata will allow for creating a 'difficulties profile' for learners with a specific mother tongue and thus will enable teachers to design more specific materials for their target groups of learners. Such materials do not exist at all for Romanian and are obviously long overdue by both learners and instructors. More precisely, based on the learner corpus (and, in many cases, a contrasting, language-target corpus), numerous research questions can be addressed: *How does second language evolve across different levels of proficiency? Which errors are developmental (specific to all learners) and which are likely to be caused by transfer from the native language? What are the specific features of interlanguage at a given proficiency level for a given population of learners?* For Romanian as a target language, Vasiu (2020) tries to identify, based on an own corpus what is the specificity of interlanguage at A1 level with respect to the learners' native language. Using quantitative analysis, the author reaches conclusions such as: at A1 level, for all native language groups, preposition acquisition is the most difficult; all A1 learners tend to

[1] Corpora of beginners are in general infrequent (Tracy-Ventura et al., 2021) and corpora with truly longitudinal data are accordingly rare.

omit adverbs; there are agreement errors between nouns and adjectives, except for possessive adjectives (for 1st and 2nd person, singular), which are memorized as formulas (*mama mea* 'my mother', *profesorul meu* 'my father'); Arabic learners tend to omit the copulative verb most frequently; Romance speakers superfluously use the preposition *la* 'at', etc.

LECOR can also be used for language teachers training and for language testing (Callies and Götz, 2015). On the other hand, the corpus will have an immediate pedagogical use; it will be available for use in classrooms or by learners themselves, since this kind of data is relevant for the (error) producers.

LECOR can be used also for native language automatic identification[2], in forensic linguistics. Non-native speakers of Romanian make errors characteristic of learners with a specific mother tongue. Thus, the native language of a malicious individual can be discovered by mapping the type of errors made in his/her use of Romanian. This is an important means of identifying such individuals and it is very useful in the context of increasing social media threats.

The learners' errors identified in LECOR can be used also to improve the technology for automatic translation (McEnery et al., 2015).

LECOR can also be used for automatic grammar- and spell-checking and automated scoring of L2 written and oral performance (also Granger et al. (2015)).

2 Related work

In the last three decades, the construction of learning corpora has experienced a remarkable development, as evidence of their increasing importance, as can be seen in the list of about 200 corpora provided on the website of the Catholic University of Louvain[3] or in the CLARIN infrastructure[4].

The series of these corpora was opened at the time of the publication of the International Corpus of Learner English (Granger et al., 2009) and is by far dominated by the broad interest in learning English, but there are also corpora with written, audio or multimodal content for learning many other languages from different language families, such as Arabic, Czech, Finnish, French, German, Greek, Mandarin, Japanese, etc.

The Romance languages, of which the Romanian language is a part, are also well represented in this field, with written or spoken corpora, of which we mention the general ones, with native students of different languages and a unique target language: COPLE2 (Mendes et al., 2016) for Portuguese, the Spanish learner corpora (SLC) (Alonso-Ramos, 2016), CELI (Spina et al., 2022), LIPS (Gallina, 2017) or VALICO (Corino and Marello, 2017) for Italian, or the FLLOC platform (Marsden et al., 2002) or PAROLE (Hilton, 2009) for French. For the Romanian language, apart from small in-house bespoke corpora, there are only two printed corpora (Constantinescu and Stoica, 2020; Vasiu, 2020), which gather Romanian raw texts produced by foreign students. The corpus compiled by Constantinescu and Stoica (2020) comprises more than 450 samples (380 written samples / 65,000 words, and 79 oral transcriptions / 60,000 words); it was produced by 61 A1-B2 learners in the period 2004-2016 in various instructional contexts. Vasiu (2020) corpus contains transcriptions of oral samples produced by 172 A1 students at proficiency tests in 2014-2017; its size (70,000 words) is comparable to the oral part of the previous corpus. The digitalization and integration in our project of the two printed corpora would be a difficult endeavour, in terms of copy right issues and collaboration between independent working teams. Moreover, we had a different design in mind: large-scale corpus, richer metadata, longitudinal scope, internationally used annotation schemes, etc. In this perspective, our project comes to cover an important gap in this field.

For our project, we also benefited from the experience of building other corpora, such as the corpus

[2] For the identification of the native language (NLI), a large-sized corpus and a high-quality dataset (comparable to the International Corpus of Learner English (ICLE), used for NLI research, which comprises 6,085 essays written by speakers of 16 different L1s, see Jarvis and Paquot (2015)) are necessary, with a large number of native languages to enable comparison; uniform topics; comparable text sizes; thoroughly evaluated proficiency levels (Jarvis and Paquot, 2015). LECOR will be a medium-sized learner corpus, containing 4,000 samples, scalable (with the possibility to increase over time), covering L1 languages at least as diverse as those ones in ICLE.

[4] https://www.clarin.eu/resource-families/L2-corpora (accessed 01.08.2023).

for Czech, CzeSL (Rosen et al., 2020), for Latvian, LaVA (Darģis et al., 2022) or for Croatian, CroLTeC (Preradović et al., 2015) and many others. From these we took as a model the set of metadata, the text annotation with POS and error codes, the association of student texts with variants corrected by teachers or multi-level error annotation. Regarding the corpus query interface, although many of the existing corpora use the TEITOK interface (COPLE2, CzeSL, CroLTeC, etc.), we followed LaVA's example by adopting the NoSketch Engine interface, due to operating system version and configuration incompatibilities between our server and TEITOK.

3 Raw-Material Collection and Organization

The corpus is collected from foreign students coming for studies in Romania from Eastern countries (Far East, Near East, Middle East), South-eastern Europe, Latin America and, less often, Western and Central Europe; their native languages (Arabic, Chinese, Bulgarian, Albanian, Serbian, Turkish, Greek etc.) are therefore both typologically distant from Romanian and from each other. They are learning in mixed groups. The learners are generally high school graduates, but there are also masters and PhD students (aged between 18 and 25 years). The one-year program they are enrolled in is intensive, totalling 800 hours of classroom instruction. In the first part of the academic year, they have in their curriculum 28 hours per week of general course of Romanian, while in the second part, 30 hours per week (with the addition of languages for specific purposes). In general, students' interlanguage progress is documented from absolute beginner (A1) to intermediate level (B1 or B2).

The raw material of the corpus (scans of the hand-written work samples, digital textwork samples, audio and video recordings) comes from different sources (it was collected by several teachers from the foreign students enrolled in the one-year intensive program "Preparatory year" at Faculty of Letters, University of Bucharest), in different folder and archiving structures (organized by student, by work sample or by teacher, archived or not archived) and in different file formats (.mp3/.mov/.mp4 for audio/video, .jpg/.png/.heic/.pdf for scans, Word/PDF for digital texts). Moreover, some scans cover more than one work sample and have to be split through different methods, according to their format: e.g., .pdf files are automatically page-split, .png/.jpg files are manually cropped in Paint. Then .heic/.png/.jpg files are converted to .pdf, for harmonization and because PDF format offers small size and quick loading with unsignificant loss in quality together with the possibility to concatenate photos depicting different pages of the same work sample. Video files are converted to audio files and the common chosen format was .mp3.

All scanned and audio/video files are manually transcribed following common orthographic transcription guidelines; some of the transcription principles are: (1) do not take into account strikethrough words in the scanned files or hesitations/repetitions in the audio/video files, but transcribe only the final version of a word provided by the student; (2) ignore syllabification of words at the end of the line, including the erroneous ones; (3) transcribe bracketed words; (4) keep the paragraph structure of the original but do not mark the original indenting; (5) for errors in lower/upper case spelling, only the ones concerning proper names or beginning of sentence are transcribed; other inappropriate uses of case spelling are ignored. In this manner, a transcribed .txt version of each work sample (further referred to as transcribed student form) was created, which is the basis for all preprocessing, correction, annotation and indexing steps in the corpus generation flow.

In order to protect the integrity of learners, we followed guidelines for research data management from University of Bucharest[5] and Catholic University of Leuven[6], which address various issues about anonymization, pseudo-anonymization, and encryption of sensitive data. All files are completely manually anonymized to protect student's right to privacy (see an example in Figure 1). This procedure is done after checking the transcripts, generally at the same time of samples correction. Despite the task not being performed automatically, due to the fact that not all samples contain personal data (e.g. only about 15% of audio files require anonymization), the total time required for the task is reasonable, e.g. 1-2 minutes to clear personal

Figure 1: A handwritten learner text with anonymizations and its transcript version with pseudonymizations. The sample belongs to an A2 learner (male) with Arabic as mother tongue; the text topic is summer holidays.

information from an audio sample. "Coding" sensitive data is relatively easy.

The sensitive data in scanned images is covered in Paint (for PDF sources they are converted to Paint, anonymized and converted back to PDF), audio sensitive data are replaced with beep sounds in Audacity, while the personal information in text documents is pseudonymized, i.e. replaced with similar plausible data (e.g. "Mohammed" is replaced with "Ahmed", "35 years old" is replaced with "29 years old", etc.) to maintain the morpho-syntactic coherence of the sentence (full anonymization, e.g replacing "35 years old" with "xxx" will impact negatively on the POS-tagging performance in future steps). The sensitive data we are targeting in the anonymization/pseudonymization process concerned student's name, age, birth date and birth place, previous school/university/work place, etc. (our internal list is broadly similar to that in Megyesi et al. (2018)). In case the pseudonymized word have morphological features like gender/number/case, they have to be replaced with similar values: e.g., feminine, genitive etc. For more challenging cases, where covering up sensitive data would affect the overall message of the text (e.g., replacing the name of a town with another would make its description inappropriate), we decided to keep the original place name.

Next step is producing the corrected form for each sample, further called teacher form. The correction is made by linguists/Romanian language teachers on the transcribed student sample by using commonly agreed general principles: e.g., 1. minimal corrections (if possible, we do not change the part of speech and the words order or number), 2. we do not provide more correction alternatives, but only one correct option; 3. semantic accuracy is preserved: e.g. if the work sample is made based on an image and the image depicts a "red skirt", the "yellow skirt" syntagm provided by the student is considered an error and corrected. A distinction is made between actual errors affecting form, grammar, vocabulary, punctuation, etc., and infelicitous constructions, register and stylistic inaccuracies and other awkward language (for a similar approach, see Granger et al. (2022)). The category of infelicities includes, for example: informal language, such as the short demonstrative forms *asta, ăsta* ('this (one)') instead of the standard (long) ones *această/aceasta, acest/acesta* ('this (one)'), the shortened forms of numerals (*treișpe*, instead of *treisprezece* 'thirteen'), address formulae with an inappropriate degree of politeness, text sequences with unclear meaning, etc. At the moment, it has not been decided how exactly infelicities will be annotated, but the annotation will definitely be done manually.

This preprocessed material is than organized in two steps:

1. According to the student: each student has a unique ID and a metadata file containing information associated to that specific student; the name format of a student folder is *StudentID_student* and the metadata file is in the .tsv format (see examples in Table 1).

2. Inside the student folder, the files are organized in folders dedicated to different work samples: work samples also have unique IDs (unique in a list of work samples of a specific student) and

Table 1: Example of the corpus folder structure. File names are in italics and folder names are in normal text.

associated text metadata files containing information corresponding to that specific work sample. The name format of a work sample folder is *StudentID_WorkID_text* (see examples in Table 1) and the folder has the following structure: original student form file + transcription of the original form file + teacher corrected form file + metadata file. For the file name convention, *o* stands for original form, *s* stands for student form, and *t* stands for teacher form. The original student form file (name format: *StudentID_WorkID_o*) can be: (a) a scanned work sample in the .pdf format; (b) an audio work sample in the .mp3 format; or (c) a student digital text work sample in .docx or .pdf format. The transcription (name format: *StudentID_WorkID_s*) and the teacher corrected transcription (*StudentID_WorkID_t*) are text files. The corresponding metadata is a .tsv file (see examples).

Metadata are collected in shared online Excel files (one for students and another for work sample). The StudentID field connects work sample metadata entries with student metadata entries. Important student/learner metadata fields specify gender, age, region for learning Romanian, native language(s), (bi/tri)linguality information, languages studied in parallel with Romanian, motivation for studying Romanian, degree of motivation, frequency of interaction with Romanian native speakers, mode of study, etc. Important work sample fields refer to spontaneity, time/length limits or requirements, writing type (hand-written or digital), use of diacritics, level of proficiency of the student, etc. Some of this metadata fields will be indexed and used at searching, while others will only be displayed in the search results. Scripts were designed to automatically extract metadata from the shared files and distribute them in the proper folders in .tsv format.

4 Annotation Procedure

Once the source files are organized in the manner presented above, the annotated corpus is created based on a procedure that includes the following two stages:

1. morphosyntactic annotation (POS-tagging) of the student version and the teacher one;

2. comparing student–teacher texts, which involves the alignment of the two versions and the automatic annotation of errors/differences.

This procedure is semi-automated, requiring the corpus files to be passed through the external POS annotation platform (located on a server other than the corpus server), then the annotated files are uploaded to the LECOR server for automatic error annotation. To make working with a large volume of data more efficient, scripts were created to detect and process only files added to the LECOR corpus or modified after the last annotation.

4.1 POS-tagging

Both the student and teacher forms of the work samples were annotated automatically in the RELATE platform (Păiș et al., 2020), dedicated to processing Romanian language. For this purpose, an export script was devised to transfer the documents to the platform. Following the annotation, an import script was used to transform the annotated documents into the LECOR specific format. From the multiple text processing pipelines available in RELATE (Păiș et al., 2019; Păiș, 2020), for the purpose of the LECOR project, we used UDPipe (Straka et al., 2016) with a recent model (Păiș et al., 2021) trained on the Romanian RRT corpus version 2.7 (Barbu Mititelu et al., 2016).[7]

The resulting documents, in CoNLL-U Plus format, included the following: segmentation (sentence and token), lemma, part-of-speech (UPOS and MSD tags), see Figure 2 for the student version (on the first five columns) and the teacher version (on the following five columns).

The CoNLL-U Plus format allows for additional annotation levels to be included in the future, if

[7] The tagger performance on a general corpus (the test subcorpus of RRT) was evaluated at: 99.88 F1 for token segmentation; 97.39 F1 for sentence segmentation; 95.91 accuracy for lemmatization; 97.15 UPOS accuracy for POS tagging. Further evaluation of the tool on LECOR corpus remains to be done at the end of the project; we expect important decrease in the tagger performance, given the specificities of a learner corpus.

Figure 2: Differences between student and teacher variants.

needed.

4.2 Comparing Student–Teacher Texts

The student and teacher versions of the work samples were aligned at token level. First, an automatic process was used, employing a modified Dynamic Time Warping (DTW) algorithm. This allowed matching partial words or words with mistakes and marking such issues. Considering two tokens T1 and T2 (each with the attributes form and lemma), the matching formula is:

```
Match(T1,T2)=(T1.form==T2.form || T1.
lemma==T2.lemma || removeDia(T1.form)==
removeDia(T2.form) || removeDia(T1.lemma
)==removeDia(T2.lemma) || lev(removeDia(
T1.form), removeDia(T2.form))<2)
```

In this equation, removeDia is a function that removes Romanian diacritics, lev is the Levenshtein edit distance. Parts of this equation may seem redundant (such as comparing both form and lemma). However, due to possible mistakes in the student work samples, the lemmatization process may produce different results. For example, the Ro manian word *copii* may have either the lemma *copil* ("child") or the lemma *copie* ("copy"/"duplicate"), depending on the context. Similarly, words with different forms may yield the same lemma, for example in the case of wrong singular/plural form. Furthermore, the equation was devised without having in mind a particular lemmatization algorithm.

Following the automatic process, a manual process was needed to confirm the differences between the teacher and student forms. The result is a CoNLL-U Plus file containing 5 columns for each of the student and teacher versions (token id, word form, lemma, UPOS, MSD) and an 11th column with the error type as labelled by the aligning algorithm (no error, missing word, additional word that is not needed, spelling mistake), see Figure 2.

Figure 3: NoSketch Engine interface for LECOR.

4.3 Corpus Query Interface

The LECOR corpus will employ the NoSketch Engine (Rychlỳ, 2007; Kilgarriff et al., 2014) open-source corpus query platform to allow searching access. The primary content indexed in the platform is represented by the differences file with error annotations, as described in the previous subsection. In addition, metadata about the student and the work sample will be indexed in order to allow querying sub-corpora based on different criteria. For this purpose, a dedicated script was created to convert from the CoNLL-U Plus file to the "vertical" file format used by NoSketch Engine, with the additional metadata inserted into specific file structures. A small sample of the LECOR corpus is currently available online in the NoSketch Engine installation[8]. The interface allows for both simple querying (based on words or lemmas) or complex CQL based queries. Solutions for accessing the original annonymized scanned or audio work sample from the NoSketch Engine interface, by clicking on a query result, will be explored.

Figure 3 shows the search result for the lemma *domn* ("mister, sir") with the option to provide the lemma and MSD for KWIC only. At the bottom of the figure, the full text of the first line of concordances has been opened, containing the student's text along with the related corrections. The red words belong to the student and the green ones are their corrected forms. This mixing of student-teacher versions creates the problem of getting matches for wrong and corrected forms indiscriminately. For example, line 2 in Figure 3 matches the wrong form, and line 3 matches the corrected form. This problem needs to be corrected.

Figure 4: Access to word annotation.

In Figure 3 we have selected for display only the MSD and lemma for KWIC, but the interface has access to all the information associated with each word, represented in Figure 4, except the last column. The information in the last column concerns the type of error committed by the student and will be subject to further processing including manual annotation by the teacher and searches by error type.

As seen in Figure 4, under each word in the text, the information about the lemma as well as the part of speech (UPOS) and the morpho-syntactic descriptions (MSD) are available. For example, for the first word Ro. *dar* "but", the annotated information is *dar*/CCOMJ/Ccssp where the lemma is *dar*, UPOS is CCONJ (coordinating conjunction) and MSD is Ccssp (see MULTEXT-EAST specifications[9]).

5 Conclusions and Further Work

In this study we presented the design stage of the LECOR corpus emphasizing the conceptual framework for building and utilization of the corpus. The next phase involves the quantitative accumulation of primary material.

Regarding the text correction, we have already established the general criteria and developed a proofreading manual, and further we will validate these criteria by correcting a representative volume of texts in parallel and establishing the Inter-Annotator Agreement.

Error annotation in this phase is done at a basic level and is strongly correlated with automatically detected differences between the student/teacher versions. This phase is very useful for what we intend to do, which is a manual error annotation, on multiple levels, as is already practiced in the field. The inventory of errors is already established, it remains to build the technical annotation method, especially for errors whose correction involves changes in the word order.

The NoSketch Engine query interface will be explored further to see how well it can be adapted to the project's goals. For example, a distinction must be made between the student version and the teacher version, possibly with separate searches on each version. We will investigate whether the option of querying parallel corpora provided by NoSketch Engine solves this desideratum. Another issue concerns the use of metadata about students and work samples. We consider using the platform's option to create subcorpora, which can potentially be selected by certain metadata values.

Abstract

Multi-document summarization (MDS) is a difficult task in Natural Language Processing, aiming to summarize information from several documents. However, the source documents are often insufficient to obtain a qualitative summary. We propose a retriever-guided model combined with non-parametric memory for summary generation. This model retrieves relevant candidates from a database and then generates the summary considering the candidates with a copy mechanism and the source documents. The retriever is implemented with Approximate Nearest Neighbor Search (ANN) to search large databases. Our method is evaluated on the *MultiXScience* dataset which includes scientific articles. Finally, we discuss our results and possible directions for future work.

1 Introduction

Multi-document summarization is performed using two methods: extractive (Wang et al., 2020; Liu et al., 2021) or abstractive (Jin et al., 2020; Xiao et al., 2022). So-called extractive methods rank sentences from source documents that best summarize them. These methods reuse important information well to construct a good summary but they lack coherence between sentences. To overcome this issue, abstractive methods are studied to imitate human writing behavior. They show great performance in human writing style but they often miss key information.

To make abstractive models aware of essential information, (Dou et al., 2021) guides their model with additional information like a set of keywords, graph triples, highlighted sentences of source documents, or retrieved similar summaries. Their method, which uses every guidance previously mentioned, improves summary quality and controllability compared with unguided models. However, guidances require specific training data, especially for keywords, graph triples, and highlighted sentences.

Our proposal is that by guiding with pre-existing summaries, the model can draw inspiration from the summary as a whole. But also be able to extract keywords and phrases using a copy mechanism. Consequently, this work focuses on guidance by similar summaries extracted from a knowledge base using a similarity metric between source documents and pre-existing summaries. The model, inspired by RAG (Lewis et al., 2020), is fully differentiable. In addition, the model generator uses a copy mechanism on the candidates returned from the knowledge base, inspired by (Cai et al., 2021). The findings of these two studies motivated the development of our model for the multi-document text summarization task.

We demonstrate the potential of our method on *MultiXScience* (Lu et al., 2020). This dataset gathers scientific articles where we have to generate the *"related work"* part with the *"abstract"* of the source article and the *"abstracts"* of the citations. In the case of scientific articles, we believe that the source documents are insufficient to generate the *"related work"* part because external knowledge is necessary to write such a paragraph.

In this work, we investigate a sequence-to-sequence model guided by a memory retriever of similar summaries. Specifically, source documents are the input of the memory retriever, which returns the top k similar summaries from a potentially large database using an approximate nearest neighbor search. Then, the decoder generates the summary taking into account the source and retrieved summaries and is trained to identify interesting texts for the targeted summary. The code of our work is available on GitHub[1].

Proceedings of Recent Advances in Natural Language Processing, pages 153–158
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_017

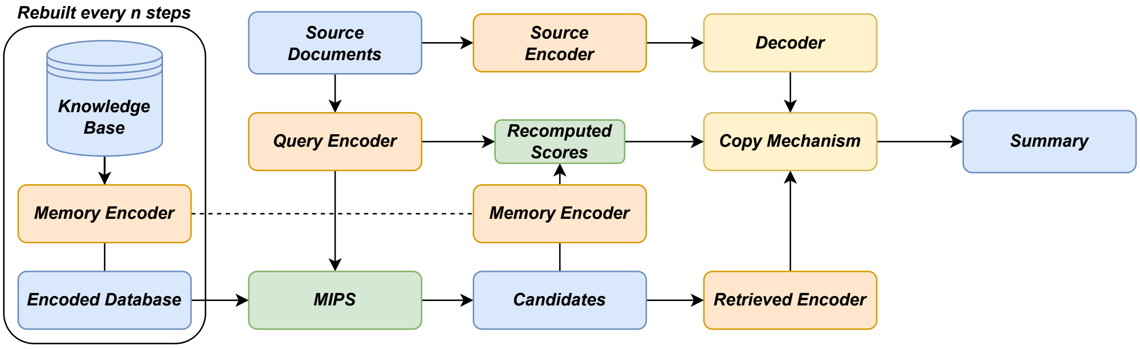

Figure 1: In the first step, the knowledge base is built by encoding all documents with the memory encoder. Then the source documents are transformed with a query encoder and with a source encoder, the query encoder is used to search the knowledge base. The encoded source is used to represent the source documents for the generation of the summary. After retrieving the top-k of the search, they are encoded with the retrieved encoder and again with the memory encoder to recalculate the relevance score for back-propagation. Then, the decoder takes as input the source documents and the relevant documents for the generation of the summary.

Our contribution is twofold: firstly, we integrate a retriever to retrieve candidates for the generation of the summary, and secondly, we make use of a copy mechanism to incorporate these candidates into the generation procedure.

2 Related Work

We start with a brief review of related work. (Cohan et al., 2018) proposes to capture the structure of the document to better represent the information of the source document. Their method is applied to scientific articles from *Arvix* and *Pubmed* which are long documents. For the same purpose, (Cohan and Goharian, 2018; Yasunaga et al., 2019) propose to generate a summary from the articles that cite the article to be summarised. The disadvantage of these methods is that they cannot be used when writing an article. In this work, we use references and not the papers that cite the documents to be summarised. More recently, (Xiao et al., 2022) proposed a pre-training strategy dedicated to multi-document text summarisation, their masking strategy showed significant improvement for the MDS task. They applied their method to the *MultiXScience* dataset.

The models using guidances are close to our work, indeed (Cao et al., 2018; Dou et al., 2021) use retrieved summaries to better control the summary generation. However, they use information retrieval systems such as *ElasticSearch* to find candidates for summary generation. Also, (An et al., 2021) has introduced dense search systems for text summarization, but they do not train the retriever with the summary generator. In our case, the retriever is dense and trainable to find the most relevant candidates for the generation of the summary.

In addition, retrieval-augmented models share commonalities with our work. RAG, (Lewis et al., 2020) which introduced this type of model, is used for the question-answering task, where a context is given to answer the question. The model retrieves several contexts with a retriever and then answers the question using each of the retrieved candidates. These types of models are also used in the translation task, where (Cai et al., 2021) translates a sentence with a pre-established translation base. Their model searches this base for translations close to the sentence to be translated and then incorporates them into the generation of the translation through a copy mechanism. This approach shares some similar intuition with our proposed approach because our architecture is based on an augmented retriever that incorporates the memory by means of a copy mechanism. It is interesting to investigate whether the encouraging success of the copy mechanism recently obtained in translation carries over to the MDS task.

3 Proposed Method

Inspired by (Cai et al., 2021), we propose a model composed of a memory retriever and a copy generator. Figure 1 illustrates our framework, where we start by encoding the entire knowledge base. After an arbitrary number of steps during the training, the encoded knowledge base is updated. Then, the forward pass encodes source documents and finds similar documents. Retrieved documents are encoded and fed to the generator with the source documents.

Our memory retriever has multiple encoders, one for encoding the query, one for the knowledge base, one for the sources documents, and one for the retrieved candidates. Our copy generator is a decoder with a cross-attention mechanism on source document embeddings and a copy mechanism on retrieved candidates, which is placed at the top of the decoder. We begin describing the retriever and then show how our generator works.

3.1 Memory Retriever

The retrieval approach consists of source documents as query and documents from a knowledge base denoted respectively by q and c. Documents are often too long to be encoded with a *Transformer* (Vaswani et al., 2017), so we used a *LongFormer* (Beltagy et al., 2020) model. *LongFormer* has a Transformer-like architecture that can deal with long input sequences by attending tokens with windowed attention and global attention on a few tokens. We encode source documents and candidates documents with a pretrained *LongFormer* model separated by a special token (*[DOC]*) :

$$h^q = LED^q_{enc}(q)$$
$$h^m = LED^m_{enc}(m)$$

where the *LongFormer* encoder is denoted by LED_{enc}. All documents in the knowledge base are encoded and stored in an index. For retrieving candidates, we take the *[CLS]* token of encoders output that we normalize and we define a relevance function :

$$h^q_{cls} = norm(h^q_{cls})$$
$$h^m_{cls} = norm(h^m_{cls})$$
$$score(x, y) = x^\top \cdot y$$

We then calculate the relevance score on normalized tokens, which represents the cosine similarity between source documents q and candidate documents m that fall in the interval $[-1, 1]$.

For fast retrieval, we retrieve the top-k candidates $m_{topk} = (m_1, \ldots, m_k)$ using the maximum inner product search (MIPS) implemented with FAISS (Johnson et al., 2021). At each training step, we calculate the actual embedding of candidates $\{h^m_{cls,i}\}^k_{i=1}$ and compute their relevance scores $\{s_i = score(h^m_{cls,i}, h^q_{cls})\}^k_{i=1}$ for back-propagation as in (Cai et al., 2021; Lewis et al., 2020). The recalculated score biases the decoder copy mechanism , which we detail in section 3.2.

The memory encoder does not re-encode all the knowledge base at each training step because this would be expensive computation. Instead, the knowledge base and the MIPS index are updated at regular intervals defined arbitrarily. On the other hand, we encode the retrieved top-k candidates and the source documents with two encoders, LED^r_{enc} and LED^s_{enc}, as shown below:

$$h^s = LED^s_{enc}(q)$$
$$h^r_{topk} = LED^r_{enc}(m_{topk})$$

These two results are forwarded to the copy generator, which we detail in the next section.

3.2 Copy Generator

In the generation part of our model, we use the decoder from *LongFormer* and apply a copy mechanism to previously retrieved candidates. Formally, we have :

$$h^d = LED_{dec}(y, h^s)$$

where LED_{dec} corresponds to the decoder part of the *LongFormer* model, and y is the targeted summary. The decoder attends over source documents h^s and previous tokens $y_{1:t-1}$, producing a hidden state h^d_t at each time step t. The probability of the next token is calculated with a $softmax$ function:

$$P_{dec}(y_t) = softmax(W_d \cdot h^d_t + b_d) \qquad (1)$$

where W_d is a $hiddens_{size} \times vocab_{size}$ matrix and b_d is the bias; both are trainable parameters.

Then, we incorporate the top-k candidates m_{topk} with a copy mechanism by calculating a cross attention between h^d_t and h^r_{topk}. To this end, we reuse the cross-attention part of *LongFormer* to add it after its original decoder. This new layer has only one attention head in order to use the attention weights as the probability to copy a word from top-k candidates.

Given k documents encoded in h^r_{topk}, then we can construct a set of token embedding $\{r_{i,j}\}^{L_i}_{j=1}$ where $i \in [1, k]$, $j \in [1, L_i]$ and L_i is the length of document i. Formally, the attention weight of the jth token in the ith relevant document is expressed as,

$$\alpha_{ij} = \frac{\exp(h^{d\top}_t W_a r_{i,j} + \beta s_i)}{\sum^k_{i=1} \sum^{L_i}_{j=1} \exp(h^{d\top}_t W_a r_{i,j} + \beta s_i)}$$
$$c_t = W_c \sum^k_{i=1} \sum^{L_i}_{j=1} \alpha_{ij} r_{i,j}$$

where α_{ij} is the attention weight of the jth token in the ith relevant document, W_a and W_c are learnable parameters, c_t is a weighted representation of top-k candidates and β is a learnable scalar that controls the relevance score between the retrieved candidates and the decoder hidden state, enabling the gradient flow to the candidates encoders as in (Cai et al., 2021; Lewis et al., 2020). Equation 1 may be rewritten to include the memory:

$$P_{dec}(y_t) = softmax(W_d \cdot (h_t^d + c_t) + b_d) \quad (2)$$

Thus the next token probability takes into account the attention weights of the top-k candidates. The final next token probability is given by:

$$P(y_t) = (1 - \lambda_t) P_{dec}(y_t) + \lambda_t \sum_{i=1}^{k} \sum_{j=1}^{L_i} \alpha_{ij} \mathbb{1}_{r_{ij}=y_t}$$

where λ_t is a gating scalar computed by a feed-forward network $\lambda_t = g(h^d, c_t)$. The model is trained with the log-likelihood loss $\mathcal{L} = -\log P(y^*)$ where y^* is the target summary.

3.3 Training Details

Our model is composed of several encoders and one decoder based on the *LongFormer* (Beltagy et al., 2020) large model. Therefore, the size of our model attains 1.9B of trainable parameters. Then we used the *DeepSpeed* (Rasley et al., 2020) library for the training. Our model uses the *LongFormer* pretrained models available on *HuggingFace*[2].

The training of the model makes use of *MultiX-Science* data comprising 30,369 scientific articles for training, 5,066 validation, and 5,093 test articles. The objective is to generate the related work using the abstract of the article and the abstracts of the cited articles. This is an interesting dataset to experiment with because writing a related work part requires knowledge beyond the scope of the source documents.

Cold start problem At the beginning of the training, the weights are randomly initialized. Therefore the retriever selects low-quality candidates that don't send out a good signal for training. Under these conditions, the retriever cannot improve, and the model will ignore the retriever's candidates. To overcome this cold start problem, we pre-trained the retriever on the *MultiXScience* data to improve the quality of the retriever. The objective is to maximize the similarity between the abstract and the related work section. These two sections are encoded with the two encoders of the retriever to calculate the cosine similarity.

In concrete terms, pre-training works as follows. For a batch size equal to N, we have N "abstract" sections encoded with $A = \{LED_{enc}^{q}(a_i)\}_{i=1}^{N}$ and N "related work" sections encoded with $B = \{LED_{enc}^{m}(b_j)\}_{j=1}^{N}$, in order to obtain a cosine similarity equal to 1 when $j = i$ corresponds to positive examples and -1 otherwise for negative examples. We calculate for each element in A, the following errors:

$$\mathcal{L}_i(A, B) = -\log \frac{\exp\left(score(A_i, B_i)/\tau\right)}{\sum_{j=1}^{N} \exp\left(score(A_i, B_j)/\tau\right)}$$

where τ is an arbitrarily chosen temperature parameter. The final error is $\mathcal{L} = \sum_{i=1}^{N} \mathcal{L}_i$ backpropagated in the two encoders of the retriever.

4 Experiments

In this section, we report on the experiments performed on the *MultiXScience* dataset to evaluate our model. Training the full model is more difficult due to its size but also due to the cold start problem. The latter corresponds to the fact that the similar summaries retrieved are not sufficiently relevant to help the model. In addition, we have trained two other methods adapted to text summarisation as a comparison, *Bart* (Lewis et al., 2019) and *T5* (Raffel et al., 2020). We detail the training procedure for each of them. All models use the beam search method to generate summaries. We chose a beam size of 4, a length penalty of 1.0, and limited the repetition of tri-grams. The rouge scores (Lin, 2004) on the *MultiXScience* dataset are reported in table 1.

Method	**R-1**	**R-2**	**R-L**
Ours	30.6	6.5	17.7
Bart (Our run)	32.4	7.2	17.3
T5 (Our run)	29.6	6.3	17.0
Primera*	31.9	**7.4**	18.0
PointerGenerator*	**33.9**	6.8	**18.2**

Table 1: The ROUGE score (R-1/R-2/R-L) of our preliminary results on the *MultiXScience* test dataset. The * symbol means that the results have been borrowed from (Xiao et al., 2022).

[2] https://huggingface.co/allenai (visited on 11/08/2023)

Reduced model To reduce the computational burden, we used a reduced model where the knowledge base is not reconstructed. In addition, the memory encoder parameters were frozen in order to reduce the complexity of the training. These two modifications reduced the training time considerably. Indeed, the burden of reconstructing the knowledge base was overwhelming. The reduced model has fewer trainable parameters (1.4B). The model was trained for 12.000 steps on four v100 GPUs with Adam optimizer and a learning rate of $3e-5$, a batch size of 64, a top-k of 5 for the retriever, and with 2.000 warmup steps and linear decay. Despite its reduction in size, we observe that the model is competitive with the state of the art.

Bart We fine-tuned a *Bart-large* model on the *MultiXScience* dataset using a single v100 GPU over two days. The model weights were updated for 20,000 steps with a learning rate of 3.0e-5. A linear warmup for 2,000 steps was applied to the learning rate. We also limited the norm of the gradient to 0.1. The training aims to minimize cross-entropy with a smoothing label of 0.1. The *MultiXScience* articles have been concatenated using the '\n\n' separator. The results show that Bart is competitive with the state of the art.

T5 The *T5-large* model was fine-tuned on the same dataset as before. The training lasted 4 days on a single v100 GPU, this model is slightly larger and was trained in fp32 precision. As T5 is a text-to-text model, we have used the prefix 'summarize:' for the input documents, which are separated by the separator '\n\n'. The model was trained for 7,000 steps with a learning rate of 1.0e-4 and a batch size of 64. A linear warm-up of up to 2000 steps and a gradient norm limitation of 0.1 was applied. The error to be minimized is the cross-entropy with a label smoothing of 0.1.

5 Conclusion and Future Work

This paper presents an architecture for multi-document text summarization inspired by retrieval-augmented models. This architecture includes a retriever that searches a knowledge base to find relevant documents for the generation of a summary. These documents are integrated in the generation by means of a copy mechanism. A reduced version of the model was evaluated on the *MultiXScience* dataset. The preliminary results are already competitive with the state of the art however we expect to improve our results further by: 1) properly fixing the cold start problem, and 2) training the full model. In the future, we also plan to increase the size of the knowledge base with new data and apply our method to other MDS benchmark datasets.

Acknowledgments

We gratefully acknowledge support from the CNRS/IN2P3 Computing Center (Lyon - France) for providing computing and data-processing resources needed for this work. In addition, This work was granted access to the HPC resources of IDRIS under the allocation 2022-AD011013300 made by GENCI. Finally, we would like to thank Roch Auburtin from Visiativ for his advice.

Beyond Information: Is ChatGPT Empathetic Enough?

Abstract

This paper aims to explore and enhance ChatGPT's abilities to generate more human-like conversations by taking into account the emotional state of the user. To achieve this goal, a prompt-driven Emotional Intelligence is used through the *empathetic dialogue* dataset in order to propose a more empathetic conversational language model. We propose two altered versions of ChatGPT as follows: (1) an emotion-infused version which takes the user's emotion as input before generating responses using an emotion classifier based on ELECTRA (Clark et al., 2020); and (2) the emotion adapting version that tries to accommodate for how the user feels without any external component.

By analyzing responses of the two proposed altered versions and comparing them to the standard version of ChatGPT, we find that using the external emotion classifier leads to more frequent and pronounced use of positive emotions compared to the standard version. On the other hand, using simple prompt engineering to take the user emotion into consideration, does the opposite. Finally, comparisons with state-of-the-art models highlight the potential of prompt engineering to enhance the emotional abilities of chatbots based on large language models.

1 Introduction

Conversational agents have become increasingly popular in recent years, with applications ranging from customer service (Ando and Zhang, 2005) to mental health therapy (Abd-Alrazaq et al., 2019). However, while these agents have the potential to provide information in natural language, their current abilities to generate human-like and empathetic conversations are limited (Rapp et al., 2021; Belainine et al., 2020b,a).

To address this challenge, this study explores the emotional abilities of ChatGPT in generating empathetic responses. Specifically, we investigate the effectiveness of incorporating external emotion classifiers using prompt engineering to take the user's emotional state into account when generating responses. This study is motivated by the fact that emotions play a crucial role in human communication, and empathetic responses are essential for building rapport and trust in human-machine interactions (Chen et al., 2021). In customer service for instance, it was shown that up to 40% of consumers' requests are rather emotional without specific informational intents (Xu et al., 2017). Thus, we compare standard ChatGPT that generates responses to simple conversation prompts from the *Empathetic Dialogues dataset* (Ma et al., 2020) to two slightly modified versions with prompt engineering. The first one is an emotion-infused version that takes the user emotion as an additional input before generating responses using an ELECTRA-based emotion classifier; while the second, emotion adapting version tries to consider how the user feels without any external component.

Our study adds to the expanding literature on conversational agents and emotional intelligence and its results have implications for the design and development of conversational agents that can provide personalized and effective support to users. In the following sections, we provide a brief review of the related work (Section 2) then present some relevant preliminary information (Section 3). Section 4 contains a detailed description of our experimental design while our evaluations and results will be presented in section 5. Finally, section 6 concludes this paper and gives some future perspectives.

2 Related Work

According to Allouch et al. (2021), a conversational agent can be defined as *"a dialogue system that can also understand and generate natural language content, using text, voice, or hand gestures, such*

as sign language". Even though the first chatbot in the literature dates back to 1966, with the Rogerian psychotherapist chatbot Eliza developed by Joseph Weizenbaum (Weizenbaum, 1966), chatbot development has only exploded over the past several years (Adamopoulou and Moussiades, 2020). Their applications have been appearing across a variety of industries thanks to huge data sources, machine learning advancements (Grudin and Jacques, 2019), and Large Language Models (LLMs).

Conversational agents can be classified based on the response generation method: rule-based systems choose responses from hand-crafted predefined rules but suffer from dull and repetitive responses (Prendinger and Ishizuka, 2005). Retrieval-based methods use techniques such as keyword matching to find the most approprite response from a fairly large corpus but don't seem very natural (Grudin and Jacques, 2019), and generative chatbots provide more diverse conversations but require massive training data (Sutskever et al., 2014).

Despite all the advancements in the conversational agents research, it appears that people still prefer natural communication to machine-like interactions and feel that a human can understand them better (Rapp et al., 2021). In fact, it was shown in recent studies that customers still prefer interacting with humans over machines (Adam et al., 2021) because generating empathetic and human-like responses is a challenging task for chatbots, as it requires an understanding of the user's emotional state and the ability to respond appropriately.

Several studies have explored the use of different techniques to improve the emotional abilities of conversational agents. For example, Asghar et al. (2018) used a heuristic search technique in order to ensure variety and emotional relevance in the generated replies. Other research aimed to identify the emotion of the input message by embedding each input word in a three-dimensional emotion embedding space which dimentsion are Valence, Arousal, and Dominance (VAD) (Warriner et al., 2013). To address the relevance of the emotional responses, Lin et al. (2019) proposed the empathy hypothesis stating that the type of generated emotion should be consistent with the contextual emotional state of the user, while Wei et al. (2019) argued that we can't assume that the output emotion has to match the input emotion. They claimed that using a predefined label to train the response generator results in poor response quality. Zhang et al. (2018) proposed to generate multiple responses for six emotional categories and the best response is then selected with a ranking algorithm.

In recent years, the field of natural language processing has witnessed an unprecedented race to develop new LLMs based on the transformer architecture (Vaswani et al., 2017) which showed a great potential at capturing complex patterns in language data. For instance, GPT-3 by OpenAI (Brown et al., 2020) has proven its capacity to produce coherent and human-like language, PALM by Google (Chowdhery et al., 2022) has contributed to reducing the computational requirements for training large models and PaLM 2 promised advanced reasoning and general capabilities compared to the current state of the art of language models (PaLM2).

Recently, ChatGPT has demonstrated its remarkable ability to understand and converse with humans fluidly. Since its release in November 2022 with impressive language abilities, there has been a growing interest in evaluating the conversational language model for different aspects of Natural Language Understanding (NLU). For instance, Bang et al. (2023) evaluates the multilingual performance of ChatGPT on three tasks of language identification, sentiment analysis, and machine translation. Lai et al. (2023) evaluates the performance of ChatGPT, beyond English on many Natural Language Processing (NLP) tasks such as NER, NMT, POS, NLI, QA, CSR. Kocoń et al. (2023) tried to evaluate ChatGPT on 25 different NLP tasks and found that it did very well in most of them, but didn't outperform the state of the art in any particular task. However, to the best of our knowledge, there is still no work on the evaluation of ChatGPT on the emotional intelligence level.

The exceptional performance of LLMs on a variety of tasks, even with zero-shot or few-shot settings, has inspired NLP academics to reevaluate the predominant training paradigms from previous years. For example, prompt engineering is a relatively new promising technique that appears to improve LLMs' performance on downstream tasks. For example, in the context of zero-shot mathematical reasoning, Kojima et al. (2022) found that simply prompting GPT-3 with "Let's think step by step" quadrupled the accuracy on the MultiArith arithmetic dataset, from 18% to 79%!

In this paper, we focus on the potential of prompt engineering and external emotion classifiers to enhance the emotional abilities of ChatGPT. Our study builds upon previous research on prompt engineering and explores the effectiveness of external emotion classifiers in improving ChatGPT's ability to generate empathetic responses.

3 Preliminaries

In this section, we introduce some important notions that would be important to understand the design and implementation sections.

3.1 Problem formulation

A multi-turn dialogue defined as $D = \{U_1, ..., U_M\}$ consists of M alternate utterances of two interlocutors (Belainine et al., 2022). Each utterance U_i can be associated with an emotion label E_i. Given a dialogue D, we aim to generate the next utterance U_{M+1} that would be coherent, not only with the previous semantics, but also with the previous emotional state(s).

3.2 Emotion classification

Emotions are states of feelings resulting from internal or external changes in our lives and depend on the speaker's attitude and personality (Al-Omari et al., 2020). They can be classified into 6 basic categories according to Ekman (1992) or 8 classes according to Plutchik (1980). However, a recent study showed that using 27 emotion labels in addition to a neutral label can be effective for fine-grained emotion classification (Demszky et al., 2020). Using Principal Preserved Component (PPCA) Analysis (Cowen et al., 2019), they showed that the 28 used labels are highly significant.

One of the most challenging problems in the automated understanding of language is emotion recognition & classification. However, transfer learning can leverage the effectiveness of pre-trained LLMs to tackle such a task more effectively (Chronopoulou et al., 2019; Belainine et al., 2020b,a). By re-training (or fine-tuning) the pre-trained model on a smaller dataset that is tailored to the new task (emotion classification for example) while keeping some or all of the pretrained weights unchanged, the model we obtain is adapted to the new task. Compared to training the model from scratch, this method can result in faster convergence and greater performance using a fraction of the processing power (Pan and Yang, 2010).

3.3 Prompt engineering

Prompt Engineering can be defined as the design of instructions (prompts) in a way that improves the quality of the results from existing language models without further training on new datasets (Liu et al., 2023). As mentioned earlier, this technique has shown promising results in steering Large Language Models and improving their results without retraining or even fine-tuning (Kojima et al., 2022).

3.4 The ELECTRA model

The ELECTRA (*Efficiently Learning an Encoder that Classifies Token Replacements Accurately*) model is a type of neural network architecture that was introduced by researchers at Google (Clark et al., 2020). It has been shown to outperform other pre-trained language models such as BERT (Devlin et al., 2018) on several NLP benchmarks, including sentiment analysis (Mala et al., 2023).

The main innovation behind the ELECTRA model is *replaced token detection* instead of *masked token prediction*. In fact, for popular LLMs like BERT (Devlin et al., 2018) and XLNet (Yang et al., 2019), the pre-training job is masking a portion of the unlabeled input and then training the network to retrieve this original input. This method works well, but its data efficiency is limited because it only learns from a fraction of the tokens. Researchers from Stanford University and Google Brain proposed replacing certain tokens with plausible substitutes produced by a small language model as an alternative to masking then trying to determine if each token is an original or a replacement using the pre-trained discriminator. This resulted in a significantly more computationally efficient model thanks to learning from the entire set of input tokens. Studies such as B et al. (2023) have shown that the proposed method greatly speeds up training and improves performance on downstream NLP tasks (Clark et al., 2020).

3.5 ChatGPT

ChatGPT is a Large Language Model based on the GPT-3.5 architecture and developed by OpenAI (Ouyang et al., 2022). It was trained on massive textual corpora and can provide human-like replies to a variety of natural language cues, from straightforward queries to more complicated dialogues. Using a transformer-based design, the model is able to capture long-range relationships in the input data and produce output that is incredibly fluent and coherent (Guo et al., 2023). It was originally trained based on InstructGPT (Ouyang et al., 2022) but it is also continuously improved using RLHF (Stiennon et al., 2020).

4 Experimental Design

In this section, we present a detailed description of the three ChatGPT versions used in these evaluations as well as the dataset used and the ELECTRA-based emotion classifier that we will need for the emotion infused version and for the evaluation part.

4.1 The Emotion Classifier

4.1.1 Datasets

For emotion classification, we used the GoEmotions dataset (Demszky et al., 2020), a large dataset of over 58k Reddit comments manually annotated with 28 fine-grained emotion labels by up to five different human annotators. It includes basic emotions like joy and anger but also more complicated ones like nervousness and caring. The authors argue that the chosen emotion labels are highly significant according to the Principal Preserved Component Analysis (PPCA) (Demszky et al., 2020). Figure 1 shows that the distribution of emotion labels is not balanced. We should keep this in mind when choosing appropriate evaluation metrics.

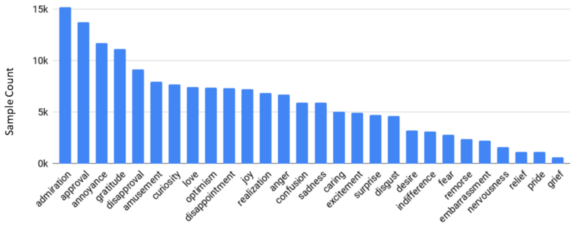

Figure 1: Labels distribution in GoEmotions dataset.

To analyze the dialogue performance of the chatbot systems, we will be using the Empathetic Dialogues dataset (Rashkin et al., 2018). This is a large-scale dataset made up of over 25,000 human-to-human dialogues designed to elicit sympathetic reactions. It was constructed by asking the participants to share personal tales and then to respond sympathetically to the stories of others. The dataset is all about emotionally grounded personal situations and therefore it is rich in terms of emotions.

4.1.2 Fine-tuning

Thanks to its impressive perfomance on the sentiment analysis task (Mala et al., 2023), which is similar to the emotion classification task, we chose the ELECTRA pre-trained model to build our emotion classifier. We fine-tuned it on the GoEmotions dataset using the PyTorch framework by adding a three-layer classification head consisting of:

- A fully connected layer used to reduce the feature dimensionality.
- A dropout layer to prevent overfitting.
- A fully connected layer used to map the reduced feature space to the number of emotion labels in the dataset (28).

We used cross-entropy as a loss function which includes the softmax function in its computation to calculate the probability distribution over the predicted classes according to equation 1:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{M} y_{i,j}\log(p_{i,j}) \tag{1}$$

where N is the batch size (set to 128), M is the number of classes (28 in this case), $y_{i,j}$ is the binary label for the i-th example and j-th class, and $p_{i,j}$ is the predicted probability of the i-th example belonging to the j-th class.
During fine-tuning, the weights of the pre-trained ELECTRA model are frozen, and only the weights of the added classification head are optimized.

4.2 ChatGPT and emotions

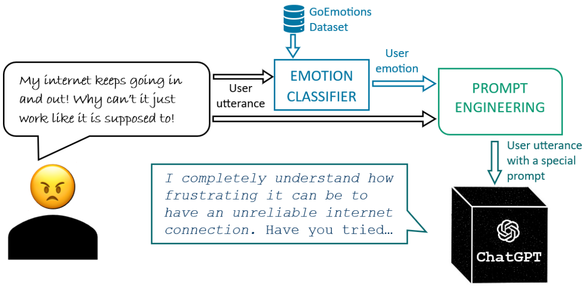
We used three versions of ChatGPT to evaluate the impact of incorporating emotions in the generation process. Each version is fed with the first $n-1$ user utterances containing the context of the conversation, while the last, n^{th} utterance in any given conversation from the Empathetic Dialogues is predicted by the different chatbot models. We ran the experiments using the ChatGPT API.

4.2.1 ChatGPT-A: Regular ChatGPT

This is the basic version of ChatGPT and it was used without any modification. It is trained to generate responses to conversation prompts using only the text prompt as input. This model serves as a baseline to compare the performance of the other two versions. It will be denoted ChatGPT-A.

4.2.2 ChatGPT-B: Emotion-Infused ChatGPT

This version of ChatGPT takes into account the emotional state of the user in generating responses. We used the ELECTRA-based emotion classifier to classify the emotion of the user input. We use the emotion class as an additional input along with the text prompt to generate a response by adding the following sentence with the ”assistant” role: ”*Looks like you're feeling [emotion]*” just before asking ChatGPT to reply. We will be calling this model ChatGPT-B and figure 2 illustrates the idea behind injecting emotions into ChatGPT.



GoEmotions Dataset
My internet keeps going in and out! Why can't it just work like it is supposed to!
User utterance
EMOTION CLASSIFIER
User emotion
PROMPT ENGINEERING
User utterance with a special prompt
I completely understand how frustrating it can be to have an unreliable internet connection. Have you tried…
ChatGPT

Figure 2: Illustration of emotion-infused ChatGPT.

4.2.3 ChatGPT-C: the Emotion-adapting ChatGPT

This version of ChatGPT uses simple prompt engineering to take the user's emotion into consideration. Specifically, we add the following sentence: *"Try to understand how I'm feeling"* in the "user" role before asking ChatGPT to continue the conversation. This chatbot version is going to be called ChatGPT-C in the following sections.

By comparing the performance of these three versions, we aim to assess the effectiveness of the proposed methods for enhancing the emotional abilities of ChatGPT in generating more human-like responses in empathetic conversations.
To illustrate the difference between the three versions of ChatGPT, here is a sample dialogue:

USER: My internet keeps going in and out and it is really bothering me! Why can't it just work like it is supposed to!
ASSISTANT: Are you on wireless, or a wired network?
USER: It is wireless. I keep on having to unplug and then plug back in the router and modem! Very frustrating!
CHATGPT-A: Some possible solutions include resetting your router, updating the firmware, checking for interference from other devices, and contacting your Internet Service Provider (ISP) for assistance.
CHATGPT-B: I completely understand how frustrating it can be to have an unreliable internet connection. Have you tried contacting your internet service provider to see if there is an issue with your service?
CHATGPT-C: I can imagine how frustrating it must be for you to have unstable internet.

5 Evaluations and Results

5.1 Emotion classification results

During fine-tuning of the ELECTRA-based classifier on the GoEmotions dataset, we experimented with different values for the hyperparameters in order to get the best results. The hyperparameters include a batch size of 128, a learning rate of 1e-4 and a number of 10 training epochs.

We divided the GoEmotions dataset into train, validation and test sets with ratios of 80|10|10 and we achieved excellent results in terms of the different metrics used. We got an AUROC score of up to 98.54%, an accuracy of 86.92% and an F1-score of 84.48%, indicating very reliable performance across all classes, despite the dataset being unbalanced. The full classification results per emotion label are illustrated in the table 1.

	Precision	Recall	F1-score
Admiration	0.91	0.91	0.91
Amusement	0.95	0.87	0.91
Anger	0.86	0.88	0.87
Annoyance	0.86	0.76	0.80
Approval	0.80	0.86	0.83
Caring	0.80	0.81	0.81
Confusion	0.88	0.84	0.86
Curiosity	0.77	0.94	0.85
Desire	0.80	0.86	0.83
Disappointment	0.80	0.81	0.80
Disapproval	0.76	0.87	0.81
Disgust	0.87	0.84	0.86
Embarrassment	0.90	0.87	0.89
Excitement	0.72	0.92	0.80
Fear	0.93	0.88	0.90
Gratitude	0.96	0.93	0.94
Grief	0.86	0.86	0.86
Joy	0.84	0.88	0.86
Love	0.90	0.95	0.92
Nervousness	0.69	0.75	0.72
Optimism	0.90	0.83	0.86
Pride	0.88	0.78	0.82
Realization	0.80	0.88	0.84
Relief	0.82	0.90	0.86
Remorse	0.64	0.86	0.73
Sadness	0.80	0.78	0.79
Surprise	0.74	0.93	0.82
Neutral	0.92	0.87	0.90
AUC			0.99
Accuracy			0.87
Macro avg	0.83	0.86	0.84
Weighted avg	0.87	0.87	0.87

Table 1: The detailed emotion classification results.

By examining table 1, we can see that almost all emotion labels achieved above 80% in precision, recall and F1-score. The lowest scores correspond to labels with the least training examples (such as pride that has less than 10 examples). This is expected since the labels with the most examples would be easier for the model to classify (such as admiration that has over 300 training examples). Overall, despite the big number of classed to choose from, our emotion classifier achieves impressive results, especially compared to the BERT-based model in the (Demszky et al., 2020) paper which only reached 40% 63% and 46% in precision, recall and F1-score, respectively. We can therefore assume that our model can be reliably used to predict the user and chatbot emotional expressions.

5.2 ChatGPT-B vs. ChatGPT-A

To compare the performance of the emotion-infused ChatGPT (ChatGPT-B) to the regular ChatGPT (ChatGPT-A), we ask both models to predict the last reply of each conversation as described in section 4.2. We then give an emotion label to each reply of both chatbots using our ELECTRA-based emotion classifier.

When examining results, we found that in 45% of the conversations from Empathetic Dialogues, both ChatGPT versions' replies were given the same emotion label. However, if we can use the probability of each emotion as an indication of the emotion intensity, we can plot the change in percentage of each emotion label probability in figure 3 and see some interesting results, even for replies with the same emotion label.

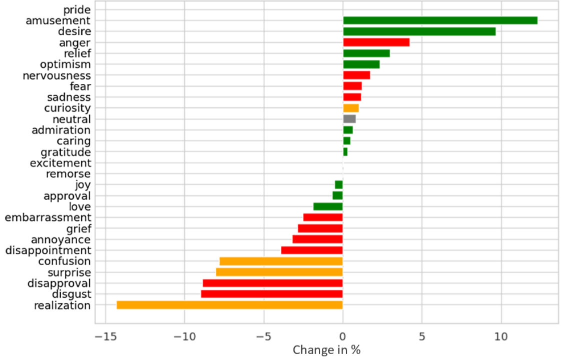


Figure 3: ChatGPT-A vs. ChatGPT-B emotion intensity.

As we can see in figure 3, positive emotions (with the green color) tend to be more pronounced in the emotion-infused ChatGPT, while negative (red-colored) and ambiguous (orange-colored) emotions were less intense overall. This indicates that when giving the user emotion as an input to ChatGPT, the chatbot tends to use more empathetic language. The "anger" emotion seems to be the exception here. This means that the replies that express this negative emotion are more pronounced with the emotion-infused ChatGPT. This can be explained by the fact that the chatbot tries to be empathetic by expressing anger about the same thing that the user was angry about

We also analyzed the replies of which the emotion label changed according to the emotion classification model, representing 55% of the conversations we tested. We plot the frequency change in percentage in the horizontal bar chart of figure 4.

Overall, the emotion-infused ChatGPT-B tends to use positive emotions more frequently whereas negative and ambiguous emotions were used more rarely compared to regular ChatGPT. There are few exceptions out of the 28 emotion labels, though: remorse and sadness are used more, which shows more empathy towards the user, and relief and excitement are less often used, showing more understanding of the user request and less asking for elaboration. More importantly, the negative emotions like disgust, disappointment, anger etc., saw the biggest drop in use by ChatGPT-B. We can also notice that the neutral emotion is used less often, indicating more emotional replies. To analyze the results further, we created a confusion matrix to see the frequency change in each emotion label per user emotion to see which emotion labels were becoming what. This matrix is in the figure 5.

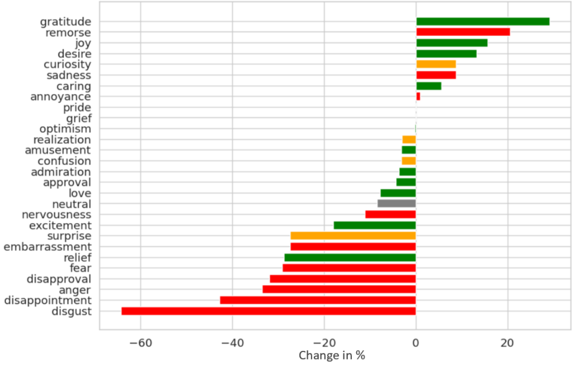

Figure 4: ChatGPT-A vs. ChatGPT-B emotion frequency.

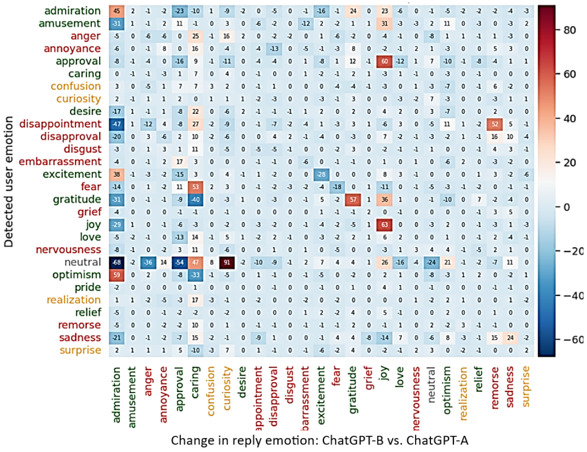

Figure 5: ChatGPT-B: Reponse emotion per user emotion.

Examining the heatmap, we can see that ChatGPT-B uses "caring" and "joy" emotions more often compared to the regular ChatGPT. The most noticeable change however is the use of the "curiosity" emotion. In fact, it is used much more often when it detects that the user is neutral. This indicates that the chatbot expresses interest in what the user is saying and that it is making inquiries in an attempt to learn more about the issue of the human.

5.3 ChatGPT-C vs ChatGPT-A

The emotion adapting version of ChatGPT, ChatGPT-C, which used the prompt *”try to understand how I’m feeling”* at the end of the user’s utterance shows different results. In figure 6, we can see that the chatbot tends to use negative emotions more often and positive emotions less often. This is likely due to the fact that this particular prompt is associated with negative emotions. In fact, a person wouldn’t say ”try to understant how I feel” when expressing joy or excitement, but rathen when he feels sad or annoyed; and ChatGPT tries then to match the emotion of the user in this case. To confirm that, we can examine the emotion frequency change per user emotion illustrated in the heatmap of the figure 7. The most noticeable changes are in the following situations:

- When the user is neutral, the chatbot expresses admiration much less often and instead tries to mimic either the ”caring” emotion or the ”anger” and ”sadness” emotions.
- When the user appears to be sad, the chatbot expresses ”approval”, ”joy” noticeably less often and expresses more ”caring” and ”sadness” instead.
- If the chatbot finds that the user is fearing something, it expresses the ”fear” emotion instead of ”approval” or ”curiosity”.

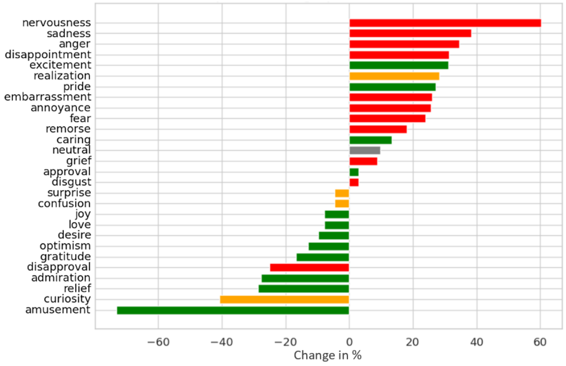

Figure 6: ChatGPT-C vs ChatGPT-A emotion frequency.

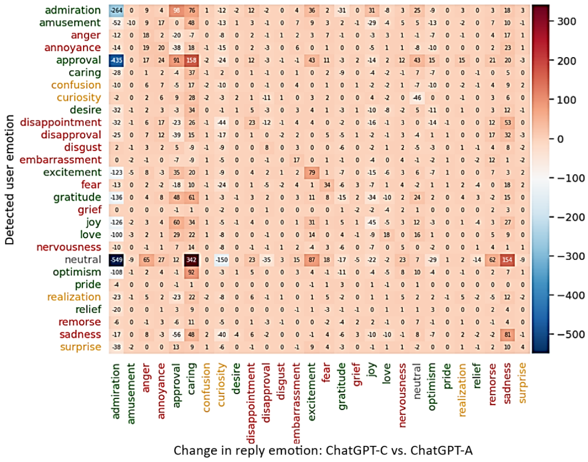

Figure 7: ChatGPT-C: Reponse emotion per user emotion.

5.4 Comparaisons to the SOTA Models

We also compared our three ChatGPT versions with other emotion-aware chatbot models as proposed in the literature (SOTA). The original transformer model (Vaswani et al., 2017) proposed in 2017 uses a self-attention mechanism to generate responses to user input. Emoprepend (Rashkin et al., 2018) is an improved version of the transformer with an emotion classifier trained to minimize the joint generation and classification loss. EmoEL (Lin et al., 2019) is a transformer-based model that combines responses from different decoders corresponding to different emotions. EmpDG (Li et al., 2019) is another chatbot model that uses both coarse-grained dialogue-level and fine-grained token-level emotions to generate empathetic responses.

	Response emotion choice				Perplexity
	Acc.	*Prec.*	*Recall*	*F1*	
Transformer	15.04	17.74	7.2	5.46	89.89
Emoprepend	15.04	**18.15**	7.72	5.58	94.77
MoEl	15.59	16.96	7.52	5.69	112.3
EmpDG	15.19	14.92	7.87	6.02	111.9
ChatGPT-A	28.64	13.19	**14.14**	**12.4**	30.63
ChatGPT-B	**39.55**	14.1	13.35	12.34	28.38
ChatGPT-C	22.71	10.03	12.23	9.4	**26.35**

Table 2: Benchmarking with other empathetic chatbots.

We compared our proposed ChatGPT versions with these models, in terms of the output emotion compared to the emotion label of the Empathetic Dialogues considered as ground truth response emotion. We also compared the fluency of the responses generated by each chatbot model to see which ones produce the most coherent replies.

The results in table 2 show that our proposed ChatGPT-B, the emotion-infused ChatGPT, outperformed both EmoEL and EmpDG in terms of emo-

Source	Utterance
Context	**Yeah about 10 years ago i had a horrifying experience . it was 100 % their fault but they hit the water barrels and survived . they had no injuries but they almost ran me off the road .**
Reference	*Did you suffer any injuries ?*
Transformer	Oh no , i am so sorry to hear that .
emoprepend	Oh no , did they catch them ?
moel	Oh no ! i hate spiders !
emp_DG	Oh no ! i am so sorry . i am so sorry . i am so sorry . i am so sorry to hear that .
ChatGPT-A	Wow, that sounds really scary! Have you been able to cope with the experience since then?
ChatGPT-B	I'm sorry to hear about your scary experience. It's alarming to think about what could have happened, but I'm glad you're okay.
ChatGPT-C	That sounds really scary and traumatic, and it's understandable that you would still remember it vividly.

Table 3: Reply examples from the different chatbot models.

tion response accuracy. Specifically, ChatGPT-B, with zero-shot, gave the highest emotion accuracy of up to 39.5%, while the regular ChatGPT gave the highest recall, and F1-score of 14.14% and 12.4%, respectively. These scores might appear to be on the low side, but we need to keep in mind that neither of the different ChatGPT versions were ever trained on the Empathetic Dialogues dataset, unlike the other models, and nevertheless produce impressive zero-shot results. Furthermore, we used a large number of emotion labels (28 fine-grained labels) which makes it harder to match the reference emotion exactly. In fact, a conversational agent can appear empathetic and emotional with several classes of emotions. For example, when looking at the answers from chatbots, we find that sometimes in the reference the answer to something like ”I had an accident” is a question like ”are you okay now?” which expresses the emotion ’curiosity’ while the chatbot says ”I hope you are okay now” which represents the emotion ”caring”. Moreover, in the reference, 25% of the answers are questions (expressing the ”curiosity” emotion) while our chatbot responds are dominated by emotion “caring.” Despite this, the ChatGPT versions perform the best overall with no prior training on the Empathetic Dialogues, in contrast to the other models.

On the perplexity front, it's clear that GPT-3.5-based ChatGPT models outperform the other chatbot models. In fact, since a lower perplexity generally means a more coherent expression (Bahl et al., 1983), we can see that ChatGPT-based models are vastly superior on this level. Specifically, the emotion-adapting ChatGPT-C has the lowest perplexity score of 26.35 while the emotion-infused ChatGPT-B has a slightly higher perplexity score of 28.38. The emotion-aware versions of ChatGPT are slightly more coherent when compared to the regular ChatGPT-A that got a perplexity of 30.63, likely thanks to the responses being more emotionally informed. While this is the worst score out of the three ChatGPT models, it is still well ahead of all the other models that have a perplexity score of more than 89.89. To see why this is the case, we can examine some examples in table 3. We can clearly see that ChatGPT models' responses are more natural and coherent compared to other models. For example, while emp_DG's reply does express remorse, it does so in a repetitive and unnatural sentence structure: *”oh no ! i am so sorry . i am so sorry . i am so sorry . i am so sorry to hear that .”* which explains the bad perplexity score for this model.

6 Conclusions and Future Work

In this study, we looked at how ChatGPT may elicit emotional reactions. Our findings imply that using prompt engineering and external emotion classifiers to augment conversational bots' emotional intelligence can be successful.

Our research adds to the expanding pool of knowledge regarding conversational agents and their emotional intelligence. The findings suggest that external knowledge sources, such as emotion classifiers, can provide a more nuanced understanding of the user's emotional state, and can lead to more effective and natural responses. Additionally, our study highlights the potential of prompt engineering to steer existing language models to produce outcomes tailored to our preferences without re-training or even fine-tuning. Future research might examine how well ChatGPT performs with other prompt designs. Other datasets can also be examined to see how that impacts the generated replies. We can also conduct a cross-lingual study to explore the benefits and limits of prompt engineering in generative AI.

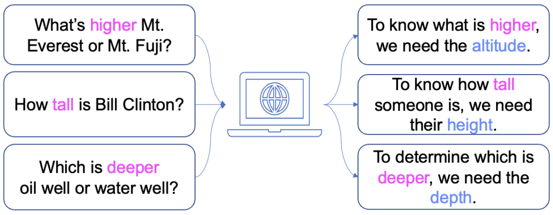
Abstract

One of the many advantages of pre-trained language models (PLMs) such as BERT and RoBERTa is their flexibility and contextual nature. These features give PLMs strong capabilities for representing lexical semantics. However, PLMs seem incapable of capturing high-level semantics in terms of compositionality. We show that when augmented with the relevant semantic knowledge, PMLs learn to capture a higher degree of lexical compositionality. We annotate a large dataset from Wikidata highlighting a type of semantic inference that is easy for humans to understand but difficult for PLMs, like the correlation between age and date of birth. We use this resource for fine-tuning DistilBERT, BERT large and RoBERTa. Our results show that the performance of PLMs against the test data continuously improves when augmented with such a rich resource. Our results are corroborated by a consistent improvement over most GLUE benchmark natural language understanding tasks.

1 Introduction

Given their recent success in various natural language processing (NLP) tasks, there has been increasing work on understanding the abilities of pre-trained language models (PLMs) beyond what they can memorize. Having been trained on billions of words, BERT (Devlin et al., 2019) has shown impressive language representation abilities. However, there has not been much work on the degree of knowledge that BERT could infer about different topics from just the lexical information that they are trained on. Therefore, there has been a growing interest in probing PLMs on all kinds of linguistic, syntactic and semantic features (Huang et al., 2021; Beloucif and Biemann, 2021; Huang et al., 2021; Mosbach et al., 2020; Tenney et al., 2019; Peters et al., 2018b,a; Devlin et al., 2019; Radford and Narasimhan, 2018; Broscheit et al., 2022).



What's higher Mt. Everest or Mt. Fuji?
How tall is Bill Clinton?
Which is deeper oil well or water well?
To know what is higher, we need the altitude.
To know how tall someone is, we need their height.
To determine which is deeper, we need the depth.

Figure 1: Multiple inferences are systematic for humans; however, they are much harder for NLP models to capture.

Figure 1 shows a few examples of high-level semantics relating to compositionality. For instance, when asked questions such as "What's higher Mt. Everest or Mt. Fuji?´´ or "How tall is Bill Clinton?´´, a person would most likely, and naturally think about *altitude* and *height* respectively, to accurately answer this question. When it comes to reasoning and inferences between semantic attributes (*net worth*) and their values (*rich*), humans can systematically infer between these concepts. The closer semantics in NLP that fits this case is compositional semantics since we investigate how different words in a sentence are linked to other words i.e. net worth being linked to wealth, and altitude is linked to the height of a mountain.

In this paper, we create a large dataset from Wikidata (Vrandečić and Krötzsch, 2014), where each sentence contains two words that are semantically related. We then fine-tune three pre-trained language models, namely BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and DistilBERT (Sanh et al., 2019), using this data. We create test data that has the same style as the training data, but with different objects and inferences. We obtained a remarkable boost in the quality on the test data. Furthermore, we also report a consistent improvement over the GLUE benchmark for natural language understanding (Wang et al., 2018).

Our main contributions are:

Proceedings of Recent Advances in Natural Language Processing, pages 170–178
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_019

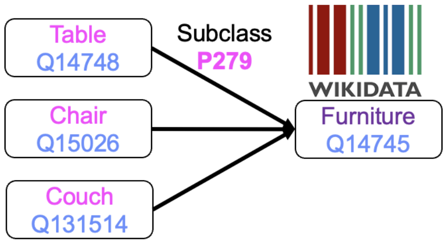


Figure 2: The hierarchical structure of Wikidata(Vrandečić and Krötzsch, 2014) allows us to have access to semantically sound data using different Wikidata entities as objects.

- a large dataset containing high-level semantics inferences,
- fine-tuning BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and DistilBERT (Sanh et al., 2019) on a more semantically sensitive dataset using the masked language model predictions,
- improvements over the test data as well as the GLUE benchmark for natural language understanding.

2 Probing Pre-trained Language Models

Using probes has become a common way to investigate the knowledge encoded in transformer-based (Vaswani et al., 2017) pre-trained language models such as BERT. These investigations have varied from linguistic features to include commonsense knowledge and social biases that PLMs might have learned during the training. Wallace et al. (2019) used question answering to show that PLMs fail at rational reasoning when it comes to capturing the numerical commonsense. More work has focused on studying different linguistic features and the level of linguistic competence in different PLMs (Mosbach et al., 2020; Tenney et al., 2019; Peters et al., 2018b) by making use of fine-tuning and sentence-level semantics. Probes were also used to identify social toxicity and bias towards different interest groups as we as gender bias (Ousidhoum et al., 2021; Stanczak et al., 2021). Other probing experiments have been proposed to study the drawbacks of PLMs in areas such as the biomedical domain (Jin et al., 2019), syntax (Hewitt and Manning, 2019), semantic and syntactic sentence structures (Yenicelik et al., 2020; Tenney et al., 2019; Peters et al., 2018b), linguistics (Belinkov et al., 2017; Clark et al., 2020; Tenney et al., 2019) and commonsense knowledge (Petroni et al., 2019; Davison et al., 2019; Talmor et al., 2020). When it comes to language understanding, Yenicelik et al. (2020) showed that when it comes to polysemy, BERT creates closed semantic regions that are not clearly distinguishable from each other. Another finding relating to semantics (Beloucif and Biemann, 2021) conveys that, unlike syntax, semantics and general world knowledge are not inherently learned, and thus not brought to the surface by the representations obtained from pre-trained language models.

3 Data Creation

We use the knowledge graph extracted from Wikidata to construct the dataset. Wikidata (Vrandečić and Krötzsch, 2014) is a collaborative knowledge base, containing triples (entity id, property id, value id) that define a type of relation holding between an entity and a value. Wikidata also contains labels and aliases for the properties, entities, and values, which makes it the perfect resource for extracting similar objects that are likely to have similar values. We then investigate the ability of PLMs to capture the semantic relationship between the attribute-value pairs and further fine-tune PLMs to capture this relation effectively. [1]

Algorithm 1: Creating fine-tuning data from Wikidata objects.

```
Result: fine-tuning dataset
fine-tuning-data=; while keyword in (food,
  furniture, city, tool) do
    AllData=extract all subclasses of keyword from
      Wikidata,
end
while i=0, i<size(alldata), i++ do
    BERT − sent(i)= BERT prediction on
      sentence i, extract all subclasses of keyword
      from Wikidata,
    if BERT-sent(prediction) == accurate-prediction
     then
        fine-tuning-data=fine-tuning-data +
          BERT-sent(i)
    else
end
```

In the knowledge graph, we focused on entities that were labeled *food*, *furniture*, *city* and *tool*, with *nutritious-healthy*, *wider-width*, *rainfall-humidity* and *longer-length* as entity-value pair respectively.

[1] The final dataset and the code are available here: `https://github.com/mihir86/Fine-Tuning-BERT-with-Wikidata`

Model	Top Prediction Accuracy				Top 5 Prediction Accuracy			
	PTLM	one-word-fine-tuned	two-word-fine-tuned	all-words-fine-tuned	PTLM	one-word-fine-tuned	two-word-fine-tuned	all-words-fine-tuned
DistilBERT-base	24%	62%	56%	**66%**	46%	**96%**	94%	92%
RoBERTa-large	20%	**38%**	**38%**	8%	44%	**78%**	70%	42%
BERT-Large	0%	**26%**	24%	22%	0%	**42%**	36%	40%

Table 1: The Performance of BERT on the test data.

Food is selected as the key because food items exhibit the attribute of *nutrition*, and thus comparing the subclasses of *food*, in terms of their nutrition can enable us to compare which food item is more *healthy*. For *city*, different cities have different *rainfall* and thus comparing the *rainfall* between different subclasses and instances of *city* can enable us to compare which city has more *humidity*. We applied the same analysis to *furniture* and *tool*.

In order to capture the semantic relationship between the attribute-value pairs, we create a dataset from the sentences where the value in the attribute-value relationship had been accurately predicted by BERT. The subclasses and instances of the keys *food*, *furniture*, *city* and *tool* were extracted from the knowledge graph and then used in combination with each other to create sentences of the form “Which is [attribute], and thus has more [value], [object 1] or [object 2]´´ where the objects represent the words used for comparing the attribute-value pair. For example, to analyze the ability of PLMs to capture the semantic relationship between *wider(attribute)* and *width(value)*, we consider *bed(Object 1)* and *chair(Object 2)* to be the chosen subclass combinations of the key *furniture*. Therefore, the sentence “Which is wider, and thus has more width, bed or chair?´´, is constructed with *width(value)* being masked.

Our final dataset contains around 8,000 fine-tuning samples, using five distinct attribute-value pairs. We divided our data into three categories, a dataset containing: (1) one-word objects, such as chairs, and couscous; (2) one-word objects and two-word compounds, such as folding chairs and bean sprout; and (3) all possibilities, including three-word compounds, such as aged cheddar cheese and slip joint plier. The purpose is to check how compound words affect the accuracy of the fine-tuned model, or in other words, does it matter to the PLM whether a noun is a compound or not?

4 Fine-Tuning PLMs for High-level Semantics

We used Huggingface(Wolf et al., 2019, 2020) for fine-tuning BERT (Devlin et al., 2019), RoBERTa(Liu et al., 2019) and DistilBERT(Sanh et al., 2019) [2]. For the fine-tuning, 15% of the tokens were masked randomly and the PLMs are fine-tuned with a masked language model objective by minimizing the loss based on the gold standard. The fine-tuned model is then evaluated on the test dataset, which consists of 50 different sentences with different semantic relationships.

5 Experimental Setup

Test data When finetuning the PLMs, one of the most challenging tasks is to prove that model could learn from the finetuning and is not just overfitting to the specific task. For that reason, we are testing on two different datasets: A Wikidata-based test set and the GLUE benchmark for natural language understanding (Wang et al., 2018). BERT-based models have significantly increased state-of-the-art over the GLUE benchmark, and most of the best scoring models for this benchmark include or elaborate on BERT.

We train our model on five topics, with different objects, but we test on 50 different attribute-value pairs. In order to show a certain generalization over the training data, we made sure that no attribute-value pair from the training is part of the test data. The masked word is then predicted by different PLMs. The accuracy of the top one and top five predictions is calculated. We purposefully diversify our test set from our training set to show that the improvement is not mere memorization. Our test data contains different objects such the *Eiffel Tower* or *Burj Khalifa*, which are both instances

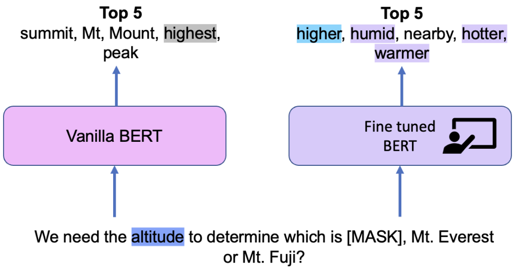
RoBERTa-FT	**83.6**	**64.7**	89.4 / 89.2	**91.5**	**94.1**	**92.4**	**72.6**	95.0	**92.6**	54.9
BERT	79.5	60.5	86.7 / 85.9	89.3	92.7	72.1	70.1	94.9	86.5	56.3
BERT-FT	**80.3**	**61.1**	86.6 / **86.5**	**90.9**	**93.6**	**72.4**	**72.9**	92.4	**90.2**	56.3

Table 2: The Performance of all three models on the GLUE benchmark.



Top 5
summit, Mt, Mount, highest, peak
Top 5
higher, humid, nearby, hotter, warmer
Vanilla BERT
Fine tuned BERT
We need the altitude to determine which is [MASK], Mt. Everest or Mt. Fuji?

Figure 3: BERT cannot predict the correct predictions when it comes to the mountain context. After fine-tuning, the predictions are more relevant to the context, even though *altitude* was not part of the fine-tuning data.

of the subclasses *observation tower* and *tourist attractions*. We report the accuracy (Table 1) in two distinct cases: (1) is the top one prediction correct?; and (2) is the correct prediction within the top five predictions?

Results Table 1 shows the prediction accuracy for all three models, before and after fine-tuning. The performance gain is consistent across the top one prediction and the top five predictions. We note from Table 1 that DistilBERT has the highest improvement compared to RoBERTa and BERT large. RoBERTa and BERT large are more sensitive to compound words, and they perform best with the one-word object and two words object. For the top five prediction accuracy, all three models perform best without compound words. In Figure 3 we show a concrete example from DistilBERT fine-tuning. We note from the example that, even though *altitude* is not part of the fine-tuning dataset, PLMs are now able to generalize from the concepts, rather than just memorize the words.

Testing on the GLUE benchmark corroborates this finding even further. Table 3 shows a significant improvement for some tasks and a slight improvement on other tasks. More specifically, we note that for the single task datasets, such as the Corpus of Linguistic Acceptability, CoLa (Warstadt et al., 2019), and for The Stanford Sentiment Treebank, SST-2 (Socher et al., 2013) there is a significant gain for the fine-tuned models. The same applies to inference tasks; Microsoft Research Paraphrase Corpus, MRPC, the Quora Question Pairs datasets, and the Semantic Textual Similarity Benchmark, STS-B (Cer et al., 2017), achieve a similar improvement. The consistent improvement over the semantically driven tasks shows that our fine-tuning helps PLMs capture more high-level semantics.

6 Conclusion

In this paper, we investigate how PLMs capture a very specific type of compositionality between different concepts. We also finetune two different PLMs on five different attribute-value pairs and test the model on 50 annotated themes. The training data and the test data have different topics and wording. Additionally, we purposefully limited the fine-tuning data for the scope of this short paper, since we did not want to make PLMs memorize all possible concepts. Our results show that, by having a resource that contains a basic level of lexical compositionality, we indeed help improve PLMs accuracy. However, we also show that there is more improvement in the GLUE tasks that are more semantically sensitive.

7 Limitations

Compositionality is a strong human characteristic when it comes to languages. In this paper, we created a synthetic dataset in order to help PLMs learn high-level semantics compositionality. The main limitation is the difficulty to test all possible cases. Compositionality is a challenging task, we show that we are able to generalize over limited test data, however, given their complex architecture, it is challenging to make test generalizations in the human sense. The second point is related to the created dataset, although widely accepted in the field, synthetic data suffers from human authenticity. More specifically, in an everyday conversation, when a person is asked about their age, the deduction in the human brain is automatic. It is challenging to present that concept through a sentence, which is what we tried to do here for testing and enabling the finetune.

Abstract

This paper proposes an open-ended task for Visual Question Answering (VQA) that leverages the InceptionV3 Object Detection model and an attention-based Long Short-Term Memory (LSTM) network for question answering. Our proposed model provides accurate natural language answers to questions about an image, including those that require understanding contextual information and background details. Our findings demonstrate that the proposed approach can achieve high accuracy, even with complex and varied visual information. The proposed method can contribute to developing more advanced vision systems that can process and interpret visual information like humans.

1 Introduction

As Computer Vision research moves beyond "bucketed" identification and toward resolving multimodal problems, language and visual problems like picture captioning and Visual Question Answering (VQA) have become prominent (Fang et al., 2015). Issues in the nexus of vision and language are complex due to the complicated compositional structure of language (Fukui et al., 2016) (Kafle and Kanan, 2017). However, recent research has shown that language can also provide a strong prior that can lead to good performance on the surface even when the underlying models do not fully comprehend the visual information.

Our approach to solving the VQA problem involves the development of three distinct models, each with its strengths and limitations: The first model is a simple baseline model that utilizes a pre-trained Convolutional Neural Network (CNN) and Recurrent Neural Network (RNN) architectures to extract visual and textual features from the input image and question, respectively. These features are then concatenated and fed into a simple feed-forward neural network that outputs the final answer. The second is an attention-based model that builds upon the baseline model by incorporating attention mechanisms to selectively focus on relevant parts of the image and question during the feature extraction process. This allows the model to attend to different regions of the image and words in the question, depending on their relevance to the answer. The third model is a more complex, multi-modal transformer-based model that uses a pre-trained transformer architecture to extract visual and textual features from the input image and question. The transformer model incorporates self-attention mechanisms that allow it to learn the relationships between different input parts and selectively attend to the most relevant information. This model also incorporates a Visual-Linguistic Transformer (ViLT) module that learns joint representations of both the image and question, allowing for a more seamless integration of visual and textual information. The experimental results show that our models employ different approaches to feature extraction and utilize various neural network architectures to tackle the VQA problem.

2 Related Work

Wang et al. (2021) proposed a new framework for unbiased visual recognition called Causal Attention. The framework improves visual recognition accuracy by explicitly modeling the causal relationship between image regions, which helps avoid introducing biases in the data. Incorporating this framework into VQA models helps address biases in visual recognition tasks and improves the accuracy of the models. However, our proposed work has a more flexible architecture that allows the image to be appended or prepended to the question sentence or placed in the middle of the question tensor through co-attention. This flexibility enables our models to capture better nuances and complex-

Proceedings of Recent Advances in Natural Language Processing, pages 179–186
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_020

ities of various VQA datasets and questions.

In another work, Dai et al. (2022) proposed a method to enable Contrastive Language-Image Pre-training (CLIP), a Computer Vision model, to generate multimodal outputs from a single prompt using distillation techniques that transfer knowledge from a separate multimodal generator model. Their proposed method achieves state-of-the-art performance on various multimodal tasks, including image captioning, text-to-image synthesis, and image synthesis from textual prompts. However, our proposed method differs from CLIP in several ways; The attentional Long Short Term Memory (LSTM) selectively attends to specific parts of the input sequence, while Inception V3 effectively extracts visual features from the input image. Combining these models leverages both strengths and provides better representations for multimodal understanding. Additionally, the multimodal system is trained on smaller and more targeted datasets, making it more effective in scenarios where the training data is limited or biased.

Huang et al. (2023) introduced a framework called "Kosmos-1" for VQA task that aligns perception with language models. Their approach involves a two-stage training process where a pre-trained image encoder is fine-tuned on a small set of VQA tasks before being integrated into a multi-modal transformer architecture. Additionally, the authors showed that their approach improved the interpretability of VQA models, allowing for a better understanding of model decision-making processes. Our proposed method introduces three different architectures. The approach allows for a more direct and intuitive way to associate image information with the textual inputs and exploit the interactions between visual and textual inputs in a more fine-grained manner. Kosmos-1 uses a single-stream architecture that processes textual and visual information in separate streams, leading to information loss and incomplete modeling of the interactions between the two modalities.

3 Dataset Description

The Microsoft Common Objects in Context (MSCOCO) VQA V2 dataset is a large-scale VQA task dataset (Lin et al., 2014). It is a subset of the MSCOCO dataset, comprising over 330,000 images and 2.5 million object instances. The MSCOCO VQA V2 dataset contains 265,016 images, and each image is accompanied by at least three open-ended questions and ten human-generated answers for each question.

This dataset evaluates various visual reasoning and language understanding capabilities, including object recognition, spatial reasoning, counting, and reasoning about actions and events. The questions in the dataset cover a wide range of topics, from ordinary objects and scenes to more complex and abstract concepts.

Using the MSCOCO VQA V2 dataset for VQA tasks enables researchers to develop and evaluate new visual reasoning and language understanding techniques essential in fields such as autonomous vehicles, robotics, and human-computer interaction.

3.1 Data Split and Statistics

The dataset is split into train, validation, and test sets. The training set contains 443,757 questions, while the validation and test sets have 214,354 and 135,024 questions, respectively (Lin et al., 2014).

There are no predefined answer options for the open-ended questions in the dataset. Ten human-generated solutions are provided for each question, offering a variety of potential accurate responses.

Each image in the MSCOCO VQA V2 collection also has metadata, such as item labels, characteristics, and spatial data. Through the addition of additional visual and contextual information, this metadata can be used to enhance model performance on the VQA task.

3.2 Question Types and Difficulty

The questions in the MSCOCO VQA V2 dataset cover various topics and require different levels of visual reasoning and language understanding (Tapaswi et al., 2016). Some examples of question types in the dataset include:

- Object recognition: "What is the color of the shirt?"

- Spatial reasoning: "What is the cat sitting on?"

- Counting: "How many cupcakes are on the table?"

- Reasoning about actions and events: "What is the man doing?"

- Abstract concepts: "What is the woman's emotion in the painting?"

The questions in the dataset are designed to be challenging and require a combination of visual and linguistic reasoning (Vinyals et al., 2015). Some questions are more complicated than others, requiring more complex reasoning or a deeper understanding of language and context.

3.3 Balancing the Dataset

The model's accuracy depends critically on the dataset quality, according to our VQA research. A class imbalance is a problem that frequently occurs in VQA datasets when some answer categories have an excessively high number of samples. This may result in models that are biased and underperform in some categories.

To address this issue, we employ techniques to balance the dataset and ensure an equal number of examples for each answer category (Wu et al., 2016). By increasing or decreasing the number of examples in each class, we can change the relative frequencies of each class using both oversampling and undersampling. We also employ more sophisticated approaches like data augmentation and Transfer Learning to enhance the dataset's quality.

Data augmentation involves creating new examples by applying transformations to existing data, such as rotating or flipping images (Hodosh and Hockenmaier, 2016). Transfer Learning involves using a pre-trained model on a different but related task to extract features that can be used to improve the accuracy of the VQA model.

Especially for large datasets with numerous classes, balancing the dataset might be difficult (Yang et al., 2016). As a result, we assess the performance of several approaches on our particular dataset. The accuracy of VQA models can be significantly increased by using a mix of oversampling, undersampling, data augmentation, and Transfer Learning, especially for datasets with class imbalance problems, according to our research.

Figure 1: Types of questions and images in the dataset.

3.4 Preprocessing the Dataset

The first step in pre-processing the MSCOCO VQA V2 dataset is data cleaning (Lei et al., 2018). This involves removing any incomplete or erroneous data from the dataset. Preliminary data may include images without associated questions or answers or questions without related answers. Inaccurate data may consist of images or questions with incorrect or misleading information. In addition to removing incomplete or erroneous data, data cleaning also involves standardizing the data format. For example, all questions and answers were converted to lowercase, or punctuation may be removed to ensure consistency.

The second step of pre-processing is data augmentation. It creates new training data by applying transformations to the existing data. In the case of the MSCOCO VQA V2 dataset, data augmentation may involve image transformations such as rotation, cropping, or scaling to the images in the dataset (Hodosh and Hockenmaier, 2016). This helps increase the diversity of the data and improve the performance of Machine Learning (ML) models. It also involves generating new questions and answers based on existing data. For example, further questions can be generated by replacing a word in an existing question with a synonym or by rephrasing the question differently.

The final step in pre-processing the dataset is data formatting (Zhou et al., 2016). This involves converting the data into a format that machine learning algorithms can easily use. For example, the images in the dataset were resized and normalized to a fixed size. The questions and answers may be converted into numerical representations such as one-hot encoding or word embeddings.

3.5 Inception v3

Using pre-trained models in deep learning has become a standard practice in many computer vision applications, including the MSCOCO VQA V2 dataset. In this paper, we use the Inception v3 model (Zhou et al., 2015) as a pre-trained model to extract features from the images in the dataset. By leveraging the pre-trained model's capabilities, we can more accurately predict answers to the questions posed about the images. The Inception v3 model has been demonstrated to achieve high accuracy on the ImageNet dataset, making it a suitable choice for image recognition tasks such as those presented in the MSCOCO VQA V2 dataset.

Through transfer learning and feature extraction, we can improve the performance of the VQA model in answering questions about images (Hodosh and Hockenmaier, 2016). Overall, our results demonstrate the effectiveness of using pre-trained models in deep learning and their ability to improve the accuracy of computer vision tasks.

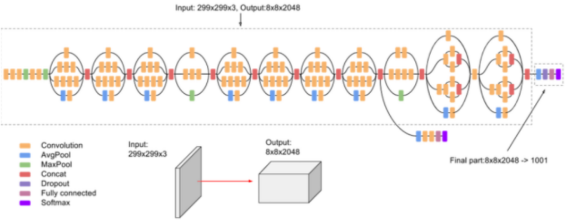

Figure 2: Inception-v3 complete architecture. It is based on CNN and used for image classification. It uses Label Smoothing, Factorized 7x7 convolutions, and an auxiliary classifier

3.6 Vocabulary Building

In this paper, we utilize the NLTK word tokenizer to break down the text data into smaller pieces called tokens, which are then used to build the vocabulary.

To create the vocabulary, we use the response vector generated by the Label encoder as a basis for developing a dictionary of words (Saito et al., 2017). The Label encoder is a tool that assigns a unique numerical value to each word in the response vector, which is then used to create a vocabulary of words. The vocabulary is built by counting the frequency of each word in the response vector and assigning it a numerical value based on its frequency. Words that occur more frequently are assigned lower numerical values, while words that occur less frequently are assigned higher numerical values.

To ensure that the vocabulary is robust and comprehensive, we fit the output of the NLTK word tokenizer to the training questions and replies. This allows us to capture a wide range of words and phrases used in the dataset and create a complete vocabulary. Additionally, we convert the output of the NLTK word tokenizer to a data frame for enhanced text interpretation, which enables us to visualize better and analyze the text data. By creating a comprehensive dictionary of words used in the corpus, we can more accurately interpret and analyze the text data and improve the overall performance of the VQA model (Selvaraju et al., 2017). Our results demonstrate the effectiveness of this approach and highlight the importance of vocabulary building in NLP.

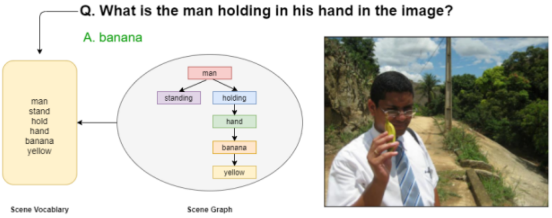

Figure 3: It describes the scene vocabulary for the given question. Vocabulary helps pre-process corpus text which acts as a classification and storage location for the processed corpus text.

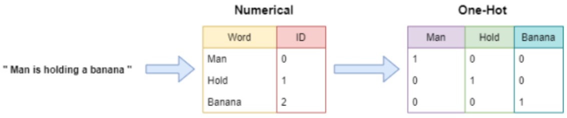
3.7 One-hot Encoding

One-hot encoding is popular in various machine learning tasks, including classification, Natural Language Processing (NLP), and Computer Vision. In this paper, we use our dataset to investigate the application of one-hot encoding (Saito et al., 2017) in the context of the VQA task.

We proposed using one-hot encoding to represent each answer as a vector of binary values. Each element corresponds to a unique answer option in Shih et al. (2016). By converting the answer vectors into one-hot encoded vectors, the model can better capture the complex relationships between the visual input, question, and answer options, leading to improved performance.

Our experimental results show that one-hot encoding outperforms the methods in Saito et al. (2017), achieving higher accuracy and F1-score on the VQA task using the MSCOCO VQA v2 dataset.



Numerical

Word	ID
Man	0
Hold	1

0	1	0
0	0	1

Figure 4: In this scenario, the integer representation can be encoded with a one-hot encoding. The VQA problem was treated as a classification problem, and all answer vectors were turned into one hot-encoded vector.

4 Models and Experiments

We propose three VQA models, utilizing Recurrent Neural Networks (RNNs) and image embeddings to answer questions based on visual content. The models differ in adding the image to the input question tensor.

We provide an overview of our approach before describing each step in detail in the following subsections. The first model, Appending Image as Word Model, appends the image features to the end of the question features, creating a concatenated vector fed into an LSTM layer for prediction. The second model is Prepending Image as Word Model, which prepends the image features to the beginning of the question features, creating a concatenated vector fed into an LSTM layer for prediction. The third model is the Co-Attention Model, which utilizes a co-attention mechanism, where the image and question features are combined at every time step using attention weights. This model then feeds the integrated features into an LSTM layer for prediction.

All three models are evaluated on the MSCOCO VQA v2 dataset and compared to the state-of-the-art approaches (Shin et al., 2016). An ablation study is conducted to investigate the impact of different hyperparameters and variations of the models on the VQA task's performance. The experiments show that adding image features to the input question tensor can significantly improve the model's performance and highlight the importance of the RNN's architecture and the number of image features utilized.

4.1 Model 1 - Adding Image after Word

In the first approach, we provide a novel model for the VQA task that utilizes an embedding layer and an RNN-like GRU to generate answers to questions based on visual content. The model first obtains word-level embeddings using the embedding layer offered by TensorFlow [1]. The input picture is then processed as a word and attached to the terms corresponding to the appropriate question, resulting in a complete input question tensor.

The complete input question tensor is fed into the GRU RNN, which processes the tensor and generates a sequence of output vectors (Saito et al., 2017). The RNN's output is further processed through a softmax-activated final dense layer to improve the model's performance. This layer's output is the final answer to the inquiry.

The proposed model is evaluated on the MSCOCO VQA v2 dataset and compared with state-of-the-art approaches. The results show that the model achieves competitive performance on the dataset, outperforming several previous models.

Moreover, an ablation study is conducted to investigate the impact of different hyperparameters and variations of the model on its performance. Our work shows that the model's performance is sensitive to the size of the word embeddings, the number of layers in the RNN, and the size of the final dense layer.

The proposed model demonstrates the effectiveness of using an embedding layer and an RNN for the VQA task and provides insights into the impact of different hyperparameters on the model's performance. The findings can be utilized to develop more accurate and efficient VQA models in the future.

4.2 Model 2 - Adding Image before Word

In our second approach, we provide an alternative model for the VQA task, where the image is added to the input question tensor before the words. This model is comparable to the Adding Image after Word Model but significantly differs in how the image is integrated into the model. In this model, the image is prepended to the question tensor, and the resulting tensor is then fed into an LSTM for further processing.

The LSTM processes the concatenated tensor and generates a sequence of output vectors (Agrawal et al., 2016). The output vectors are then passed through a final dense layer with softmax activation. Similar to the Adding Image after Word Model, the output of the LSTM is further processed through a softmax-activated final dense layer to improve the model's performance. This layer's output is the final answer to the inquiry.

We conduct experiments on the MSCOCO VQA v2 dataset to evaluate the proposed model and compare its performance with state-of-the-art approaches (Donahue et al., 2015). The results show that the model achieves competitive performance on the dataset and outperforms several previous models.

Furthermore, we conduct an ablation study to investigate the impact of different hyperparameters and variations of the model on its performance. The study reveals that the model's performance is sensitive to the size of the word embeddings, the number of layers in the LSTM, and the size of the final dense layer.

[1] https://github.com/tensorflow

4.3 Model 3 - Attention-based Model

In our third approach, we propose an attention-based model, an advanced technique that seeks to address the limitations of the previous models. This model utilizes a co-attention mechanism that simultaneously attends to visual and textual inputs to generate more accurate results. In this model, we propose an alternating co-attention architecture focusing on the image's issue at both the sentence and word levels.

In contrast to the previous models, the attention-based model dynamically attends to the most relevant parts of the input data, allowing the model to focus selectively on the most critical information important for answering the question (Huang et al., 2023). This approach enhances the model's understanding of the complex relationship between the image and text and generates more accurate predictions.

The co-attention mechanism is implemented by alternately attending to the question and the image features using a series of attention layers. The model then aggregates the attended features and passes them through a final dense layer with softmax activation to generate the answer.

This co-attention-based approach is significantly more effective than the previous models as it allows the model to capture complex relationships between the image and the text (Li et al., 2023). The attention mechanism enhances some parts of the input data while diminishing others, enabling the network to focus more on the crucial aspects of the data that influence the answer to the question. This capability to selectively focus on specific parts of the input data results in better accuracy and overall performance of the model.

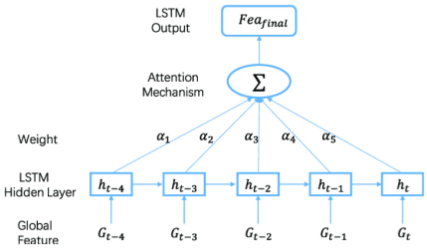

Figure 5: Attention Mechanism in LSTM. It helps to look at all hidden states from the encoder sequence to make predictions. The effect enhances some parts of the input data while diminishing other parts — the thought being that the network should devote more focus to that, a small but essential part of the data.

5 Results

We evaluate the three models trained on the train splits of both the unbalanced and balanced datasets by testing on the balanced test set as done in Agrawal et al. (2016).

Training on the balanced dataset works well. This may be because the models trained on flat data must learn to extract visual information to answer the question correctly since they can no longer exploit language biases in the training set. Whereas models trained on the unbalanced set are blindsided into learning strong language priors, which are then not available at the test step.

The results of Model-1, Model-2, and Model-3 are summarized in Table 1, Table 2, and Table 3, respectively.

	Unbalanced	Balanced
Yes/No	45.02	47.45
Number	40.24	42.78
Other	39.87	40.89

Table 3: Evaluation of test accuracies of Model-3 on Balanced and Unbalanced Dataset.

6 Conclusions

Our proposed framework addresses the limitations of existing VQA models by combining the attentional LSTM and Inception v3 models to create three different models for VQA. By appending or prepending the image as a word in the question sentence or using a co-attention model, we can better capture the relationship between images and questions, improving VQA performance.

Abstract

Large language models (LLMs) and generative AI have emerged as the most important areas in the field of natural language processing (NLP). LLMs are considered to be a key component in several NLP tasks, such as summarization, question-answering, sentiment classification, and translation. Newer LLMs, such as ChatGPT, BLOOMZ, and several such variants, are known to train on multilingual training data and hence are expected to process and generate text in multiple languages. Considering the widespread use of LLMs, evaluating their efficacy in multilingual settings is imperative. In this work, we evaluate the newest generative models (ChatGPT, mT0, and BLOOMZ) in the context of Indic languages. Specifically, we consider natural language generation (NLG) applications such as summarization and question-answering in monolingual and cross-lingual settings. We observe that current generative models have limited capability for generating text in Indic languages in a zero-shot setting. In contrast, generative models perform consistently better on manual quality-based evaluation in Indic languages and English language generation. Considering limited generation performance, we argue that these LLMs are not intended to use in zero-shot fashion in downstream applications.

1 Introduction

Since the release of instruction-based ChatGPT, large language models (LLM) have taken the language generation research landscape by storm. Recent transformations in natural language processing (NLP) are largely enabled by pretrained LLMs such as T5 (Raffel et al., 2020), GPT3 (Brown et al., 2020), and LLaMa (Touvron et al., 2023) to name a few[1]. These models demonstrate impressive results in various NLP tasks, including language generation (NLG). Accordingly, the use of such off-the-shelf LLMs in solving downstream applications, such as conversational agents and creative copywriting, is rising. Secondly, although the performance has reached a near-human level, most of these works focus on European languages. Specifically, the latest generative models, such as ChatGPT and Bard, generate near-perfect content in English and other high-resource languages. However, English is not the native language for most of the world's population. One prime example of this is India, where people interact in one of their native languages daily. Considering India is the most populated country in the world[2], it is imperative to evaluate the latest progress in NLP (and NLG) and the potential of LLMs to be used as-is in the downstream tasks with a focus on Indic languages.

So far, the LLMs have shown considerable prowess in tackling monolingual applications. But with increasing globalization and demand for information, research in cross-lingual approaches is gaining attention. This upcoming field consists of methods to enable information access across multiple languages. With this work, we provide an initial performance evaluation in monolingual and cross-lingual settings for Indic languages.

There has been a spurt of research in the direction of evaluating generative models. Recent works include LLM evaluation in multilingual learning (Lai et al., 2023), cross-lingual summarization (Wang et al., 2023a), and multi-task, multimodal, and multilingual setting (Bang et al., 2023). Evaluating LLMs as an alternative to human annotators and evaluators is also explored in (Wang et al., 2023b; Huang et al., 2023; Törnberg, 2023; Guo et al., 2023). As a part of our analysis, we report preliminary observations on evaluating and anno-

[1] Henceforth, we use generative models and LLMs interchangeably.

tating powers of generative models.

This work focuses on NLG tasks such as summarization and question-answering. We use LLMs such as ChatGPT variant (GPT-3.5), mT0, and BLOOMZ to evaluate zero-shot (monolingual and cross-lingual) settings. We compare the zero-shot performance of these LLMs with state-of-the-art (SOTA) baselines for the above tasks. We manually evaluate the results on quality metrics such as relevance, correctness, and fluency. We present our observations on the various generative models and generation tasks, such as summarization and question-answering in monolingual and cross-lingual settings.

The main findings of this work are as follows:

1. To the best of our knowledge, this work is the first to explore the zero-shot performance of LLMs for Indic languages. We also experiment with cross-lingual settings to analyze the correlation with the English language.

2. We observe that in terms of the ROUGE metric, the current open-source LLMs display limited performance in text generation in Indic languages. Results for cross-lingual generation (generation from Indic languages to English) also show a similar trend.

3. It should be noted that using off-the-shelf LLMs in downstream applications in Indic languages is not advisable. Results show that fine-tuned models perform far better than the zero-shot LLMs. Fine-tuning using task-specific and language-specific data is essential for better performance.

4. Content generated by LLMs is observed to be more relevant, fluent, and correct than human-generated content in mono-lingual and cross-lingual settings. It is worth noting that the manual evaluation for quality metrics reports observations contradictory to the ROUGE metric evaluation, reiterating the fact that automatic metrics do not correlate well with human evaluations.

2 Related Work

With rapid advancements in generative models, there has been a lot of interest in understanding and evaluating the performance of these models. Since many of these models have not completely disclosed their technical and data specifications (e.g., Bard and ChatGPT), experimenting in different settings is one way to test their behavior. Recently, targeted efforts have been observed to evaluate the performance of these LLMs in the context of multiple languages, modalities, and tasks. Lai et al. (2023) perform a thorough evaluation of ChatGPT for its performance in multiple languages across multiple tasks. Similarly, Bang et al. (2023) extensively investigate ChatGPT in multilingual, multimodal, and multitask setting with a focus on reasoning and hallucination. Liu et al. (2023) documents experiments evaluating ChatGPT's Text-to-SQL performance to explore its capability of generating structured SQL text for given natural language text. Wang et al. (2023a) document the performance of ChatGPT-like LLMs for cross-lingual summarization. They consider *English* and *Chinese* languages as a part of their study. In contrast, we focus solely on NLG tasks for Indic languages. We consider *English* as a part of the cross-lingual generation setup.

Using generative models for annotation or evaluation is an interesting application, and many works have been reported to explore the same. Wang et al. (2023b) explore the possibility of using ChatGPT to evaluate the quality of natural language. Guo et al.(2023) extensively investigate ChatGPT for its closeness to human experts. On similar lines, Tornberg et al. (2023) reports that ChatGPT outperforms experts and crowd-workers in annotating for certain tasks. These works consider high-resource languages such as English and Chinese. Several other works, such as (Zhu et al., 2023; Kuzman et al., 2023; Chen et al., 2023), explore using generative models as an alternative to human annotators and evaluators. Our work focuses on low-resource Indic languages to evaluate generative models for their ability to annotate and evaluate linguistic content.

3 Methodology

This work aims to evaluate the performance of generative models for NLG tasks in Indic languages in mono-lingual and cross-lingual settings. By definition, a monolingual setup considers a single language for input and output, whereas, in a cross-lingual setting, input and output content are in different languages. For example, generating an English summary from an English article is a monolingual task, while generating a Tamil summary from an English article or vice versa is a cross-lingual task. Considering continuing developments in generative models, we restrict this work to popular LLMs and selective tasks. But we are cognizant of the fact that continuous effort is required for exhaustive experimentation. In this work, we consider two broad NLG areas, viz. Summarization (SUM) and Question-Answering (QA). We use the **IndicNLG** benchmark dataset (Kumar et al., 2022) covering 11 Indic languages. These languages belong to Indo-Aryan and Dravidian language families, the main difference between them being the agglutinative nature of Dravidian languages. We also manually evaluate the generated content for quality metrics such as relevance, fluency, and correctness.

3.1 Summarization

Summarization is the process of compressing given textual content into concise and short form by preserving the most important content. It is achieved by paraphrasing or rewriting the salient information from the given input document. Recent improvements in LLMs have illustrated high-level language understanding, reasoning abilities, and fluent generation skills essential for summarization. We choose **Headline Generation** task to evaluate LLMs for their summarization capabilities. This task aims to generate a crisp and short one-sentence summary/title for a given news article.

3.2 Question-Answering

Question-Answering (QA) is a popular research area with many applications in search, recommender systems, and smart-assistants. QA systems provide a way to retrieve relevant information by querying structured and unstructured data sources. Given a user's requirements, these systems must scan given data sources, understand the query and context, collate relevant information, and apply reasoning abilities to generate appropriate responses. We seek to assess recent LLMs for their QA abilities, which will help us understand their comprehension and reasoning abilities. To this extent, we consider the following two themes for our experiments:

- *Question Generation*: generating an appropriate question for an answer and a given text content.
- *Answer Generation*: extracting an appropriate answer to a question from a given text content

3.3 Large Language Models

We explore the following LLMs in the context of Indian languages in monolingual and cross-lingual settings.

- **ChatGPT (GPT-3.5)** is known to be created by finetuning the GPT-3.5 variant using reinforcement learning from human feedback (**RLHF**) (Christiano et al., 2017). We evaluate this model using the ChatGPT platform between 11th May to 15th May 2023.
- **BLOOMZ** (Muennighoff et al., 2023) is an open-source multilingual LLM. Multitask prompted finetuning (MTF) is applied to pretrained BLOOM LLM (Scao et al., 2022) to build the fine-tuned variant, BLOOMZ. BLOOMZ family consists of models with 300M to 176B parameters and supports 59 languages.
- **mT0** (Muennighoff et al., 2023) is the fine-tuned variant of pretrained multilingual mT5 language model. Like BLOOMZ, MTF is applied to mT5 to produce mT0 with model variants ranging from 300M to 176B.

  BLOOMZ and mT0 families have been trained on xP3 and xP3MT, consisting of 13 training tasks in 46 languages. Dataset xP3 uses English prompts, whereas xP3MT uses prompts that are machine-translated from English in 20 languages.

3.4 Prompting Strategies

Recent developments in generative models predominantly focus on instruction tuning with prompt engineering as the most viable method to interact with these LLMs. We heuristically design the prompting strategies for various tasks. We experimented with multiple variations of prompts, considering different paraphrases and instruction sequences. The selected prompts are chosen considering the best possible responses across different LLMs.

Summarization We consider monolingual and cross-lingual summarization for our experiments. In the following prompts, language is specified at `{lang}` and the prompts are followed by the textual content in place of `{content}` in one of the Indic languages.

- **MSUMM**:- This prompt guides LLMs to generate the summary in the same language as that of the given content:
  `I want you to act as a summarizer. I will provide the article in {lang}, and I want you`

```
to generate a one-line summary
for the given article. I want
the generated summary in {lang}.
Content: {content}
```

- **XSUMM**:- This prompt is used for cross-lingual summarization where content is given in one of the 11 Indic languages, and LLMs are instructed to generate a summary in English. We use the modified MSUMM prompt by changing the second {lang} to English.

Question-Answering Question-Answering task is further categorized into *Question Generation* and *Answer Generation*. We interchange the question and answer requirements according to the task. The language is specified at {lang}, context at {context} and Answer(/Question) {answer/question}.

- **MQG/MAG:**- This prompt guides LLMs to generate relevant question(answer) in the same language as that of the given context and answer(question):

```
I want you to act as a question(answer) generator. I
will provide the text as a
context in {lang} and an answer(question) based on the
text in {lang}. I want you to
generate a question(answer) for
the given answer using given
text as context. I want the
generated question(answer) in
the same language as that of
the given answer(question).
Context: {context}
Answer(/Question):
{answer/question}
```

- **XQG/XAG**:- This prompt is used for cross-lingual question generation and answer generation. The context is given in one of the 11 Indic languages, and LLMs are instructed to generate question (answer) in English. As earlier, we use a modified MQG/MAG prompt by using 'English' in place of the second {lang}.

3.5 Quality Metrics

With the increase in popularity of NLG systems, there is a need for devising a proper way of evaluating generated content and thereby comparing systems' performances. Till now, automatic metrics such as BLEU and ROUGE are widely used even though they show little correlation with human judgment (Sai et al., 2022). In this study, we consider a randomly selected subset of articles from the *Summarization* dataset and manually evaluate the generated summaries on quality metrics such as *fluency*, *relevance*, and *correctness*. We define these metrics as follows:

Language	**Task**	
	HG	**QG**
Assamese (as)	59,031	98,027
Bengali (bn)	142,731	98,027
Gujarati (gu)	262,457	98,027
Hindi (hi)	297,284	98,027
Kannada (kn)	155,057	98,027
Malayalam (ml)	20,966	98,027
Marathi (mr)	142,590	98,027
Odia (or)	72,846	98,027
Punjabi (pa)	60,635	98,027
Tamil (ta)	75,954	98,027
Telugu (te)	26,717	98,027

Table 1: IndicNLG Benchmark datasets statistics for Headline Generation (HG) and Question Generation (QG) for 11 languages.

Fluency refers to the correctness of the generated text with respect to grammar and word choice, including spelling (Sai et al., 2022).

Relevance evaluates whether the generated content is related to the given input data.

Correctness assesses whether the information provided in the generated content is consistent with the source or input data.

4 Experimental Setup

Datasets As mentioned earlier, we primarily use task-specific datasets from **IndicNLG** benchmark (Kumar et al., 2022). Table 1 presents data distribution for both **Headline Generation** and **Question Generation**, benchmark datasets.

To evaluate *Summarization* performance, we choose **Headline Generation** benchmark dataset from **IndicNLG** (Kumar et al., 2022). This dataset consists of news articles and corresponding headlines in Indic languages, with a total of 1,316,268 samples distributed across 11 Indic languages. We randomly select 50 samples from every 11 languages for the monolingual summarization task. To evaluate cross-lingual capabilities, we generate the output summary in English and compare it with the English translation of the corresponding reference summary.

We consider the **Question Generation** benchmark dataset from **IndicNLG** to evaluate QA capabilities. This dataset is repurposed from SQuAD question-answering dataset (Rajpurkar et al., 2016). The question, corresponding answer, and the sentence containing the answer is extracted and translated into Indic languages. The dataset consists of around 98K samples each for 11 languages. For monolingual *Question Generation* and *Answer Generation*, we randomly select 50 samples from each language-specific data samples. For cross-lingual experiments, we generate the questions in English and compare them with English translations of reference questions. Following a similar translation methodology for cross-lingual experiments, we use LLMs to generate answers in English for comparison with English translations of answers in the ground truth.

Baselines We compare the performance of zero-shot LLMs with fine-tuned **IndicBART** and **mT5** models. **IndicBART**(Dabre et al., 2022) is a pre-trained model that focuses on all 11 Indic languages considered in this work. Similarly, **mT5** (Xue et al., 2021) is a pre-trained multilingual model covering 101 languages, including Indic languages, in focus for this work. We consider results reported in (Kumar et al., 2022) for comparative analysis.

Metric Since baseline results are reported in ROUGE metric, we ROUGE-1/2/L (Lin, 2004) for our evaluation. The ROUGE score considers the lexical overlap between generated content and given reference text based on unigram (R-1), bigram (R-2), and the longest common subsequence (R-L). For ROUGE score computation, we use *multi-lingual rouge* toolkit[3].

Implementation We use official API with default settings for ChatGPT (**GPT-3.5**). For **mT0** and **BLOOMZ**, we use Huggingface checkpoints, mt0-large and bloomz-1b1, respectively. We use a subset of around 50 samples from the summarization dataset and score the corresponding generation results on the above quality metrics.

5 Results & Analysis

In this section, we present results and analysis for *Summarization*, *Question Generation*, and *Answer Generation* tasks.

5.1 Monolingual Generation

Table 2 reports the experimental results for *summarization*, whereas Table 3 lists the results for *Question Generation*. Table 4 documents *Answer Generation* results.

Fine-tuning helps in certain tasks It can be seen that fine-tuning is extremely effective in the case of *Summarization*. We can see that the fine-tuned models, mT5 and IB, consistently show stronger performance than the zero-shot generative models in all 11 languages. In the case of *Question Generation*, the performance gap between fine-tuned models and zero-shot models is narrow, although

LN	GPT-3.5	mT0	BLOOMZ	mT5	IB

Table 3: Experimental results (ROUGE-L scores) for **Monolingual** *Question Generation* for 11 Indic Languages (**LN**). IndicBART (**IB**) and **mT5** are finetuned state-of-the-art results.

[3] `https://github.com/csebuetnlp/xl-sum/tree/master/multilingual_rouge_scoring`; Last accessed: 08/11/2023

the fine-tuned models have better performance.

Does model architecture play a role in the performance? GPT-3.5 and BLOOMZ are decoder-only architectures, whereas mT0 is based on the encoder-decoder architecture of transformers. Although BLOOMZ performance is consistently worse in *Question Generation* and *Answer Generation*, there is no clear winner. Hence, no definite conclusion can be drawn from the observed performance results. Possible directions to evaluate are the training data size, training data sources, and prompting strategies. We keep this study for the future.

Monolingual Answer Generation is easily adaptable We observe from Table 4 that both GPT-3.5 and mT0 display strong ability to adapt to modified tasks like *Answer Generation* with comparable results. In contrast, BLOOMZ consistently lags behind, reiterating the need to analyze different LLMs in depth.

LN	GPT-3.5	mT0	BLOOMZ
as	11.88	18.91	4.79
bn	15.78	24.00	4.72

ta	16.20	21.42	6.50
te	18.04	4.97	4.47

Table 4: Experimental results (ROUGE-L scores) for **Monolingual** *Answer Generation* for 11 Indic Languages (**LN**).

5.2 Cross-lingual Generation

In cross-lingual generation experiments, we aim to generate English content corresponding to the input given in one of the Indic languages. Table 4 reports the results for the three tasks in this setting.

Adapting to cross-lingual setting. We observe that cross-lingual generation is not easily achievable using off-the-shelf generative models. Only GPT-3.5 demonstrates a strong capability for cross-lingual generation. mT0 performs equally well in *Question Generation* but lags behind in cross-lingual *Summarization* and *Answer Generation*. BLOOMZ does not adapt at all to the cross-lingual setting. One possible reason is that the generative models are unaware of such an application since it is not a part of their pre-training. Cross-lingual generation is not a typical NLG task, and hence zero-shot generative models fail to adapt for the same. We believe that additional efforts in terms of dataset and fine-tuning are necessary for better cross-lingual capabilities. Another possibility is that the prompts used in the experiments may be better suited for GPT-3.5 than the other two. We believe that more experiments with prompt engineering may improve the performance of mT0 and BLOOMZ.

5.3 Evaluation on Quality Metrics

Despite the popularity of automatic metrics like ROUGE, it is well-known that these metrics do not correlate well with human judgment for generated content quality. Figure 1 depicts the quality evaluation of generated content and corresponding average scores on each quality metric.

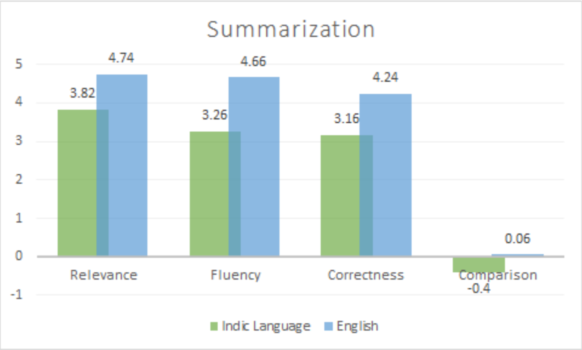

Figure 1: Manual evaluation of GPT-3.5 responses on quality metrics.

LLMs can parse the Indic languages but have better articulation in English In all quality measures, the English language generation consistently ranks higher than the generation in the Indic languages. In other words, the generative models or LLMs possess some parsing capabilities towards Indic languages, but it is not reflected in the generation process.

Generative models are better writers than humans We also compare the generated content with the reference text, with the last column representing the comparison. It can be seen that the mono-lingual generation is of lower quality as compared to the reference text, whereas the English generation is slightly better. We are conscious of the

fact that extensive experiment with a large dataset is essential to establish the above observations.

5.4 Language-specific Evaluation

Aside from Hindi, all other Indic languages are categorized under low-resource or extremely-low-resource languages (Lai et al., 2023). These languages have a lower representation in the data corpus used for training LLMs. Despite that, LLMs perform comparatively well on these languages. In some cases, performance for Punjabi (pa) and Odia (or) languages is surprisingly better than that of the relatively high-resource Hindi language.

6 Concluding Remarks

With recent remarkable progress in generative models, it is essential to see no one is left behind. Advancements in low-resource languages, such as Indic languages, are lagging due to the shortage of quality data sources and technological thrust. Understanding and evaluating current progress for such under-represented languages is extremely important to identify gaps for future research. With this work, we hope to assess the generative capabilities of recent generative models in the context of Indic languages. We note that the generative models have limited capability in Indic languages in their zero-shot setting. In contrast, these models are known to perform relatively well in generating relevant English QA content highlighting their superior understanding and reasoning abilities. Off-the-shelf use of these LLMs in a zero-shot manner is observed to be suboptimal, underscoring the need for fine-tuning and task-relevant data sources. In comparison with a human evaluation of quality metrics, these models perform far better than actual reference content. It is observed that generative models may be useful as an alternative to manual annotation and evaluation efforts. We plan to continue this evaluation work by including GPT-4 and Bard. We also hope to compile more human evaluations to better understand the efficacy of generative models as an annotator or an evaluator.

7 Ethics-Impact Statement

All the datasets and pre-trained models used in this work are publicly available for research. The authors foresee no ethical concerns or copyright violations with the work presented in this paper.

Limitations We evaluate the performance of LLMs on generative tasks such as *summarization*, *question generation*, and *answer generation*. There are some limitations to note: 1) Prompts are crucial in guiding LLMs for a specific task. We have heuristically identified certain prompts, but future work could involve exploring better prompts to get better generation results. 2) We note that the evaluation comparisons need more rigor with more samples and human evaluations. Due to limitations on API usage, this work considers a subset of the dataset for comparison.

Measuring Spurious Correlation in Classification: ”Clever Hans” in Translationese

Abstract

Recent work has shown evidence of ”Clever Hans” behavior in high-performance neural translationese classifiers, where BERT-based classifiers capitalize on spurious correlations, in particular topic information, between data and target classification labels, rather than genuine translationese signals. Translationese signals are subtle (especially for professional translation) and compete with many other signals in the data such as genre, style, author, and, in particular, topic. This raises the general question of how much of the performance of a classifier is really due to spurious correlations in the data versus the signals actually targeted for by the classifier, especially for subtle target signals and in challenging (low resource) data settings. We focus on topic-based spurious correlation and approach the question from two directions: (i) where we have no knowledge about spurious topic information and its distribution in the data, (ii) where we have some indication about the nature of spurious topic correlations. For (i) we develop a measure from first principles capturing alignment of unsupervised topics with target classification labels as an indication of spurious topic information in the data. We show that our measure is the same as purity in clustering and propose a ”topic floor” (as in a ”noise floor”) for classification. For (ii) we investigate masking of known spurious topic carriers in classification. Both (i) and (ii) contribute to quantifying and (ii) to mitigating spurious correlations.

1 Introduction

The term *translationese* refers to systematic linguistic differences between originally authored texts and translated texts in the same language (Gellerstam, 1986). Important aspects of translationese have been identified in the linguistic literature (Toury, 1980; Baker et al., 1993; Teich, 2012; Volansky et al., 2013), including source language interference, over-adherence to target language, simplification, explicitation, and implicitation. Translationese may manifest itself at lexical, syntactic, semantic, and discourse-related levels of linguistic description. While translationese signals are subtle (especially for professional human translation), corpus-based linguistic methods (Baker et al., 1993) and machine learning based classification methods (Volansky et al., 2013; Rabinovich and Wintner, 2015; Rubino et al., 2016; Pylypenko et al., 2021) are able to reliably distinguish between original and translated texts in the same language, genre, and style. While basic research focuses on identifying and categorizing aspects of translationese, research has also shown that translationese clearly impacts practical cross-lingual tasks that involve translated data (Singh et al., 2019; Zhang and Toral, 2019; Clark et al., 2020; Artetxe et al., 2020). Finally, translationese is sometimes regarded as (one of) the final frontier(s) of high-resource machine translation (Freitag et al., 2020, 2019; Ni et al., 2022).

In this paper, we focus on translationese classification (into original O and translated T data) using machine learning based approaches. Early work on translationese classification focused on manually engineered and linguistically inspired sets of features (n-grams, POS, discrete LM-based features etc.), using supervised classification models such as decision-trees or support vector machines (SVMs) (Baroni and Bernardini, 2005; Volansky et al., 2013; Rubino et al., 2016).

More recently, research focused on feature-and-representation learning neural network methods for translationese classification (Sominsky and Wintner, 2019; Pylypenko et al., 2021). Pylypenko et al. (2021) show that BERT-based approaches outperform handcrafted feature and SVM-based approaches by a large margin (15-20 accuracy points absolute). Amponsah-Kaakyire et al. (2022) show

Proceedings of Recent Advances in Natural Language Processing, pages 196–206
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_022

that this performance difference is due to learned features (rather than the classifiers).

Using Integrated Gradient (IG) based input attribution methods (Amponsah-Kaakyire et al., 2022) also show that BERT (Devlin et al., 2019a) sometimes exploits topic differences between O and T data as spurious correlations with the target classification labels (original O and translation T) as short cuts, rather than "true" translationese signals: the T part of the (Europarl-based) data, translations from Spanish into German, happens to contain mentions of Spanish locations while German originals O tend to mention German location names. Spurious correlations in the data with target classification labels may cause "Clever Hans" behavior (Lapuschkin et al., 2019; Hernández-Orallo, 2019), where the classifier picks up accidental patterns in the data correlated with but otherwise unrelated to the classification target, in the case at hand, topic/content differences rather than proper linguistic indicators of translationese.

To the best of our knowledge, to date, we do not know how to measure spurious correlations between topic signals in the data and target classification labels, such as translationese (O and T). At the same time, this is an important question, as an answer would allow us to better understand to what extent we can trust a classifier to pick up on information truly relevant to the target classification labels, and to which extent a classifier is exploiting "Clever Hans", i.e. spurious correlations in the data with the target labels. This is especially pertinent with subtle classification targets and challenging low-resource data settings, as in translationese classification: translationese data sets tend to be small, and translationese signals are subtle while competing with many other signals in the data.

We approach our research question of "measuring spurious topic correlation in the data with respect to target classification labels" from two opposing ends: (i) where we assume no prior knowledge about topics in the data and (ii) where we have some idea about spurious topic signals in the data. We refer to (i) as **Chasing Unknown Unknowns** (Section 4 below)[1] and (ii) as **Chasing Known Unknowns** (Section 5 below). For (i) we use unsupervised topic modeling (LDA and BERTopic) and we develop a measure from first principles that captures the alignment of (unsupervised) topics with target classification labels. Based on this we propose the concept of a "topic floor" in classification, akin to the concept of a "noise floor" in Electronic Engineering. We show that our alignment-based measure is the same as purity with respect to target classes in clustering. Given data, target classification labels and unsupervised topic models, our measure and noise floor provide an upper bound on how much spurious topic information may account for target classification labels. For (ii) we use masking of already identified spurious topic information, such as location names, in the data and measure classification accuracy with masked and unmasked versions of the data, to quantify the impact of the identified source of spurious correlation.

Our main contributions include the following:

1. We present a measure that, given a data set and target classification labels, quantifies the possible impact of *unknown spurious topic information* on classification. The measure is based on aligning unsupervised topics with the target labels. Based on this we propose the concept of a "topic floor" (akin to "noise floor" in Electronic Engineering) in classification.

2. We use masking to both quantify and mitigate *known spurious topic information*.

3. We present empirical results for topic floor and masking to quantify "Clever Hans" in the translationese data of Amponsah-Kaakyire et al. (2022). We use IG attribution to show that in masked settings where known spurious correlations are mitigated, BERT learns features closer to proper translationese.

2 Related Work

Puurtinen (2003); Ilisei et al. (2010); Volansky et al. (2013); Rabinovich and Wintner (2015); Rubino et al. (2016); Pylypenko et al. (2021) train classifiers to distinguish between originally authored and translated data. Many of them explore handcrafted and linguistically inspired feature sets, manual feature engineering, and a variety of classifiers including Decision Trees and Support Vector Machines (SVMs) and use feature ranking or attribution methods to reason back to particular dimensions of translationese and their importance in the data and classification results. Feature engineering

[1] Readers may relate this to a 2002 hearing with the then US Secretary of Defence Donald Rumsfeld. In one scenario we do not know the topics and their impact, the unknown unknowns; in the other we have some indication about a spurious topic but again do not know its impact, the known unknowns.

based translationese classification used SVM feature weights (Avner et al., 2016; Pylypenko et al., 2021), decision trees or random forests (Ilisei et al., 2010; Rubino et al., 2016), training separate classifiers for each individual feature (or feature sets) and comparing accuracies (Volansky et al., 2013; Avner et al., 2016), to explain results.

More recent research uses feature and representation learning approaches (sometimes augmented with hand-crafted features) based on neural networks (Sominsky and Wintner, 2019; Pylypenko et al., 2021). Pylypenko et al. (2021) shows that feature learning based approaches (e.g. a pretrained BERT based classifier) outperform hand-crafted and feature engineering based approaches (SVM) by as much as 15 to 20 percentage points absolute in classification accuracy. Amponsah-Kaakyire et al. (2022) show that the difference in classification accuracy is due to feature learning rather than the classifiers, and, using Integrated Gradients (IGs) (Sundararajan et al., 2017), provide evidence that the feature learning methods exploit some spurious correlations with the classification labels in the data, that are clearly not translationese, but topic related cues: the data are German originals O and translations T (into German) from Spanish, and Spanish place names are highly IG-ranked, given the trained classifiers.

Dutta Chowdhury et al. (2022) use divergence from isomorphism based graph distance measures to show that translationese is visible even in O and T word embedding spaces. While POS features have been used in feature-engineering-based translationese classification, some experiments in (Dutta Chowdhury et al., 2022) use POS (instead of the surface words) to mitigate possible topic influences on the graph divergence results. This is an approach we develop further (e.g. in terms of partial masking using NEs) in our work below.

3 Data

Our experiments use the monolingual German dataset from the Multilingual Parallel Direct Europarl (MPDE) corpus (Amponsah-Kaakyire et al., 2021) consisting of 42k paragraphs, with half of the paragraphs German (DE) originals (below we call this O) and the other half translations (below we call this T) from Spanish (ES) to German. The average length (in terms of tokens) per training example is 80. Like all of MPDE, the DE-ES subset contains only data from before 2004, since for post-2004 data, it may not be known whether or not the source language SL is already the result of a translation (Bogaert, 2011). While this limits the amount of data, it ensures that the O and T data are clearly identifiable and ”pure” O or T. Both O and T are German, but T is German translated from Spanish, and both coming from MPDE ensure that they are the same Europarl genre and style.

4 Chasing Unknown Unknowns

In this section, we assume that we have no prior information about topics and their distribution in the data. Because of this, we use unsupervised topic modeling. We develop a measure that checks whether, and if so to what extent, the topics established in this fashion *align* with the target classes O and T in our data. The measure quantifies to which extent topic is a giveaway for translationese.

4.1 How to Measure Topic Bias Relevant to Translationese Classification?

The goal is to investigate the amount and distribution of topic signal in O and T data, that could be used as a spurious signal in translationese (i.e. O and T) classification. As initially we do not know anything about possible topics and their distribution in the data, we use standard approaches to unsupervised topic modeling, like Latent Dirichlet Allocation (LDA) (Blei et al., 2001) and BERTopic (Grootendorst, 2022). Both LDA and BERTopic will cluster our data into classes, i.e. topics. How can we measure whether the topics established by the topic model are potentially relevant to translationese classification? Topics are relevant to O and T translationese classification if the paragraphs in each of the topics are either mostly O paragraphs or if they are mostly T paragraphs, in other words if topics are well *aligned* to either O or T. If this is the case, a translationese classifier may learn to use topic, rather than proper translationese signals (or a mix of both) in translationese classification. To give a simple (and extreme) example, suppose we take the union[2] of O and T and cluster the union using LDA into, say, two topics (classes) top_1 and top_2. If (and this is the extreme case) $top_1 = O$ and $top_2 = T$ (or vice versa, i.e. $top_1 = T$ and $top_2 = O$), then topic perfectly predicts O and T. We would like our measure to capture this, and we would like the measure to be symmetric, i.e. give the same

[2] As O and T paragraphs are disjoint, this is the same as their concatenation.

result no matter whether $top_1 = O$ and $top_2 = T$ or vice-versa. Now consider another (extreme) case: lets say top_1 is half O and half T, with top_2 the same but with the other halfs of O and T. In this case topic is not able to distinguish between O and T (beyond chance). What about cases in between the two extreme cases? Lets say, top_1 is 3/4 O and 1/4 T, and therefore top_2 is 1/4 O and 3/4 T (or vice versa - swap top_1 and top_2). In this case topics top_1 and top_2 are pretty good indicators of O and T, and a translationese classifier may pick up on topic signals rather than just translationese proper.

To design a measure that captures the relevance of topic classes to (binary) translationese classification, we need our measure to be symmetric, generalize to more than 2 topic classes, and factor in possible O and T class imbalance. To keep things simple[3], here we present a straightforward and easy to use measure we call *alignment of topic top_i with O and T*, denoted

$$align_{O,T}(top_i) \tag{1}$$

with the majority class O or T covered by top_i (whatever it is for a given top_i) given the benefit of the doubt as the "correct" translationese class. We assume that $Data = O \cup T$, $O \cap T = \emptyset$, $\bigcup_{i=1}^{n} top_i = Data$ and $\bigcup_{i \neq j} top_i \cap top_j = \emptyset$, i.e. topic partitions our data, as does O and T. With this

$$align_{O,T}(top_i) = \frac{\max(|top_i \cap O|, |top_i \cap T|)}{|top_i|} \tag{2}$$

$\max(\cdot,\cdot)$ makes the measure symmetric. Given $align_{O,T}(top_i)$, the weighted average is simply:

$$avg\_align_{O,T}(tops) = \sum_{i=1}^{n} w_i \times align_{O,T}(top_i) \tag{3}$$

where a weight $w_i = |top_i|/|Data|$ is just the proportion of paragraphs in topic top_i divided by the total number of paragraphs in the data.

It is easy to see that the definition generalizes to n topic classes top_1 to top_n, that it adapts to different top_i topic sizes as well as the class imbalance between O and T[4]. $align_{O,T}(top_i) \in [0.5, 1]$ where $align_{O,T}(top_i) = 1$ signals perfect alignment of topic top_i with one of O or T, and that $align_{O,T}(top_i) = 0.5$ signals that top_i is maximally undecided with respect to O and T. And the same for $avg\_align_{O,T}(top)$.

Our alignment-based measure[5] is in fact the same as cluster *purity* (Zhao and Karypis, 2001) defined as

$$\frac{1}{M} \sum_{clu \in Cluster} \max_{cla \in Class} (clu \cap cla) \tag{4}$$

where M is the size of the data, $Cluster$ and $Class$ the set of clusters and classes, respectively. With this we have

$$\begin{aligned} & avg\_align_{Class}(Cluster) \\ &= \sum_{clu \in Cluster} w_{clu} \times align_{Class}(clu) \\ &= \sum_{clu \in Cluster} \frac{|clu|}{M} \times \frac{\max_{cla \in Class}(clu \cap cla)}{|clu|} \\ &= \frac{1}{M} \sum_{clu \in Cluster} \max_{cla \in Class} (clu \cap cla) \end{aligned} \tag{5}$$

4.2 Experiments

We use LDA (Blei et al., 2001) as our main unsupervised topic model, as it provides a standard and well-understood baseline[6]. LDA makes two key assumptions: (1) documents are a mixture of topics, and (2) topics are a mixture of words. LDA generates a document-term matrix (DTM), where each document is represented by a row and the terms (words) corresponding to each document are represented by the columns. The DTM is decomposed into a document-topic matrix and a topic-word matrix. LDA assigns every word to a latent topic (top_i) through iteration, computing a topic word distribution (θ) in the data. To build this distribution, LDA uses two parameters: α which controls the per-document topic distribution, and β (the Dirichlet parameter) which controls the per-topic word distribution. LDA requires us to specify the number of topics n in advance. In our experiments we explore n over three orders of magnitude, roughly doubling n at each step, starting with $n = 2$ and going up to $n = 500$.

[3] We could design an entropy-based measure of the distribution of topic classes with respect to O and T, factor in classification probabilities of LDA etc.

[4] To see this, note that as O, T partition the data and as $\bigcup top_i$ also partition the data, if, let us say, $O \ll T$ and for some $top_i = O$, then there is nothing of O left to any of the other $top_{j \neq i}$. Note that in our data we have $|O| \approx |T|$).

[5] One of our reviewers suggested we compare our measure to existing cluster quality measures.

[6] We use the *Gensim* (Rehurek and Sojka, 2011) implementation of *Mallet* LDA (McCallum, 2002).

As LDA requires us to specify n in advance, we also use BERTopic (Grootendorst, 2022), which can find an optimal n given the data[7]. By default, BERTopic utilizes contextual sentence embeddings (SBERT), dimensionality reduction (UMAP), clustering (HDBSCAN), tokenizing (CountVectorizer), and a weighing scheme (c-TFIDF) to perform topic modeling. We choose the embedding model 'T-Systems-onsite/cross-en-de-roberta-sentence-transformer' from *Huggingface* (Wolf et al., 2020) and the defaults for all other modules.

For LDA, we explore a number of topics n with $n = 2, 5, 10, 20, 30, 50, 100, 200, 300, 400$ and 500, over three orders of magnitude. BERTopic returns 207 topics[8].

For each document (here paragraph), we use the highest probability LDA or BERTopic topic assigned to the document to label the document. A topic is then represented by the set of documents labeled with the topic. For each topic top_i, we compute how well the topic is aligned with O and T, i.e. we compute $align_{O,T}(top_i)$, and the weighted average over the topics: $avg\_align_{O,T}(top_1, ..., top_n)$.

4.3 Results

We plot $avg\_align_{O,T}(top_1, ..., top_n)$ in Fig. 1, varying n from 2 to 500, at each step roughly doubling n for LDA, and with $n = 207$ for and as determined by BERTopic. An average alignment of 0.5 (the dashed green line) shows topics maximally undecided with respect to O and T, while a score of 1 indicates perfect alignment where topics completely predict O and T. Fig. 1 shows topic alignment with O and T in the range of 0.55 to 0.62, depending on n, with BERTopic achieving the overall highest score of 0.62 at $n = 207$. For LDA, scores are highest (0.611 - 0.618) for $n = 10, 20,$ and 30. For good choices of topic numbers n, both LDA and BERTopic topics are able to predict O and T (i.e. translationese) by close to 0.62.

4.4 Discussion and Interpretation: the "Topic Floor" in Classification

This is an interesting and perhaps somewhat surprising result, but what exactly does it mean? There are two important caveats:

First, the fact that topic is able to predict O and T by close to 0.62 in the data does not necessarily mean (i.e. prove) that a high-performance BERT translationese classifier, such as the one presented in (Pylypenko et al., 2021), necessarily uses spurious topic information aligned with O and T in the data. At the same time, however, it cannot be ruled out. As a sanity check we tested how well a BERT classifier can learn to predict LDA topic classes for $n = 2, 10, 20$ and 30 and for BERTopic's 207. The results are $0.83, 0.64, 0.42, 0.44$ and 0.57 (all acc. and well above the largest class baseline). Given how well BERT-based classifiers can pick up patterns in the data, it is prudent to assume that BERT will be sensitive to and use topic signals spuriously aligned with O and T.

Second, we cannot at this stage completely rule out (other than perhaps through laborious manual inspection) that some LDA or BERTopic topics may in fact reflect genuine rather than spurious signals. LDA, e.g., uses lexical information, and perhaps some such information is a genuine translationese signal (unlike the place names clearly identified as a spurious topic signal in (Amponsah-Kaakyire et al., 2022)), such as e.g. certain forms of verbs (see Section 5 on the Known Unknowns).

The two caveats are aspects of the "unknown unknowns" we are chasing in this part of the paper. We have a clear indication that topic aligns with and hence can predict O and T in our data up to 0.62. There are very good reasons (but no proof) to assume that it is likely that a high-performance BERT classifier may use this, while we cannot completely rule out that some of the supposedly spurious topic signal may actually be genuine translationese. Given this, 0.62 is an *upper bound* of how well topic may predict O and T in our data. We may be well advised to take inspiration from the concept of a "noise floor" in Electronic Engineering. The noise floor is the hum and hiss (of a circuit) due to the components when there is no signal, and below which we cannot identify a signal. Given our findings, perhaps we should regard the 0.62 topic alignment with O and T in our data as a "topic floor" for translationese classification. This is in fact the recommendation we take from our work: instead of using 0.5 as a random baseline for our (roughly) balanced binary translationese data set, we should require 0.62 as established by the topic alignment experiments as a safe(r) baseline. Put differently, given our data we cannot really be

[7] We partly do this as a sanity check to assess whether our steps increasing n across three orders of magnitude for LDA missed an important region of number of topics.

[8] BERTopic is stochastic due to UMAP and returns a different number of topics for each run, however, the differences are small.

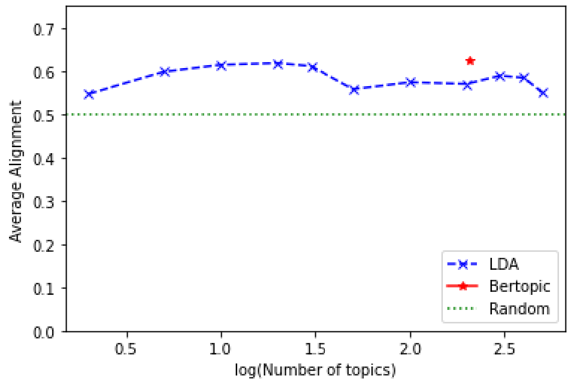

Figure 1: Average Topic - Target Classification Alignment $avg\_align_{O,T}(top_1, ..., top_n)$ for LDA and Bertopic

sure about O and T classification results ≤ 0.62. Suffice it to say, even with a 0.62 baseline, (most of) the classifiers presented in (Pylypenko et al., 2021; Amponsah-Kaakyire et al., 2022) easily surpass that baseline (with acc ≥ 0.9).

5 Chasing Known Unknowns

In this section, we assume that we have some knowledge about spurious topics in our data and that we want to both quantify and mitigate this spurious topic information in translationese classification. The difference in classification accuracy between a classifier that has access and one that does not have access to spurious topic information quantifies the impact of the spurious topic information in question. Using IG, Amponsah-Kaakyire et al. (2022) show that high-performance BERT-based classifiers use location names (Spanish names in the T, and German names in the O data) in the classification, clearly not a proper translationese but a spurious topic signal. Similarly, named entities (NEs) are often highly ranked in LDA topics. Therefore, the most straightforward approach towards mitigating specific spurious topic information in translationese classification is identifying NEs and masking them in the data.

5.1 Named Entity Recognition on Europarl

We focus on a scenario where we identify (and later mask) NEs automatically, rather than manually. While automatic NER is noisy, unlike potentially high-quality manual NER, it scales and constitutes a realistic application scenario. To assess NER performance, we experiment with a number of SOTA NER models, namely SpaCy (Honnibal and Montani, 2017), FLERT (Schweter and Akbik, 2020), multilingual-BERT (Devlin et al., 2019b), XLM-RoBERTa (Conneau et al., 2020), DistilBERT (Sanh et al., 2019), and BERT-German (Chan et al., 2020), comparing F1, precision and recall for each of the models against a gold standard NE tagged dataset (Agerri et al., 2018). The gold standard consists of 800 sentences from the Europarl German data manually annotated following the ConLL 2002 (Tjong Kim Sang, 2002) and 2003 (Tjong Kim Sang and De Meulder, 2003) guidelines, with a total of 433 named entities.

NER model	Precision	Recall	F1-score
SpaCy	0.26	0.56	0.35
FLERT	0.39	0.35	0.37
mBERT-large	0.33	0.31	0.32
XLM-R-base	0.20	0.33	0.25
XLM-R-large	0.19	0.31	0.24
DistilBERT-large	0.34	0.31	0.32
BERT-German	0.65	0.42	0.52

Table 1: Comparison table for NER models on the gold standard dataset from (Agerri et al., 2018)

Table 1 shows that BERT-German (a fine-tuned version of bert-base-multilingual-cased on the German WikiANN dataset) has the highest precision, second-highest recall and the highest F1 (0.52) among all the NER models. Hence, we choose BERT-German for all our NER experiments.

5.2 Translationese Classification

To quantify the impact of NE-based spurious topic information on translationese classification, we modify our data by masking NEs (Section 5.2.1), and, in a separate experiment, we explore full masking of the data using POS (Section 5.2.2).

Following (Pylypenko et al., 2021), we use multilingual BERT (Devlin et al., 2019b) (BERT-base-multilingual-uncased) and fine-tune BERT on the training set of our data set using the *Huggingface* library. We use a batch size of 16, a learning rate of $4 \cdot 10^{-5}$, and the Adam optimizer with $\epsilon = 1 \cdot 10^{-8}$.

We compare our models with the BERT model reproduced from (Pylypenko et al., 2021): a pretrained BERT-base model (12 layers, 768 hidden dimensions, 12 attention heads) fine-tuned on translationese classification using unmasked data.

5.2.1 Named Entity Masking

We use Bert-German to replace NEs with one of three course-grained NE-type tags: [LOC], [PER], and [ORG]. For example, the unmasked string ”*John will go to Berlin.*” is NE masked as ”[PER] *will go to* [LOC]”. In our train-dev-test sets, we have 202036, 42072, and 43489 NEs.

We carry out experiments with four train-test configurations: masked-masked, unmasked-masked, masked-unmasked, and the original unmasked-unmasked. For each of these configurations, we fine-tune BERT to the specifics of the training set (i.e. masked or unmasked). We supply the three NE-type tags as special additional tokens to the BERT tokenizer to ensure that they are consistently represented by their NE-type token (and that no sub-word splitting is applied to NE-type tokens). If NEs are responsible for spurious topic information in translationese classification, we expect masking NEs to mitigate spurious correlations in the data and to result in reduced translationese classification accuracies, allowing us to quantify this aspect of spurious topic correlations.

5.2.2 Part-Of-Speech (POS) Full Masking

To analyze BERT's performance on fully delexicalized data, we use the finer POS tagger from SpaCy (Honnibal and Montani, 2017) which utilizes the TIGER Treebank (Brants et al., 2004)[9]. Given: "*Jetzt solle erneut ein Antrag gestellt werden* .", the POS tag sequence is: "ADV VMFIN ADJD ART NN VVPP VAINF $.". We pretrain BERT on POS-tagged data from 3% of the German Wikipedia dump (1.5 million sentences) on the BertforMaskedLM objective for 2 epochs. We use BertWordPieceTokenizer for tokenization. To adjust the BERT model to the small vocabulary, we use only 6 encoder layers (instead of 12), a learning rate of 5.10^{-6}, and the Adam optimizer with $\epsilon = 1.10^{-8}$. We use the POS-pretrained model and fine-tune it with the POS-tagged monolingual German dataset from the MPDE corpus (Amponsah-Kaakyire et al., 2021) (same fine-tuning parameters as other experiments).

5.3 Integrated Gradients (IG)

Amponsah-Kaakyire et al. (2022) use IG attribution scores to show that BERT utilizes spurious correlations in the data, for example, German T data translated from Spanish contain mentions of Spanish geographical areas, such as 'Spanien', 'Barcelona' etc. as top tokens identified by IG. Here we use IG on BERT trained on masked data, and compute the top tokens with the highest attribution scores on average across the masked test sets. We also compute the top POS tags by performing IG on BERT trained on fully POS-tagged data.

5.4 Results

Train-Test	Test Set Acc (%)	95% CI

5.4.1 Results NE Masking

Table 2 shows test set accuracies for the NE masking experiments outlined in Section 5.2.1. We use Bootstrap Resampling, with 100 samples and 95% confidence intervals. Results (u-u against all others) are statistically significant. Consistent with expectation, under all training-test data conditions, masking NE-related information lowers classification results. Compared to the (Amponsah-Kaakyire et al., 2021) unmasked-unmasked baseline, the performance drop is between 0.026-0.032 points absolute. In absolute terms, the performance drop incurred in mitigating spurious topic information

Table 5: Top-10 tokens with highest IG average attribution score (AAS) for the POS-tagged test set (TIGER Treebank tags). Corresponding UPOS tags are given in braces. We use the conversion table from `https://universaldependencies.org/tagset-conversion/de-stts-uposf.html` (last accessed 11 Aug, 2023).

in terms of NEs masking is visible but small, in the order of 3 to 4 % points absolute, if classification accuracy is expressed as % points. This indicates that this type of spurious topic information and the ensuing ”Clever Hans” is a small part of the strong BERT translationese classification performance.

5.4.2 Results Full POS Masking

Table 3 shows that translationese classification results on fully de-lexicalized POS-masked data are much lower than for NE-masked data[10]. In this regime, BERT is missing much valuable information. At the same time, the classification accuracy of almost 0.78 shows that BERT is able to pick up on morpho-syntactic aspects of translationese. We also performed an analogous experiment with Universal POS tags (see Appendix, section A.3), and obtained accuracy of almost 0.77.

5.4.3 Integrated Gradients NE and POS

Table 4 shows the top-20 IG token attributions for O and T data in the masked-masked condition. Unlike (Amponsah-Kaakyire et al., 2022) the ”translationese” column does not show any Spanish or other place names. At the same time the ”original” column still contains a few location tokens (or possible subwords of location tokens), such as ”alpen”, ”##enland”, ”ez” (as in (Amponsah-Kaakyire et al., 2022)), confirming the fact that automatic NER is not perfect (see P, R and F1 scores in Table 1).

It is interesting to note that hand-in-hand with the reduction of spurious NE-based cues, many of the observations from (Amponsah-Kaakyire et al., 2022) are confirmed and in fact come to the fore. In the T class we observe an even stronger presence of verbs in Präteritum form (this time not only regular, but also irregular verbs), which Amponsah-Kaakyire et al. (2022) link to the fact that translators might have preferred to use a more written style while translating the transcribed speeches.

Table 5 presents the top-10 IG attributed tokens for the POS-tagged test set, for BERT trained on POS-tagged data. Interestingly, the top tags are APPO (postpositions) for the translationese class T, and ADV (adverbs) for the originals class O, which confirms findings in (Pylypenko et al., 2021) who show that relative frequencies of adverbs and adpositions are among the highest-ranked features that correlate with predictions of various translationese classification architectures, including BERT (even though their experiment is performed in the multilingual setting, and not on just German data like ours). They also show that the ratio of determiners is an important feature, and we see many tags corresponding to this category in our list: PPOSAT (attributive possessive pronouns), PRELAT (attributive relative pronouns), PDAT (attributive demonstrative pronouns), etc. The results for UPOS tags are similar (see Appendix, section A.3).

6 Conclusion

We present a measure that, given a data set and target classification labels, quantifies the possible impact of *unknown spurious topic information on classification*. The measure is based on aligning unsupervised topics with target labels and is equivalent to *purity* in clustering. We propose the concept of a ”topic floor” (akin to ”noise floor”) as an upper bound of the impact of spurious topic information on classification in classification. We use masking to quantify and mitigate *known spurious topic information*. We present empirical results for topic floor and masking to quantify ”Clever Hans” in the translationese data of (Amponsah-Kaakyire et al., 2022). We use IG attribution to show that in masked settings where known spurious correlations are mitigated, BERT learns features closer to proper translationese.

Acknowledgements

We are grateful for the insightful and critical feedback from our three reviewers. The research was funded by the Deutsche Forschungsgemeinschaft (DFG)-ProjectID 232722074-SFB 1102.

[10] For fully PoS-masked data it does not make sense to report mixed train-test conditions.

A Appendices

A.1 Topics by LDA and Bertopic

Here we take a closer look at LDA and Bertopic topics. While we do not find much evidence for geographic LDA topics, we do find quite a few geographic BERTtopic topics, for example, Topic 10 consists of word tokens ”türkei, türkischen, türkische, kriterien, helsinki, daß, politischen, kurdischen, menschenrechte, die”, Topic 14: ”palästinensischen, israel, arafat, israelischen, palästinensische, sharon, autonomiebehörde, palästinenser, frieden, israels”, Topic 23: ”kuba, kubanischen, kubaner, kubas, kubanische, dissidenten, volk, castro, cotonou, havanna” predominantly consist of geographical terms.

A.2 Topic Classification

To understand if BERT is able to learn the topics identified by the topic modeling experiments, we perform topic classification by finetuning pretrained-BERT on the topics found by LDA and BERTopic.

We use a similar ratio for each topic as the train:dev:test (29580:6336:6344) ratio for the translationse classification experiments.

n	**Test Set Acc (%)**	**95% CI**	**Baseline Acc**
2	0.832±0.00	[0.83,0.84]	0.50
10	0.636±0.01	[0.62,0.64]	0.18
20	0.417±0.00	[0.41,0.42]	0.13
30	0.442±0.00	[0.44,0.45]	0.11
207 (BT)	0.569±0.00	[0.56,0.57]	0.002

Table 6: Topic Classification experiments pretrained-BERT-ft Acc(uracy); n(umber of topics), CI(Conf. Interval), BT (BERTopic).

Table 6 shows the topic classification results for the topics output by LDA and BERTopic. We also show baseline accuracies, when the model only predicts the largest class.

A.3 Full UPOS Masking

Apart from full masking with detailed tags from the TIGER Treebank, we also explore full masking with the more general Universal POS tags. BERT was pre-trained and fine-tuned on the POS-tagged data in the same way as described in section 5.2.2 for the TIGER tags. The translationese classification accuracy (Table 7) is slightly lower than for the detailed tags (Table 3).

Test Set Acc (%)	**95% CI**

Abstract

A fundamental challenge in the current NLP context, dominated by language models, comes from the inflexibility of current architectures to "learn" new information. While model-centric solutions like continual learning or parameter-efficient fine-tuning are available, the question still remains of how to reliably identify changes in language or in the world. In this paper, we propose WikiTiDe, a dataset derived from pairs of timestamped definitions extracted from Wikipedia. We argue that such resource can be helpful for accelerating diachronic NLP, specifically, for training models able to scan knowledge resources for core updates concerning a concept, an event, or a named entity. Our proposed end-to-end method is fully automatic, and leverages a bootstrapping algorithm for gradually creating a high-quality dataset. Our results suggest that bootstrapping the seed version of WikiTiDe leads to better fine-tuned models. We also leverage fine-tuned models in a number of downstream tasks, showing promising results with respect to competitive baselines[1].

1 Introduction

Handling new information is one of the most critical (and vastly unresolved) challenges in the current NLP landscape, mostly because language models (LMs) such as BERT (Devlin et al., 2019), T5 (Raffel et al., 2020), GPT-3 (Brown et al., 2020) or PaLM (Chowdhery et al., 2022) can only learn from information they have seen during pretraining. This is an important limitation when it comes to dealing with updates in the world and language changes alike, since these updates, if not dealt with properly in an LM-centric system, can cause *temporal misalignment* (Luu et al., 2021; Lazaridou et al., 2021; Jang et al., 2022), which is especially harming in knowledge-intensive tasks, such as closed-book QA.

Unsuprisingly, thus, there is a significant body of work concerned with, for instance, updating language models by pretraining them on in-domain data (Gururangan et al., 2020), editing specific facts (De Cao et al., 2021; Zhu et al., 2020; Dai et al., 2021), continual learning (Agarwal and Nenkova, 2021; Del Tredici et al., 2018; Giulianelli et al., 2020; Dhingra et al., 2022; Loureiro et al., 2022), pre-training with an objective specifically designed to handle infusion of newly coined terms (Yu et al., 2021), or directly modifying the attention mechanism to account for temporality (Rosin and Radinsky, 2022). All these, in addition to the extensive body of work on diachronic and dynamic (contextualized and static) word embeddings (Hamilton et al., 2016a; Rudolph et al., 2016; Hamilton et al., 2016b; Rudolph and Blei, 2018; Hofmann et al., 2020).

Regardless of the method, however, a critical component of time-aware NLP is to have access to dynamically changing facts about language and the world so that LMs are exposed to them. As Jang et al. (2022) argues, collaborative resources such as Wikipedia or Wikidata can satisfy this desideratum, since they provide a dynamically updated[2] *life-long* resource. Given this, with WikiTiDe we put forward a benchmark comprised of definition pairs annotated in terms of whether they are the same or not, and if not, if this difference can be attributed to a fundamental change in that term, event or entity (as opposed to, for instance, semantic variations such as introduction of a paraphrase or stylistic nuances). We construct WikiTiDe in a weakly supervised manner via bootstrapping, and evaluate a number of LM-based baselines on the

	WikiTiDe Definitions	Label
p^{def}_{first}	”All or Nothing” is a song by German dance-pop group Milli Vanilli.	0
p^{def}_{second}	”All or Nothing” is a song by German dance-pop group Milli Vanilli.	
p^{def}_{first}	”Along the Navajo Trail” is a country/pop song, written by Dick Charles (pseudonym for Richard Charles Krieg), Larry Markes, and Edgar De Lange in 1945.	1
p^{def}_{second}	”Along the Navajo Trail” is a country/pop song, written by Dick Charles (pseudonym for Richard Charles Krieg), Larry Markes, and Eddie De-Lange in 1945.	
p^{def}_{first}	Alan Sheffield Ball (born March 29, 1985) is an American football cornerback for the Jacksonville Jaguars of the National Football League.	2
p^{def}_{second}	Alan Sheffield Ball (born March 29, 1985) is a former American football cornerback in the National Football League for the Dallas Cowboys, Houston Texans, Jacksonville Jaguars, and Chicago Bears.	

Table 1: Examples of WikiTiDe for each label. In these specific examples, there is full agreement between all ChatGPT instances that performed the annotation.

task of determining the type of difference between two timestamped definitions. Our results suggest that bootstrapping is helpful, and that this dataset can be used for both aiding in lexical semantics tasks, as well as for efficient scanning for critical updates in Wikipedia.

2 Related Work

This paper can be broadly positioned within two areas, namely lexicograhpic *definitions* (understood as a lexicographic resource but also as a high quality source of information for augmenting LMs), and *diachronic NLP*. We therefore make a clear distinction between them in the review of relevant works.

Definitions Definitions have traditionally played a crucial role in NLP and computational lexicography. As the building blocks of dictionaries and encyclopedias, they are used when the meaning of a word is sought (Navigli and Velardi, 2010), and thus the task of automatically constructing glossaries and terminologies is a well established task in NLP and Information Retrieval (Espinosa-Anke and Schockaert, 2018; Spala et al., 2019, 2020; Veyseh et al., 2020; Azarbonyad et al., 2023).

However, definitions have also been leveraged to improve the quality of NLP systems. For instance, Delli Bovi et al. (2015) and Espinosa-Anke et al. (2016) harnessed definitions to build knowledge bases by extracting semantic relations from them; Joshi et al. (2020) used definitions to provide additional context to LMs in reading comprehension tasks; Yu et al. (2021) pre-trained BERT on tasks that exploit definitions, specifically seeking to improve contextual representations of rare terms; and Xu et al. (2022) used definitions as the backbone of prompt-based taxonomy learning.

In a parallel strand of work, others have explored *definition modeling* systems (i.e., given a term and potentially some context, generate a definition) (Gadetsky et al., 2018; Zhu et al., 2019; Mickus et al., 2019, 2022; Bevilacqua et al., 2020), and these systems have been applied in tasks such as *controlled* definition modeling, e.g., jargon or varying technical complexity (August et al., 2022; Huang et al., 2022), as well as lexical semantics tasks like word sense disambiguation and word-in-context classification (Pilehvar and Camacho-Collados, 2019).

Diachronic NLP While there is agreement in that continual learning helps to mitigate the fundamental issues of temporal misalignment (Jang et al., 2022) and catastrophic forgetting (Cossu et al., 2022), the availability of benchmarks for retrieving new facts and evaluating LMs on their capacity to account for them is not overwhelming. Social media seems to be a particularly well suited domain for exploring temporal generalization, given its naturally fast-paced nature, and so we find a number of Twitter-specific benchmarks (Osborne et al., 2014; Yogatama et al., 2014). Moreover,

Algorithm 1 Collect Definition Pairs

```
Let $P$ be the set of Wikipedia pages
Let $D$ be the list of definition pairs
Let $n$ be the desired number of definition pairs ($n = 10,000$)
Let SRP$(p, tl)$ be a function for *selecting a random page* given a specific timeline $tl$
$D = \{\}$
while $|D| < n$ do
    Find a random $p \in P$ with timeline $tl_y$
    $tl_y \leftarrow$ SortYearsAscending$(tl_y)$
    $m \leftarrow$ FindMedian$(t)$
    $p_{first} \leftarrow$ SRP$(p, tl_y \leq m)$
    $p_{second} \leftarrow$ SRP$(p, tl_y \geq m)$
    $p^{def}_{first} \leftarrow$ GetDefinition$(p_{first})$
    $p^{def}_{second} \leftarrow$ GetDefinition$(p_{second})$
    $D \leftarrow D \cup \{(p^{def}_{first}, p^{def}_{second})\}$
```

other resources such as arXiv papers (Lazaridou et al., 2021) or Wikipedia (Jang et al., 2022) have been benchmarked for evaluating temporal generalization, as well as temporal variations of existing relation extraction datasets (Dhingra et al., 2022).

In this context, we argue that Wikipedia is indeed a valuable and underutilized resource for training and evaluating LMs on their language and knowledge update capabilities. While, as Jang et al. (2022) points out, not all changes in Wikipedia or Wikidata correspond to an actual change in the real world, we aim to alleviate this limitation by focusing on changes in definitions alone. In this way, we drastically reduce the chances of falsely confusing one superfluous change in a Wikipedia entry with a change that results in a necessary update of our understanding of a concept or entity. In what follows, we discuss how we create our seed for the WikiTiDe dataset, the algorithm for growing it, and then report on several experimental evaluation results.

3 WikiTiDe

In this section, we discuss, first, the process of retrieving candidate definition pairs for annotation. Then, we provide details about the annotation process, and finally, present examples and summary statistics, aimed to shed light on the properties of WikiTiDe.

The process of creating the required definition pairs of WikiTiDe is shown in Algorithm 1. In a nutshell, we start from the set P of Wikipedia pages, and construct, by sampling two sufficiently distant definitions (that is, the first sentence of a Wikipedia article $p \in P$), a dataset D which contains 10,000 unannotated definition pairs. After this, we randomly select 30% from D for annotation, which we perform combining the annotations of 4 instances of GPT-3 (Brown et al., 2020)[3]. The main motivation for "replacing" manual annotation with a LM is twofold. First, we posit that we can leverage the knowledge embedded in ChatGPT's parameters about well known entities, concepts and events (well known because they have a corresponding Wikipedia page). Second, recent work has shown that leveraging ChatGPT can outperform other annotation frameworks, for example Amazon Mechanical Turk (Gilardi et al., 2023). The four rounds of annotations we perform differ in the instruction, as the hyperparameters remain fixed (specifically $temperature = 0$ and $top\_p = 1$). The instruction combines a prompt and a few examples (potentially - but not always - covering all possible labels). The specific variations involve paraphrasing some of the instructions or definitions of labels, or selecting different examples[4]. As for the labels, we define our task as a 3-label classification problem, and hence the 3 different labels (and how they are described to ChatGPT) can be broadly defined as follows:

1. Class **0**: p^{def}_{first} and p^{def}_{second} essentially convey the same information, with negligible differences in terms of style.

2. Class **1**: p^{def}_{first} and p^{def}_{second} may be semantically similar but conveying analogous information, or else convey different information, however these differences cannot be attributed to a fundamental change or update in our understanding about p.

3. Class **2**: p^{def}_{first} and p^{def}_{second} are different, *and* this difference can be unequivocally attributed to some fundamental changes happening to p and/or our shared understanding of p, which changed during the period that spanned between p^{def}_{first} and p^{def}_{second}.

The final labels are selected as follows: We only select instances labeled as class **2** if all instances of

[3] Specifically, the version powering ChatGPT: `gpt-3.5-turbo`.

[4] One example of a prompt is provided in the appendix of this submission.

ChatGPT label it as such, thus ensuring the tightest possible agreement for this label, which is both the most interesting and infrequent in the dataset. Then, for the rest, we resort to the label assigned by the majority among three ChatGPT annotators, and only in case of draw, we incorporate a fourth one, which acts as referee. At the end of this process, we annotate 3,000 instances out of the 10,000 initial set, with a Fleiss-Kappa Agreement score of (Fleiss, 1971) of 24.84, which according to the literature, falls within the *fair* agreement range. Table 1 shows illustrative examples of definition pairs in WikiTiDe. This 3k *training set* (TS) has the following label distribution: 1,082 examples for label 0; 1,830 for label 1; and 87 definition pairs for the most interesting label 2. In the following section we describe how we use TS to fully annotate D.

4 Bootstrapping WikiTiDe

With TS being the ChatGPT-annotated seed dataset in WikiTiDe (with a label set $L = \{0, 1, 2\}$), let DS be the remaining unannotated 7,000 instances, and $D = TS \cup DS$. We seek to iteratively bootstrap a development set with "high confident" predictions, starting from a seed classifier trained, in a first iteration, only on TS. We argue that this approach, which can be traced back to applications in word sense disambiguation and definition extraction (Yarowsky, 1995; Espinosa-Anke et al., 2015), can be effectively applied to our use case as each newly bootstrapped definition pair will be reliable indicatives of the source training set, which can contribute to increase recall as the model will have seen more positive examples.

As summarized in Algorithm 2, the bootstrapping process requires at a minimum an annotated training set TS and an unannotated test set DS, and optionally held-out test set HS to monitor performance. At the first iteration, we set $|TS| = 2160$; $|DS| = 7,000$; and $|HS| = 840$. We then fire the bootstrapping process, in which, first, a model is trained and applied on DS, then we extract the K most confident predictions for each label, append them to TS, and remove them from DS. Every time we exhaust all labels in L, we evaluate a new instance of the model on HS.

Algorithm 2 Bootstrapping on WikiTiDe

```
Require: Initial training set $TS$
Require: Development set $DS$
Require: Held-out test set $HS$
Require: Label set $L = \{0, 1, 2\}$
Require: K $\leftarrow$ 10
Require: Temperature $T > 0$
while $|DS| \geq$ topnPreds $\cdot\, |L|$ do
    model $\leftarrow$ trainModel($TS$)
    model($DS$) // Apply model to $DS$
    for $l \in L$ do
        $DS_l \leftarrow \{x \mid x \in DS, \text{label}(x) = l\}$
        $P_l \leftarrow \{P(x, l) \mid x \in DS_l\}$
        Sort $P'_l$ in descending order
        $DS'_l \leftarrow$ Top K instances from $DS_l$ based on $P'_l$
        $TS \leftarrow TS \cup DS'_l$
        $DS \leftarrow DS \setminus DS_l$
    evaluateModel(model, $HS$)
```

In terms of classifier, we select a wide range of models to evaluate, all of them based on the Transformers architecture (Vaswani et al., 2017), namely BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), DistilBERT and DistilroBERTa (Sanh et al., 2020), Tiny-BERT (Bhargava et al., 2021; Turc et al., 2019) and XLM-Roberta-base (Conneau et al., 2019)[5]. Finally, in terms of manipulating the inputs to these models, we opt for minimal preprocessing, simply injecting special tokens '< y>' and '</y>' for isolating timespans, and '<t>' and '</t>' in order to mark the target term.

4.1 Results and Discussion

We flesh out the results obtained by different models in the task of predicting, given a pair of definitions from Wikipedia, the labels introduced in Section 3. As can be seen in Table 2, the bootstrapped models are consistently better than their base counterparts (which, we recall, are equivalent models but being trained only on TS). RoBERTa-based models are superior to the rest, and crucically, they also reach to the best performing iteration at later stages, which suggests they tend to overfit less to the training set. In terms of gap between base and boostrapped models, this is rather large, and largest for label **2**. As an example, RoBERTa-large is almost 40 points more precise when bootstrapped, and 27 F1 points better. Interestingly, our intuition of using a multilingual model to handle "foreign" (non English) spellings, typically used in Wikipedia definitions for non English entities or concepts, seems to not work well, with XLM-

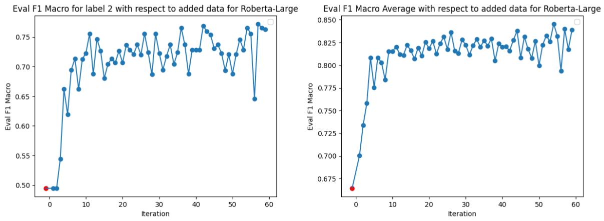

Figure 1: Macro-F1 scores of Roberta-Large with respect to Number of Iterations

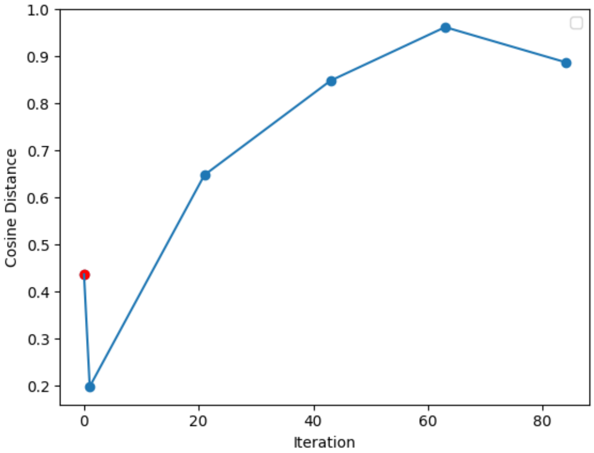

Figure 2: Cosine Distance of definition pairs for Label 2 with respect to bootstrapping iterations

roBERTa-base being the 2nd to last model, only surpassing BERT-tiny.

In terms of analyzing the bootstrapping iterative process, we can see in Figure 1 that the improvements of the bootstrapped models becomes apparent after few iterations, both for the most relevant label 2 (left plot) and on average (right plot). We also see less "up and down spikes" for the average results, suggesting that performance on the other labels becomes smoother over time. Moreover, in order to gain further understanding on the effects of the bootrsapping process into the differences in definition pairs over time, we measure *semantic drift*, i.e., whether (or, more precisely, the extent to which) the bootstrapped training set exhibits an increasingly diverse set of definitions, measured by how dissimilar they are as they are iteratively fetched from DS. We focus on label 2, and plot the results of this analysis in Figure 2, which clearly shows an increasing drift in average distances. This confirms that the bootstrapped training set is semantically more diverse than the seed ChatGPT-annotated version.

As a form of qualitative evaluation, we list in Table 3 a set of bootstrapped instances from one of the best performing models (RoBERTa-base). Note that these are not carefully selected examples, as we have simply listed an instance of high confidence classifications per label. We can see the improvement in quality of 2-labeled instances, especially between iterations 1 and 83, in which the difference in knowledge concerning Carlos Alberto Valencia is minimal in terms of string edit distance, however the model correctly identified a critical change for this named entity, specifically, the fact that he changed teams.

5 Case Study: WiC-TSV

The WiC-TSV (Word in Context-Target Sense Verification) task (Breit et al., 2021) is a "shootoff" from the original WiC task (Pilehvar and Camacho-Collados, 2019). It proposes a binary classification problem, where the input is a pair of sentences: the first one, a sentence with a target word in context, and the second one, a definition of that target word. This is a suitable test bet for a model fine-tuned on WIKITIDE, since this is a dataset which essentially measures definition similarity. However, since WIKITIDE is a multilabel dataset, we combine labels 1 and 2 as label 0 in WiC-TSV and assume equivalence between the notion of "change" in WIKITIDE and polysemy in WiC-TSV. For our model to work, both input sentences must be definitions, however, this is not always the case in WiC-TSV. To work around this limitation, we replace the non-definition sentences in WiC-TSV with a definition generated using ChatGPT (Brown et al., 2020). Both sets of results (directly applying our model to WiC-TSV as well as replacing one of its sentences with a ChatGPT-generated definition) are reported, for train, test and development sets[6] (which is possible as we cast this problem as an unsupervised classification task), in Table 4.

Table 4: F1 (top) and accuracy (bottom) results on WiC-TSV. The Vanilla columns refer to instances where we run inference with a classifier trained on WikiTiDe directly, without adapting inputs or further fine-tuning. GPT3.5 columns denote a use case where we use GPT3.5 for generating a definition of the target word in the first sentence of the dataset instance, and then run inference on this updated input.

Moreover, we report results reported in previous works to further contextualize the results we obtain, which, to reiterate, are from an unsupervised model not directly optimized for this task. Breit et al. (2021) reports the *all true* baseline on the test split has having Accuracy of 50.8% and F1 of 67.3%. Additionally, they obtain Accuracy scores of of 54.4% and F1 scores of 26.2% with an unsupervised BERT-based model, whereas they find significant improvements (Accuracy, 76.0% and F1-score, 78.8%) for a supervised GBERT-based model. We also find in the work by Zervakis et al. (2022), where they propose target sense verification as an analogy detection task, that they achieve Accuracy scores of 78.6% and F1 of 79.7% on the test set (for supervised approaches), and Accuracy of 61.2% (and 51.3% F1) for an unsupervised approach.

The results of our experiment display the ability of the models before and after bootstrapping on all three sets (train,deveopment and test). The bootstrapped approach considerably increases the Macro-F1 performance of the models with respect to WiC-TSV's Task 1 unsupervised setting baselines (Breit et al., 2021). The results also suggest that while BERT shines on a few occasions, the RoBERTa family of models show the highest performance, with RoBERTa-large bootstrapped being the best with F1 score of 0.53. The vanilla versions of the models perform within a range between 0.30 to 0.34. The bootstrapped versions outperform their non-bootstrapped counterparts in all three datasets, with respect to F1 score. We also observe that the difference in F1 scores between before and after bootstrapped versions can go as high as 17 points, which signify that the models learns better during the bootstrapping process. Finally, we also find that the larger models with more parameters outperform their distilled counterparts in most of the dataset versions.

6 Conclusion

We propose a dataset and methodology to design a classifier for detecting temporal changes in temporal definition pairs. We use weak supervision technique by boostrapping the model an unlabelled dataset in output controlled setting. We also see that bootstrapping a model improves the accuracy of the model as well as makes the model more robust. However, the process requires more time to bootstrap the model and the success of the process depends on the initial training. Although the process has its own limitations, we conclude that the idea of using a classifier to detect information changes in with respect to temporality and training it with boostrapping can result in easement of defining which information is relevant to update a model's knowledge base and can help to mitigate the issues that a language model suffers due to temporal misalignment.

Ethics and Broader Statement

This paper is concerned with the automatic construction of a dataset by combining publicly available information in the web. Therefore, it might be possible that incorrect or harmful information is present in this derived dataset, although we welcome efforts by the community to contribute mitigating these risks. The dataset construction process did not involve humans.

Potential risks in the dataset might also include incorrectly flagging new knowledge about any article, as our data source Wikipedia is a publicly editable data source. Therefore the possibility of having conflicting or incorrect information also increases. However, the difference of information, which our classifier is trained to detect can help to detect such outliers and provide some insights about it.

Abstract

Transformer-based language models such as Bidirectional Encoder Representations from Transformers (BERT) are now mainstream in the NLP field, but extensions to languages other than English, to new domains and/or to more specific text genres are still in demand. In this paper we introduced BERTabaporu, a BERT language model that has been pre-trained on Twitter data in the Brazilian Portuguese language. The model is shown to outperform the best-known general-purpose model for this language in three Twitter-related NLP tasks, making a potentially useful resource for Portuguese NLP in general.

1 Introduction

Transformer-based language models such as Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019) are now mainstream in the NLP field, but extensions are still much in demand. New BERT models have been fine-tuned or built from scratch for many languages other than English (e.g., Maltese in (Micallef et al., 2022)), for specific domains (e.g., mental health in (Ji et al., 2022)), and for particular text genres (e.g., Twitter data in (Nguyen et al., 2020)).

In the case of our target language - Brazilian Portuguese - the first and best-known representative of this trend is BERTimbau, a general purpose BERT model built from a large collection of web documents (Souza et al., 2020). Despite its popularity among the Portuguese NLP community, however, we notice that the particular kind of language employed on contemporary social media may be distinct from the training data considered in previous work, making existing models potentially less suitable to handle recent social media text. In particular, we notice that tweets are not only shorter and less structured than pieces of news, but words such as 'Covid' may not be recognised by older language models.

Based on these observations, we may ask whether Twitter-related applications may benefit from a more genre-specific model built from social media data - as opposed to more standard or general text - perhaps along the lines of BERTweet, a Twitter-specific model for the English language described in (Nguyen et al., 2020), or the multilingual TwHIN-BERT (Zhang et al., 2022), also built from Twitter data. To shed light on this issue, this work introduces BERTabaporu, a BERT model built from a collection of 238 million tweets written by over 100 thousand unique Twitter users, and conveying over 2.9 billion tokens in total. The model has been evaluated in three Twitter-related text classification tasks, and its results are compared to those obtained by the general purpose, web-based BERTimbau in (Souza et al., 2020). In doing so, our goal is to introduce a novel resource for Portuguese NLP, and foster further applications based on Twitter text data in this language.

The main contributions made in this work are (i) a novel BERT model trained on large Twitter corpus in the Portuguese language; and (ii) comparison with the best-known existing Portuguese BERT in three Twitter text classification tasks, namely, stance, mental health and political alignment prediction.

The rest of this article is structured as follows. Section 2 reviews existing work that have introduced BERT-like models for Portuguese, for other languages and domains. Section 3 describes how our current work, the BERTabaporu model, has been built. Section 4 introduces the downstream tasks in which BERTabaporu is to be assessed. Section 5 reports results obtained for each of the evaluation tasks, and compares these to the results obtained by existing work. Finally, section 6 draws our conclusions and suggestions of future work.

2 Background

Since the original English and multilingual (or mBERT) models described in (Devlin et al., 2019), similar resources devoted to these and to dozens of other languages have been created. Models of this kind are either trained from scratch or fine-tuned (often from mBERT) using either general purpose or domain- or genre-specific text data. Noteworthy examples include BERTweet (Nguyen et al., 2020), a 16-billion token model built from Twitter data in the English language, domain-specific models fine-tuned for mental health (Ji et al., 2022), abusive language use (Caselli et al., 2021), biomedical texts (Schneider et al., 2020) and others, alongside general purpose models for a wide range of languages including, e.g., Estonian (Tanvir et al., 2021), Maltese (Micallef et al., 2022), Romanian (Masala et al., 2020) and Czech (Sido et al., 2021).

In the case of the Portuguese language, although model repositories such as Hugging Face provide a considerable number of BERT models - particularly for the Legal domain, and even including a few models trained on Twitter data - we have identified only three models of this kind that are more fully documented in the NLP literature. These are summarised in Table 1 and further discussed below.

Two of the existing Portuguese models - BioBERTpt and PetroBERT - are fine-tuned to perform domain-specific tasks in the clinical/biomedical and oil and gas industry domains, respectively. This makes web-based BERTimbau (Souza et al., 2020) the more closely related alternative to our own work (BERTabaporu, on the top row of the table). BERTimbau is the first, and arguably the best-known Portuguese BERT model to date, and it has been trained from scratch using a general purpose web corpus in which great care has been taken to minimise the effects of duplicate data, making it a suitable baseline to our current work.

Based on these observations, our present work BERTabaporu may be seen as a general purpose, Twitter-specific alternative to BERTimbau built from a slightly larger dataset (2.9 billion tokens against 2.7 billion in BERTimbau), and which should be able to outperform the existing web-based model in Twitter-oriented tasks.

3 The BERTabaporu model

In order to gather unlabelled text data to built BERTabaporu, we selected a number of existing tweet repositories and collected additional data online. As a means to minimise the effect of duplicated training data, BERTabaporu has been built from tweets originally posted by over 100 thousand unique Twitter users excluding their retweets. In this user-centred method, although some data duplication may still occur (namely, if an individual rewrites the same text that another user has authored), we assume that the effect of duplicates is likely to be small.

Users were selected from a number of pseudo-random tweet sources based on a number of seed topics, such as Covid-19, politics, mental health and others, and then their entire public timelines were collected regardless of the topics under discussion. Thus, it should be clear that the data is by no means limited to these topics, and that we did not search for *individual tweets* about any particular topic, but rather used the seed topics as a guideline to identify *users* timelines, and then collect all their publications (which will inevitably discuss a very broad range of subjects besides the seed topic.) In other words, our data consists of a collection of pseudo-random user timelines, and not a collection of tweets about the seed topics, and should not be seen as being significantly biased towards any particular topic.

Selected user timelines comprised three main categories: (i) timelines of random users (about 33%); (ii) timelines of users who discussed Covid-19, politics, mental health issues, vaccines or other Covid-19 measures at least once (about 46%); and timelines of friends with whom these users most frequently interact (about 21%).

From the selected timelines, all non-Portuguese tweets were removed. From the remainder, emoticons, non-alphabetic characters, URLs and usernames were removed, and numbers were replaced by '1'. Finally, timelines conveying fewer than 80 tweets were discarded. Table 2 summarised descriptive statistics of our training dataset.

From the above unlabelled data, we pre-trained a monolingual BERT model from scratch using both BERT-BASE and BERT-LARGE architectures. The base version uses 12 transformer layers, a hidden size of 768, and 8 attention heads. The large version uses 24 transformer layers, a hidden size of 1024, and 16 attention heads. In both cases, the vocabulary is initialised with 64K tokens. Pretraining is performed across 1M steps, with a sequence length of 128 for the first 90% of the steps

Model	Domain	Text genre	Tokens	Training
BERTabaporu (ours)	general	Twitter	2.9 bi	from scratch
BERTimbau (Souza et al., 2020)	general	web	2.7 bi	from scratch
BioBERTpt (Schneider et al., 2020)	clinical/biomed.	notes, abstracts	44.1 mi	fine-tuned
PetroBERT (Rodrigues et al., 2022)	oil and gas	notes, reports, theses	na	fine-tuned

Table 1: Documented pre-trained BERT models devoted to the Portuguese language.

User source	Timelines	%	Tweets (th)	Sentences (th)	Tokens (th)
Random	32,879	32.6 %	102,489	113,183	1,111,397
Covid-19	9,021	9.0 %	18,384	21,945	233,968
Politics	5,767	5.7 %	12,416	16,614	155,380
Mental health	3,790	3.8 %	8,653	9,541	100,734
Vaccine	27,861	27.7 %	57,913	83,048	898,287
Friends' timelines	21,369	21.2 %	38,044	44,154	436,929
Overall	100,687	100.0 %	237,899	288,485	2,936,697

Table 2: BERTabaporu training data descriptive statistics.

and a sequence length of 512 for the remaining 10% steps. The models use a batch size of 512, and a warm-up of 1% of the total number of steps. Training was performed on v2-8 TPUs, taking approximately 120 hours for both configurations. The resulting language model is publicly available for reuse[1].

4 Evaluation

We envisaged a number of Twitter text classification experiments to compare our current Twitter BERTabaporu model with the general-purpose alternative in (Souza et al., 2020). In doing so, we would like to show that genre-specific BERTabaporu obtains superior results in these evaluation scenarios.

4.1 Downstream evaluation tasks

Evaluation will focus on three downstream tasks - stance, mental health statuses and political alignment prediction - all of which modelled as binary classification tasks, and based on Twitter text data in the Portuguese language. Two of these tasks - stance and political alignment prediction - consist of classifying individual tweets, whereas mental health prediction consists of classifying Twitter users (or rather, the sets of tweets published on their Twitter timelines.) The choice of these tasks is intended to provide variation in input definition (i.e., individual tweets versus entire timelines), in the degree of explicitness of class labels (e.g., learning the stance explicitly expressed in text versus the implicit political leaning of its author), and in corpus labelling methods (tweet- and user-level annotation, or label propagation) as discussed in the next section.

Stance prediction is the computational task of inferring an attitude in favour or against a set target topic (Mohammad et al., 2016; dos Santos and Paraboni, 2019). For instance, '*A universal basic income would alleviate poverty*' conveys a stance in favour of the target 'universal basic income'. The task is analogous to sentiment analysis, but stance and sentiment are not necessarily correlated (Aldayel and Magdy, 2021; Pavan et al., 2020). In our current setting, we focus on six stance prediction tasks based on targets that have been popular discussion topics on Brazil social media (Brazilian presidents, Covid-related measures, and local institutions.) In these tasks, given an input tweet known to convey a stance towards a particular target, the goal is to decide whether this represents a stance in favour or against it.

Mental health statuses prediction consists of determining whether an individual is prone to a mental health disorder based on their publications, e.g., on social media. Computational models of this kind have been popular in the NLP field (Shen et al., 2017; Losada et al., 2017; Cohan et al., 2018) under multiple task definitions. These include, for instance, deciding whether an individual is depressed or not (Yazdavar et al., 2020), measuring the degree of severity of the underlying disorder (Mann

[1] https://huggingface.co/pablocosta/bertabaporu-large-uncased

et al., 2020), symptoms detection (Yazdavar et al., 2017), and others. In our current setting, we focus on two independent subtasks of this kind, namely, depression and anxiety disorder prediction. Given a set of tweets published by a particular individual (i.e., a Twitter timeline), and which may or may not disclose mental health information, the goal is to predict whether the individual is likely to receive a diagnosis for depression/anxiety in the future.

Finally, political alignment prediction is the task of inferring whether an individual is a supporter of the former (right-leaning) government of Brazil or not, based on tweets that they have authored. The task may be seen as an instance of author profiling (Rangel et al., 2016, 2020; dos Santos et al., 2020b; Pavan et al., 2023), in which the goal is to infer, e.g., the political leaning (or other demographics) of the individual who published a given tweet that may or may not convey politics-related information. We notice that the task is distinct from previous stance prediction in that the target (i.e., the issue of being for or against the government) is generally not under discussion. Thus, for instance, '*Churches are not supposed to pay taxes*' would more likely be written by a supporter of a conservative government.

4.2 Task datasets

For the stance prediction task, we used a corpus of for/against stances towards six polarised target topics (presidents Lula versus Bolsonaro, the Covid-19 Sinovac vaccine versus Hydroxychloroquine, and a TV network versus the church) described in (Pavan and Paraboni, 2022). The dataset comprises 46.8K manually labelled tweets, and the for/against classes are roughly balanced across targets.

For the mental health prediction task, we used two datasets comprising Twitter timelines of individuals with a diagnosis for depression and anxiety disorder described in (dos Santos et al., 2020a, 2023). The depression dataset contains 13.5K timelines, and the anxiety dataset contains 17.8K timelines in total. As in (Yates et al., 2017) and others, the positive class (i.e., the diagnosed-related data) consists of timelines of individuals who self-disclosed a depression/anxiety diagnosis, as in e.g., '*Last week the doctor told me I have anxiety disorder*'[2]. The negative class, on the other hand, consists of timelines of random users, and it is designed so as to be seven times larger than in the positive class, making this a heavily imbalance classification task. Positive instances are manually labelled at the user (or timeline) level, and matched to their seven random counterparts according to gender, publication dates and number of tweets.

Finally, for the political alignment prediction task, we used a corpus of tweets written by individuals who were identified as being supporters of the current Brazilian president, or against him. The distinction was made based on the use of certain hashtags as described in (da Silva and Paraboni, 2023). For instance, individuals who use the hashtag '#EleNão' ('not him', a popular anti-government slogan during the presidential elections) are labelled as being anti-government, and so every tweet that this individual wrote is labelled in the same way (by label propagation) regardless of its actual contents. The present dataset consists of a random selection of 4010 politically-related tweets from this corpus, and it is class-balanced.

Table 3 summarises descriptive statistics about the evaluation corpora under consideration by reporting the number of positive and negative instances and overall number of tokens of each subset.

4.3 Models

The six stance classifier models were built by making use of a common architecture that was further optimised for each task through grid search. This common architecture consists of a token embedding layer, a recurrent layer of Bidirectional Long Short-Term Memory cells, a multi-head self-attention mechanism and a dense layer with sigmoid activation to produce the output predictions. All layers use dropout regularisation in their inputs. The parameters to be optimised through grid search were the number of BERT layers (last only, or last four), the number of LSTM layers (1 or 2), the number of LSTM hidden dimensions (16 or 1280), attention density (32 or 64) and the number of attention heads (1 or 16). The token embedding layer consists of the pre-trained BERT language models (either from the general-purpose BERTimbau in (Souza et al., 2020), or from our present genre-specific BERTabaporu), and the output is taken to be the hidden state of selected last layers as determined through grid search. In the cases in which there are multiple layers for a single token, these are concatenated. In the 'last four' layers setting,

[2] The self-report itself not included in the corpus data, which conveys only publications prior to the moment of the diagnosis.

Task	(-) instances	(+) instances	Tokens
Stance-Lula	4,514	3,806	422,064
Stance-Bolsonaro	5,565	3,849	259,521
Stance-Hydroxychloroquine	3,978	4,017	277,824
Stance-Sinovac	4,058	3,915	252,663
Stance-Church	3,539	3,598	322,289
Stance-Globo TV	3,341	2,672	214,876
Depression	1,684	11,788	231.26 mi
Anxiety	2,219	15,533	323.75 mi
Political alignment	1,995	2,015	64,275

Table 3: Evaluation corpora descriptive statistics.

we use a 3072-dimensional vector as the embedding representation for each token.

The two mental health classifier models (for depression and anxiety disorder prediction, respectively) were built by using a BERT model (once again, either BERTimbau or BERTabaporu) that has been fine-tuned to each of these two individual tasks. Due to the 512-token input limitation in BERT, these models are trained and tested at 10-tweet batches, which are subsequently combined to decide the final (user-level) class label according to a majority vote. This procedure is repeated for 50 epochs using a random starting point within the user's timeline to select 10 consecutive tweets as the input to the pre-trained BERT model, whose final layer represents the actual text to be classified. This representation is fed into a Bidirectional Long Short-Term Memory layer using RELu activation followed by a fully connected output layer using softmax activation and dropout regularisation, and using binary cross-entropy with balanced class weights as a loss function. The model is trained in a maximum of three epochs and, given 80% of all tweets in the corpus are up to 30-tokens long, the input to BERT is zero-padded to 30 tokens.

Finally, for the political alignment prediction task, we simply used a vanilla BERT architecture consisting of either of the two BERT models under evaluation with softmax activation to produce the output predictions.

5 Results

Table 4 summarises the results obtained by using the general web-based BERTimbau model (Souza et al., 2020) and our current, domain-specific Twitter BERTabaporu model across tasks. In all cases, we follow the existing train-test split available from each corpus and report results over the test set.

From these results we notice that domain-specific BERTabaporu (right side of Table 4 outperforms the more general BERTimbau model in all tasks. The perceived gain is statistically significant at $p < 0,001$ according to a McNemar test (McNemar, 1947) in all tasks except for the smaller political alignment task, in which case results from both models were found to be equivalent. This outcome suggests that using a more genre-specific pre-trained language model may indeed improve results if compared to more general alternatives.

6 Final remarks

This paper introduced BERTabaporu, a BERT language model pre-trained on Twitter data in the Brazilian Portuguese language. Compared to previous work, the present models has been found to outperform the best-known general-purpose model for this language in three Twitter-related text classification tasks, namely, stance, mental health status, and political alignment prediction, and may be potentially useful to many others Twitter-related applications in the Portuguese language.

As future work, we intended to extend the present analysis by assessing the use of BERTabaporu in other Portuguese NLP tasks. Moreover, since the present model has been trained on a considerably large dataset, there is the question of whether BERTabaporu may be helpful even in non-Twitter evaluation settings. An investigation along these lines is also left as future work.

Abstract

Despite rapid developments in the field of Natural Language Processing (NLP) in the past few years, the task of Multilingual Entity Linking (MEL) and especially its end-to-end formulation remains challenging. In this paper we aim to evaluate solutions for general end-to-end multilingual entity linking by conducting experiments using both existing complete approaches and novel combinations of pipelines for solving the task. The results identify the best performing current solutions and suggest some directions for further research.

1 Introduction

Entity linking (EL) (Hoffart et al., 2011), (Cucerzan, 2007) is the task of mapping mentions in unstructured text to entities in an existing Knowledge Base (KB). It has drawn the attention of many researchers in the past few years due to its application in different areas of NLP, including Question Answering (De Cao et al., 2019), (Yin et al., 2016), (Wang et al., 2021), Relation Extraction (Baldini Soares et al., 2019), Dialogue (Chen et al., 2017a), (Bordes et al., 2017), (Wen et al., 2017) and Biomedical systems (Bhowmik et al., 2021), (Zheng et al., 2015). Even though there has been a significant improvement in the field recently (Cao et al., 2021), (Wu et al., 2020), (Ayoola et al., 2022), the task of EL and especially in the cross-lingual (Ji et al., 2015), (McNamee et al., 2011), and MEL setups remain challenging. Different approaches have been proposed for solving this task, some of which are based on more traditional methods (Brank et al., 2017), (Delpeuch, 2020) and others exploit the recent discoveries in the field of natural language processing (Cao et al., 2021), (Wu et al., 2020), (Ayoola et al., 2022), (Botha et al., 2020). This paper will present experiments comparing the performance of various methods for a MEL task.

2 Multilingual Entity Recognition and Disambiguation Methods

In EL, also known as named-entity recognition and disambiguation (NERD) words of interest in an unstructured text are mapped to corresponding unique entities in an existing target KB. Formally it can be defined as the task of linking a given entity mention *m* in a given context *c* to the corresponding entity e in a KB. For the multilingual definition a set of languages L is added and the context is defined as language specific (context *c* of language *l*). It also requires a multilingual KB. As the name NERD suggests, the task consists of two subtasks, namely named-entity recognition (NER) and entity disambiguation (ED). Two general groups of EL methods exist. One focuses on performing entity disambiguation but requires correctly annotated entities or at least entity spans in its input. The second takes plain text input and performs both recognition and disambiguation in one or more steps.

NER (Sundheim, 1995) is a fundamental task in NLP which consists of recognising entities in text, and identifying their types. In the past years, different approaches have been developed, including statistical machine learning methods (Zhou and Su, 2002), (Agerri et al., 2014), neural networks based ones (Strubell et al., 2017), (Xia et al., 2019) and a combination of both (Huang et al., 2015), (Chen et al., 2017b). The recent advances in the field of NLP introduced the application of richer contextual embeddings computed via Transformer models (He et al., 2021), (Devlin et al., 2019), (Vaswani et al., 2017) and have significantly improved the state-of-the-art (SOTA) of the task. In particular, these impressive results were achieved on benchmark datasets such as CoNLL03 (Tjong Kim Sang and De Meulder, 2003) and OntoNotes (Hovy et al., 2006). Nevertheless, it has been stated that the

Proceedings of Recent Advances in Natural Language Processing, pages 224–233
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_025

reason for this improvement lays not only on the model, but the fact that the benchmark datasets lack the presence of multiple practical challenges and these new models actually have problems detecting and classifying complex or unseen entities (Augenstein et al., 2017), (Meng et al., 2021). To address this issue, the dataset MultiCoNER (Malmasi et al., 2022) was developed which includes complex entity mentions with higher granularity on the type definition. With the introduction of the MultiCoNER2 task (Fetahu et al., 2023), which focus on tackling multilingual named entity recognition (NER) in fine-grained and noisy scenarios, a lot of promising approaches for general entity recognition have been proposed (García-Ferrero et al., 2023), (Tan et al., 2023).

mGENRE (De Cao et al., 2022), a MEL system based on autoregression, has emerged as the state-of-the art as measured on the major multilingual datasets. It is therefore a main focus of the experiments in our work.

3 Evaluated Approaches

In our work we experiment with three different end-to-end EL approaches: a classical approach, Wikifier (Brank et al., 2017), and two systems that we build as a combination of mGENRE (De Cao et al., 2022) with a multilingual NER model and a multilingual EBD method.

3.1 Wikifier

Wikification is a simple approach for multilingual text annotations, a process in which a text is annotated with relevant concepts from Wikipedia. Each Wikipedia article is treated as a Wikipedia concept and the relations between the concepts are expressed by the links between the articles. Wikipedia is large, multilingual and contains general knowledge and is therefore a popular choice for a target database in different entity linking approaches.

We experiment with a Wikifier (Brank et al., 2017) based on page rank and global disambiguation which provides a semantic annotation in 100 languages. Instead of trying to detect separate entities in the text and then map them to corresponding Wikipedia concepts, Wikifier sees the text as a whole and aims at finding suitable annotations which are supported by multiple mentions of the text. In this way it follows the intuition that most mentions in a text should be similar and related to common topics. Based on the page rank of a concept and its support by mentions in the text, a decision is made if it is a suitable annotation for the given text. When returning the final list of annotations for a text, Wikifier does not return the exact mention match for the concept, but a list with all mentions in the text which support the annotation. Wikifier is available as a public web service which we used for our experiments.

3.2 mGENRE Disambiguation

mGENRE (multilingual GENRE) (De Cao et al., 2022) is a system for general MEL, which predicts the label of the corresponding entity in a multilingual KB from left to right, token-by-token using autoregression which enables it to effectively cross-encode mention and entity labels to capture more interactions than the standard dot product between mention and entity vectors. It is also capable of fast search in KBs even for mentions that are not part of mention tables and without need of large-scale vector indices. In contrast to most MEL approaches which implement a single representation for each entity, mGENRE maps against entities in multiple languages and with that enables exploiting relations between mention in text and target name.

It also works in a zero-shot setting for languages without any training data, since it processes the target language as a latent variable and marginalises it during prediction. mGENRE ranks each element in a knowledge base by computing a score with an autoregressive formulation. It is based on a fine tuned mBART (Liu et al., 2020) architecture. Beam search is used to pre-select top-k linking candidates for each entity. GENRE employs a prefix tree (trie) to enable constrained beam search and then generate only valid entity identifiers. In order to extend GENRE in multilingual settings, the authors use canonical entity representation and multilingual entity representation for training and marginalisation during testing and inference.

mGENRE has achieved SOTA results for MEL on several datasets (Mewsli-9 (Botha et al., 2020), TR2016 (Tsai and Roth, 2016), KBP2015 (Ji et al., 2015)) and is currently the best general MEL system so we have decided to use it in our experiments and combine it with a suitable entity (boundary) detection algorithms. In our experiments, we apply the pre-trained mGENRE model provided by its authors which is fine-tuned an mBART (Liu et al., 2020) model that had been pre-trained on

125 languages using Wikipedia hyperlinks in 105 languages.

3.3 EBD + mGENRE Entity Disambiguation

The entity boundary detection (EBD) (García-Ferrero et al., 2023) is a transformer-based multilingual masked language model pre-trained on text in 100 languages (Conneau et al., 2020), and works as follows: Given unlabelled text as input, it predicts the boundaries of a named entity by analysing the structure of the input sentence. This task is presented as a sequence labelling task in which the model predicts for each token if it is part of an entity or not by classifying it in one of the categories: ”B-ENTITY”, ”I-ENTITY”, and ”O”, where ”B-ENTITY” stands for beginning of an entity, ”I-ENTITY” is for inside an entity and ”O” means no part of entity.

The approach is based on a multilingual XLM-RoBERTa-large model (Conneau et al., 2020) with a linear token classification layer on top of each token representation. Its is based on the sequence labelling implementation of the Huggingface open-source library (Wolf et al., 2020). Five different independent models have been trained and then a majority vote has been used as the ensemble strategy at inference time. No trained model was available, however, there were instructions and code available on how to replicate the training of the models. Therefore we followed these instructions and trained five different models, choosing the best one afterwards using the same strategy described in the paper.

The boundaries detected by the EBD model are then processed using the mGenre model presented in the previous subsection.

3.4 SpaCy multilingual NER + mGENRE Entity Disambiguation

SpaCy (Honnibal and Montani, 2017) is an open-source Python library focusing on advanced NLP. Currently SpaCy supports more than 70 languages and provides pre-trained pipelines for NER. SpaCy comes with a separate pipeline for each of the languages. While a multilingual model exists, it is quite small and limited so individual language pipelines need to be used. However, since it is one of the most used and reliable libraries for NLP (Lorica and Nathan, 2021) we consider it an interesting candidate for performing the entity recognition part of an end-to-end entity linking system.

SpaCy returns the start and end indices for each annotation so it can be combined with mGENRE EL in the same way as the EBD model described previously.

4 Experiments

4.1 Datasets

In our experiments we use two datasets, one freely available multilingual dataset Mewsli9 (Botha et al., 2020), which contains mentions linked to Wikidata and one custom dataset, consisting of documents in three languages extracted from the Database of Known Fakes (DBKF) (Tagarev et al., 2021). The choice of Mewsli-9 is justified by the fact that mGENRE has already been tested on it and therefore using Mewsli-9 will allow us to compare the entity disambiguation of Wikifier and mGENRE. On the other hand, Mewsli-9 is an entity disambiguation dataset in which not all mentions have been tagged and therefore it is not a suitable dataset for testing end-to-end entity linking. For this reason, instead of using another entity disambiguation dataset, we chose to compare overall performance of the three approaches on a small selection of text from the DBKF (Tagarev et al., 2021). It is multilingual, it contains fact checking news articles on recent events which can be more challenging to link to a KB. These texts would give a better view on how the tested systems perform in a real world scenario.

4.1.1 Mewsli9 Dataset

Mewsli-9 (Botha et al., 2020) (short for ”Multilingual Entities in News, linked”) is a large multilingual dataset which contains nearly 300,000 mentions across 9 languages from different language groups (English, German, Spanish, Arabic, Serbian, Japanese, Turkish, Persian, Tamil). The dataset is freely available and each mention is linked to a WikiData item, which makes the dataset suitable for our experiments.

An interesting feature of the dataset is that it contains many entities that lack English Wikipedia pages and which are thus not accessible to a lot of cross-lingual systems. Mewsli-9 consists of 289,087 entity mentions (with no predefined splits) which are to be found in 58,717 originally written news articles from WikiNews, covering different genres. In contrast to other multilingual datasets, which cover only European languages (e.g. VoxEL (Rosales-Méndez et al., 2018)), the Mewsli-9 corpus contains languages which represent five language families and six orthographies. The dataset is however not balanced between the languages.

4.1.2 DBKF Dataset

Apart from Mewsli9 we also use a small selection of debunks from the Database of Known Fakes (DBKF) (Tagarev et al., 2021) consisting of 90 documents in three languages, English, German and Spanish. The test dataset contains two document types, claims and claim reviews. Claims are short texts describing a (false) claim and reviews are whole debunking articles. The documents are not annotated with ground truth annotation, which means that during evaluation only precision could be measured. An approximation of recall can be estimated based on the total number of unique valid annotations produced by the three systems.

4.2 Experimental Design

As the goal of the paper is to explore and compare end-to-end entity linking systems, we have defined two types of experiments covering different parts of the tested approaches.

The first is to run Wikifier on Mewsli-9 dataset. Since mGENGRE achieves state-of-the-art results on Mewsli9 and we want to allow comparison between the two approaches, we have decided to test Wikifier on Mewsli-9. Such an experiment focuses on evaluation of the entity disambiguation part, but we also try to analyse the overall performance based on the results.

The second is to compare the three end-to-end entity linking solutions on the DBKF extract. The three solutions compared, as described in Section 3, are Wikifier, EBD + mGENRE and SpaCy + mGENRE.

5 Results

5.1 Results on Mewsli-9

We first evaluate the performance of Wikifier on the Mewsli-9 dataset in order to compare performance with mGENRE disambiguation. The results are shown in Table 1. Clearly, applying Wikifier on the dataset provides an immediate challenge in that Wikifier doesn't simply link already annotated entities but discovers them within the text. This leads to a significant mismatch in recognised entities between Wikifier and the gold standard (Note: here a partial overlap is treated as two mismatches).

In order to compare the performance of the algorithm to the existing approaches, we define a precision score that is applied only to entities that are in the gold standard and recognised by Wikifier. This means the results are not completely comparable but they are calculated over a subset of the Mewsli-9 annotations.

Table 2 shows the results of running the mGENRE model on Mewsli-9 (De Cao et al., 2022). While technically the numbers for accuracy over the whole dataset are lower than the precision of Wikifier, it is important to consider that the Wikifier precision is only calculated on a subset of the annotation.

At this point we need to consider the two major concerns with our approach to evaluating Wikifier on the Mewsli-9 dataset. They both stem from the fact that the Named Entity Recognition (NER) has a significant mismatch. Immediately relevant is the issue with gold standard entities that are not recognised by Wikifier. Referencing Table 1 again, we see that Wikifier in fact fails to precisely recognize over 40% of all annotation in the gold standard.

On the other hand is the concern that Wikifier recognizes many concepts that are not part of the gold standard and cannot be evaluated. Actually there are almost three times as many entities tagged by Wikifier than can be found in the gold standard and it is important to understand what is in there. We have expected this behaviour, since as already mentioned Mewsli-9 is a EL datasets in which not all mentions are tagged. In order to achieve a fair comparison of the three tested systems, we proceeded with manually evaluated experiments on our custom dataset.

5.2 Results on Manual Evaluation

For the next part of the experiments we annotated all 90 documents from our custom dataset with all three systems of interest. We then randomly selected a subset of all annotations (200 per system) that were annotated by multiple annotators reaching agreement. The evaluation included two judgements- entity recognition and entity disambiguation. For the first step, we defined three possibilities, exact, partial and false as we also want to examine if entities which are not exactly detected by the first step of an approach can be correctly linked to Wikidata by the Entity Disambiguation part of the systems. In other words, check whether the ED step is capable of fixing errors of NER or

Lang	Errors	Only WF	Only GS	Both	Precision	Recall	F1
en	1235	173483	38560	41093	0.96	0.51	0.67
de	1378	173910	21114	43807	0.96	0.67	0.79
es	1187	152925	22495	33240	0.96	0.59	0.73
ar	37	42846	3442	3166	0.98	0.43	0.60
fa	9	1925	214	307	0.97	0.57	0.72
ta	28	9156	1588	1098	0.97	0.41	0.58
tr	78	7015	3272	2464	0.96	0.42	0.59
ja	134	108708	16563	17741	0.99	0.51	0.68
sr	543	68643	13982	21687	0.97	0.61	0.75
all	4629	738611	121230	164603	0.97	0.57	0.72

Table 1: Results form running Wikifier over the Mewsli-9 dataset.

EBD and with that can improve the overall performance. The second step includes evaluation of ED in which again three categories were defined: correct, wrong and invalid entity. The latter category is defined when no entity to link exists within the span. The results for all evaluated systems can be seen in Table 3. It is important to note here that the columns presenting the ED results (”ED(ve)” and ”ED(vp)”) show the accuracy of the ED only on the correctly recognised entities, exact and partially. In this way we want to assess the ED of each system independently from its mention detection part. Column ”end-to-end EL” presents the overall accuracy of each system and is the best indicator for the performance of the whole system. Since our custom data is not previously annotated, we cannot formally analyse the recall of the entity linking performed. However, we could infer an estimated recall based on the results that we have combined with the total number of annotations for the whole dataset for each system (presented in column ”Total number of annotations”). From the results presented in 3 we can conclude the following:

Lang	Accuracy
ar	94.7
de	91.5
en	86.7
es	90
fa	94.6
ja	89.9
sr	94.9
ta	92.9
tr	90.7
micro	90.2
macro	91.8

Table 2: Reported results of mGenre model on Mewsli-9 dataset.

- SpaCy produces the highest number of annotations, however also the highest number of incorrect ones. The general performance of the SpaCy + mGENRE system on the manually annotated annotations is also lowest. We assume that the recall for the system is quite high, however its low accuracy makes it less reliable in comparison to the other two systems.

- When linking exactly extracted entities, mGENRE performs very well and combined with EBD achieves results comparable with the ones reported in the paper (around 90% accuracy). In a combination with SpaCy, on the other hand it performs worse (80% accuracy). We suspect the reason is that SpaCy detects many annotations of types date and cardinal, which are then wrongly linked to unrelated Wikidata items by mGENRE. mGENRE also works well with partial entities (around 80% in both systems) which is a good indicator that mGENRE is capable of ”fixing” errors with respect to the extraction of the mention.

- EBD has a very low score when considering the exact matches (66%), however it achieves a very good result of over 90% correctly recognised entities when we loosen the restriction on correctness and allow partially matched entities. The overall performance of the EBD-mGENRE systems in terms of accuracy is also satisfactory (75%), but notably lower than the overall accuracy achieve by Wikifier (86%).

EL System	NER (e)	NER (p)	ED (ve)	ED (vp)	end-to-end EL	Total number of annotations
WF	88,5	99	93,2	88,3	87,5	482
SpaCy	62	79,5	81,2	78	63	2398
EBD	66	92	90	82	75,5	618

Table 3: Accuracy in % for all end-to-end EL systems for each step. The first column is the name of the EL system, WF for Wikifier, SpaCy for SpaCy + mGENRE, and EBD for EBD + mGENRE. Column NER(e) shows the percentage of exactly recognised entities, column NER(p)- partially recognised entities. Columns ED(ve) and ED(vp) describe the results for the Entity Disambiguation part for valid exactly recognised and valid partially recognised entities, respectively. The column end-to-end EL shows the overall performance of the system and the last column presents the total number of annotations for each model on all documents.

- Wikifier achieves the best accuracy results in single components of the system and also end-to-end. This result is expected since Wikifier is not a true EL system. It does not link a concrete part of the text (mention) to an entity in a KB, but instead it sees the text as a whole and finds Wikipedia article which are related to the it. Wikifier, however, produces the lowest number of annotations overall (482) which means the inferred upper bound on recall is quite low (e.g. we estimate EBD annotated 90 additional accurate concepts over the dataset).

- We also noticed that Wikifier has difficulties detecting entities in short text. For 11 of the 90 documents, Wikifier produced no annotations. All these 11 documents are short documents (one or two sentences) in English. For comparison the other two systems found annotations in 87 (EBD + mGENRE) and 90 (SpaCy + mGENRE) documents.

- EBD + mGENRE seems like a good balance between precision and recall. However, its law accuracy requires further improvement.

5.3 Effect mGENRE Linking Threshold

t	-0.2	-0.3	-0.4	-0.5
missed	11.9	6.6	4.6	1.3
fixed	77.1	66.7	58.3	50

Table 4: Comparison of the trade off between correct missed and wrong fixed for different mGENRE thresholds. The ”missed” row analyses the percentage of correctly recognised (both exact and partial) and linked entities which would be discarded for each threshold value presented in the columns. The ”fixed” column present the percentage of the wrongly extracted or linked entities which are discarded when applying the corresponding threshold.

Further analysis suggests a method to improve the accuracy of the EBD + mGENRE system. Alongside the best linking candidate, mGENRE also returns a score. We decided to experiment with a threshold for this score and discard all annotations which return a score below the threshold. We hope to remove wrongly detected (or linked) entities while not losing many of the correctly recognized and linked ones. Table 4 presents the trade off between the discarded correct entities (column ”missed”) and the removed wrongly detected or linked entities (”column fixed”) for various thresholds. Our result show a clear connection between mGENRE score and correctness of the detected entities. We conclude that mGENRE is capable of fixing errors of the entity detection method it is combined with.

Table 6 presents the number of right an wrong annotations from the mGENRE system after the entities were discarded by the corresponding threshold as well as the system overall accuracy in each case. It is clear that with the implementation of the threshold, the EBD + mGENRE approach can match or even exceed the accuracy of Wikifier(87.5%).

With the discarded entities, the total number of annotations also declines. Table 6 shows expected number of annotations produced each threshold. We see that for t=-0.3 the EBD + mGENRE system has higher precision than Wikifier, for t=-0.5 it has a higher recall but for t=-0.4 it has the best trade-off in accuracy and recall with more annotations and higher accuracy than Wikifier.

6 Discussion

Our comparison between Wikifier and mGenre with respect to entity disambiguation shows that mGenre outperforms Wikifier on Mewsli-9. However, the linking accuracy of Wikifier is comparable to one reported for mGenre and the difference comes from the ER step. Based on analysis of the

t	-0.2	-0.3	-0.4	-0.5	none
Accuracy	0.92	0.89	0.87	0.86	0.75
Annotations (right)	133	141	144	149	151
Annotations (wrong)	11	16	20	24	48

Table 5: Accuracy of the end-to-end performance of the EBD + mGENRE system for different values of the mGENRE score. "Annotations (right)" and "Annotations (wrong)" present the number of correct and wrong annotations after applying the threshold in each case.

t	-0.2	-0.3	-0.4	-0.5	none	Wikifier
total number of annotations	404	455	493	527	618	482
number of expected correct annotations	371	404	428	453	463	419

Table 6: Accuracy of the end-to-end performance of the system for different values of the mGENRE score. "Annotations (right)" and "Annotations (wrong)" present the number of correct and wrong annotations after the by the threshold discarded annotations in each case.

overall performance of the three end-to-end systems, we conclude that SpaCy + mGENRE is the least reliable systems due to its very low accuracy and the fact that it detects many more mentions than the other two systems cannot overcome this issue. The other two systems both produce satisfactory results with each of them having different advantages and disadvantages. Wikifier has high accuracy for all components of the system but performs rather poorly on short texts and produces fewer annotations overall. EBD + mGENRE combined with a threshold achieves slightly higher accuracy than Wikifier while detecting more entities but the threshold selection is not part of the current training process. It also performs well on short texts while having some difficulties extracting entities from longer texts. EBD itself achieves underwhelming results when considering only exact matches, however including partial matches, the performance significantly improves. Fortunately, mGENRE is capable of "fixing" entity boundary detection errors and thus boosting the overall performance of the system. Improvements in the entity detection is the most promising approach for improving the overall solution.

7 Conclusion and Further Work

In this paper we attempted to explore and compare different end-to-end entity linking systems. Apart from testing existing systems, we also build our own solutions as a combination of the state-of-the-art entity disambiguation model mGENRE with suitable named entity recognition or entity boundary detection methods. Our results show that Wikifier is capable of entity disambiguation which is slightly worse that the one achieved by mGENRE. On the other hand its performance with respect to entity recognition is not satisfactory and requires significant improvement.

Another significant outcome of our work is that a combination of entity boundary detection method with mGENRE and threshold filtering achieves the best overall performance on our custom dataset. In terms of Entity Disambiguation, mGENRE demonstrates comparably high results to the ones reported, which is an indicator for its reliability. Based on the separate results for entity (boundary) recognition and entity linking, we conclude that the performance of mGENRE regarding correctly detected entities (boundaries) is quite satisfactory and can be applied in real world applications.

For the improvement of the recall and precision of the end-to-end solution, improvements in the entity extraction is recommended. A possible future research direction in this field could be using Large Language Models, LLMs (Zhao et al., 2023) for named entity recognition (as proposed in (Wang et al., 2023), (Ashok and Lipton, 2023)). Apart from that, very recently, a transformer-based, end-to-end, one-pass multilingual system BELA (Plekhanov et al., 2023) was released. A comparison of this system to the solutions explored in this work would also be valuable.

Abstract

This paper presents the methodology and data used for the automatic extraction of the Romanian Academic Word List (Ro-AWL). Academic Word Lists are useful in both L2 and L1 teaching contexts. For the Romanian language, no such resource exists so far. Ro-AWL has been generated by combining methods from corpus and computational linguistics with L2 academic writing approaches. We use two types of data: (a) existing data, such as the Romanian Frequency List based on the ROMBAC corpus, and (b) self-compiled data, such as the expert academic writing corpus EXPRES. For constructing the academic word list, we follow the methodology for building the Academic Vocabulary List for the English language. The distribution of Ro-AWL features (general distribution, POS distribution) into four disciplinary datasets is in line with previous research. Ro-AWL is freely available and can be used for teaching, research and NLP applications.

1 Introduction

Since academic language differs from everyday social language and is an essential acquisition target in current education, extracting salient features contributes to linguistic, register, genre and disciplinary feature identification that can benefit students, teachers and educational app developers alike. Compiling an Academic Word List (AWL) is an effective solution to support both language teaching and NLP tasks. From the didactic perspective, AWLs reflecting either the L1 (i.e. mother tongue) or the L2 (i.e. foreign language) academic vocabulary can be used to offer linguistic support to novice academic writers in the form of discipline-specific and general lexical prompts. Teachers of all disciplines can integrate AWLs into teaching materials to help students write better (see, for example, Wangdi and Shimray (2022)).

NLP studies can exploit AWL datasets on topics such as text classification (Zampieri, 2012) and topic modelling (Murakami et al., 2017). For example, field-specific academic lists can be used to automatically classify texts into disciplinary areas. The same can be applied for the automatic distribution of texts in academic versus non-academic batches. In machine learning methods for language modelling tasks, AWLs are essential in training models to generate accurate academic writing samples. By combining NLP tasks with linguistic approaches in relation to AWLs, important advances can be achieved in the frame of lexical and syntactic analyses that evaluate the use of collocations and phraseology specific to the academic varieties. For the Romanian language, there have been few attempts to extract a valid Romanian Word List (Szabo, 2015) and only one study has extracted and analysed multiword units using academic writing corpora (Muresan et al., 2022).

In recent years, researchers have worked to create several academic writing corpora. EXPRES – Corpus of Expert Writing in Romanian and English (Chitez et al., 2022b) is one of them. It is the only bilingual multidisciplinary corpus capturing the Romanian academic writing context. By combining datasets representing the Romanian Frequency List (Szabo, 2015) based on the ROMBAC Corpus (Ion et al., 2012), and EXPRES disciplinary datasets (Chitez et al., 2022b), we were able to generate an empirically based Romanian Academic Word List. Ro-AWL is made publicly available[1] and can be used for teaching, text classification and language modelling.

2 Related Work

Most academic vocabulary lists have been developed in the context of English for Academic Pur-

poses (EAP). On the whole, two categories of lists exist. One list type aims to identify academic words commonly used in EAP across disciplines, which students could be made aware of. The studies aiming to provide cross-disciplinary academic word lists usually use large corpora containing expert academic writing from various disciplines. The widely used lists of this type are the Academic Word List (AWL) (Coxhead, 2000) and the Academic Vocabulary List (AVL) (Gardner and Davies, 2014). The second type of list seeks to identify discipline or field-specific words worth teaching. Various specialised lists have been developed for fields such as veterinary medicine (Ohashi et al., 2020) or nursing (Yang, 2015).

While there is a growing interest in building cross-disciplinary academic word lists for languages other than English, these academic word lists remain few. See, for example studies conducted for French (Cobb and Horst, 2004), Persian (Rezvani et al., 2016), Portuguese (Baptista et al., 2010), Swedish (Carlund et al., 2012), and Norwegian (Johannessen et al., 2016). An explanation for this scarcity might be that academic language data sets are rare and often not freely available due to copyright. This can be especially true for low-resource languages, such as Romanian. Access to a representative corpus is crucial, as the validity and reliability of an academic word list highly depend on the quality of the data set.

Apart from the limited availability of academic writing corpora, an additional challenge may be that there is no standard procedure for extracting academic word lists. Scholars are still exploring and testing various methodologies. For example, some studies build on the methods used for the AWL or the AVL (Johannessen et al., 2016; Rezvani et al., 2016). One study uses the translated version of the AVL in Portuguese as a starting point for its investigation (Baptista et al., 2010). Another study proposes a new word list extraction method different from previous ones (Carlund et al., 2012).

In the case of Romanian, no previous studies have compiled specialised or general academic word lists. Although in the last 10-15 years, several research institutions and projects have been involved in developing corpus resources in Romanian, relatively few have focused exclusively on general academic writing. Some of the most significant corpora recently compiled, such as ROMBAC (Romanian Balanced Annotated Corpus, see Ion et al. (2012)), with more than 30 million words, CoRoLa (Corpus of Contemporary Romanian Language, see Mititelu et al. (2014)), or The Balanced Romanian Corpus (BRC, see Midrigan-Ciochina et al. (2020)) cover only few disciplines or subsets: 5 sections for ROMBAC (journalism, literature, medical texts, legal texts, biographies), uneven and unfiltered distribution of resources in CoRoLa (the collection of academic writing texts is based on agreements with publishing houses and journals, without filtering of the content on quality criteria) and BRC (literary text samples, research articles, news, spoken data). The ROMBAC corpus (excluding the medical subcorpus) was already used to develop the Romanian Word List (RWL, see Szabo (2015)), targeted at Romanian L2 learners (e.g. from the Hungarian minority in Romania). The list is a general list of words, not focused on academic language. As far as discipline-specific corpora are concerned, smaller corpora such as SiMoNERo (medical corpus, Mitrofan et al. (2019)), BioRo (Mitrofan and Tufiş, 2018), PARSEME-Ro (news articles), LegalNERo (legal, Păiș et al. (2021)), MARCELL (legal, multilingual, see Váradi et al. (2020)), CURLICAT (multilingual, containing several domains: Economics, Education, Health, Sciences, etc., see Váradi et al. (2022)) have been compiled. However, apart from compiling the datasets and conducting a series of descriptive studies, no special attention is given to the lexical level.

In this context, the EXPRES corpus (Corpus of Expert Writing in Romanian and English) is the first corpus of discipline-specific academic writing in the Romanian context (academic writing in Romanian L1 and academic writing in English L2 produced by Romanians) (Bucur et al., 2022; Chitez et al., 2022a). Covering four disciplines – Linguistics, Economics, Political Sciences, Information Technology –, the Romanian subset contains 200 open-access research articles from each domain, published in the past 5-10 years in peer-reviewed journals (see Chitez et al. (2022b)). The rigorous selection criteria (Rogobete et al., 2021) contribute to the representativeness of the corpus, making it a suitable candidate for testing a possible Romanian Word List and narrowing it down to an Academic Word List. Furthermore, the EXPRES corpus is the first Romanian expert academic corpus available on an open-access query platform. Unlike other Romanian corpora, which offer limited access to third parties and poor resources for downloading search results or statistics, the EXPRES corpus support platform has been implemented as a cross-platform distributed web application (Chitez et al., 2022b).

3 Data

This work uses two different corpora: the academic corpus EXPRES and the Romanian Academic Word List (Szabo, 2015) compiled from the general corpus ROMBAC. The Romanian language sub-corpus of EXPRES[2] (Chitez et al., 2022b) consists of 800 research articles, 200 articles for each of the four fields: Linguistics (LG), Economics (EC), Information Technology (IT) and Political Sciences (PS). The articles from the corpus were manually processed to preserve the anonymity of the authors (e.g., the name of the authors were replaced with AUTHOR_NAME) and the beginning and end of the title, abstract and sections are annotated with corresponding XML tags (e.g., <TITLE>, </TITLE>) (Chitez et al., 2022b). Table 1 shows the distribution of words in EXPRES, without counting the manually added tags. The corpus contains more than 3 million words, with more than 200 thousand unique words.

Domain	Tokens	Types
EC	1,092,846	48,807
LG	674,277	73,667
IT	750,236	40,494
PS	963,061	62,096
Total	3,480,420	225,064

Table 1: EXPRES Statistics

The Romanian Academic Word List (Szabo, 2015) contains a frequency list for all the words in the Romanian Balanced Annotated Corpus (ROMBAC) (Ion et al., 2012). ROMBAC (Ion et al., 2012) is a large general collection of texts from the Romanian language. It contains texts from five domains: news, medical, legal, biographies and fiction. The texts from ROMBAC are tokenized and lemmatized. The version we use in this paper contains more than 25 million lemmas, of which 1 million are unique (Table 2). The dataset was previously used to derive other linguistic resources, such as the Romanian Word List and Romanian Vocabulary Levels Test (Szabo, 2015). We use the ROMBAC corpus in our work because it is the largest corpus available in Romanian that was not web-scraped, and it is a reference corpus for the contemporary Romanian language (Ion et al., 2012). Even if another larger corpus for the contemporary Romanian language exists, namely CoRoLa (Mititelu et al., 2014), it is not publicly available and cannot be downloaded; it can only be queried online[3]. The other reference corpus recently compiled, BRC (Midrigan-Ciochina et al., 2020), was not an option either, since its size is smaller than ROMBAC and lacks disciplinary variation.

Domain	Tokens	Types
News	1,922,109	50,945
Medical	6,783,005	362,782
Legal	6,269,543	248,354
Biographies	3,716,031	223,592
Fiction	6,950,371	105,346
Total	25,641,059	991,019

Table 2: ROMBAC Statistics

4 Methodology

Data preprocessing. The Romanian Academic Word List, with words from the ROMBAC corpus, provides the lowercase lemma for each word in the corpus and its frequency. Therefore, no preprocessing step was done on this data. Even if we use the word frequencies from the Romanian Academic Word List, we will refer to this data as the ROMBAC corpus, given that the list contains all the words from ROMBAC.

The EXPRES corpus is organised in multiple .txt files, one for each article from the four domains LG, IT, PS, and EC. For each document, we removed specific tags used for article anonymisation, such as JOURNAL_TITLE, AUTHOR_NAME, etc., and the specific XML tags used to mark the beginning or end of the title (<TITLE>, </TITLE>), abstract (<ABS_INT>, </ABS_INT>), or different sections of the article (<INTROD>, </INTROD>), etc. The EXPRES corpus statistics regarding the words and word types in the corpora are shown in Table 1. For preprocessing the text, we used Stanza (Qi et al., 2020) for lemmatising and extracting part-of-speech tags. All the lemmas from the texts are transformed into lowercase. The Stanza toolkit was chosen for its good performance for the Romanian language, compared to other NLP tools (Paiș et al., 2021). However, we performed a manual analysis of the extracted lemmas and observed that some of them are incorrect: "sociales" instead of

[2] https://expres-corpus.org/

[3] https://korap.racai.ro/

"social" (En: "social"), "europes" instead of "european" (En: "European"), and others. Even if previous works have shown a good performance of the Stanza toolkit for lemmatisation in the Romanian language (Paiș et al., 2021), we chose to use the lemmas from the ROMBAC corpora for the words that appear in ROMBAC. We used Stanza only for extracting the lemma of words that were not part of ROMBAC. This way, the noise of lemmatisation was diminished, as the lemmas provided in the ROMBAC corpus were accurate and have been previously validated (Ion et al., 2012).

Building the academic word list. For constructing the academic word list, we follow the methodology for building the Academic Vocabulary List for the English language (Gardner and Davies, 2014), comprising different frequency measures for lemmas. We chose to use the methodology from Gardner and Davies (2014) instead of the procedure from Coxhead (2000) because the former method provides an academic list with almost twice the latter's coverage. The approach from Coxhead (2000) is based on word families, while the method from Gardner and Davies (2014) relies on lemmas. A word family is represented by the base word from which other words are derived with suffixes and prefixes. This can be problematic in the case of academic words, as the base of a word family can be an academic word, but their derivations might not be academic (Gardner and Davies, 2014).

The methodology is based on four measures: ratio, range, dispersion and discipline measure. The ratio is used to exclude general high-frequency words from the corpus, while the other three metrics exclude technical or discipline-specific terms. We further expand on each metric below.

Ratio. Similar to Gardner and Davies (2014), general high-frequency words (in our case, lemmas) are removed from the academic word list. The ratio is computed to keep in the list words with a higher frequency in the academic corpus than in the general non-academic corpus. We computed the normalised frequency per million words of each word in the two corpora, EXPRES and ROMBAC. The ratio is calculated by dividing the academic corpus's normalised frequency by the general corpus's normalised frequency for each word. Gardner and Davies (2014) use the frequency ratio of 1.5 in their method, but mention that the measure is not a gold standard. We experimented with values between 1.2 and 2.0 for ratio, and, in our case, the 1.2 ratio was a suitable value, to not have important academic words excluded from our list, such as "metodologic" (En: "methodological"), "clasificare" (En: "classification"), "activitate" (En: "activity"), "distinge" (En: "distinguish"), "sugera" (En: "suggest"), which are found in the original AVL for the English language.

Range. The range measure allows for selecting words that only occur in multiple disciplines, and filtering out discipline-specific words. Gardner and Davies (2014) proposed that a word should have at least 20% of the expected frequency in 78% of the sub-corpora (i.e. 7 out of 9 domains). For computing the expected frequency, we first calculated each word's frequency in relation to the corpus by dividing the word count by the total number of words in EXPRES. Afterwards, the frequency in relation to the corpus is multiplied by the number of words in a given sub-corpora to get the expected frequency in each sub-corpora. In our case, EXPRES has only four domains, and we chose words that had at least 20% of the expected frequency in at least three out of four fields, corresponding to 75% of sub-corpora.

Dispersion. The measure used for dispersion is Julliand's D (Juilland and Chang-Rodríguez, 1964), which shows how evenly a word appears in a corpus. The formula is as follows:

$$Juilland'sD = 1 - \frac{\sigma}{\bar{x}} \times \frac{1}{\sqrt{n-1}}$$

where σ represents the standard deviation and $\bar{x}$ represents the mean frequency of a word. n is the number of sub-corpora.

The values of dispersion range from 0.01 (corresponding to words that appear in a small part of the corpus) to 1.00 (meaning that a word is spread evenly in the corpus). Unlike the range measure, which estimates if a word has the expected frequency in the four domains, the dispersion measure ensures that a given word is distributed uniformly in the four sub-corpora. Gardner and Davies (2014) chose 0.80 dispersion, while, in other works, the dispersion measure varies between 0.30 to 0.60 (Oakes and Farrow, 2006; Johannessen et al., 2016; Lei and Liu, 2016). We decided to use a dispersion value of 0.50 in our work.

Discipline measure. This measure is used for filtering out words with a very high frequency in a given domain, which may be technical discipline-specific words. Gardner and Davies (2014) proposed that a word cannot have more than three times the expected frequency in any domain. Following a similar approach, we remove words with more than three times the expected frequency in any of the four domains.

As an additional measure, we excluded words with low frequency in the academic corpus, because the metrics mentioned above do not filter them out. Inspired by Coxhead (2000) and Lei and Liu (2016), we remove from the final academic list the words that have a minimum frequency of 28.57 per million words, corresponding to the minimum frequency originally proposed by Coxhead (2000) of 100 times in the 3.5 million words corpus they used in their work. We also performed a manual analysis of the academic word list and removed the noise, such as proper nouns (e.g., "București", En: "Bucharest"), some numerals, and some words that were not academic and that were not filtered out by the measures mentioned above.

5 Results

The final Romanian academic word list consists of 673 lemmas with their corresponding part of speech tags. The list comprises 332 nouns, 167 adjectives, 157 verbs, and 17 adverbs. We automatically translated into Romanian the words from the AVL developed for English (Gardner and Davies, 2014) that contains 3015 words. We found that 381 words in our list are in the original AVL. There are some cases of academic words found in our Romanian academic list and in the AVL for English for which the automatic translation fails to provide the correct match. For example, the noun "adoption" from AVL was translated as "adopție", which is not in the Ro-AWL, but the word "adoptare" is an academic word from Ro-AWL with the same meaning. The fact that we found more than half of the Ro-AWL in the original AVL, even though in some cases the translation fails to capture the correct meaning of the words, makes us confident that the measures used are reliable for building a Romanian academic word list.

In line with previous works (Gardner and Davies, 2014; Coxhead, 2000; Carlund et al., 2012), to demonstrate the viability of the newly developed academic word list, we measured the coverage of the Ro-AWL in two corpora: the academic corpus EXPRES and in the general corpora ROMBAC. The academic words from our list cover 15.25% of the EXPRES corpus and 6.73% of ROMBAC. In line with the English AVL results, Ro-AWL has a higher coverage in the academic corpus and a lower coverage in the general corpus. Regarding the coverage in EXPRES, we show the coverage of academic words categorised by their part-of-speech tags in Table 3. The coverage of the Romanian academic word list varies in the four domains. The coverage is 17.75% for the Economics sub-corpora, 11.82% for Linguistics, 17.03% for Information Technology and 13.17% for Political Sciences.

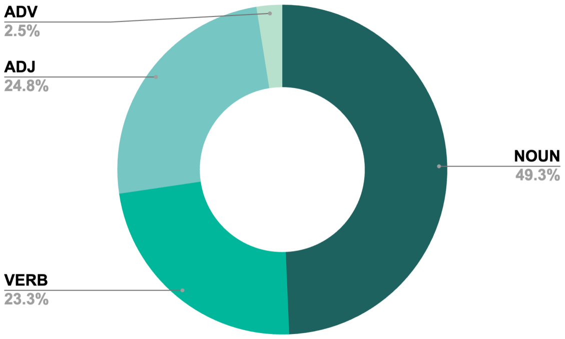

Figure 1: The distribution of the words in terms of part-of-speech from Ro-AWL

	EC	LG	IT	PS
VERB	4.98%	3.95%	5.33%	3.95%
NOUN	9.74%	6.02%	9.20%	6.82%
ADJ	0.33%	0.27%	0.24%	0.16%
ADV	2.70%	1.59%	2.26%	2.24%
Total	17.75%	11.82%	17.03%	13.17%

Table 3: Coverage of Ro-AWL in the EXPRES corpus

6 Discussion

A first observation concerns the different coverages of Ro-AWL in the EXPRES corpus (see Table 3). The lower percentages in Linguistics and Political Sciences (with a total coverage ranging between 11% and 14%) and the higher ones in Economics and IT confirm that "The SSH community is characterised by the embedment of research in the local context and by linguistic diversity in producing and disseminating knowledge" (Kancewicz-Hoffman and Pölönen, 2020). Researchers in the Romanian context in SSH (Social Sciences and Humanities) tend to favour a more "creative" dimension of the language used in academic writing, using figurative language in constructing rhetorical structures. Although in English language academic writing "the dichotomy of soft and hard sciences is rather fluid and as such insignificant" (Stotesbury, 2003), discipline-specific peer-review practice in the Romanian setting seems to influence the academic writing style. This is particularly visible in the EXPRES subset of Political Sciences and Linguistics. Romanian academic writing in SSH seems rather unfocused, descriptive and rich in rhetorical structures. In contrast, research articles in Economics and Information Technology contain many statistics, tables, and formulas, making the writing in the discipline less descriptive.

Secondly, although our extraction measures were successful in filtering most of the technical vocabulary, small amount of technical language remains in the Ro-AWL (terms such as "dauna", En: "damage" - in contexts related to insurances; "institutional", "security", "electronic" etc.). Nevertheless, the majority of the Ro-AWL components are discipline neutral, thus contributing to academic discourse cohesion and coherence.

Thirdly, a technical challenge regarding the functionality and accuracy of the Romanian POS tagger should be mentioned. An overview of the assigned tags revealed the difficulty of the tagger to distinguish between adjectives and adverbs (for instance: "important", "social", "european" were assigned as adverbs, but the contexts prove their prevalent use as adjectives). It also confused past participles ending with "-t" (e.g. "accentuat", En: "emphasised". This technical difficulty can be observed in Table 3, with the coverage of adverbs being higher than the one of adjectives, because most of the adjectives had the part-of-speech mislabeled by the POS tagger. These errors of the POS tagger are due to the homonymy between the two POS, most adverbs being homonymous to their adjective counterparts (Vasile and Croitor, 2017).

A technical advantage of the Romanian POS tagger, however, is its capacity to recognise nouns with a definite article while being a part of prepositional phrases ("în pofida", En: "despite", "în jurul", En: "around"). This also explains the increased percentage levels of nouns, adverbs and verbs and the lower values for adjectives (see Figure 1).

Despite some of the technical challenges, the extraction of the Romanian AWL using the EXPRES corpus resulted in successfully identifying the recurrent discourse conventions used by Romanian researchers. During the process and alongside the extraction procedure per se, translating the Academic Vocabulary List (AVL) (Gardner and Davies, 2014) was a helpful procedure, as it is well accepted that academic writing, irrespective of the language, contains a large number of words of Greek and Latin origin (see e.g., Rasinski et al. (2008); Green (2015)).

7 Conclusions and Future Work

This study reports the extraction of the first Romanian Academic Word List (Ro-AWL), which can be used to check the degree of academic vocabulary coverage in discipline-specific and general language samples. Ro-AWL consists of 673 lemmas, distributed among the main part-of-speech categories (nouns, verbs, adverbs, adjectives). Our methodology adopted measures used for the Academic Vocabulary List for the English language, such as ratio, range, dispersion and discipline measures. The percentages calculated by testing Ro-AWL on the disciplinary datasets in the EXPRES corpus (Chitez et al., 2022b), indicate a lower coverage for Linguistics (11.82%) and Political Sciences (13.17%) and a higher coverage for Information Technology (17.03%) and Economics (17.75%). Also, the academic vocabulary coverage in ROMBAC, a general language reference corpus, is 6.73%, while the coverage is much higher (15.25%) in EXPRES, an expert academic writing corpus. This aligns with previous research, since Ro-AWL coverage is similar to thresholds for academic vocabulary (Nation, 2001).

Despite several computation constraints (e.g. Romanian POS tagger not being able to distinguish between adjectives and adverbs), our study provides important insights into the academic writing vocabulary in Romanian by proposing a validated Romanian Academic Word List. Our findings also have pedagogical implications, as the list can be used to support academic writing teaching activities and NLP tasks focusing on Romanian. For example, the Ro-AWL can be paired up with the freely available EXPRES corpus platform to develop corpus-assisted learning activities commonly known as Data-Driven Learning (DDL) (see e.g., Bennett (2010)). However, even if the coverage test results in the EXPRES are encouraging, further research is needed to test the validity of the Ro-AWL on corpora containing academic writing from more disciplines. Future work can be conducted in at least two directions: refining the lists from a contrastive perspective, by developing a discipline-specific AWL, or, on the contrary, by searching for highly frequent academic words present in an extended corpus containing more disciplines.

Acknowledgements

We would like to thank Csaba Z Szabo for giving us access to the Romanian Frequency List and Ștefan Daniel Dumitrescu for his valuable insights into the data and methods used in this paper. This work was supported by a grant of the Ministry of Research, Innovation and Digitization, CNCS/CCCDI – UEFISCDI, project number 158/2021, within PNCDI III, awarded to Dr Habil Madalina Chitez (PI), from the West University of Timisoara, Romania, for the project DACRE (*Discipline-specific expert academic writing in Romanian and English: corpus-based contrastive analysis models*, 2021-2022).

Abstract

Stance prediction – the computational task of inferring attitudes towards a given target topic of interest – relies heavily on text data provided by social media or similar sources, but it may also benefit from non-text information such as demographics (e.g., users' gender, age, etc.), network structure (e.g., friends, followers, etc.), interactions (e.g., mentions, replies, etc.) and other non-text properties (e.g., time information, etc.). However, so-called hybrid (or in some cases multimodal) approaches to stance prediction have only been developed for a small set of target languages, and often making use of count-based text models (e.g., bag-of-words) and time-honoured classification methods (e.g., support vector machines). As a means to further research in the field, in this work we introduce a number of text- and non-text models for stance prediction in the Portuguese language, which make use of more recent methods based on BERT and an ensemble architecture, and ask whether a BERT stance classifier may be enhanced with different kinds of network-related information.

1 Introduction

Standard stance prediction concerns the inference of for/against attitudes towards a target topic of interest from text data. The task may be seen as analogous to sentiment (e.g., positive or negative) analysis, but stance and sentiment do not necessarily correlate (Aldayel and Magdy, 2021). For instance, consider the following statement:

> *'People who refuse the vaccine should be banned from entering the premises'*

In this example, given the intended target 'vaccination', the statement suggests a favourable stance. Still, the overall sentiment (particularly in the use of the word 'banned') may be regarded as being more on the negative side.

Computational models of stance prediction, which often take social media text as an input, have been applied to a wide range of topics, including moral or social issues (Pavan et al., 2023; Geiss et al., 2022), politics (Darwish et al., 2017; Lehmann and Derczynski, 2019; Cignarella et al., 2020), and others. The task has become particularly popular in the field since the SemEval-2016 shared task (Mohammad et al., 2016) and accompanying corpus, focusing on stance prediction from Twitter text in the English language.

In addition to using text data (Zhang et al., 2020; Allaway et al., 2021; Pavan et al., 2020), recent work in stance prediction has addressed the use of non-text data as well (Aldayel and Magdy, 2021). Studies of this kind are largely motivated by the notion of *homophily* (McPherson et al., 2001), that is, the concept of 'similarity breeds connection', and take into account a range of well-known non-linguistic stance predictors. These include, for instance, the use of demographics information (e.g., users' gender, age, etc.) (Lehmann and Derczynski, 2019; Geiss et al., 2022), network structure (e.g., social media friends, followers, etc.) (Lai et al., 2020b), interactions (e.g., mentions, replies, retweets, etc.) (Magdy et al., 2016; Darwish et al., 2017), and other network properties (e.g., number of replies, time information, etc.) (Espinosa et al., 2020), which are often combined with standard text models. Hybrid models of this kind, although not necessarily using images, audio or other media, will be hereby called *multimodal*.

Existing work in stance prediction based on hybrid data are often derived from two main NLP initiatives: (1) the Iberaval-2017 shared task (Taulé et al., 2017), devoted to the Catalan and Spanish languages, and (2) the EVALITA-2020 shared task (Cignarella et al., 2020) for the Italian language, in both cases providing social media corpora and accompanying non-text data. The Iberaval-2017

Proceedings of Recent Advances in Natural Language Processing, pages 242–248
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_027

corpus is however limited to text and gender information, whereas EVALITA-2020 is a truly hybrid corpus that provides both text and network-related information. Similar hybrid resources (most notably for English and a few other European languages) do exist (Lehmann and Derczynski, 2019; Lai et al., 2020b). However, we are not aware of any study in stance prediction based on hybrid data that has been devoted to our target language – Portuguese.

In addition to the language gap, we notice that existing work in stance prediction based on hybrid data often relies on text representations based on feature counts (e.g., bag-of-words), in many cases combined with support vector machine (SVM) or other similarly time-honoured classification methods. As discussed in (Espinosa et al., 2020), some of these choices may be explained by the challenges involved in combining large text representations with (usually) much smaller non-text models (e.g., representing interactions, demographics, etc.).

Based on these observations, in this work we investigate whether stance prediction using a more contemporary text representation – namely, built from BERT (Devlin et al., 2019) – may be enhanced with different kinds of network-related information. Using a large multimodal stance corpus in the Portuguese language as an input, we envisaged a number of experiments to assess stance prediction models in an ensemble architecture of text- and network-related classifiers. The contributions made in this work are as follows:

- Hybrid (text and non-text) stance prediction approach using BERT and ensemble of classifiers.
- Stance prediction models for the Portuguese language.
- Best-performing strategy combining text, structural, and interaction information.

The remainder of this article is structured as follows. Section 2 reviews existing work in stance prediction and related resources. Section 3 describes our current experiment setting by presenting the models under consideration and the corpus to be taken as train and test data. Section 4 presents the results of our experiments. Finally, Section 5 presents our final remarks and future opportunities of investigation.

2 Related work

Table 1 summarises a number of recent studies that are devoted to stance prediction using text and non-text data, or which introduce a dataset for the task. These are organised according to text source (p=political discourse, r=Reddit, t=Twitter), language (Ar=Arabic, Ca=Catalan, Da=Danish, En=English, Fr=French, It=Italian, Sp=Spanish), the number of learning instances, the choice of text features (w=word, p=part-of-speech tags, c=characters, we=word embeddings, bp=BERT class probabilities), the kind of non-text feature under consideration (dem=demographics, m=mentions, r=replies, rt=retweets, dom=domain- or task-specific information, fr=friends, fo=followers, h=time of posting, dist=distance to other users, int=interactions), and main computational method (SVM=support vector machine, LR=logistic regression, etc.). Further details are discussed below.

Generally speaking, existing work in the field is largely based on Twitter, a preference that may be motivated by the ease of access to text and non-text data through the Twitter API.

All of the selected studies are devoted to English or other European languages. Among these, there are several studies focuses on Catalan and Spanish, including the work in (Lai et al., 2017), which has been developed in the light of the Iberaval-2017 shared task (Taulé et al., 2017), and which obtained the overall best results among the participant systems. Similarly, several recent studies have focused on the Italian language, including (Espinosa et al., 2020), which was the overall best-performing system at the EVALITA-2020 task B (contextual stance detection) shared task (Cignarella et al., 2020).

Although presently not shown, we notice also that language and topic choices usually come hand-in-hand, that is, existing stance datasets tend to favour target topics that are of interest to a rather local audience. This trend has been observed since the SemEval-2016 English corpus (Mohammad et al., 2016), which includes US-specific topics such as Trump and Hillary Clinton among more general topics such as climate change, etc. Similarly, the Catalan/Spanish study in (Taulé et al., 2017) focuses on stances towards the Catalan independence movement; the Arabic study in (Darwish et al., 2017) addresses the issue of stance towards Saudi/Egyptian islands ownership; the Danish cor-

Table 1: Stance prediction methods using non-text features.

pus in (Lehmann and Derczynski, 2019) focuses on Danish immigration policies; the Italian shared task in (Cignarella et al., 2020) focuses on stance towards the Sardine's movement, and so forth. This relation between language and topic is likely to be necessary as a means to model meaningful tasks, and to obtain the necessary amount of data. However, this may also suggest that in studies focused on a particular language – as in the present work, focused on Portuguese – the benefits afforded by using corpora developed for other languages may be limited.

Dataset sizes are often within a few thousand instances, which is close to the text-only SemEval-2016 stance corpus in (Mohammad et al., 2016) with 4.2K labelled instances. We notice, however, that the two largest stance corpora in the present review – used in (Magdy et al., 2016) and (Geiss et al., 2022) – are not manually annotated at the text level, resorting to label propagation or similar methods instead.

Text data is usually modelled in a bag-of-words or similar approach (e.g., using words, part-of-speech tags, or character n-grams), which may be explained by the need to combine well-balanced sets of text and non-text features as discussed in (Espinosa et al., 2020). Moreover, since some of these studies are more focused on the dataset (and not necessarily on any particular classifier method), the use of simpler text representations tends to be preferred. As a result, the use of word embeddings is less common, and the use of more recent transformed-based language models such as BERT (Devlin et al., 2019) appears only in one study, the aforementioned work in (Espinosa et al., 2020). Even in this case, however, the language model is used only as a means to obtain class probabilities to be taken as learning features, rather than modelling a full text representation directly.

Regarding the use of non-text features, Twitter-related network features are common and, to a lesser extent, this is true also of demographics (mostly gender), and domain-dependent information (e.g., information related to political affiliation, opposition, etc.). In the case of Reddit-based studies, we notice that non-text information is largely limited to interactions between users, whereas Twitter-based studies may also make use of friends and followers information, among others.

Computational methods for stance prediction based on hybrid data are often simple, well-known classifiers such as SVM or logistic regression. This may be explained by the relatively low dimension of these models if compared to what would normally be required for, e.g., text modelling. Moreover, in the case of shared tasks participant systems, it may be the case that execution times are also a concern, which might have favoured the use of these methods over more computationally-expensive (e.g., neural) alternatives.

3 Stance prediction based on hybrid data

The main objective of the present work is to investigate which combinations of network-related information, if any, may be added to an otherwise standard text-based model to improve stance classification results in the Portuguese language. As in the work described in (Espinosa et al., 2020), which is devoted to the Italian language, we will also focus on Twitter data, and on the use of friends, followers and mentions (e.g., users with whom they interact on Twitter) information. However, instead of resorting to BERT class probabilities as learning features, we shall make use of a full text representation built from BERT, and will investigate a range of simple ensemble approaches to combine (large) text and (comparatively small) non-text feature sets as a single model.

3.1 Models

We envisaged an ensemble approach to stance prediction that combines text features (or ‘t’ for short) with one or more sources of network-related information, namely, friends (‘fr’), followers (‘fo’), mentions (‘me’), or any combination of these, making seven binary (for/against) classifier alternatives as follows:

- t+fr: *text+friends*
- t+fo: *text+followers*
- t+me: *text+mentions*
- t+fr+fo: *text+friends+followers*
- t+fr+me: *text+friends+mentions*
- t+fo+me: *text+followers+mentions*
- t+fr+fo+me: *text+friends+followers+mentions*

In all our classifier alternatives, the basic text component is a standard BERT classifier described in (da Costa et al., 2023). This consists of token and Bi-LSTM layers followed by multi-head self-attention and a dense layer using sigmoid as an activation function and dropout. The token embedding layer is built from a BERT model pre-trained on Brazilian Portuguese Twitter data called BERTabaporu (da Costa et al., 2023)[1].

Friends and followers features correspond to the lists of all friends and followers of every individual as provided by the Twitter API. Mentions features correspond to the list of all usernames mentioned in the corpus timelines (and which may or may not coincide with a friend, a follower, or both), which are marked by the ‘@’ character in Twitter text data. Features are modelled in a so-called bag-of-users approach using tf-idf counts (i.e., building bag-of-friends, bag-of-followers, and a bag-of-mentions vectors, respectively). Feature vectors are taken as an input to a logistic regression classifier with parameters C, *tol* and $penalty$ optimised through grid search for each task.

Regarding the ensemble approach, predictions made by the individual model components are combined as a single output by majority voting. In the case of a tie, a random (for/against) prediction is made. As an example, Figure 1 illustrates the architecture of the full model *t+fr+fo+me*.

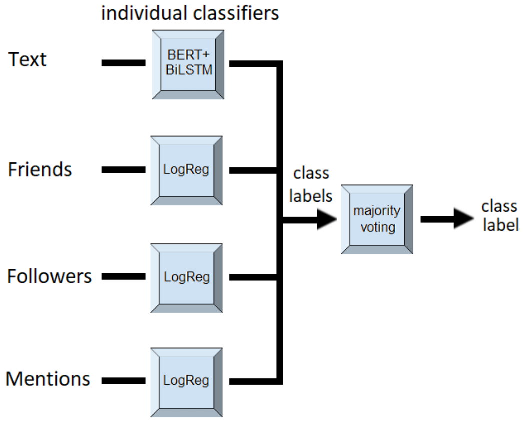

Figure 1: Example model architecture.

The use of BERT prediction in the (t)ext component of the ensemble is comparable to the use of BERT class probabilities in (Espinosa et al., 2020). In the present work, however, we use the actual label (for/against) predictions rather than class probabilities.

3.2 Data

The present work uses the Twitter corpus UstanceBR r2, whose preliminary version (r1) appeared in (Pavan and Paraboni, 2022). The corpus conveys stances towards six topics (two Brazilian presidents, two Covid-related treatments, and two local institutions) often regarded as having either a liberal or a conservative political leaning.

The corpus contains about 46.8K manually labelled tweets in the Portuguese language, and network-related information representing their friends, followers, and mentions. The text portion of the corpus has been previously applied to text-only stance prediction in (Pavan and Paraboni, 2022), but the use of its non-text portion in a hybrid setting – as in the present work – is novel.

Table 2 summarises text- and network-related corpus descriptive statistics across target topics by presenting their number of instances (tweets), tokens, friends (Fr), followers (Foll), and mentions (Ment).

4 Evaluation

All models were created and evaluated using the original train-test split provided by the corpus. Evaluation was carried out by computing average F1 scores. Statistical significance was assessed by using a McNemar test (McNemar, 1947) to compare model pairs. Table 3 summarises stance pre-

[1] https://huggingface.co/pablocosta/bertabaporu-large-uncased

Target	Inst.	Tokens	Fr.	Foll.	Ment.
Lula	8,320	422K	463K	677K	98K
Bolsonaro	9,414	259K	346K	536K	60K
Hydrox.	7,995	278K	577K	732K	406K
Sinovac	7,973	253K	821K	1164K	488K
Church	7,137	322K	962K	1547K	183K
Globo TV	6,013	215K	743K	1168K	122K

Table 2: Data descriptive statistics.

Model	Lula	Bols	Hydr	Sino	Church	Globo
t+fr	0.88	0.91	0.86	0.86	0.82	0.81
t+fo	0.85	0.90	0.85	0.82	0.70	0.79
t+me	0.87	0.91	0.89	0.87	0.83	**0.82**
t+fr+fo	0.91	0.94	0.88	0.84	**0.86**	0.75
t+fr+me	**0.92**	**0.96**	**0.94**	**0.92**	0.83	0.79
t+fo+me	**0.92**	0.95	0.93	0.90	0.85	0.79
t+fr+fo+me	0.91	0.95	0.90	0.87	0.84	0.77

Table 3: Stance prediction F1 results using (t)ext, (fr)iend, (fo)llower, and (me)ntion features. The highest F1 score for each task is highlighted.

diction results obtained by the models described in the previous sections across the six target topics.

Results show that simply using all available information, as provided by the full model *t+fr+fo+me*, is not the best strategy at all. On the contrary, it is the use of text, friends and mentions information alone, as provided by *t+fr+me*, that actually delivers best results across most topics, although clearly the advantage over the second best alternative may in some cases be minimal.

In order to verify the possible overall advantage of *t+fr+me*, this and the other top-performing model for each topic were compared by using a McNemar test. In doing so, the advantage afforded by *t+fr+me* over the selected alternative strategy across topics was found to be statistically significant as follows: Lula ($\chi = 9.8$, p <0.01), Bolsonaro ($\chi = 3.0$, p <0.05), Hydroxychloroquine ($\chi = 8.0$, p <0.05), Sinovac ($\chi = 4.0$, p <0.001), Church (not significant), and Globo TV ($\chi = 21.0$, p <0.001). This outcome further suggests a general preference of *t+fr+me* over the alternatives.

5 Final remarks

This paper has addressed the issue of stance prediction by reporting a number of experiments that combine text data with network-related information – represented by Twitter friends, followers and mentions – in a voting ensemble architecture. Results show that the use of friends and mentions, but not followers, obtained overall best results for the present setting.

The present work leaves a number of opportunities for further improvement. First, we notice that the present ensemble architecture is limited to the use of a simple majority voting method, and that more sophisticated strategies may increase overall model accuracy. This may be the case, for instance, of stacking (Wolpert, 1992), and others.

Second, the current bag-of-users approach – which has been taken as the basis for the present network-related models – may be replaced for a dense network representation provided by node embeddings. Models of this kind, which may be computed from, e.g., node2vec (Grover and Leskovec, 2016), would make the current friends, followers and mentions models more informative (or less sparse), and this may have a positive impact on the current results.

Regarding the text portion of the model, the current task may benefit from multiple, well-known NLP methods and applications. Among these, we may consider the use of hate speech detection methods (Basile et al., 2019; Mishra et al., 2019; da Silva et al., 2020), authorship attribution (Custódio and Paraboni, 2021; Barlas and Stamatatos, 2021), or author profiling (López-Santillán et al., 2020; Rangel et al., 2020). The latter, comprising the computational task of determining individuals' demographics from text, may help determine their stance towards a particular topic by taking into account, for instance, information regarding their political orientation (Flores et al., 2022), personality traits (Verhoeven et al., 2016; dos Santos et al., 2019), moral values (dos Santos and Paraboni, 2019; Pavan et al., 2023), and others.

Finally, it is worth noting that, for simplicity, our task definition has been presently limited to binary (for/against) stance classification. In more realistic settings, however, it would be arguably useful to consider the intermediate (or neutral) class as well. This possible extension is also left as a suggestion of future work.

From Stigma to Support: A Parallel Monolingual Corpus and NLP Approach for Neutralizing Mental Illness Bias

Mason Choey
The Nueva School
San Mateo, California, USA
mason@choey.com

Abstract

Negative attitudes and perceptions towards mental illness continue to be pervasive in our society. One of the factors contributing to and reinforcing this stigma is the usage of language that is biased against mental illness. Identifying biased language and replacing it with person-first, neutralized language is a first step towards eliminating harmful stereotypes and creating a supportive and inclusive environment for those living with mental illness. This paper presents a novel Natural Language Processing (NLP) system that aims to automatically identify biased text related to mental illness and suggest neutral language replacements without altering the original text's meaning. Building on previous work in the field, this paper presents the Mental Illness Neutrality Corpus (MINC) comprising over 5500 mental illness-biased text and neutralized sentence pairs (in English), which is used to fine-tune a CONCURRENT model system developed by Pryzant et al. (2020). After evaluation, the model demonstrates high proficiency in neutralizing mental illness bias with an accuracy of 98.7%. This work contributes a valuable resource for reducing mental illness bias in text and has the potential for further research in tackling more complex nuances and multilingual biases.

1 Introduction

Globally, 970 million people are currently living with mental illness. Each year, 14.3% of deaths, or approximately 8 million people, are caused by mental disorders. Depression affects over 300 million people worldwide, affecting people of all demographic and socioeconomic backgrounds. Anxiety disorders are almost as common, affecting 284 million people worldwide (Children's Hopechest, 2022). During the first year of the COVID-19 pandemic, incidences of depression and anxiety increased by an astounding 25% (WHO, 2022). In addition to depression and anxiety disorders, suicidal ideation, bipolar disorder, autism spectrum disorder (ASD), substance use disorder, and eating disorders such as bulimia and anorexia nervosa fall under the umbrella of mental illness (Zhang et al., 2022).

Mental illnesses have traditionally been one of the most stigmatized health conditions. Stigma and derogatory language about mental illness can be found everywhere, from casual conversations to media, even among medical professionals. Language can be used to reinforce stigma or fight it. Guidelines for responsible reporting by the media emphasize how language used in media can either encourage help-seeking behavior or inadvertently lead to suicide contagion (Reporting on Suicide, 2023). As an example, the phrase "committed suicide" is commonly used but has been replaced by the preferred "died by suicide" to avoid an association with "committing (a murder)" and demonstrate compassion through word choice (Mental Health Coalition, 2021).

In casual conversation, mental health diagnostic terms are frequently used to describe a non-medical event, such as the weather as "bipolar" or a situation as "insane". Although seemingly harmless, misusing diagnostic terms can lead to misunderstandings about mental illness by undermining the severity of mental illness and reinforcing negative stereotypes (Volkow, 2021).

Biased language affects how those with mental illnesses view themselves, how others treat them, and whether they seek help (Rose et al., 2007). People with mental illnesses, particularly

Proceedings of Recent Advances in Natural Language Processing, pages 249–254
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_028

substance use disorder, who perceive a high degree of public stigma about their condition, were half as likely to seek help as those who perceive a low degree of stigma (Canadian Centre for Substance Abuse and Addiction, 2019). Medical professionals and mental health service providers with bias against mental illness are less likely to offer appropriate treatment or refer those with mental illness to the specialty care they need (Volkow et al., 2021).

Natural Language Processing presents an opportunity to apply a language model to identify biased language and neutralize it by suggesting more respectful and compassionate language to replace it.

This project aims to develop an NLP system to identify text (in English) biased against mental illness and automatically replace it with proposed edits of neutral language without changing its original meaning.

2 Related Work

2.1 NLP Studies in Mental Illness

To date, NLP studies in mental illness have focused on (1) sentiment analysis (Nadkarni et al., 2011), (2) symptom detection (Jackson et al., 2017), (3) mental health surveillance (Mukherjee et al., 2020) (4) mental health portrayal in print media (Chen et al., 2017), and (5) text classification (Ive et al., 2020).

Most studies applying NLP to mental illness have focused on early indicators to support detection, prevention, and treatment (Zhang et al., 2022).

Existing studies have also focused on specific mental illnesses, such as PTSD or post-traumatic stress disorder (Sawalha et al., 2022), suicide, depression, or data sources such as social media and non-clinical texts (Zhang et al., 2022).

No studies have been conducted on neutralizing biased language related to mental illness.

2.2 Automatically Neutralizing Subjective Bias in Text

Pryzant et al. (2020) pioneered the development of the first generative model designed to mitigate biased text. They also introduced three valuable tools and frameworks into the discourse: the Wiki Neutrality Corpus (WNC), a corpus of 180,000 sentence pairs of subjective and neutralized text from Wikipedia, and two generative models that were trained on the WNC to (1) identify subjective bias in text, and (2) propose edits to neutralize it.

Notably, the groundbreaking use of a joint embedding architecture to integrate bias identification and text generation sets their work apart. Their paper is considered the first to successfully combine both tasks and utilize the identification algorithm to directly fine-tune a generative algorithm. Furthermore, the construction methodology of the Wiki Neutrality Corpus serves as a valuable framework for constructing other types of bias-related corpora. It is worth mentioning that their work focuses exclusively on subjective bias, but their methodology provides a promising foundation for exploring the mitigation of other forms of bias.

This project builds upon the model proposed by Pryzant et al. (2020) and extends its application to specifically address mental illness bias by creating a parallel corpus, fine-tuning Pryzant et al.'s (2020) model, and then evaluating the results.

3 Mental Illness Neutrality Corpus (MINC)

This paper introduces the Mental Illness Neutrality Corpus (MINC)[1], a novel parallel monolingual (specifically, English) corpus of mental illness-biased text. This dataset is comprised of 5500+ mental illness-biased text, neutralized sentence-pairs, and metadata. To construct the MINC, several language guides[2] were referenced to compile a list of biased expressions and suggested text replacements of appropriate and respectful word choices. In addition to general terms describing mental illness, the corpus contains biased text describing substance use and eating disorders, which fall under the umbrella of mental illness as defined by several of the language guides mentioned above.

To create sentences with biased text, ChatGPT (OpenAI, 2023) was prompted to pull real-world

[1] https://github.com/masonchoey/from-stigma-to-support

[2] National Recreation and Park Association's Mental Health Substance Use Disorder Language Guide, Well Beings' Mental Health Language Guide, The Mental Health Coalition's Language Guide, Hogg Foundation of Mental Health's Language Matters in Mental Health, DBSA's 10 Ways to Combat Discrimination with Compassionate Language, Canadian Centre on Substance Use and Addiction's Overcoming Stigma Through Language: A Primer, and "280 Labels Used to Stigmatize People with Mental Illness" (Rose et al. 2007).

examples of biased text (i.e., source sentence), which was paired with suggested neutralized replacements (i.e., target sentence). ChatGPT is an AI language model trained on data obtained from books, web texts, Wikipedia, news articles, scientific journals, and social media; in total, 570 GB of data and pieces of writing were collected from the internet. In a few instances, ChatGPT's content restrictions would prohibit prejudicial language from being included in our prompts. In these cases, we performed the reverse task of prompting ChatGPT to generate the target sentences, which were then paired with corresponding biased text.

After referencing literature on a list of commonly used biased text about mental illness, four categories of mental illness language bias were identified:

1. **Derogatory depiction of mental illness**: words intended to degrade those living with mental illness.
2. **Outdated language for mental illness**: words without harmful intentions but have been replaced with more respectful and compassionate language.
3. **Person-first language**: words that focus on a person's abilities instead of their limitations; putting the person first before the mental illness.
4. **Using mental illness as a metaphor**: words to describe something other than a person experiencing the disorder, using a metaphor to describe something unrelated to mental illness.

Each biased sentence is annotated in MINC into one of these four categories (refer to Table 1 for examples). Each biased sentence was paired with suggested edits (i.e., target sentence) of neutralized text to form sentence-pairs.

Source	**Target**	**Category**
The **crackhead** was unable to hold down a job due to their addiction.	The **person with cocaine use disorder** was unable to hold down a job due to their addiction.	Derogatory depiction of mental illness.
Struggling with depression for many years ultimately led him to **kill himself.**	Struggling with depression for many years ultimately led him to **die by suicide**.	Outdated language for mental illness.
Hospitalized for malnutrition, the **anorexic's** weight had dropped too low.	Hospitalized for malnutrition, the **person living with anorexia nervosa's** weight had dropped too low.	Person-first language.
The weather was **bipolar** today, with sunshine and rain alternating throughout the day.	The weather was **oscillating** today, with sunshine and rain alternating throughout the day.	Using mental illness as a metaphor.

Table 1: Samples from MINC. Biased text and neutralized text are in bold. Each sentence-pair is annotated with category.

Subcategory	**% of corpus**
Derogatory depiction of mental illness	33.3
Outdated language for mental illness	21.33
Person-first language	16.00
Using mental illness as a metaphor	29.33

Table 2: Percentage of mental illness biased text by category in MINC.

4 Approach

This project employs the CONCURRENT system proposed by Pryzant et al. (2020) and fine-tunes it using MINC. This CONCURRENT model architecture consists of two different modules, a detection module, and an editing module. The detection module aims to identify which word in the sequence is likely to be biased. It is a neural-sequence tagger that estimates p_i, or the chance that a word is biased using the equation:

$$p_i = \sigma(b_i, W_b + e_i, W_e + b) \qquad (1)$$

where b_i represents the semantic meaning of the contextualized word vector as produced by BERT. W_b, W_e, and b are learnable parameters. The editing module takes a subjectively biased sentence s and edits it to a more neutral replacement sentence t. First, a bi-LSTM encoder takes the problematic sentence and converts it to a sequence of hidden states H_1 , H_2 , H_3 … then the LSTM decoder generates text one token at a time, according to which tokens are more likely to be biased.

First, when taking an input, the detection module labels the sentences according to which words are more likely to be biased. Once the potentially biased sentence has been identified with the words that are most likely to be biased, the detection and editing modules are connected using a *join embedding* mechanism, which, using the probabilities of each word being biased from the detection module $p = (p_1, \ldots, p_n)$, is added to the hidden state in the editing module using the following equation:

$$h_i' = h_i + p_i + v \qquad (2)$$

where v is the *join embedding* vector that is multiplied by the probabilities, then added to each hidden state. In doing so, the words that are more likely to be biased are weighted higher in the encoder-decoder architecture. Finally, a token-weighted loss function is used to evaluate the model.

5 Training

Using the new MINC, the CONCURRENT system (Pryzant et al., 2020) is fine-tuned. The MINC data was split 85% training data and 15% testing data, with roughly 4120 sentences used for training data and roughly 730 sentences used for testing data. The fine-tuning process was implemented using PyTorch and the Adam optimizer with a learning rate 5e-5. Batch size of 16 and all vectors of length h=512. Gradient clipping with a maximum gradient norm of 3 was used and a dropout probability of 0.2 for the inputs of each LSTM cell. The BERT model was initialized using the bert-based-uncased pre-trained parameters (Devlin et al., 2019). The other parameters were randomly initialized on the range [-0.1, 0.1]. After pre-training using the neutral text, the CONCURRENT model was fine-tuned using the training data in addition to 710 sentences of neutral data for 20 epochs. The training time was approximately 3 hours, using the Apple M1 chip.

6 Results and Analysis

6.1 Evaluation

After employing human evaluation by three validators, the results were divided into three categories: Perfect (P), Good (G), and Incorrect (X). A "P" rating denotes results in which the model corrected the biased sentence to the sentence proposed in the corpus. This includes neutralized sentence data points in which (1) the model did not replace the answer and (2) sentences that the model corrected by removing biased language and inserting the language in the target sentence. A "G" rating is given when the model correctly identifies and neutralizes harmful language but inserts a synonym or slightly different word(s) instead of the suggested replacement word(s) in the target sentence. However, these instances were included in the accuracy score since the source sentence's bias was correctly identified and neutralized. Finally, an "X" rating is given when the model either (1) does not correct the biased language, (2) tries to correct a neutral example, or (3) results in a grammatically incorrect sentence. Human intervention for evaluation and annotation was necessary to detect grammatical errors.

Category	% of total	Counted towards accuracy
P	40.0	Yes
G	58.7	Yes
X	1.3	No
Accuracy	98.7	

Table 3: Summary of human annotations of results.

6.2 Analysis

The results indicate that the model performed very well at neutralizing biased language and performed exceptionally well at identifying biased language. "G" ratings came up frequently since the dataset included multiple suggested replacements to neutralize biased text (e.g., living with, experiencing, etc.) As such, the model cannot accurately predict which will occur in the target sequence, and they are subsequently given a "G" rating. Combining "P" and "G" ratings provides a more accurate view of how successfully the model neutralizes text.

7 Conclusion

Bias against mental illness is pervasive in our culture, frequently appearing as biased language in the media or casual conversation. Although bias can be nuanced, implied, or unconscious, language biased against mental illness has a negative impact on those living with mental illness. Identifying and reducing bias is crucial to reducing prejudice and helping those with mental illness seek and obtain the needed treatment.

The proposed models in this study were highly proficient in providing appropriate neutralized suggestions for reducing subjective bias for the biased sentences generated by ChatGPT.

This paper presents the annotated corpus of mental illness biased text (MINC). The MINC is a novel monolingual parallel corpus generated by ChatGPT from real-world text and trained on data from a wide variety of sources such as news media, social media, Wikipedia, books, personal websites, etc. Human intervention was necessary for annotation and review of grammatical errors. Several language guides for journalists and writers were consulted to obtain a list of commonly used biased terms and phrases and replacements that were respectful and compassionate towards those with mental illness.

This paper is a first step towards reducing bias in language describing mental illness, but further study should tackle more complex text such as multi-word, multilingual, and cross-sentence bias, as well as nuances and implicit language, taking into consideration that language, slang in particular, is ever-evolving. Also worth noting is the MINC is entirely in English. Additional work to study language bias and applying our model to non-English languages would be a logical next step.

Language is a complex, ever-evolving field of study. While NLP is increasingly sophisticated, it has yet to replace human language cognition completely. However, using NLP models to reduce bias in real-world text is a significant step toward addressing and lessening mental illness bias in our society. Given the substantial negative impact of biased language used to describe those with mental illness, creating more sophisticated detection models should be a high priority.

Abstract

Legal document summarization aims to provide a clear understanding of the main points and arguments in a legal document, contributing to the efficiency of the judicial system. In this paper, we propose BB25HLegalSum, a method that combines BERT clusters with the BM25 algorithm to summarize legal documents and present them to users with highlighted important information. The process involves selecting unique, relevant sentences from the original document, clustering them to find sentences about a similar subject, combining them to generate a summary according to three strategies, and highlighting them to the user in the original document. We outperformed baseline techniques using the BillSum dataset, a widely used benchmark in legal document summarization. Legal workers positively assessed the highlighted presentation.

1 Introduction

Pending judicial processes are a prevalent and significant issue affecting legal systems worldwide. The number of pending cases can vary significantly depending on population size, legal system, and backlog of cases. While in some countries, there may be only a few thousand pending processes, it can amount to millions in others. This scenario motivates the research of computational techniques that can help accelerate judicial analysis, select similar cases for judging in batches, or identify patterns that could lead to better decision-making. The automatic summarization of legal documents to synthesize their essence is critical in this context.

The goal of automatic text summarization is to create summaries that are similar to human-created summaries (Allahyari et al., 2017). This is a challenging task since natural language is complex and nuanced. Text summarization algorithms must consider the intended audience, the purpose of the summary, as well as the type and format of the original text. Text summarization is valuable for various applications, such as news aggregation, document management, and legal document summarization.

Most works use extractive summarization to generate summaries, defined in (Anand and Wagh, 2019), as "the generation of a summary containing a sentence subset of the original text after identifying the important sentences". Several techniques were explored for extractive legal text summarization, including word relevance (Polsley et al., 2016), graph-based ranking models (Dalal et al., 2023; Jain et al., 2023), statistical models (Jain et al., 2022; Merchant and Pande, 2018), and deep learning (Anand and Wagh, 2019). More recently, BERT (Devlin et al., 2018) has been leveraged in the legal area (Furniturewala et al., 2021), inspired by state-of-the-art results achieved in general extractive text summarization (Liu, 2019).

Another approach used in the legal documents area is BM25 (Robertson et al., 2009), a ranking function commonly used in information retrieval to determine the relevance of a document concerning a search query. The combined use of BERT and BM25 is recurrent for information retrieval in legal documents (Askari et al., 2022; Althammer et al., 2021), but it is still in the initial stages in the legal documents summarization area. BERT is a powerful language model that captures complex relationships between words and sentences, while BM25 is an effective information retrieval algorithm to rank documents. The strengths of these techniques can be joined to produce high-quality summaries and help to overcome some of the traditional methods' hurdles (e.g., feature engineering, long documents).

According to (Jain et al., 2021), there needs to be more analysis of the readability of the generated summaries, and how to present them. In the legal area, summary presentation is addressed using highlighting (Licari et al., 2023) and heatmaps

Proceedings of Recent Advances in Natural Language Processing, pages 255–263
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_029

(Polsley et al., 2016) representing the relevance of sentences within the original document. However, the relevance of a sentence may be a secondary aspect for legal workers, who seek the main arguments within their context.

In this article, we propose BB25HLegalSum (BERT + BM25 + Highlighting Legal Documents Summarization), a novel method for the extractive summarization of legal documents. It leverages BERT and BM25 to identify relevant sentences in a legal document and combine clusters of sentences to generate candidate summaries, which are selected using metrics against a reference summary. We generate summaries using three strategies to identify the best parts of a document, focused on the precision of the selected sentences, their coverage of the text (recall), and a trade-off between these two criteria. Another distinctive feature is the presentation of the generated summary. We propose a subsidiary highlighting approach that represents, using different colors, the sentences contained in the summaries generated according to each strategy. In this way, the user can identify and distinguish in their original context the relevant sentences of the document according to distinct points of view that emphasize precision, coverage, or both.

Our experiments address the following research questions: (1) How does the performance of BB25HLegalSum compare to baseline methods for legal document summarization? (2) How does the length of the reference summary impact the recall and precision of the generated summary using BB25HLegalSum? (3) Which type of document summary is more readable in the legal context: focused on precision, recall, or f-measure?

Our method outperformed baseline works in a benchmark dataset (Jain et al., 2021). We observed that the length of the reference summary impacts the recall and precision of the generated summaries and that BB25HLegalSum performs better for larger-than-average summaries. A qualitative assessment by legal workers has shown that highlighting with distinct colors enables identifying different types of information captured by each summarization strategy. They pointed out that higher recall is the most critical criterion for summarization in the legal context, since it avoids missing relevant information.

The main contributions of our article are:
(1) a method that leverages BERT and BM25 to generate legal document summaries. It outperforms baselines (Anand and Wagh, 2019; Mihalcea and Tarau, 2004; Erkan and Radev, 2004) in a benchmark dataset;
(2) a presentation method for the generated summaries using different colors that highlights in their original context the importance of sentences according to distinct points of view (precision vs. coverage). Legal workers positively assessed this presentation.

The remaining of this work is structured as follows. Section 2 presents related work. Section 3 describes BB25HLegalSum in detail. Section 4 presents our experiments. Section 5 outlines the conclusions and future work.

2 Related Work

Extractive summarization forms summaries by selecting and concatenating the most important spans (typically sentences) in a document (Liu, 2019). Legal document summarization has explored various techniques. CaseSummarizer (Polsley et al., 2016) combines standard summary methods based on word relevance (i.e., TF-IDF) with domain-specific knowledge to summarize legal documents. Graph-based ranking models, notably LexRank (Dalal et al., 2023) and TextRank (Jain et al., 2023), explore the relationships and similarities between nodes representing the text to select the relevant portions of legal documents. Statistical models have been utilized for scoring the relevance of sentences in legal documents, including Bayesian optimization (Jain et al., 2023), Kullback-Leibler (Jain et al., 2022), and Latent Semantic Analysis (Merchant and Pande, 2018). The contextual nuances and semantic dependencies in legal documents are explored for generating summaries using deep learning (Anand and Wagh, 2019). More recently, a trend is to deploy pre-trained models such as BERT (Furniturewala et al., 2021), which capture complex relationships between words and sentences.

The focus in some works is the presentation of the generated legal summary. (Licari et al., 2023) uses different colors to highlight the top-5 sentences, and (Polsley et al., 2016) proposes a heatmap to distinguish the importance of sentences. However, the relevance of a sentence may be a secondary aspect for legal workers, given that they generally seek the key arguments within a legal document.

The quality of generated summaries is typically assessed by comparing the generated summary against some reference summary using ROUGE (Recall-Oriented Understudy for Gisting Evaluation) (ROUGE, 2004). In the context of ROUGE, recall refers to how much of the reference summary is captured in the system summary, precision measures how much of the system summary is relevant, and F1 combines recall and precision. Necessary assessments on legal text summarization remain unaddressed, such as properties of the readability of the summaries (e.g., the trade-off between conciseness and completeness) and the relationship between performance efficiency and reference summaries, typically used as the gold standard to evaluate the proposed summary systems (Jain et al., 2021).

BM25 (Robertson et al., 2009) is a well-established information retrieval algorithm that ranks documents based on their relevance concerning a query. The combined use of BERT and BM25 is recurrent for document retrieval in the Competition on Legal Information Extraction/Entailment (COLIEE) (Askari et al., 2022; Rosa et al., 2021; Althammer et al., 2021), but its potential has not been fully examined for legal document summarization. The resulting summarization model can benefit from the strengths of both approaches to produce high-quality summaries and help to overcome some of the traditional methods' hurdles, such as the reliance on feature engineering and the difficulty in handling long documents.

Our work contributes with a solution that leverages BERT and BM25 to produce legal document summaries, and with a method for presenting the generated summaries using highlighting that enables the examination of the trade-off between conciseness and completeness for readability of legal documents summaries.

3 BB25HLegalSum overview

BB25HLegalSum is a novel method for the extractive summarization of legal documents. It assumes as input a legal document D, composed of a legal description (*desc*), and a reference summary (*refSum*). Given a document D, the goal is to select from *desc* a set of relevant sentences and to combine them to produce a *generated summary*, hereafter *GSum*. Our premise is that, for a lawyer, the most important aspect of legal document summarization is the extraction of the most relevant arguments and the ability to identify their importance within a context. Hence, the *refSum* may synthesize the document, but it does not necessarily provide all the useful information a legal worker needs.

Our method comprises four main steps: (1) select from *D.desc* a set of unique, relevant sentences by leveraging BERT to explore similarity thresholds and BM25 to rank sentences; (2) aggregate relevant sentences to select a set of *candidate summaries* ($candSum_m$) by combining clusters of related sentences; and (3) select among the candidate summaries the most representative one, as measured by ROUGE against the reference summary (*D.refSum*); (4) present the generated summary *GSum* in the original document by highlighting the selected sentences using different colors, combining multiple perspectives of importance.

A significant concern in our work is understanding the trade-off of conciseness and completeness as a measure of the quality of the generated summaries. Hence, our method proposes and assesses three strategies to select the best-generated summary, given a set of possible candidates, according to the metrics used for the selection (precision, recall, and f-measure, respectively). The remaining of this section provides details on our method.

3.1 Extracting BERT and BM25 candidate sentences

Given a legal document D(desc, refSum), the goal is to decompose D.*desc* into a set of sentences s_i (where $0 < i <$ *D.desc.length*), and explore BERT and BM25 to select the most relevant ones. We refer to these as *sentence filters*. The goal is to output three sets with sentence indices (minSizeFilterIDX, BERTFilterIDX, BM25FilterIDX), where each index is a set $\{a \mid 0 \leq a \leq$ *D.desc.length*$\}$, such that there exists a sentence $s_a \in$ D.*desc*.

(a) minimum size filter: the first issue is the minimum sentence size required for each sentence to be a candidate, using a *size_threshold*. The rationale is to remove sentences that are too short because in legal datasets usually the reference summary is comprised of long sentences. Given a set of documents, we defined the value of *size_threshold* experimentally. First, we measured the shortest sentence in the reference summary of all documents and then calculated the average (*shortestSentsrefSumAvg*). In our experiments, $size\_threshold = 2 * shortestSentsrefSumAvg$. The list *minSize-*

FilterIDX contains the index of the D.*desc* sentences with minimum size.

(b) BERT Filter: the goal of the BERT filter is to eliminate duplicated sentences. Initially, each sentence s_i is transformed into an equivalent BERT representation br_i according to a pre-trained BERT model. To determine that a sentence br_i is duplicated, we calculate its similarity with regard to all other br_j previously selected. We defined uniqueness according to a maximum *similarity_threshold*; otherwise, it is considered a duplicate and it is discarded. We defined $similarity\_threshold = 0.9$ experimentally, as a good trade-off to distinguish between repetitive sentences and sentences about a similar topic. The list *BERTFilterIDX* contains the index of the non-duplicate sentences in D.*desc*, considering the *similarity_threshold*.

(c) BM25 Ranking filter: BM25 is a bag-of-words retrieval function that ranks documents based on the query terms appearing in each document. The rationale of this filter is to select the sentences that are more representative according to the overall document, affecting the precision of the generated summary. We used as query terms all the tokens extracted from *D.desc*, and then ranked the sentences s_i according to their relevance. We select the top-n best-ranked sentences as the relevant ones. Experimentally, we defined $top - n = 50\%$. The list *BM25FilterIDX* contains the index of the top-n most relevant sentences according to BM25 ranking.

Finally, we compute *filteredSentencesIDX* as the intersection between *minSizeFilterIDX*, *BERTFilterIDX* and *BM25FilterIDX*. *FilteredSentences* is a set of sentences fs_i, where $i \in$ *FilteredSentences*.

3.2 Generating and selecting candidate summaries

In this stage, we generate a set of candidate summaries $candSum_m$, selecting the best one in terms of ROUGE metrics concerning D.*refSum*. To that end, we cluster all *FilteredSentences* from the previous step, and interactively aggregate clusters of sentences to generate a set of $candSum_j$. The generated candidates are compared against the *D.refSum* at each iteration, and the best one is selected. *GSum* is the set of sentences from the best combination of clusters (i.e., the best $candSum_j$).

(a) Clustering of relevant sentences: the goal of this step is to find groups of related relevant sentences. Recall that due to the BERT filter, sentences in a cluster are more related than strongly similar. The rationale is to group related sentences according to a subject or topic and combine them to compose the candidate summaries. This approach also has the advantage of reducing the search space of sentences to include in the generated summary, since instead of testing combinations of sentences, we assess combinations of sentence clusters. In this way, we reduce the possible combinations and, consequently, the execution time.

As the input, we used the BERT representations of the sentences from *FilteredSentences*, created in the previous step. We performed the clustering using the K-means algorithm, comparing the BERT representation of the sentences using a similarity function. This step results in a set *C* of k clusters. One of the challenges of using K-Means is to find the appropriate value for k. To do that, we varied the value of k from 2 to 50, selecting the best clustering. We tested two approaches for this selection: the clustering with the best Silhouette score (Rousseeuw, 1987) and the Elbow method using SSE (Sum of the Squared Error) (Umargono et al., 2020). For the silhouette scores, we used the *silhouette_score* function of the sklearn.metrics library, choosing the clustering with the highest silhouette. The Elbow method consists of plotting the explained variation (measured using SSE) as a function of the number of clusters and picking the elbow of the curve as the number of clusters to use. The results reported in this paper were produced using the best Silhouette score as the criterion for selecting k.

(b) Generating candidate summaries: given a set of k clusters, the goal of this step is to generate candidate summaries by combining clusters of sentences encompassing different topics. We iteratively create candidate summaries $candSum_j$ from the combination of l clusters from C, compare them with *D.refSum* using ROUGE-1 scores and then use the winning candidate to create combinations of $l + 1$ clusters. At each step, we save the combination of l clusters with the best score ($candSum_l$). *GSum* is the final winning $candSum_j$ for a particular criterion. Due to computational restrictions, in our experiments we varied $l = 2..6$ (i.e. combinations of sentences of 2 up to 6 clusters).

Rouge-1, Rouge-2, and Rouge-L can be used to evaluate the quality of generated summaries. They measure the overlap between a generated summary and the *refSum* regarding unigrams, bigrams, and longest common subsequences, respectively. We adopted the Rouge-1 given that precise wording and specific terminology are critical in legal documents.

We select the best candidate summaries, and ultimately the *GSum* for a document, according to three strategies, as represented by Rouge metrics: a) *precision-oriented summary* (***PoSum***), focused on conciseness; b) *recall-oriented summary* (***RoSum***), focused on completeness; and c) (*f-measure-oriented summary* (***FoSum***), as a trade-off. Conciseness refers to conveying the message clearly and succinctly without including unnecessary details. Completeness relates to the inclusion of key information from the original text. A summary with good conciseness and completeness will be easy to read and understand, ensuring that produced summaries convey key information from the legal document to the target audience. Conducting a qualitative assessment of summary readability is crucial to ensuring that the research findings can have a real-world impact on legal workers, and we qualitatively assessed the summaries generated according to each strategy in terms of conciseness and completeness.

3.3 Highlighting summaries in the legal document

To be useful, it is important that the generated summaries are readable. We propose to present them as highlights in the original text. Highlighting text improves the reader's knowledge and understanding of the topic being explored (Roy et al., 2021) and it allows the reader to fully grasp not only the relevant words but their context, which can be inspected whenever necessary.

We chose to present the three types of summaries within a single document, using three different colors, one for each criterion-focused summary (green for PoSum, blue for FoSum, and red for RoSum). This allows the reader to understand the different nuances for each highlighted color while condensing the three generated summaries into a single text. We chose to highlight with three colors in a subsidiary way (*subsidiary highlighting*) instead of highlighting the colors of the intersections (*intersectional highlighting*), since the latter could make the reading more difficult. Compared to related work (Polsley et al., 2016; Licari et al., 2023), we provide the context for the relevant sentences and highlight them according to different points of view (precision vs. coverage).

Our method relies on the premise that PoSums are shorter than the FoSums, which in turn are shorter than RoSums. Given the PoSum, FoSum and RoSum generated for a given document D, we start by highlighting with green every tri-grams that appear in the PoSum. Then we highlight in blue every tri-grams that appear in the FoSum that were not included in the PoSum. Finally, we highlight in red all tri-grams that appear in the RoSum and which have not been highlighted yet.

4 Experiments and Results

4.1 Datasets and model

Our experiments are based on the BillSum dataset[1], which is extensively used to measure the performance of summarization methods over legal documents (Kornilova and Eidelman, 2019). It is a dataset that contains the summarization of US Congressional and California state bills. Each bill contains a title, a textual legal description, and a summary. This dataset is divided into training data and test data. Since our method is unsupervised, we used only the test datasets. US test data contains 3269 bills, and CA test data has 1238 bills.

We run our method in all bills in the test datasets. Since we use three criteria to select the winning summaries (f-measure, precision, and recall), for each bill, we generated three types of summaries (FoSum, PoSum and RoSum), measuring the respective precision, recall, and f1 measures for ROUGE-1, ROUGE-2, and ROUGE-L. We implemented our solution using Python 3.6 and libraries such as itertools, sklearn, SentenceTransformer, gensim and numpy. We used the embedder 'distiluse-base-multilingual-cased-v1'.

4.2 Experiment 1

This experiment addresses the following research question: "*How does the performance of BB25HLegalSum compare to baseline methods for legal document summarization?*". As a baseline, we have used the best results compiled in (Jain et al., 2021), namely LSTM with word2vec, LexRank and TextRank. We report the results considering all three strategies for selecting the winning summary (FoSum, PoSum, RoSum). The results presented in Tables 1 and 2 are the average of the scores for all bills in the US test data and CA test data, respectively.

Table 2: Performance on CA test data

We outperformed the baselines in most cases. Overall, the RoSums yielded the best scores in the US test data, while the FoSums display the best performance in the CA test data. If we consider 9 criteria for each dataset, by combining the types of ROUGE score and metric, we outperformed 15 out of 18 criteria for the FoSum strategy and 14 out of 18 for the RoSum strategy. The PoSum strategy outperformed all baselines in terms of precision.

Although we did not achieve the best results in all cases, there are many comparable results. In the US dataset, for the ROUGE-L f-measure and recall, BB25HLegalSum RoSum scores 0.3661 and 0.5330 in comparison to LSTM-with-w2v 0.3664 and 0.5358, respectively. The same can be observed in CA dataset for the ROUGE-2 f-measure criterion, where BB25HLegalSum RoSum scores 0.1979 in comparison to TextRank 0.2015. Therefore, the performance was encouraging even when our system did not outperform the baselines.

4.3 Experiment 2

In this experiment, we address the following research question: "*How does the length of the reference summary impact the recall and precision of the generated summary using BB25HLegalSum in the legal document summarization?*". We divided the reference summaries into different length intervals (number of characters), and aggregated the different scores for each interval. We analyzed the summaries generated using the three strategies (PoSum, FoSum, RoSum). The results of our evaluation provide insights into the effectiveness of different summarization techniques for different lengths of reference summaries.

Results for the US test data are presented in Figures 1, 2 and 3 for PoSum, RoSum and FoSum strategies, respectively. All tables provide ROUGE-1, ROUGE-2 and ROUGE-L precision, f-measure, and recall averaged values according to the reference summary length intervals in characters.

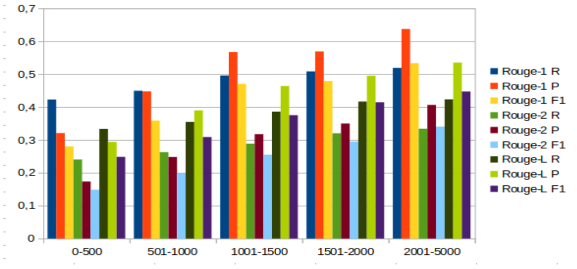

Figure 1: PoSum scores (US test Data)

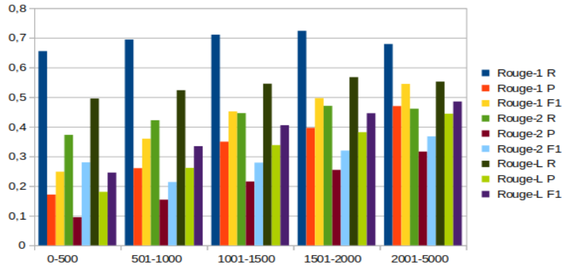

Figure 2: RoSum scores (US test Data)

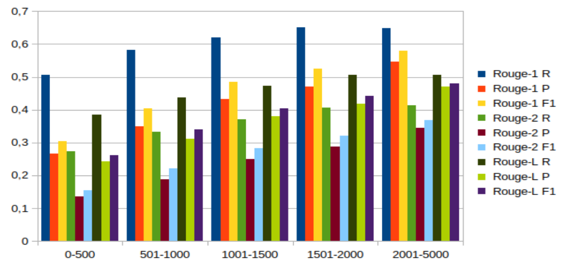

Figure 3: FoSum scores (US test Data)

As shown in Figure 1, the ROUGE-1 precision scores of PoSums more than double when comparing 0-500 to 2001-5000 reference summary range. As we can see in Figure 2, using the RoSum strategy, BB25HLegalSum behaved well on longer reference summaries, with a slight recall decrease on reference summaries longer than 2000 characters. The scores for the FoSums, displayed in Figure 3, present a more balanced score, having a positive impact on score values as the length of the reference summaries increase. Regardless of the summarization strategy, in general all scores increased with longer reference summaries.

We conclude that the length of the reference summary impacts the recall (RoSum) and precision (PoSum) scores of the generated summaries. On the other hand, the proposed solution performs better when the reference summary has a size larger than average.

4.4 Experiment 3

4.4.1 Method

This final experiment targets the following research question "*Which type of document summary is more readable in the legal context: focused on precision, recall, or f-measure?*". To assess the most suitable strategy for generating legal documents summaries, we have selected specific bills from a set of US test data, and used them to assess the quality of the summaries produced by BB25HLegalSum for creating accurate and useful legal document summaries.

To be able to assess a significant amount of summaries about the trade-offs between completeness and conciseness, we adopted two criteria for selecting bills from the US dataset: a) the generated PoSums have at most 1000 characters, a criterion met by 30% of this type of summary; and b) the FoSums are larger by at least 250 characters the corresponding PoSums. The bills meeting these two criteria were then sorted in ascending order of difference in length between the respective FoSum and PoSum. We selected the first 50 bills of this ranking.

The assessment was performed by three lawyers, who received 50 highlighted bills to read, and the corresponding reference summary. The highlights were produced using the sentences of the respective PoSum, RoSum and FoSum, as described in Section 3.3. Table 3 displays a representative example of how the text was highlighted. It compares the reference summary and the highlighted text of bill 723 from US test data. The first column shows the reference summary, while the second column displays the bill's text with different colors.

Upon reading, they were asked to answer the following questions:

(1) Regarding the reference summary, do the three colored highlights outline the main arguments?
(2) Regarding the highlights in GREEN, do the highlights in BLUE or RED seem to bring new relevant information?
(3) Based on the highlights alone, can you understand the context, only the main arguments, or both?
(4) Among the three forms of highlighting, which method do you believe is the most suitable for lawyers and jurists and why? Consider the following options: (a) emphasis only in GREEN; (b) highlight in GREEN + BLUE; (c) griffin in GREEN + BLUE + RED. Write your observations in a few lines.

4.4.2 Results and Discussion

All participants answered *yes* to the first and second questions. One of the lawyers emphasized that the highlights helped better understand the context. For example, the green color (i.e., extracted from the PoSum) exposes the topic, while the red highlights (RoSum) complement it with more details, such as the bill's purpose. The usefulness of the blue griffin (FoSum) was perceived as limited.

Regarding the third question, two participants agreed on the possibility of inferring context and the main arguments from the highlights alone. The other subject responded that it is not possible to inquire about the main arguments by the highlights alone, but since they are being presented with the full document, the inference of context from reading the highlighted and its surrounding non-highlighted text is uncontested.

In the fourth question, all participants selected the three-colored method (GREEN + BLUE + RED) as the most appropriate one for all bills assessed, considering the perspective of lawyers and jurists. This encompasses the entire content of the RoSum with the inclusion of words related to PoSum and FoSum. They all have agreed that distinct colors help to understand the nuances and that despite conciseness being important, completeness is more useful in real-life court decisions. They justified the usefulness by noting that the highlights using all colors included in general the meaning of some of the terms, as well as relevant details such as objectives/purpose, criteria, and requirements. At times, it also included the name of the act. Hence, the level of detail provided was regarded as appropriate.

For instance, Bill 723 in Table 3 deals with the requirements for a particular relocation subsidy. It shows that the words in the PoSum and FoSum do not encompass key arguments. Examples are the requirement highlighted in blue in line 7 (not included in the PoSum) and the one highlighted in red in line 10 (not encompassed by the FoSum). On the other hand, the words from the RoSum sometimes bring unnecessary words, such as "For purposes of this section" given that it benefits completeness, rather than conciseness. However, this is deemed irrelevant in comparison to missing key arguments because it is a lot better for the lawyer to have all key arguments highlighted, even if some unneces-

Reference summary	Precision oriented (green), F-measure oriented (green + blue) and Recall oriented (green + blue + red) summaries
American Worker Mobility Act of 2014 - Authorizes the Secretary of Labor to grant a relocation subsidy of up to $10,000 to an individual who: (1) has been totally unemployed for at least 26 consecutive weeks. (2) has exhausted all rights to state or federal unemployment compensation. (3) has not received a relocation subsidy for the two-year period preceding the subsidy application. And (4) is able to work, available to work, and actively seeking work. Prescribes subsidy program requirements. Directs the Secretary to issue regulations to prevent program fraud or abuse.	SECTION 1. SHORT TITLE. This Act may be cited as the "American Worker Mobility Act of 2014". SEC. 2. RELOCATION SUBSIDIES FOR THE LONG-TERM UNEMPLOYED. (a) In General.–The Secretary of Labor may grant a relocation subsidy to an eligible individual who meets the requirements of this section. (b) Meaning of Eligible Individual.–For purposes of this section, an eligible individual is an individual who, as of the date of the application for a relocation subsidy under this section– (1) is totally unemployed and has been totally unemployed for at least 26 consecutive weeks; (2) has exhausted all rights to regular compensation under the law of a State or under Federal law with respect to a benefit year (excluding any benefit year ending before July 1, 2008); (3) has not received a relocation subsidy under this section in the 2-year period preceding such date of application; and (4) is able to work, available to work, and actively seeking work. (c) Requirements for Grant.–The Secretary of Labor may not grant a relocation subsidy to an eligible individual under this section unless the Secretary determines that– (1) the relocation subsidy will assist such individual in relocating within the United States, at least 60 miles from the individual's current residence, for the purpose of attaining employment; (2) such individual filed an application with the Secretary not later than January 1, 2019; and (3) such individual– (A) has obtained a bona fide offer of suitable employment affording a reasonable expectation of long- term duration in the area in which the individual wishes to relocate; or (B) wishes to relocate to an area that has an unemployment rate that is at least 2 percentage points less than the unemployment rate of the area of the individual's initial residence. (d) Amount of Subsidy.–A relocation subsidy granted to an eligible individual under this section shall be equal to the lesser of $10,000 or the amount that any contribution by a potential employer of the individual to the individual's relocation expenses is exceeded by the sum of– (1) 90 percent of the reasonable and necessary expenses incurred in transporting the worker, the worker's family, and household effects, plus (2) a lump sum equivalent to 3 times the individual's weekly benefit amount for the most recent benefit year (as such terms are defined in the State law), up to a maximum payment of $1,250. (e) Regulations.–Prior to granting any relocation subsidies under subsection (a), the Secretary of Labor shall issue regulations designed to prevent fraud or abuse relating to the program established under this Act. (f) No Additional Funds Authorized.–No additional appropriations are authorized for any fiscal year to carry out this Act. (g) Definitions.–For purposes of this section– (1) the term "regular compensation" has the meaning given the term in section 205(2) of the Federal-State Extended Unemployment Compensation Act of 1970 (26 U.S.C. 3304 note), as in effect prior to January 1, 2014; and (2) the term "suitable work"– (A) means suitable work as defined in the applicable State law for claimants for regular compensation; and (B) does not include self-employment or employment as an independent contractor. (h) Reports.–Not later than March 15 of each of calendar years 2015 and 2017, the Secretary of Labor shall submit a report to Congress that identifies, by geographic region– (1) the total number of relocation subsidies granted to individuals under this section during the calendar year preceding each such calendar year; (2) the total number of relocation subsidies granted to individuals pursuant to subsection (c)(3)(A) during such calendar year; (3) the total number of relocation subsidies granted to individuals pursuant to subsection (c)(3)(B) during such calendar year, and the number of such individuals who obtained employment within 1 month, 3 months, and 6 months, respectively, after the individual's relocation; (4) the average amount of a relocation subsidy granted during such calendar year; (5) the average distance traveled for relocation by each individual receiving a relocation subsidy during such calendar year; and (6) the number of individuals who received a relocation subsidy under this section during such calendar year and subsequently applied for unemployment benefits.

Table 3: Bill 723: Reference summary and highlighted bill according to the three strategies.

sary words are highlighted as well, than to have a lack of highlights, as it happens in the PoSum and FoSum summaries shown in Table 3.

Given this assessment, we observe that the PoSums and FoSums are shorter because they usually lack key arguments. In a legal document context, having a higher recall as a suitable criterion is important because failing to identify a relevant piece of information can have serious consequences, such as missing an essential element of context or failing to make a critical argument. Another important remark is that highlighting with multiple colors allows the reader to select pieces of information more easily, faster, and more intuitively.

5 Conclusions

In this paper we described BB25HLegalSum, a method that leverages BM25 and the combination of BERT clusters to summarize legal documents. We generate a summary using three strategies to understand the role of preciseness and completeness in legal documents: PoSum, RoSum, and FoSum. The summaries are presented to users within the original document with three-colored highlighted sentences that indicate the relevant sentences according to a summarization perspective.

Our experiments revealed that this unsupervised method outperforms the baselines for the BillSum dataset (US and CA test data), and that the length of the reference summary impacts the recall and precision of the generated summaries. The larger the reference summary, the better is the performance of our system. We also conducted a qualitative assessment with three lawyers, who evaluated that summaries that target higher recall (RoSum) are more appropriate in the legal context, since they avoid missing relevant information. They also positively evaluated the three-coloring approach proposed, arguing that it provides the context of the sentences and the relevance perspective.

Future work includes improving the combination of clusters to generate summaries, and a more comprehensive readability assessment.

Abstract

Pre-trained models (PTMs) based on the Transformers architecture are trained on massive amounts of data and can capture nuances and complexities in linguistic expressions, making them a powerful tool for many natural language processing tasks. In this paper, we present SSSD (Semantic Similarity Stance Detection), a semi-supervised method for stance detection on Twitter that automatically labels a large, domain-related corpus for training a stance classification model. The method assumes as input a domain set of tweets about a given target and a labeled query set of tweets of representative arguments related to the stances. It scales the automatic labeling of a large number of tweets, and improves classification accuracy by leveraging the power of PTMs and semantic search to capture context and meaning. We largely outperformed all baselines in experiments using the Semeval benchmark.

1 Introduction

Stance Detection (SD) is the task that automatically determines whether the author of a text is in favor of, against or does not manifest about a given target. Targets can be companies, movements, people or ideas (Mohammad et al., 2016b). It was initially applied to the analysis of political debates in online forums and has become very attractive to measure public opinion on social networks (Aldayel and Magdy, 2019).

SD on social media can be categorized based on different criteria, including the type of target, the type of stance (i.e., in favor, against, or neutral), and the level of analysis (i.e., post level or network level). The features used for classification vary according to the analysis level: textual features only (post level) or user-related attributes and behaviors such as mentions and the number of followers (network level) to improve the model accuracy (ALDayel and Magdy, 2021).

The state-of-the-art methods for SD (Al-Ghadir et al., 2021; Lai et al., 2017) are based on Machine Learning (ML) and have shown to be effective in various scenarios (Aldayel and Magdy, 2019). However, they rely on manual and complex feature engineering, particularly when applied at the network level. On the other hand, Deep Learning (DL) based methods for SD (Siddiqua et al., 2019; Li and Caragea, 2019) do not require feature engineering, but they can easily overfit if not trained with enough labeled data, due to their high number of parameters (Han et al., 2021). Unfortunately, labeling data is an expensive and time-consuming task, leading to small labeled datasets for specific domains (Al-Ghadir et al., 2021).

Transfer learning (Zhang et al., 2020; Giorgioni et al., 2020) and unsupervised approaches (Darwish et al., 2020; Rashed et al., 2021; Wei et al., 2019) are promising directions for SD, but they still face challenges in achieving comparable results to supervised machine learning approaches, especially in highly polarized environments such as Twitter. This is due to the difficulty of detecting stances in a noisy and polarized platform such as Twitter, where people express their opinions in nuanced and complex ways. Despite these challenges, researchers continue to explore new approaches to improve the accuracy of SD in various contexts (Rashed et al., 2021).

Using pre-trained models (PTMs) based on the Transformers architecture (Vaswani et al., 2017), such as BERT (Devlin et al., 2018) and GPT (Radford et al., 2019), researchers can address the challenge of data scarcity and the variability and noise inherent in Twitter, while capturing the relevant semantic and contextual information needed to classify stances accurately. PTMs are trained on massive amounts of data and can capture nuances and complexities in linguistic expressions, making them a powerful tool for detecting stances. By fine-tuning these models on smaller labeled datasets,

Proceedings of Recent Advances in Natural Language Processing, pages 264–273
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_030

they can learn specific patterns of stances in different contexts, which can help overcome the challenges of variability and noise on Twitter. Additionally, PTMs can be used to search or compare tweets with similar stances through cosine similarity (Han et al., 2021), aiding the task of stance detection. PTMs represent a promising approach to improving the accuracy of DS on Twitter.

In this paper, we propose SSSD (Semantic Similarity SD), a semi-supervised method for stance detection on Twitter that leverages PTMs and semantic search to automatically label a large, domain-related corpus for training a stance classification model. The method assumes as input a domain set of tweets about a given target and a labeled query set of tweets of representative arguments related to the stances. The tweets of the domain and query sets are converted into a contextual representation using a PTM, such that a similarity function can identify the semantic proximity of the tweets of both sets. For each tweet of the query-set, the search function selects the k most similar tweets from the domain set, assigning them the respective stance label. This set of labeled tweets is then used to train an SD classification model using some ML classification algorithm. The remaining unlabeled tweets can be classified using this model. SSDS improves stance classification performance by leveraging the power of PTMs and semantic search to capture the context and meaning of tweets in a specific domain, addressing the complexity of stance labeling. It reduces the need for manual annotation, an expensive and time-consuming task, enabling the accurate automatic label of a large volume of tweets with minimal computational costs.

Our experimental setting involved three classification algorithms and the SD benchmark datasets and metrics (Mohammad et al., 2016b), which includes six targets. SSSD outperformed the baselines (Al-Ghadir et al., 2021) by 13.9 percentage points (pp) and (Lai et al., 2017) by 11.2 pp in the overall averaged f-measure metric. We also assessed the influence of the value of k on the similarity of retrieved tweets, number of labeled tweets and stance classification performance.

The main contributions of our study can be summarized as follows:

- a semi-supervised SD method that leverages PTMs and semantic search to automatically label data and train an SD classifier. By leveraging PTM and semantic search, it achieves superior performance compared to unsupervised/semi-supervised solutions (Gómez-Suta et al., 2023; Aldayel and Magdy, 2019) and outperforms state-of-the-art supervised systems (Al-Ghadir et al., 2021; Lai et al., 2017). The method is not dependent on a specific PTM or ML classification algorithm, nor requires a large, domain set of labeled data.
- A complete experimental assessment using datasets and metrics of a benchmark for stance detection (Mohammad et al., 2016b), demonstrating its effectiveness and robustness. Our approach is reproducible, and all the code is available in a public repository.

The remaining of this work is structured as follows. Section 2 presents the related work. Section 3 details the proposed semi-supervised SD method. Section 4 describes the experiments. Section 5 outlines conclusions and future work.

2 Related Work

Stance detection is a complex form of subjectivity analysis that focuses on identifying the attitude or perspective that a speaker or writer has towards a particular topic or issue. Unlike sentiment analysis (i.e., positive, negative), SD attempts to identify more subtle variations in the speaker's position, such as whether they are in favor of or against a particular policy or support or oppose a particular political candidate (ALDayel and Magdy, 2021).

The task of SD gained significant popularity following the launch of a competition on Twitter during Semeval 2016. Two tasks were proposed: supervised approaches (Task A) and unsupervised/semi-supervised approaches (Task B). The competition provided labeled data encompassing different targets and a well-defined methodology to assess the solutions, with a common evaluation metric (Mohammad et al., 2016a). Most studies in SD for the English language rely on SemEval datasets and evaluation methodology as a benchmark, which are limited in scope and size. The SemEval datasets cover only a specific set of domains and targets, and their small size may not capture the full complexity of the task, leading to overfitting or generalization issues. Therefore, it is important to create new datasets that can expand the scope of research in stance detection to other domains, languages, and targets (ALDayel and Magdy, 2021).

As a reflection of the scarcity of labeled data, state-of-the-art SD methods heavily rely on complex feature engineering techniques, making their reproduction a challenging tasks. For example, the leading SD system (Al-Ghadir et al., 2021) utilizes sentiment lexical dictionaries and ranked lists of TF-IDF weighted words to train K-NN classifiers, but its operational details are unclear, hindering its reproducibility (Gómez-Suta et al., 2023). Other studies (Aldayel and Magdy, 2019; Lynn et al., 2019; Darwish et al., 2018) leverage network information (e.g., hashtags, retweets) to enhance classifier performance. However, these approaches require additional user behavior data, which limits their applicability beyond social media platforms.

Recent studies have focused on developing unsupervised SD models using clustering techniques. The system in (Trabelsi and Zaiane, 2018) used clustering at the author and topic levels, leveraging both the content and interaction networks of the users. Clustering was leveraged in (Darwish et al., 2020) to create an initial set of stance partitions for annotation and showed that retweets as a feature provided the best performance score upon implementing the clustering algorithm. The work in (Rashed et al., 2021) introduced embedding representations of users' tweets to enhance the SD model using hierarchical clustering to analyze fine-grained polarization between groups of tweets related to the Turkish election. While unsupervised methods are useful for minimizing the need for manual labeling, they generally perform worse than supervised methods when labeled data is available. Some unsupervised approaches (Darwish et al., 2020; Wei et al., 2019) still require some level of human supervision or adjustment, but this can be done more quickly than the manual labeling of large datasets.

To address the limited availability of labeled data for SD tasks, some studies (Zhang et al., 2020; Kawintiranon and Singh, 2021) have incorporated transfer learning techniques. These works involve fine-tuning a pre-trained language model on the source target data to learn a target-specific semantic-emotion representation. The resulting representation is then used to train a classifier for stance detection on the target with limited labeled data. By leveraging the transferred representation, which encodes information about the semantic and emotional characteristics of the target, the classifier can be trained with a smaller number of labeled examples (Han et al., 2021). The transfer learning approaches CrossNet and TextCNN-E were proposed in (Zhang et al., 2020) for enhancing SD across multiple targets. However, this approach requires a large labeled dataset and falls short of surpassing current state-of-the-art systems in SD.

Works as (Giorgioni et al., 2020; Ferreira and Vlachos, 2019) have proposed Transformer-based architectures combined with data augmentation and fine-tuning. They trained specific sentence classifiers based on UmBERTo using auxiliary datasets from tasks like sentiment analysis, irony detection, and hate-speech detection. The resulting labels were then augmented as new sentences in the SardiStance dataset. This training dataset was expanded by labeling additional tweets using distant supervision based on specific hashtags. Similarly, (Hanawa et al., 2019) utilized Wikipedia articles to extract knowledge for each topic in a seven-themed dataset. These studies incorporated the concept of transfer learning by utilizing new datasets beyond the SemEval stance task.

In summary, complex feature engineering techniques and network information can improve the performance of SD classifiers, but they are difficult to reproduce and not practical for use in contexts other than social media. Unsupervised methods can minimize the need for manual labeling but generally perform worse than supervised methods when labeled data is available. Transfer learning techniques are useful for addressing the limited availability of labeled data and can be used with smaller labeled examples, but some approaches require a large labeled dataset.

We contribute to the field by proposing a novel semi-supervised method that leverages the PTMs and semantic search to automatically label a large domain-related corpus and train an accurate stance classification model. This approach reduces the need for manual and costly annotation efforts, enabling labeling a large volume of tweets with minimal computational costs.

3 SSSD Overview

SSSD is a novel approach to conducting SD on Twitter using PTMs and semantic search. It explores PTMs to capture the semantic and contextual meaning of tweets, taking advantage of the strengths of deep learning-based approaches. By leveraging the power of PTMs and semantic search, we aim to automatically label a domain corpus for training SD models. PTMs are pre-trained on extensive text data to acquire general language representations that can be further fine-tuned for specific tasks such as SD on Twitter.

SSSD is semi-supervised: it relies on a set of labeled queries as input to the semantic search algorithm that automatically labels a larger corpus of domain-related tweets, which is then used to train a stance classification model. This reduces the effort required to label a large volume of tweets, while still achieving good classification performance.

By using semantic search to identify the most relevant tweets for each query, SSSD can focus on the most important posts for the stance classification problem while ignoring irrelevant or noisy data. This is an advantage compared to unsupervised approaches, which may struggle to identify the most relevant data, especially in noisy and complex datasets like Twitter.

The remaining of this section describes the input data required by SSDS, and the semantic stance detection process.

3.1 Input Data

SSSD requires two inputs: a set of tweets representing the domain (*domain-set*) and a set of labeled tweets with representative arguments used to express a stance (*query-set*). The domain-sets are unlabeled tweets about the target, and we aim to label them. The query-sets are a sample of tweets manually annotated with stance labels, typically in favor, against, and none. They are used to automatically label tweets of the domain-set, to compose a *training set*, i.e. a set of labeled tweets used as input to some classification algorithm.

Domain-set tweets can be collected using the Twitter API. Typically, tweets are filtered within a period of interest, and keywords representative of the target. Hashtags can be a useful strategy as they tend to capture the homophily and social influence related to the target (Darwish et al., 2020). Relevant hashtags can be found in Twitter's top trends section. They also serve as seeds in a snowballing process that identify other related hashtags based on co-occurrence. It is crucial to define an appropriate search period to avoid bias. For instance, when detecting stances regarding the candidates of an election, the search period should be carefully chosen to represent the stances as the election campaign progresses.

The critical task in our approach is the definition of a proper set of seeds to compose the query-set. In case labeled data does not exist, and the knowledge about the data is limited, a possible approach is to use advanced topic modeling methods such as BERTopic (Grootendorst, 2022) to gain a global understanding of the corpus and identify tweets representing different stances. An advantage of this particular method is that it uses semantic similarity and density-based clustering, and hence topics are dense regions of similar tweets. It also provides visualization and interpretation features to explore and understand the topics and select representative documents from each topic. For instance, (Ebeling et al., 2022) identifies the representative arguments and political bias in anti/pro-vaccination stances using BERTopic.

Standard pre-processing techniques should be applied to improve the quality and effectiveness of semantic search in tweets. These include the removal of punctuation marks, case conversion, and elimination of irrelevant characters (e.g., hashtags, links, and numbers), among others.

A labeled *validation set* is necessary to evaluate the performance of the trained stance classification model, using traditional metrics such as accuracy or F-measure. This can be a separate input set, but our method assumes (part of) the query-set can also be used for this purpose. To avoid bias, we included a maximum similarity threshold in the semantic search, as explained in the next section.

3.2 Semantic Stance Detection

Capturing contextual information and nuances in language can be crucial for accurate stance detection. SSSD uses a chosen PTM to transform tweets into embedding to capture the semantic meaning of the text and enable effective comparison and retrieval of similar tweets. This process requires a search function f(q, k), which returns the k tweets from the domain-set with the highest similarity scores concerning the argument q.

We performed two adaptations to this search function. First, we assume q is a pair $<$*tweet,stance*$>$ belonging to the query-set, to enable the automatic labeling of the k most similar tweets. We also introduced an additional parameter to filter the retrieved tweets based on a maximum similarity threshold. This threshold ensures that tweets from the query sets are not included in the labeled training tweets, thus avoiding potential biases in model evaluation.

We divided our method into two steps, *Semantic Labeling*, and *Stance Detection*, detailed below.

(a) Semantic Labeling: This step is responsible for automatically labeling tweets to compose a training set, given a *domain-set* and a *query-set*. The output is a set of labeled tweets (*training-set*), which is used in the next step to train a stance classification model using a supervised ML algorithm. Table 1 presents the pseudo algorithm.

First, both the query-sets and domain-sets are converted into embeddings using a chosen PTM (e.g. BERT, GPT) or similar models (Step 1). After obtaining the embeddings, a search function is used to compare each element q of the query-set with the domain-set tweets. This comparison is

```
Function: perform_semantic_labeling(query_set, domain_set, k, similarity_threshold)
Input:
  query_set: Labeled tweets with stance labels
  domain_set: Unlabeled tweets
  k: Number of similar tweets to select
  similarity_threshold: Maximum similarity threshold
Output: training-set (Labeled tweets from domain-set)
Step 1: Convert query-sets and domain-sets into embeddings using a chosen PTM
  training set = []
  query_embeddings = convert_to_embeddings(query_set)
  domain_embeddings = convert_to_embeddings(domain_set)
Steps 2-5: Loop over each query in query_set
  for q in query_set do
    Step 2: Calculate similarity scores between query_embeddings[q] and domain_embeddings
      similarity_scores = get_scores(query_embeddings[q], domain_embeddings)
    Step 3: Select the top-k tweets with the highest similarity scores
      top_k_tweets = select_top_k_tweets(similarity_scores, k, similarity_threshold)
    Step 4: Assign the corresponding stance labels from query_set[q] to top_k_tweets
      labeled_tweets = assign_stance_labels(top_k_tweets, stance(q))
    Step 5: Add to training set, handle ties using similarity
      training_set = append_and_handle_ties (training_set, labeled_tweets)
  end for
Return: training_set
```

Table 1: Pseudo Code for the Semantic Labeling of SSSD

done by calculating similarity scores between the embeddings of query q and the embeddings of the domain-set tweets (Step 2). The similarity score can be computed using various methods, such as cosine similarity. Then, using the input k, the top-k tweets with the highest scores are selected (Step 3). There are situations where the same tweet can be present in both the labeled data and the query-sets. To avoid any biases, particularly when using part of the query-sets for performance validation, it is recommended to set a maximum similarity threshold smaller than 1 (e.g., 0.95).

The selected top-k tweets are assigned the corresponding stance label for q (Step 4). Finally, the labeled tweets are included in the training set (Step 5). It is possible that a given tweet of the domain-set is similar to different queries from the query-set. If ties occur, we select the stance associated with the highest similarity score. Notice that the higher the value of k, the higher the likelihood of ties. Therefore, it is advisable to choose an appropriate value for k to minimize ties and ensure more consistent labeling results.

This process enables to scale the labeling of tweets in the domain-set that have a similar stance to the ones in query-set, facilitating effective stance detection on Twitter. The number of labeled tweets in the training set depends on both the value of k and the size of the query-set. Increasing the value of k results in more labeled tweets, but it is important to find a balance between the number of labeled tweets and maintaining high similarity scores. The size of the domain-sets also affects the maximum number of labeled tweets that can be obtained. If the domain-sets are smaller, there will be a limit on the number of tweets that can be labeled.

Experimentation is key to determine the optimal value of k for effective stance detection on Twitter. The ideal value can be identified by varying the value of k and assessing the results using metrics such as F1-score. This iterative process of adjusting k and analyzing performance metrics leads to improved accuracy and effectiveness in the stance detection task.

(b) Stance Detection: The process described above is effective in SD, but it does have limitations. Increasing k can expand the coverage of labeled data, but it also increases the risk of more incorrect classifications due to degraded similarity scores. Training classification models using labeled data generated in the previous step is recommended to enhance accuracy and generalization. Then, the remaining unlabeled tweets of the domain-set can be assigned a label using this model.

There are various supervised machine-learning models suitable for this task, including Logistic Regression, Decision Trees, Support Vector Machines, RNNs, CNNs, and LSTMs. The choice of model and feature extraction method depends on the specific task, dataset, and available computational resources. In some cases, using the embeddings generated in the previous step as input features can be a more efficient and effective approach. The performance of the SD model can be assessed using the validation set.

4 Experiments

Our experiments were designed to assess the performance of SSSD against baseline systems and the influence of the value of k in our results. In this section we describe the data and chosen baselines, and detail the experiments. All our experiments are reproducible, and the code and tools used in their development are available in a public repository[1].

4.1 Data

We developed our experiments using the Semeval datasets (Mohammad et al., 2016b) for tasks A and B. Task A included five different targets: ”Atheism (Ath)”, ”Climate Change is a real concern (Cls)”, ”Feminism (Fmn)”, ”Abortion (Abt)”, and ”Hillary Clinton (Hlr)”. The training dataset for Task A consisted of 2,914 labeled tweets, while the testing dataset had 1,246 labeled tweets. Task B focused on an unsupervised approach with the target ”Donald Trump (Trp)”. The evaluation for Task B involved a dataset of 707 labeled tweets and 78,000 unlabeled tweets. The documentation provides further information on the period and the hashtags used for collecting this datasets[2].

We constructed the *domain-sets* for each target from scratch, using the Twitter API. We parameterized each search to use the same period as Semeval (January 1 to December 31, 2016), and the same keywords. For the creation of the *query-sets*, for each target of Task A we combined the training and testing sets. For the target of Task B, we used the validation set. Each instance in a query-set includes a tweet and a stance label, indicating support, opposition, or neutrality toward the target. A summary of the distribution of tweets across the data sets is shown in Table 2. These datasets were pre-processed as described in Section 3.1.

To evaluate the performance of the trained model for all targets, we used the respective Semeval test/validation tests. To avoid biases, we introduced a similarity threshold of 0.95. Consequently, any query result with a similarity score above 0.95 was deemed dissimilar to the original query, guaranteeing the integrity and fairness of the labeling process while mitigating potential biases in the similarity of training and test sets.

4.2 Evaluation Metrics and Baselines

The evaluation metric used for both tasks was the macro-average F1-score, which was computed for SemEval's ”Favor” and ”Against” classes for all five targets in Task A and for the single target ”Donald Trump” in Task B. This metric regards the class “None” as of no interest, i.e. a negative class in terms of Information Retrieval (IR) (Mohammad et al., 2016b). As baselines, we chose (Al-Ghadir et al., 2021) for Task A, and (Lai et al., 2017) for Task B. To the best of our knowledge, these are the state-of-the-art systems for these tasks, with F1-avg of 76.4% and 79.7%, respectively.

4.3 Experimental Setup

SDDD can be configured according to several components, and our choices are detailed below:

1. PTMs: We selected the ”all-MiniLM-L6-v2” model (Wang et al., 2020). It provides comparable quality to models like MPNET (Ahmed et al., 2020) but with significantly faster performance.
2. Classification Algorithms: To assess if the choice of algorithm influenced the results, and if any model exhibited overfitting for specific targets, we experimented with multiple classification algorithms. We report here the results of the ones that yielded the best performance, namely Logistic Regression (SSSD-RL), Support Vector Machines (SSSD-SVM) and Random Forest (SSSD-RF).
3. Feature Extraction: to extract features from labeled tweets, we employed TF-IDF and bigrams. These techniques capture important information from the text and serve as inputs to the classification models.
4. Parameter k: We conducted experiments with a range of k values, experimenting 20 values for k, starting from 5 and incrementing by 5 in each iteration. This iterative process is akin to traditional K-NN models, allowing us to determine an optimal k value that enhances classification performance.

For each target (6) and classification algorithm (3), we performed a total of 20 iterations (values of k), resulting in the creation of 60 models per target.

4.4 Experiment 1: Method Perfomance

The goal of this experiment is to compare the performance of SSSD against the chosen baselines. The best results for each Semeval task are presented in Tables 3 and 4, together with the respective k.

In Task A, our method significantly outperformed the baseline (Al-Ghadir et al., 2021), which achieved an F-score of 76.4% for overall stance detection (Favg). In contrast, SSSD-RL achieved

SSSD-SVM	**88.0%**	**93.2%**	**90.6%**	**85.2%**^{40}
SSSD-RF	80.6%	86.3%	83.4%	75.1%^{65}

Table 4: Results on Task B datasets

an impressive Favg of 90.3%, representing a substantial increase of 13.9 pp (percentage points). Similarly, SSSD-SVM achieved an Fav) of 90.6%, outperforming the baseline by 14.2 pp. SSSD-RF presented a slightly inferior performance compared to SSSD-RL and SSSD-SVM, but it outperformed the baseline by 7 pp. When considering individual targets, the performance differences were also remarkable. For instance, the SSSD-LR model showed performance differences ranging from 5.1 pp in the Hlr dataset to 15.9 pp in the Clc dataset.

Table 4 shows that all our systems outperformed the baseline for Task B proposed by (Lai et al., 2017) in terms of overall Favg, Ffavor, Fagainst, and Favg Trp. The best results were yielded by SSSD-SVM, which outperformed the baseline Overall Favg in 11.2 pp, due to an improvement in both Ffavor (8.3 pp) and Fagainst (30.3 pp). The worst results were achieved by SSSD-RF, and despite that, it also outperformed the baseline. Our solutions outperformed all metrics, in improvements that range from 0.1 pp (SSSD-RF Favg Trp) to 30.3 pp (SSSD-SVM overall Favg).

Our approach has demonstrated remarkable performance in both Task A and Task B of SemEval, positioning us as the new state-of-the-art in Stance Detection. In Task A, we achieved a substantial increase of 18.5 pp compared to the baseline proposed by (Al-Ghadir et al., 2021). This significant improvement showcases the effectiveness of our method in accurately detecting stances across different datasets. Similarly, in Task B, our systems outperformed the baseline proposed by (Lai et al., 2017) by approximately 14.1 pp, highlighting our advancements in stance detection for this task. These impressive results not only demonstrate the superiority of our approach but also solidify our position as the leading solution in the field.

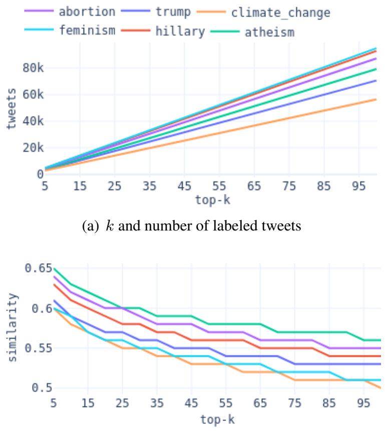
4.5 Experiment 2: Influence of K

The value for k plays a crucial role in balancing the similarity scores and the number of labeled tweets, thereby influencing the performance of our method. We assessed its impact on three variables: the number of labeled tweets, similarity scores of retrieved tweets, and the classification performance.

Figure 1 displays the results of the relationship between k and the number of labeled tweets and the similarity. In Figure 1.(a) we can observe, as expected, a linear growth of the number of labeled tweets as the value of k increases. It is interesting to note that, for all datasets, a significant number of tweets are labeled even with a low k value (e.g., about 20k tweets for $k = 25$). Figure 1.(b) displays the mean similarity value according to the value of k. It is possible to observe the degradation of similarity scores as the value of k increases.

Figure 2 illustrates a consistent pattern in the relationship between overall Favg metric (average F-score) and k across all datasets and classification algorithms. As k increases, Favg also increases until it reaches a point of stability, where there is a concentration of similar Favg values on the graph. However, as k approaches 100, very often the Favg values start to decline, indicating a degradation in scores. This pattern is particularly evident in the Trump, Atheism, and Hillary datasets. This observation is further supported by the findings presented in Figure 1.(a).

Although most of our best results were achieved with $k = 60$, establishing a fixed value for all cases is not an adequate solution. Considering the results



(a) k and number of labeled tweets

(b) k and cosine similarity

Figure 1: Relationship between k, labeled tweets, and similarity scores.

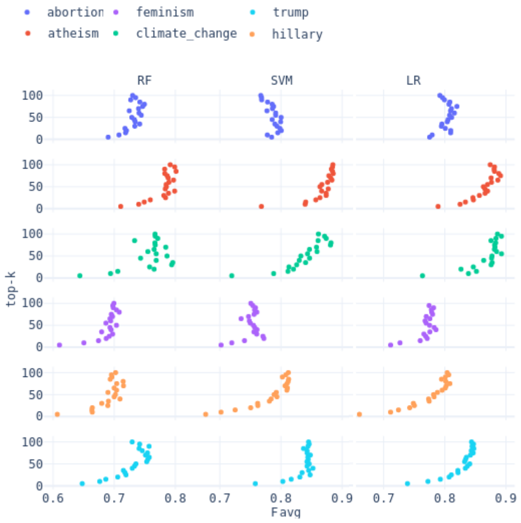


Figure 2: Relationship between K and Favg

in Tables 3 and 4, we see that for each dataset and classification algorithm, there is a specific k that provides the best trade-off between k and Favg.

The correlation matrix in Figure 3 summarizes all the points discussed so far. Higher k values positively impact the number of labeled tweets, negatively impacts the similarity, with a minor impact on Favg. We also notice a negative impact caused by high similarities concerning Favg and number of labeled tweets, confirming the need for a balance between these variables for good results.

5 Conclusions

In this work, we proposed SSSD, a semi-supervised method for SD on Twitter based on semantic search. We leverage PTMs in combination with a top-k function to retrieve and label domain-specific tweets, which are then used the automatic label a dataset to train a supervised classification model. It reduces the dependence on large annotated datasets while significant improving classification performance. We largely outperformed state-of-the-art supervised systems using the Semeval stance detection benchmark.

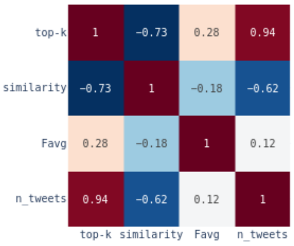

Figure 3: Correlation matrix

In our evaluation, we tested different k values, assessing their impact on performance with various datasets and classifiers. The results showed that our method is robust and has a high degree of generalization. We also found that the optimal k varied based on the specific scenario, with a trade-off between similarity scores and the number of labeled tweets to maximize ranking performance. Overall, our findings indicate that our method is effective for various SD scenarios, but the value of k needs to be identified experimentally.

We have shown that by leveraging PTM and semantic search, our method handled the nuances and complexities of stance automatic labeling. Our approach is simple, computationally inexpensive, and the encouraging results motivates us to further investigate it in other text classification tasks, making it a valuable contribution to the field of NLP by addressing the challenge of labeled data scarcity.

As future work, we intend to qualitatively evaluate our method regarding some challenges faced when analyzing social phenomena on Twitter. One of them is the bias introduced in the interpretation of topics due to hashtags to represent the objects of study. A common example is false positives, where a tweet is falsely inserted in the context of a hashtag by refuting the idea represented by it, usually through replies. There is also the scenario where a hashtag is purposefully linked to events (e.g. games, famous artists) outside of its context to increase its relevance and impact artificially.

Abstract

Formality is one of the important characteristics of text documents. The automatic detection of the formality level of a text is potentially beneficial for various natural language processing tasks. Before, two large-scale datasets were introduced for multiple languages featuring formality annotation—GYAFC and X-FORMAL. However, they were primarily used for the training of style transfer models. At the same time, the detection of text formality on its own may also be a useful application. This work proposes the first to our knowledge systematic study of formality detection methods based on statistical, neural-based, and Transformer-based machine learning methods and delivers the best-performing models for public usage. We conducted three types of experiments – monolingual, multilingual, and cross-lingual. The study shows the overcome of Char BiLSTM model over Transformer-based ones for the monolingual and multilingual formality classification task, while Transformer-based classifiers are more stable to cross-lingual knowledge transfer.

1 Introduction

According to Joos (1976), five different types of text formality are commonly identified in Linguistics: frozen style, formal style, consultative style, casual style, and intimate style. The correct use of style is important for fluent human communication and, therefore, for fluent human-to-machine communication and various Natural Language Processing (NLP) systems.

The examples of formal and informal samples for English, Brazilian Portuguese, French, and Italian languages are provided in Table 1. As we can see, for informal sentences, several attributes are typical – the usage of spoken abbreviations (for instance, *lol*), non-standard capitalization of words (all words are written in upper case), and lack of punctuation. On the contrary, in formal samples, all necessary punctuation is present, standard capitalization is used, some opening expressions can be observed in sentences (for example, *in my opinion*).

These examples are taken from two only currently available text collections with formality annotation are GYAFC (Rao and Tetreault, 2018) and X-FORMAL (Briakou et al., 2021). However, these datasets were primarily introduced for the task of style transfer. In this paper, we propose to look at these data sets from a different angle. Even for the evaluation of the results of formality style transfer, we need to calculate *style transfer accuracy*. While there is ongoing work of developing automatic evaluation metrics for formality style transfer in general (Lai et al., 2022), this work introduces a systematic evaluation of formality style classifiers.

In this paper, we aim at closing the gap by proposing a comprehensive computational study of various text categorization approaches. Namely, we argue that NLP practitioners will be benefiting from the knowledge of answers to the following questions:

Q1: What is the state-of-the-art for monolingual English formality classification?

Q2: Can we train multilingual model for simultaneous formality detection on several languages?

Q3: To what extent is cross-lingual transfer between pre-trained classifiers possible (if the phenomenon of formality is expressed similarly in various languages)?

To answer these questions, we present monolingual, multilingual, and cross-lingual experiments for formality classification for four languages—English, Brazilian Portuguese, French, and Italian.[1]

2 Related Work

2.1 Formality Datasets

Formality detection was first investigated by Pavlick and Tetreault (2016) where the authors created datasets of formal and informal sentences sourced from news, emails, blogs, and community answering services. The sentences were scored by a formality rating.

In (Rao and Tetreault, 2018), a dataset called GYAFC for formality style transfer evaluation has been proposed for the English language. After that, in (Briakou et al., 2021), the authors proposed the first multilingual dataset containing formality annotation, called X-FORMAL. The dataset features Brazilian Portuguese, Italian, and French languages and is structurally similar to the English GYAFC.

While the original papers on GYAFC and X-FORMAL provided extensive experimental results with these datasets, they all were focused on the style transfer setting and did not study the formality detection task. Our study instead focuses on text classification using these datasets.

2.2 Text Classification

Text categorization is well-established NLP task with dozens of applications ranging from topic categorization to fake news detection, with the first works dating back to the late 80-s (Hayes et al., 1988; Lewis, 1991).

Sebastiani (2002) provides a comprehensive survey on the "classic" methods on text categorization. Much more specialized text categorization methods have been developed so far, notably neural models such as CharCNN (Zhang et al., 2015) or more advanced solutions based on large pre-trained transformer networks, such as BERT (Sun et al., 2019). In (Li et al., 2022), Formality-LSTM and Formality-BERT were proposed to detect formality in answers, blogs, emails, and news.

To overcome the privilege of only monolingual models development, several multilingual pre-trained language models were introduced. In our experiments, we adjusted for sequence classification task mT5 (Xue et al., 2021) (covers 101 languages) and mBART (Tang et al., 2020) (covers 50 languages) models.

3 Datasets

Here, we provide the detailed description of the data—nature of the texts and general datasets' statistics—used for the experiments.

3.1 English: GYAFC

GYAFC—English dataset—contains 104 365 pairs of formal and informal texts obtained from Yahoo Answers. It consists of two parts split between Entertainment & Music and Family & Relationship categories. Firstly, informal texts were collected. Then, they were manually rewritten to create a formal alternative in the parallel pairs. The dataset also contains the tune and test text pairs. The creation of these pairs involved stricter control over the quality of translation. These pairs were also split in half between informal to formal translations and formal to informal translations.

Descriptive statistics of both parts of the dataset are presented in Table 2. In our experiments, we

		Informal to Formal		Formal to Informal	
	Train	**Tune**	**Test**	**Tune**	**Test**
Entertainment and Music domains	105 190	2 877	1 416	2 356	1 082
Family and Relationships domains	103 934	2 788	1 332	2 247	1 019
All domains, no duplicates	204 365	29 132	10 710	19 448	9 031

Table 2: Statistics of the GYAFC dataset.

Dataset	**Language**	**# texts**	**# formal texts**	**# informal texts**
GYAFC (Rao and Tetreault, 2018)	EN	204 365	102 182	102 183
X-FORMAL (Briakou et al., 2021)	FR+IT+BR	338 763	168 099	170 664
X-FORMAL (Briakou et al., 2021)	FR	112 921	56 033	56 888
X-FORMAL (Briakou et al., 2021)	IT	112 921	56 033	56 888
X-FORMAL (Briakou et al., 2021)	BR	112 921	56 033	56 888

Table 3: Statistics of the GYAFC ans X-FORMAL datasets.

use the dataset corresponding to the “All domains, no duplicates”.

3.2 French, Italian, and Brazilian: X-FORMAL

The X-FORMAL dataset (Briakou et al., 2021) was created on the basis of the GYAFC dataset described in the section above. The goal of this dataset is to cover formality in multiple languages. More specifically, there are three languages included: Brazilian Portuguese (BR), French (FR), and Italian (IT). All these parts of the X-FORMAL dataset were created by translating the original GYAFC dataset from English to target languages. The dataset consists of 338 763 samples in four languages. More detailed statistics of the X-FORMAL dataset are presented in Table 3.

In both datasets, the mean amount of tokens in samples is 10 ± 4 meaning that in the majority of cases we work with one-sentence samples.

4 Text Classification Models

Following (Lai et al., 2022), we address the formality detection as text classification task. We experiment with several state-of-the-art models optimizing their hyper-parameters. A detailed description of these most successful models is presented below.

4.1 Linguistic-Based Baselines

Firstly, we build with a heuristic approach based on punctuation presence in the text and capitalization of the first word denoted as “punctuation + capitalization”. It is natural to expect that all sentences in formal style should start with a capital letter and end with the presence of some punctuation. For informal sentences, that can be missed.

Secondly, we test the classic bag-of-word representation used commonly in various text categorization tasks. In addition, we also tested another simple and common word vector representation: a mean of dense vector representations. For this variant, for the embeddings, we use pre-trained fastText vectors (Bojanowski et al., 2017) for both English and multilingual experiments.[2]

On top of these types of features, we use Logistic Regression (LR), a linear model that is a workhorse for many text classification tasks.

4.2 Models based on Convolutional Neural Networks (CNNs)

To get another way of vector representations for texts, we utilize Universal Sentence Encoder (Yang et al., 2019a). This encoder is trained on 16 languages and is competitive with state of the art on semantic retrieval, translation pair bitext retrieval, and retrieval question answering tasks. Then, the obtained vectors is fed into a CNN model that consists of 2 CNN layers. The encoder is trained using Multi-task Dual Encoder Training similar to (Cer et al., 2018), and (Chidambaram et al., 2019) with a single encoder supporting multiple downstream tasks.

4.3 BiLSTMs

We also experiment with RNN for text classification as they have shown superior results in many tasks, with bidirectional LSTMs being the most popular choice. (Hameed and Garcia-Zapirain, 2020; Isnain et al., 2020; Wiedemann et al., 2018) More specifically, we test two input representations for RNNs: character-based and token/word-based. *Char BiLSTM* consists of an Embedding layer on chars followed with bidirectional LSTM layers (Graves and Schmidhuber, 2005). We tune several

[2] https://fasttext.cc. Accessed 10 January 2023

model configurations: embeddings size, number of BiLSTM layers, BiLSTM hidden layer size. According to our experiments, we achieved the best result with an embeddings size of 50, the number of BiLSTM layers of 2, and BiLSTM hidden layer size of 50.

In the *Word BiLSTM*, the embedding layer is replaced by a pretrained fastText embedding layer, and wordpunct_tokenize from NLTK is used to tokenize the text. We tune the same configurations as the Char BiLSTM and used Fastext 300d embeddings. According to our experiments, the best results were achieved with Fastext uncased 100d, the number of BiLSTM layers of 1, and the BiLSTM hidden size of 50.

4.4 ELMo

In addition to the BiLSTM architecture described above where pre-trained word embeddings are used, we also test the popular architecture for obtaining contextualized vector representations of tokens called ELMo (Peters et al., 2018). It consists of two BiLSTM layers trained on character representations of the input text.

We use a BiLSTM layer on top of the sequence of token embeddings obtained from ELMo, followed by two Dense layers and two Dropout layers.

4.5 Transformer-based Models

More recently, the state-of-the-art in a variety of text classification tasks was achieved by models based on the deep neural networks based on the Transformer blocks (Vaswani et al., 2017) pretrained on a large text corpora. In our work, we experiment with several such state-of-the-art models listed below.

BERT We utilize BERT (Devlin et al., 2019) and its distilled version—DistilBERT (Sanh et al., 2019)—models for monolingual English formality classification. We use base uncaused and cased versions of the mentioned models to check the contribution of the letter capitalization. Also, we test the next generations of BERT-like models—RoBERTa roberta-base (Liu et al., 2019) and Deberta deberta-base/large (He et al., 2021).

XLNet This model integrates ideas of autoregressive language models (Yang et al., 2019b). The usage of all possible permutations of the factorization order allows to use of bidirectional contexts of each token and outperforms the BERT model on several tasks. We fine-tune xlnet-base-cased version of this type of model.

GPT2 In contrast to the mentioned above models, which all rely on the encoder of the original transformer architecture (Vaswani et al., 2017) the GPT2 model (Radford et al., 2019) is based on the decoder of the Transformer. We utilize the raw hidden states from the last transformer block of the model gpt2 to feed it into a linear classification head.

Multilingual Language Models Experiments on the multilingual X-FORMAL dataset require additional multilingual word embeddings extraction and text classification models. For this purpose, we use multilingual available analogues of afore mentioned models where all needed languages are supported. Firstly, we use mBERT (Devlin et al., 2018) (and its distilled version of it as well—mDistilBERT) and mDeBERTa that was pretrained on 104 languages with the largest Wikipedia corpus (bert/distilbert-base-multilingual-cased and mdeberta-v3-base versions). Then, we experiment with multilingual version of XLNet—XLM-R (Conneau et al., 2020) (xlm-roberta-base, 100 languages). In addition, we provide the results of multilingual encoder-decoder-based models—mT5 (Xue et al., 2021) (mt5-base, 101 languages) and mBART (Tang et al., 2020) (mbart-large-50, 50 languages).

5 Results

5.1 Experimental Setup

Formality detection task could be cast as a binary classification task with classes formal and informal. Therefore, we report standard evaluation metrics for binary classification in experiments: Accuracy, Precision, Recall, and F1.

We report the results of three types of experiment setups to provide answers to three research questions mentioned in the introduction:

1. *Monolingual*: we fine-tune all mentioned in Section 4 type of models for monolingual English formality classification task and report Accuracy, Precision, Recall, and F1 scores; then, we use multilingual models to test them on four languages—English, Italian, Portuguese, and French—separately and report Accuracy for each language;

2. *Multilingual*: we fine-tune adapt some baselines and utilise mentioned multilingual pre-

		Formal			Informal		
Text Representation Model	Accuracy	Precision	Recall	F1	Precision	Recall	F1

Table 4: Results of monolingual formality classification for English (GYAFC dataset). **Bold** numbers represents the best results in the category, **bold and underlined** – the best results for the metric.

trained language models on all four languages and report total accuracy;

3. *Cross-lingual*: we fine-tune multilingual models on all languages except the target one (i.e. on English, Italian, Portuguese, but not French) and then perform zero-shot inference on the test set of that excluded from the training step language (i.e. French) reporting the Accuracy score.

5.2 Monolingual English Results

Firstly, we present monolingual formality classification results on English GYAFC corpus. Results of the experiments with the various models described in Section 4 are presented in Table 4.

Ranking of the models Firstly, we can observe already quite high results for the simple baseline models. The classification approach based on punctuation and capitalization presence features achieves one of the highest results for the formal class Recall score= 98.5, however failed to distinguish informal class so well (Recall= 46.4). Bag-of-words approach reaches F1 scores for both classes on the level with Transformer-based models (81.8 and 75.6 respectfully).

A significant number of Convolution-based Neural Networks exhibit superior performance in comparison to the baseline models, with certain models showcasing a notable gap in performance. Particularly, the Char BiLSTM model surpasses all other models within this category and achieves remarkably high scores across all evaluation metrics. This model excels in terms of formal class Recall and F1 scores and informal class Precision (98.8, 89.0, and 98.1 respectfully).

Among the category of classification models based on Transformers, a substantial proportion of these models exhibit notable performance, with encoder-based architectures demonstrating a slight superiority over decoder-based ones. Although certain BERT models do not surpass certain baseline models, the succeeding next generation of BERT-based models yield high performance across all evaluation metrics. Notably, within the category of Transformer-based pre-trained language models, DeBERTa attains the highest performance results among all compared models in terms of total Accuracy= 87.8 and F1 scores for both classes (89.0 for formal and 86.1 for informal).

This brings us to the answer of the question **Q1**: Deep pre-trained models like DeBERTa yield top

Text Representation Model	English	Italian	Portuguese	French	All
Linguistic-Based Baselines					
punctuation + capitalization	74.2	69.2	64.4	66.5	68.6

Table 5: Accuracy results of both monolingual and multilingual formality classification for English, Italian, Portuguese, and French (X-FORMAL dataset). Here “All” denotes that the model was trained and tested on all presented languages. **Bold** numbers represents the best results in the category, **bold and underlined** – the best results for the metric.

performance for monolingual English formality classification task. At the same time, Char BiLSTM model yield as well superior results for some metrics even outperforming DeBERTa.

Impact of case-sensitivity Within the several type of models we can observe that capitalization sensitivity is quite important for formality detection task. As such, for linguistic-based baseline, these features prove highly effective in attaining high scores, particularly for formal class. We can also compare cased and uncased versions for BERT and DistilBERT models. Although cased models demonstrate a superiority in terms of Accuracy scores (78.0 vs 77.4 and 80.1 vs 80.0), the results of other metrics do not establish a clear and definitive winner.

5.3 Monolingual and Multilingual Results for Four Languages

In this section, we report results on the X-FORMAL dataset (Briakou et al., 2021). Results of the experiments with the various models described in Section 4 presented in Table 5.

Monolingual results Firstly, we conducted experiments exploring multilingual models for monolingual classification for all languages separately – English, Italian, Portuguese, and French. As one may observe, similarly to English results, the model based on a bidirectional LSTM model with character embeddings yields the best results for all languages. Some multilingual transformer-based models such as XLM-R and mBERT also achieve good enough results but are lower than Char BiLSTM. Except Portuguese language, where mBART (cased) model has the highest accuracy.

Multilingual results We report the results of fine-tuned multilingual language models on all provided languages in “All” column in Table 5 and inference of these models on each language separately in Table 6. For all best models across different categories, we can observer a slight drop of the accuracy for all languages in comparison to monolingual results. For instance, for the best performing model Char BiLSTM, the “All” Accuracy= 82.7 is less then monolingual setups: English (83.1 vs 87.0), Italian (75.2 vs 79.1), Portuguese (74.2 vs 75.9), French (78.0 vs 81.3). However, these drops in the Accuracy scores is slight and the scores outperform the monolingual baselines and some Transformer-based models significantly.

As a result, the simultaneous fine-tuning of multilingual formality detection models does not cause a significant drop of the performance across languages in comparison of the best monolingual results. The high results of multilingual Char BiLSTM model provides a positive answer to the question **Q2**.

Train / Test	English	Italian	Portuguese	French
Universal Sentence Encoder				
Monolingual	85.4	**76.7**	**75.3**	**80.7**

Table 6: Accuracy results of cross-language transfer study on formality classification. **Bold** numbers represents the best results for the model type, underlined – the best results for cross-lingual transfer to the language, **bold and underlined** – the best results for the language.

5.4 Cross-lingual Formality Transfer Results

After multilingual experiments, we conducted cross-lingual ones trying to answer the research question **Q3**. The results of the experiments are presented in Table 6. The main conclusion that can be made from the obtained results is that cross-lingual formality detection is possible but, unfortunately, the same as for multilingual results, with a drop in the performance across languages. For all reported models, we can observe the drop of Accuracy scores in $3-5\%$.

For the best performing models from previously discussed monolingual and multilingual results—Char BiLSTM—we can observe a significant drop in the performance in comparison to its best results. However, mDistilBERT demonstrates more stable performance to unseen languages in the training set. This model has the best cross-lingual formality transfer capability with achieving cross-lingual English Accuracy$=83.6$ (vs only 74.9 from Char BiLSTM), Italian Accuracy$=75.1$ (vs 74.1 from Char BiLSTM), Portuguese Accuracy$=73.8$ (vs 71.9 from Char BiLSTM), and only for French Accuracy$=77.1$, Char BiLSTM model shows slightly better performance with Accuracy$=77.4$.

Despite the loss in accuracy compared to the best monolingual results, the illustrated results of cross-lingual experiments again provide a positive answer to the stated question **Q3**. Still, the cross-lingual tests of the best performing models overcomes the monolingual baselines. This implies the possibility to the cross-lingual formality transfer usage to perform classification on the unseen language with satisfactory accuracy.

6 Discussions

As all the above experiments results showed that none of the models achieved Accuracy and F1 scores higher 90.0, we analyzed misclassifications. In Appendix A in Table 7, we present several examples of such models mistakes. We noticed that the misclassification of formal sentences into informal appeared less often than informal into formal which confirms with high Recall scores for formal class and significantly lower scores for informal one in Table 4. For example, for the DeBERTa-large model, the rate of misclassification of formal sentences into informal is only 6.6%, while misclassification of informal sentences into formal – 18.7%. Some of the mistakes are connected with the unobvious labels of the original data.

For example, the Char BiLSTM model trained for the English language misclassified sentence *I WOULD WORK FOR ME BUT BOTH WOULD BE EVEN BETTER* into formal class. Indeed, the whole structure of the sentence and the usage of word *would* make the text looks like a formal one. We suppose that this text was marked as informal because it is fully written in the upper register.

On the other hand, there are many sentences with formal labels without an obvious reason for that. Texts like *Ignore it when people start rumors.*, *I do not want her to die.* does not look like to be written in a formal style. On the contrary, the usage of the phrase *Ignore it* seems to be quite informal.

Also, if we look at misclassification examples of mDistillBERT models, we can see examples of obvious violations of formal style. For example, we can observe sentences that are grammatically correct, but the content is toxic (*Are you serious or just that ignorant?*) or refers to some informal ways of entertainment (*After watching that, I had to consume alcohol!*). That might be that the general topic of these sentences is more closer to the topics usually discussed informally that confuses the model. In addition, we draw attention to the sample which is mostly formal, however, contains informal insertion: *I'm grateful, I now comprehend. Significantly, er, electrical.*

Such mistakes can be connected with the process of the creation of the GYAFC and XFORMAL datasets. The train part consists of informal texts and their formal paraphrases with Amazon Mechanical Turk workers. However, the tune part contains paraphrases from formal into informal styles and vice versa. The annotation process can contain some inaccuracies that may be resulting in fuzzy logic of labels assignment.

In addition, another interesting observation might be that for some Transformer-based models their multilingual versions yields higher accuracy than monolingual ones. Thus, for DistilBERT, the bets English monolingual Accuracy is 80.1, while its multilingual version achieves 86.6 score on English test set. The same observation can be applied for BERT model as well.

In the end, we can observe quit high results from Char BiLSTM model which outperform in some cases Transformer-based models. One of the explanations might be: the usage of slang or unusually modified words in informal style that can be precisely tokenized and embedded with Transformer-based encoders, however, can be learned with character-level words' split.

7 Conclusion

In this paper, we presented the first computational study on text categorization models that detect text formality. We based our experiments on two large-scale multilingual datasets—GYAFC and X-FORMAL—and tested a vast amount of baselines and state-of-the-art neural models.

The best English monolingual results are achieved by Transformer-based model—DeBERTa-large. However, other obtained results show the superiority of models based on character representation, such as Char BiLSTM models, over models based on word and BPE representations, including even large pre-trained transformer models. Notably for both monolingual and multilingual formality detection for all examined languages, Char BiLSTM model illustrates the best accuracy.

Our experiments also show that multiple models demonstrate abilities of cross-lingual transfer. While Char BiLSTM showed the best performance in monolingual and multilingual setups, it had a significant drop in the performance while trying to transfer formality knowledge to another language. In this scenario, mDistilBERT model demonstrated the best stability to new languages.

All code and data allowing reproduce our experiments are available online.[3] We release for a public usage the best Transformer-based monolingual[4], multilingual[5], and cross-lingual[6] models.

Acknowledgments

We thank Andrey Likhachev and Ivan Trifinov for preparing the first version of the experiments presented in this paper. This research was partially supported by a joint MTS-Skoltech lab on AI and the European Union's Horizon 2020 research and innovation program under the Marie Skodowska-Curie grant agreement No 860621, and the Galician Ministry of Culture, Education, Professional Training, and University and the European Regional Development Fund (ERDF/FEDER program) under grant ED431G2019/04. Additionaly, we are grateful Social Research Computing Group, TUM for the possibility to finalize this research.

8 Ethical Statement

We hope that models' research in formality classification and style transfer tasks might help to develop more sophisticated approaches for language and style studying programs. For instance, such an automated helper can detect incorrect style used for a text exercise, explain a style misusage, and recommend a correct paraphrase. This may be useful for language learners who do not realize nuances of language at the level of native speakers preventing their deeper integration in a given society.

Furthermore, the availability of formality data in four languages provides a solid foundation and we have shown that the cross-lingual formality detection is possible. We anticipate that research in the field of formality detection foster development of similar datasets in other languages as well.

Last but not least, our approach and experiments are based on large pre-trained language models, which may be prone to biases reflected in their training data. In case of real world deployments this issue shall be taken into account.

Abstract

For many languages, Wikipedia is the most accessible source of biographical information. Studying how Wikipedia describes the lives of people can provide insights into societal biases, as well as cultural differences more generally. We present a method for extracting datasets of Wikipedia biographies. The accompanying codebase is adapted to English, Swedish, Russian, Chinese, and Farsi, and is extendable to other languages.

We present an exploratory analysis of biographical topics and gendered patterns in four languages using topic modelling and embedding clustering. We find similarities across languages in the types of categories present, with the distribution of biographies concentrated in the language's core regions. Masculine terms are over-represented and spread out over a wide variety of topics. Feminine terms are less frequent and linked to more constrained topics. Non-binary terms are nearly non-represented.

1 Introduction

Wikipedia's decentralised organisation and independent communities in different languages have led it to be considered a 'global repository of knowledge' (Callahan and Herring, 2011). Easily and openly accessible, in many language environments it has displaced more traditional and specialised resources as a 'default' encyclopedic source, shaping the language landscape. This effect is noticeable in NLP research and development, where Wikipedia is a staple training data source for language models that imitate Wikipedia when generating texts or making writing suggestions.

When it comes to biographical information, Wikipedia has become a primary source of reference, especially outside of education systems. Because of the near-monopoly that Wikipedia has on public knowledge in these environments, it can define which persons are perceived as notable, which aspects of their lives deserve a mention, and how the persons are presented. The community guidelines of Wikipedia are built around the concept of 'neutrality', but the content is still inevitably shaped by societal biases, such as gender gaps (Hube, 2017). Besides the content of the biographical articles, Wikipedia also shapes the expectations the reader has in terms of format, language, style and inclusion. A 'biography' can come to invoke a Wikipedia-like structure, becoming a commonly accepted way of summarising a person's life.

Most automatically extracted datasets consists of Wikipedia backup dumps or rely heavily on the connection to Wikidata. Using Wikidata, however, makes it harder to modify or update the dataset, or replicate it for another domain. Manually collected datasets, on the other hand, are limited in size. They are almost inevitably biased towards longer, popular or better-categorised articles because poor categorisation prevents other articles to be discovered in the first place. These problems become even more apparent when creating a multilingual dataset. While different editions share a general article structure and templates, they are far from identical. As we discuss further in the paper, straightforward parsing approaches can fail if adapted directly because of the subtle markdown changes. For our biographical dataset, this often results in the omission of less well-documented (often marginalised) people.

This paper contributes an adaptable method for curating a multilingual corpus of Wikipedia biographies. We analyse general statistics and structures of the biographies for corpora in several languages and compare them with existing literature. Finally, we release the code[1] and instructions on how to create a biography dataset from an up-to-date Wikipedia dump adaptable to any language.

2 Background

2.1 Biography

We define a *biography* as the running text of an article about an individual person and their life or story (rather than a single event, or a more tailored summary of a one's professional life, i.e. a 'short bio'). We define *persons* as animate individuals, and include in this definition both real people and fictional or mythological figures. This does not actively attempt to include animals, but if the biography of an animal meets all other criteria we do not reject them, as their page is likely to also contain their life or story.

2.2 Related Work

Wikipedia is commonly leveraged as a resource in Natural Language Processing, both for its texts and the associated metadata such as edit history (Botha et al., 2018; Faruqui et al., 2018), infoboxes (Wu and Weld, 2010), and hyperlinks (Gemechu et al., 2016). Its multilingual nature makes it appealing for both cross-lingual (Perez-Beltrachini and Lapata, 2021) and translation-based tasks (Coster and Kauchak, 2011; Drexler et al., 2014).

Wikipedia biographies have been leveraged for summarisation (Gao et al., 2021) and information extraction (Hogue et al., 2014). Palmero Aprosio and Tonelli (2015) train a supervised classifier to recognise sections of Wikipedia entries as biographies. Most recently Stranisci et al. (2023) presented a task for biographical events detection accompanied with an annotated dataset, as well as intersectional analysis of writers' biographies in English Wikipedia. To extend this to other languages, a new classifier would presumably need to be trained for every target Wikipedia.

Due to its near-monopoly on up-to-date biographical information, Wikipedia is a prime resource for biographical bias studies while also allowing for comparative studies between languages (Callahan and Herring, 2011; Wagner et al., 2015; Field et al., 2022). In particular, the Wikipedia gender gap in biographical coverage and representation is well-studied. Women are less likely to write or be written about in Wikipedia articles, and the events focused on biographies of women are more often constrained to the private sphere (Klein and Konieczny, 2015; Fan and Gardent, 2022; Schmahl et al., 2020; Sun and Peng, 2021; Ferran-Ferrer et al., 2022; Wagner et al., 2015). However, there also exists a 'glass-ceiling effect', where women in Wikipedia are more present among longer and more detailed biographies and more notable, suggesting a higher barrier to entry. There is also evidence of women of non-western background being particularly underrepresented in English Wikipedia (Stranisci et al., 2023). Although there is little research covering trans and nonbinary representation in Wikipedia biographies, similar barriers may exist, and there is more of a focus on the subject's gender identity (Field et al., 2022), which is generally unmarked in biographies about cis people.

3 The Corpus

The code for creating the Wikipedia biographies corpora released with this paper is created with the purpose of exploring cultural and narrative trends, including social bias analysis. The Wikipedia articles that are collected should meet the criteria of being a biography (section 2.1). In this section, we describe the process of identifying biographies and extracting clean text; and present a data card with basic corpora statistics.

3.1 Collecting Articles/Biographies

Biographies are identified and extracted using regular expressions (see Appendix A) directly applied to the markdown (source text) of Wikipedia pages which are obtained from a Wikipedia dump. Using only the Wikipedia dump allows reproducing the dataset without incorporating other data. Not relying on Wikidata connections makes it significantly easier to create analogous datasets for other languages with limited curation.

In practice, we identify articles about persons in two ways. Our main approach checks the categories associated with that article. We look for broad category tags such as 'living people' in English as well as those tags listing birth and death years, such as 'födda 1975' (*born in 1975*). Since the markdown differs between languages despite superficially standard categorisation, manual investigation is necessary to decide which tags to use when adapting to a new language.

For languages where not all categories are explicitly listed in the markdown, there is a risk of severe under-capture, and other methods of identification must be used. For instance, in Chinese, the birth year and either the death year or 'living person' categories are in most cases not specified manually like other, non-standard, categories. Instead, a special birth and death date markdown element is inserted at the beginning of the article which adds the appropriate categories to the page. So, for the Chinese Wikipedia, we check for, e.g. ‘bd|1239年|6月17日|1307年|7月7日|Edward I’ (bd|June 6th, 1239|July 7th, 1307|Edward I; pointing to birth and death dates) instead of ‘1307年逝世’ (*died in 1307*).

There are also languages that, assign the *living people*, *born* and *died* categories fully automatically from Wikidata, without any specific mentions in markdown. This cannot be tracked in text. This applies to Russian: the category for all people – ‘Персоналии по алфавиту’ (*Personae alphabetically*) – as well as the birth and death categories – ‘родившиеся в [YEAR] году’ (*born in year [YEAR]*) and ‘умершие в [YEAR] году’ (*died in year [YEAR]*) – are applied from Wikidata based on the page template.

To capture articles in Russian, we scan for non-category elements in the markdown. We look for specific lines in the infobox, e.g ‘Дата рождения’ (*Date of Birth*), which should be present only for persons. We expect this approach to miss more articles than using categories because shorter articles may not have an infobox, but these are likely to be rejected anyway because of the minimum length requirement.

3.2 Processing Texts

Following our definition of biography as a running text, we strip all the additional markdown elements, as well as the references. These include infoboxes, illustrations and other media, footnotes, and hyperlinks to other Wikipedia pages. We also strip the sections that consist solely or primarily of external references, such as ‘External links’ and ‘See also’. While processing, we also extract some supplementary information, such as the associated categories and any alternate names.

3.3 Data Statement

Curation Rationale - The goal of the dataset was to extract biographies as per our definition in section 2.1. A regular expression per language was used to match data from a Wikipedia dump. The regular expressions were developed by the authors in their first languages who tried to find a small set of categories that would extract most biographies. In general, we use the categories *living people*, *born*, and *died*.

Languages - The languages currently available are English (en), Swedish (sv), Russian (ru), Chinese (zh), and Farsi (fa)[2]. Mentions of Chinese in this paper means the *zhwiki* which consists of both Mandarin and Cantonese. The size of the files and the number of words are in Table 1. More languages can easily be added following the guidelines in the code[3].

Author and Annotator Demographics - The authors of the texts on Wikipedia are not explicitly mentioned due to the open-source nature of Wikipedia. The latest available survey states that contributors are 86.73% male, 12.64% female, and 0.63% other (Glott et al., 2010).

No explicit annotations are included with this work, although we can consider the categories that are collected along with each biography as annotations. These categories are applied by the Wikipedia authors and, hence, annotators can be assumed to be of a similar demographic to authors.

Speech situation - The corpora are written texts intended to give neutral information[4] about people, which are aimed at a general audience. The texts are continuously and asynchronously edited by many contributors and therefore assumed to have a modern speech mode. As the speech mode and content of the articles may change along with societal shifts, it is recommended to download a suitably recent dump when working with this data.

Columns - The following columns are produced by the default biography extractor: *title*, *names*, *categories*, *body*. *Title* is the name of the biography, usually the name of a person. *Names* are the different names that link to the specific biography and may include formal titles, stage names, prior names, etc. *Categories* are the extracted categories that have been given to the biographies by the contributors. The body is the running text which has been stripped of image texts, links, tables and other markdown artefacts.

3.4 Corpora Statistics

The basic statistical analysis of the corpora collected for this paper can be seen in Table 1. The word and character counts, together with the more in-depth distributions shown in Figure 1, give a

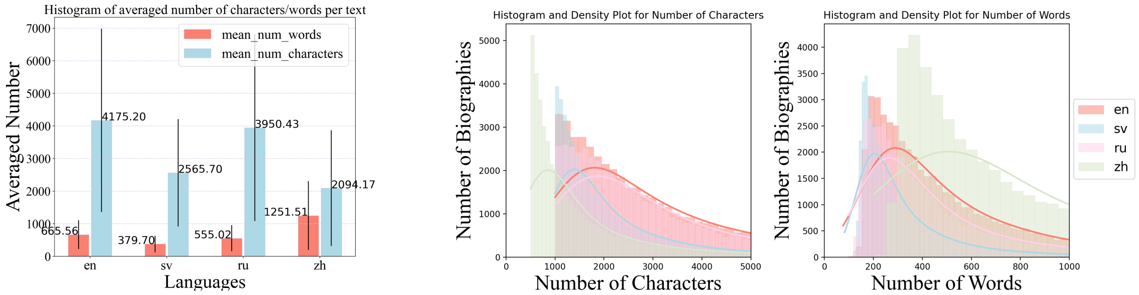
[2] Demo cases are not available for Farsi, as we did not have an L1 speaker available for the analysis.

[3] `https://github.com/antoneklund/wikipedia-biographies`

[4] Wikipedia enforces a ‘neutral point of view’ for all encyclopedic content, although in practice editor bias remains Hube (2017).

Language	Biographies	Size	avg. Char. per Article	avg. Words per Article	avg. Categories per Article
English	1, 219, 516	5.9GB	4, 175.20	665.56	10.26
Swedish	107, 868	332.9MB	2, 565.70	379.70	8.44
Russian	331, 655	2.5GB	3, 950.43	555.02	5.41
Chinese	92, 540	484.6MB	2, 094.17	1, 251.51	7.75

Table 1: Comparative overview of some basic statistics about our corpora. The averages are calculated from a sample of 50, 000 articles in each language.



(a)

(b)

Figure 1: (a): Comparisons of averaged characters per article and averaged words per article between different language biographies.(b): Density distributions of the number of characters and words of the sampled data texts.

rough overview of how the biographies manifest in different languages.

We are interested in the biographies mainly for their potential, among other use cases, in studying the narrative structure and social biases. Therefore, in the statistical analysis, only articles where the running text is sufficiently long were used. What is considered a sufficient length, is adjusted as appropriate for different languages. In this paper, for English, Swedish, and Russian, a minimum of 1000 characters of running text was used. For Chinese, a minimum of 500 characters were used because, in most cases, written Chinese uses fewer characters to represent the same amount of information as the other languages. Also, based on our statistical analysis, it is evident that Chinese biographies have an average number of characters lower than the other languages, and hence, the limit is adjusted accordingly. For other applications, scopes and languages, we suggest adjusting the character limit as appropriate.

4 Demo Cases

Two demo cases were designed to demonstrate some general usage of the corpora and to acquire more latent information about their contents. The corpora are well-situated to study societal structures and how information is relayed, and make comparisons across languages. The first demo case (section 4.1) is a study on topical differences between languages with a focus on gendered themes. The second demo case (section 4.2) is a cluster analysis of the corpora to visualise how the biographies are broadly divided into clusters depending on their running text.

4.1 LDA Topic Modelling

One main strength of the corpora is their multilinguality. A natural first study is to compare the content of the corpora for all the languages, looking for regional differences. We focus on how gendered terms are used in the biographies using a pared-down and fully unsupervised variant of the methodology described by Devinney et al. (2020).

We use gensim[5] Latent Dirichlet Allocation (LDA, Blei et al. (2003)) to model topics in the data. We use a sample of 50, 000 articles per language and pre-process the articles with lemmatisation (except for Chinese) and removal of stop-words. The stop-word list for each language was modified to allow gendered words like *he*, *she*, and *they* in the text, as we want to study the occurrences of these words in the generated topics. The Chinese stop-word list was extended to include both simplified and traditional forms. Lemmatising was done with nltk WordNet[6] (English), efselab[7] (Swedish), and

[5] https://radimrehurek.com/gensim/
[6] https://www.nltk.org/
[7] https://github.com/robertostling/

pymystem3[8] (Russian). We use the jieba[9] package to pre-process the Chinese corpus.

We generate 50 topics and used the top 30 highest-weighted terms for each topic to label them with their apparent themes (e.g. *Chinese history*, *Education/academia*). Topics were labelled by an L1 user, with an L2 user checking for agreement where possible. From these, we created 20 general themes to allow for better comparison across languages. The breakdown of general themes for each language can be seen in Table 2.

From this analysis, we can see that *Sports* and *Entertainment* make up a significant number of topics in all samples. The topics with *History*, *War/military*, *Politics/government* and *Places* account for most of the rest. The Chinese sample notably has more topics around *Entertainment* and *Sports* and only one about *Places*. The *Places* theme is more common in other languages and the English corpus has by far the most. We suspect that this theme is intermixed with *History*.

When we subdivide *History* into *History (local)* and *History (foreign)*, we can see that there is a greater number of history topics local to a language, indicating there is likely more detail or nuance latent in the data. Furthermore, the foreign history topics remain focused on history that is 'close to home', with English, Swedish, and Russian remaining quite heavily focused on European history and places. Chinese, while still including European history, has more East Asian topics.

The number of *No clear theme* topics is similar between the models. These include the captured structural elements such as tables and language artefacts foreign to a particular Wikipedia (e.g. English terms in the Russian sample). This may indicate that other cleaning choices (e.g. more thoroughly removing the tables) may be preferable depending on the task.

4.1.1 Gendered Analysis

We take a closer look at some of the gendered patterns made evident by topic modelling. We identify topics where gendered pronouns or other lexically-gendered terms are highly weighted and relate the general themes of the topics to these gendered associations.

For the English sample, masculine pronouns (e.g. *he*, *his*) appear frequently in topics related to politics, war, and inheritance, although they also appear in a number of other topics across a wide range of subjects. Feminine pronouns (e.g. *she*, *her*), in contrast, are highly weighted in only one topic: family and relationships. We find similar patterns in Russian and Swedish, where masculine terms appear in a wide range of topics and feminine terms are confined to only one or two, with a focus on the domestic sphere of family and/or romantic relationships.

Themes	en	sv	ru	zh
Entertainment	4	3	2	6
Sports	9	9	7	12
Music	2	3	2	2
Art	1	2	1	1
Literature	1	3	1	1
Journalism	1	0	0	0
Business	0	0	1	1
Science/Technology	2	0	2	0
Education/Academia	2	2	0	2
History (local)	2	2	4	6
History (foreign)	0	2	3	6
Places	13	5	7	1
Religion	2	3	1	1
War/Military	2	2	4	1
Politics/Government	3	4	2	4
Crime	1	1	1	0
Family	1	1	1	0
General Biography	0	2	1	3
(No clear theme)	2	3	4	3

Table 2: Summary of themes found for unsupervised LDA with 50 topics, run on samples of 50k biographies.

For the Chinese sample, masculine terms (e.g. 他- he, 男子- male) appear frequently in topics related to sports, history, and politics, while feminine terms (e.g. 她- she, 女子- female) are more common in topics of TV series and music, a notable departure from our other three samples. Although women are mentioned in sports-related topics, they are almost absent in the top 30 most frequently mentioned keywords of political topics.

From counting pronoun frequency in our samples (Figure 2,) we know that masculine pronouns vastly outweigh feminine pronouns[10]; and nonbinary pronouns (e.g. *ze*, *hir*) are extremely rare (where they can be clearly disambiguated from neutral or plural pronouns). The distribution of the number of gender-associated topics (masculine more frequent than feminine; nonbinary excluded) can somewhat be expected based on these term distributions. However, both are evidence of the hierarchical relationship, where men are 'more' – talked about, present in the data, valued – than

efselab

[8] https://pypi.org/project/pymystem3/

[9] https://github.com/fxsjy/jieba

[10] In the case of Russian, this may be in part due to language-specific behaviour of grammatical gender.

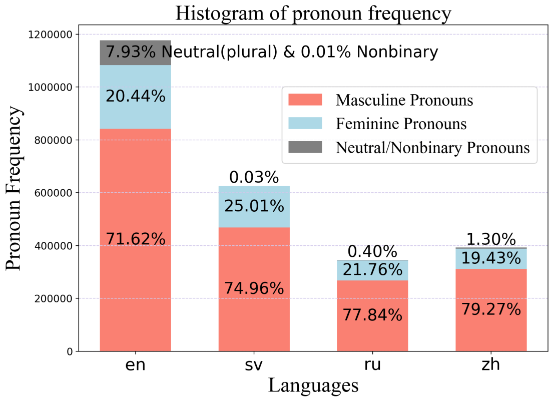


Figure 2: Pronoun frequency in each sampled corpus by gender, calculated after preprocessing.

women. We also see evidence that these hierarchies surface differently in our different samples, according to the different cultural hegemonies. The European languages relegate women to the private sphere, whereas men take up the public sphere and are treated as the unmarked norm (meaning they can ‘be’ almost anything). The Chinese sample puts men in ‘serious’ or important topics, and women in those related to entertainment and other less serious pursuits. Our findings correlate well with other research on gender bias in Wikipedia, e.g. (Sun and Peng, 2021; Schmahl et al., 2020).

4.2 Cluster Analysis

To look for writing-style patterns in the biography texts we use the BERTopic pipeline (Grootendorst, 2022) to create clusters of biographies. A random sample of $50,000$ biographies was used for each language. The text is vectorised with the multilingual model XLM-RoBERTa[11] (Conneau et al., 2020). Then, the vectors are projected to two dimensions using UMAP (McInnes et al., 2018) and then clustered with HDBSCAN (Campello et al., 2013). This results in 2D plots for each language where the clusters in theory represent biographies that are similar to each other. The plots can be seen in Figures 3(a)–3(d). The keywords are extracted using c-TF-IDF that was introduced in Grootendorst (2022) with an extended stop word list for cluster visualisation.

The structure of the vector space reveals clear clusters that have been formed for all languages. English, Swedish, Russian, and Chinese have six, six, five, and nine clusters respectively, with the model set to find coarse-grained clusters. The largest clusters could be generally labelled as being about people from the core regions of the language. E.g. an English cluster about Americans and a Swedish cluster about Swedes. The smaller clusters have more informative keywords about a specific group of biographies. This could be a topic about hockey players which are found in English, Swedish, and Russian, or other sports and TV series that were found in Chinese. Smaller clusters reveal more distinct themes such as the *Communist Party of China* or *Theatre*. This indicates that a deeper analysis with finer-granular clusters would probably reveal more interesting structures.

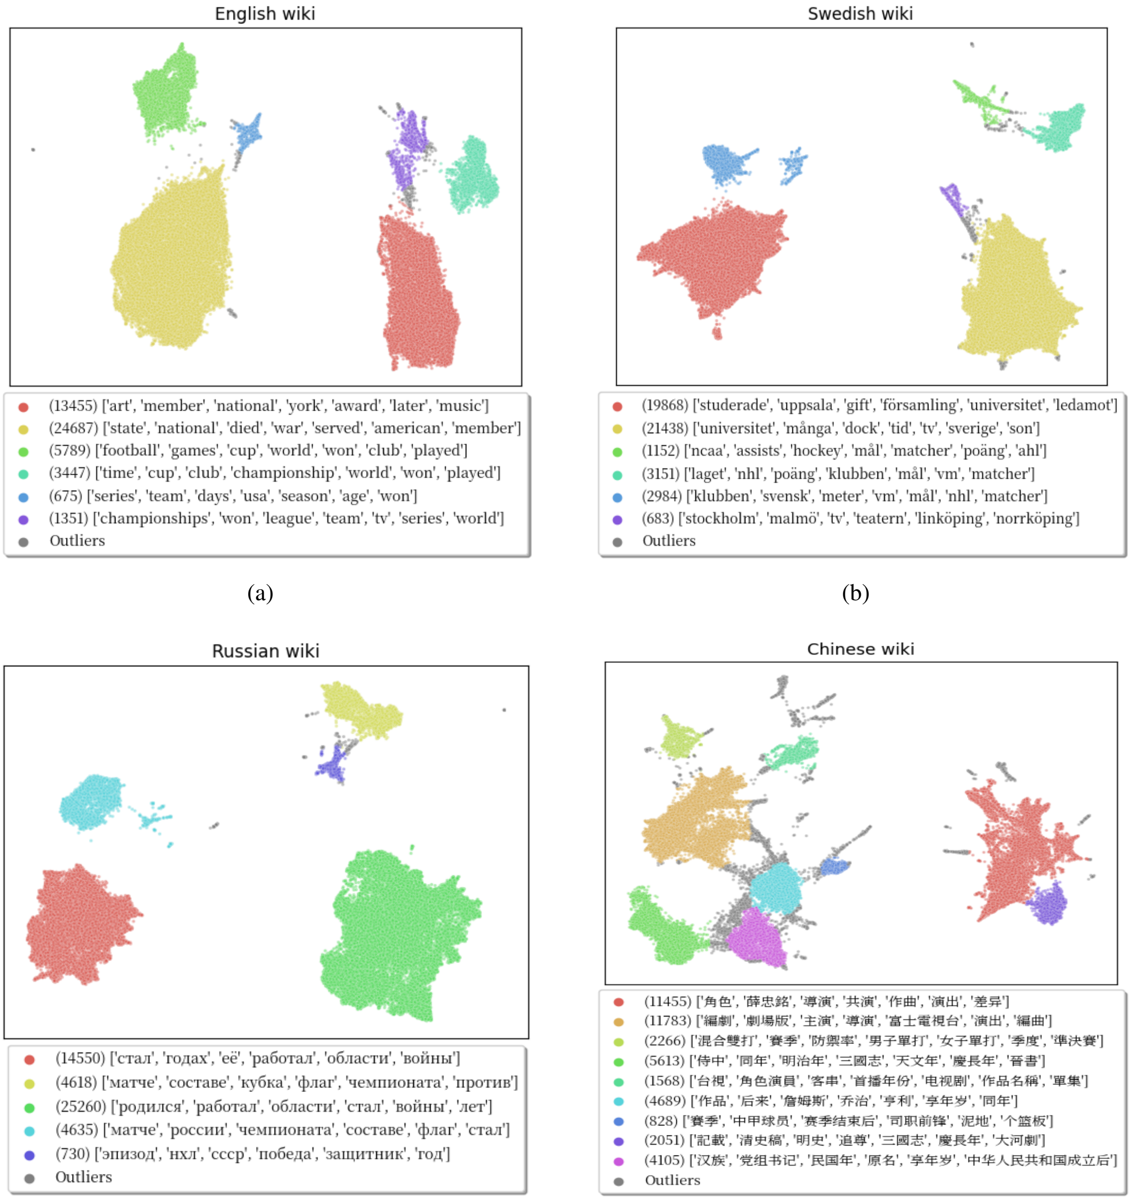
In general, many clusters are about sports for all languages. This indicates that there are many athlete biographies, which may follow a structure of writing that is distinctly different from those of other persons. These writing patterns are revealed by the clustering system which shows multiple sports clusters while the other biographies are in a larger shared cluster. This indicates that there is a writing pattern in how people related to sports differ from many other categories of biographies. These other categories, such as themes of *History* or *Entertainment* seem to share a common writing style for biographies.

5 Limitations

The aim of this work was to collect as many Wikipedia articles as possible that fit the criteria for being a biography. While the corpora presented in this study are largely biographies, there are articles that evade the filter, e.g. the Wikipedia category ‘mountaineering deaths’ includes both biographies and articles about accidents. Although these articles are easy to manually identify, we do not remove them as they must be considered individually and we found them to be extremely uncommon.

False negatives are harder to identify. We generally assume that all biographies have at least one of the patterns: ‘born’, ‘death’, or ‘living’. In cases where a person does not have these, it may be the case that they have a sufficiently mythological status (for example, the Buddha is not captured in our English corpus). More likely, however, it could be due to human error when editing the page. We recommend making manual checks with samples of biographies expected to be in the data. This is especially important when considering biographies of people belonging to marginalised groups, who

[11] https://huggingface.co/docs/transformers/model_doc/xlm-roberta



(a)

(b)

(c)

(d)

Figure 3: 2D plots of the English (a), Swedish (b), Russian (c), and Chinese (d) biographies. The larger groups formed have the keywords shown in the legend.

may be less likely to be seen as 'significant' and thus not be properly curated.

We attempted to strip the text from all links, tables and other clutter to only have the running text of the biography easily accessible in the dataset. We can not guarantee that the texts do not contain any errors from the cleaning, and some NLP applications may require different information (such as extracting links) which we do not provide.

While analysing underlying gendered patterns can be done through topic modelling, this technique is not well-suited to languages where grammatical and social gender overlap. It also fails in data-sparse contexts, such as for gender-diverse populations. Our demo is provided as a proof-of-concept of the utility of the corpora for social bias analysis, and as a warning that they should not be used uncritically: more detailed analysis and mitigation, tailored to specific use cases, will be necessary for all social biases.

Finally, these corpora should not be used as a benchmark for pre-trained models that where constructed using Wikipedia in their training data.

6 Conclusions

The Multilingual Wikipedia Biographies is mainly a method for extracting an up-to-date high-quality dataset from the Wikipedia dump. The method is easily adaptable to other languages including those with low resources. Some general structures were common between languages such as masculine terms being generally more prevalent in topics compared to feminine, which were constrained to more specific topics. The distribution of biographies is naturally highest in the language's core region and gradually declines as it extends outward. The corpora allow for comparing the structures and composition of biographies in multiple languages which is important for understanding how Wikipedia biographies shape how information about individuals, and society, as a whole is shared.

Ethical Considerations

In this paper, we explore a very surface-level understanding of gender bias, focusing on how the potential for representational harms can be seen for groups and individuals of different genders (studying masculine, feminine, and neutral/nonbinary representation). In our case, representational harm is concerned with stereotyping (e.g. women are most associated with home/family) and erasure (e.g. nonbinary people are largely not present in the samples). Although we do not explore other biases, such as race or class, as well as intersectional biases; we expect these representational harms to also be present and discoverable in the corpora, as Wikipedia is not written or curated in e.g. specifically anti-racist ways. We do not attempt to mitigate any of these harms, because we believe they provide valuable data about cultural and societal norms and attitudes, which may be important for research. However, this also means that there is an additional risk of perpetuating and even amplifying stereotypes or erasure if the data are used uncritically.

This dataset contains publicly available information about living people. Crucially, this information may go (or already be) out of date and we encourage the use of the provided code on a recent Wikipedia dump when appropriate.

Although this dataset and de facto annotations (in the form of category tags) are publicly available and can be used and shared for research under Wikipedia's Creative Commons by Share Alike license, it is still worth acknowledging that we are collecting other people's words and labour.

Statement on the use of AI tools. No parts of the text in this paper were written with the help of any generative AI.

Acknowledgements

We would especially like to thank our colleagues, Arezoo Hatefi, for her translations, quality checking, and general expertise in developing the Farsi corpus, and Henrik Björklund, for his support and feedback on our ideas.

A Categories and Regular Expressions by Language

English (en) The English corpus regular expression captures biographies only by categories, and checks for the presence of any of the following: living people, births, and deaths.

```
\[\[Category:(Living people|
.*deaths|.*births)
```

Swedish (sv) The Swedish corpus regular expression captures biographies only by categories, and checks for the presence of any of the following: Living People, Births, and Deaths.

```
\[\[Kategori:(Levande personer|
Födda.*|Avlidna.*)
```

Russian (ru) The Russian corpus regular expression captures biographies by categories (personae alphabetically, births, and deaths) and common lines from infoboxes which we expect only to be present for persons: date of birth, date of death, place of birth, and place of death. While the birth year and death year categories are automatically added and, therefore, not captured in most cases, they are included for redundancy. The same mask also captures non-automated categories related to birth and death places, causes, etc.

```
\| * [Дд]ата рождения |\| * [Дд]ата
смерти |\| * [Мм]есто рождения
|\| * [Мм]есто смерти |\[\[ Катего-
рия:(Персоналии по алфавиту|Родившиеся.*
|\
```

Chinese (zh) The Chinese corpus regular expression captures biographies by both the `bd` template (which automatically generates births and deaths categories) and the following categories: living people, births, and deaths.

```
(\[\[(Category|分类):(在世人物|.*逝
世|.*出生))|(\{\{bd\|.*\}\})
```

Farsi (fa) The Farsi corpus regular expression captures biographies only by categories, and checks for the presence of any of the following: living people, births, and deaths.

```
\[\[(*. زنده افراد |*. زادگان |*.
درگذشتگان ):رده\]\]

A Computational Analysis of the Voices of Shakespeare's Characters

Liviu P. Dinu, Ana Sabina Uban
University of Bucharest, Romania
ldinu@fmi.unibuc.ro, auban@fmi.unibuc.ro

Abstract

In this paper we propose a study of a relatively novel problem in authorship attribution research: that of classifying the stylome of characters in a literary work. We choose as a case study the plays of William Shakespeare, presumably the most renowned and respected dramatist in the history of literature. Previous research in the field of authorship attribution has shown that the writing style of an author can be characterized and distinguished from that of other authors automatically. The question we propose to answer is a related but different one: can the styles of different characters be distinguished? We aim to verify in this way if an author managed to create believable characters with individual styles, and focus on Shakespeare's iconic characters. We present our experiments using various features and models, including an SVM and a neural network, show that characters in Shakespeare's plays can be classified with up to 50% accuracy.

1 Introduction

The problem of authorship identification is based on the assumption that there exist stylistic features that can help distinguish the real author of a text from any other theoretical author, and that these can be computationally measured and exploited in order to automatically identify the true author of a text. Automated authorship attribution has a long and rich history (starting from the early 20th century (Mendenhall, 1901)) and has since then been extensively studied and elaborated upon.

One of the most influential studies in authorship attribution is the study of (Mosteller and Wallace, 1963) on the Federalist Papers, in which the authors try to determine the real author of a few of these papers which have disputed paternity. In this work, they both introduce a standard dataset and propose an effective method for distinguishing between the author's styles, based on function words frequencies, that is still relevant and used to this day. Many types of features have been proposed and successfully used in subsequent studies to determine the author of a text. These types of features generally contrast with the content words commonly used in text categorization by topic, and are said to be used unconsciously and harder to control by the author. Such features are, for example, function words (Mosteller and Wallace, 1963; Dinu et al., 2012), grammatical structures (Baayen et al., 1996), part-of-speech n-grams (Koppel and Schler, 2003), lexical richness (Tweedie and Baayen, 1998), or even the more general feature of character n-grams (Kešelj et al., 2003; Dinu et al., 2008). Recent studies focusing on stylistic variation within the writings of a single author combine traditional function word features with stylistic markers such as lexical richness and readability, as well as topic modelling, to compare the importance of the the stylome and the topics discussed in in the evolution of an author's writing (Dinu et al., 2017; Dinu and Uban, 2018).

A related problem that has been approached much less in computational linguistics and even in digital humanities scientific literature is that of distinguishing between the writing styles of fictional people, namely literary characters. This problem may be interesting to study from the point of view of analyzing whether an author managed to create characters that are believable as separate people with individual styles, especially since style is a feature of speech that is hard to consciously control. Shakespeare, as arguably the most renowned dramatist in the history of literature, is the ideal case study for understanding whether it is possible to create characters that are as individualized as humans are.

One of the first authors to study literary characters stylistically is John Burrows, who (Bur-

https://doi.org/10.26615/978-954-452-092-2_033

rows, 1987) shows that Jane Austen's characters show strong individual styles, then later Burrows and Craig (2012) look at a corpus of seventeenth-century plays and tries to cluster them by character and by playwright. Another recent study (van Dalen-Oskam, 2014) analyzes the works of two epistolary novels authors, who are known to have written their books together, and tries to distinguish automatically between passages written by each author, and between styles of each character in the novel. Dinu and Uban (2017) propose an experiment on classifying the characters in the epistolary novel *Les Liaisons Dangereuses*, showing that the characters can be automatically distinguished stylistically even using simple models and features. Muzny et al. (2017) propose a metric for characterizing spoken dialogue in the novel, which they call "dialogism", and Vishnubhotla et al. (2019) publish a study reporting automatic measures of dialogism in plays from the nineteenth and twentieth centuries by automatically classifying their characters.

In this paper we take a look at one of the most interesting authors in literary history: William Shakespeare. Shakespeare is seen by scholars and readers alike as one of the greatest dramatists in the history of literature. His characters are iconic, with strong well defined personalities. The question we propose to answer in this study is whether a computational analysis would lead to the same conclusion – did Shakespeare manage to write distinct characters with unique speaking styles, and can we measure that? Moreover, are the features that distinguish characters the same as the features that distinguish between different authors?

Shakespeare's characters have also been the subject of a few previous studies, such as Nalisnick and Baird (2013), where the authors try to map the relationships between characters. Culpeper (2009) study keyness, and use Shakespeare's *Romeo and Juliet* as a case study. In Vogel and Lynch (2008), the authors investigate the interesting problem of strength of characterization of a character, using plays of four authors, including Shakespeare. They use text similarity methods to measure how similar a character's utterances are to the lines of the other characters in the same play and in other plays, proposing that stronger characters are most self-similar compared to other characters and plays. We are also interested in how individualized and realistic the characters are in their construction, but we assume that the strength of a character relies in how belivable it is as a unique person, and that this can be measured by the ability to distinguish characters the same as we do humans, from the perspective of their writing style.

Character	Nr lines
King Lear	190
Timon	220
Cleopatra	180
Duke Vicentio	210
King Henry V	200
Hamlet	370
Iago	280
Mark Anthony	220
Othello	240
Brutus	190

Table 1: Number of lines per character for top 10 characters

2 Data and Methodology

We constructed our set of labeled texts by first splitting each of Shakespeare's plays into individual lines, labeled with the characters that speak them, and excluding characters with less than 500 lines, and were left with a total of 50 characters. Since it can be difficult to extract meaningful information from the short individual lines, we further concatenated them in groups of 10 lines (spoken by the same character) and used the resulted texts as our data points.

We artificially balanced the number of datapoints pertaining to each class during training, using oversampling. Table 1 includes the number of lines per character before rebalancing.

3 Classification Experiments

We formulated the problem as a supervised learning problem, and trained several models using various features to try and understand how well a machine learning model can predict a character based on its utterances within a play, and what are the features that help shape characters the most.

We start by tokenizing the texts in our dataset and encoding them using a bag-of-words representation, which we further use to extract features for our classifiers. We perform different kinds of feature selection in order to then compare their performance and conclude on which are the most

Character	Precision
King Lear	10%
Timon	68%
Cleopatra	22%
Duke Vicentio	66%
King Henry V	20%
Hamlet	40%
Iago	50%
Mark Anthony	59%
Othello	62%
Brutus	31%

Table 2: Precision for top 10 characters

helpful features for predicting characters. The various features extracted from text are:

All words. We first experiment with using all the words in the text as features, encoded as bag-of-words. We obtain a vocabulary of 13,559 words.

Function words. Function words have been traditionally successfully used as features for authorship attribution, and are considered to be the aspects of the text that can encode a writer's style. In some of our experiments, we try to limit our features to only function words, in order to understand whether these are as useful in distinguishing between characters as they are for distinguishing between different authors.

Content words. In a separate experiment, we try to limit our features to only content words, ignoring function words. In this way, we hope to understand how important the content or topic of the text matters for distinguishing a character. We represent a list of content words using a bag-of-words model, but each word is represented by its *tf-idf* score instead of its frequency.

K-best. We attempt to use statistical methods to extract features that contribute most to separating between our classes. We use chi^2 feature selection to limit our vocabulary to the k-best features, then use only these words as features in classification.

Character n-grams. We finally experiment with character n-grams instead of words. These are a more versatile kind of feature, able to capture subword and multi-word content as well as individual words. We consider all character n-grams from 2-grams to 10-grams and encode them with a bag-of-words representation.

We experimented with different classifiers:

SVM. SVMs have shown to be successful in authorship attribution, since the features are usually predictive enough in this task without the need for an overly-complex model.

Feature Set	Accuracy
SVM with all words	30%
SVM with K-best (100)	13%
SVM with content words	30%
SVM with function words	6%
SVM with character n-grams (2-10)	18%
MLP with all words	50%

Table 3: Overall accuracy for each feature set

Multi-layer perceptron (MLP). We use a simple feed-forward neural network (multi-layer perceptron) that takes as input our features encoded as bag-of-words, passes it through one hidden layer of 1000 units, and finally predicts the most probable class using Softmax on the final layer. The vocabulary size is approximately 13K words, equal to the number of input units.

Classification accuracy was measured for each character separately, in a series of experiments where the model was trained on 80% of the texts, and tested on the remaining 20%. The overall accuracy was obtained by averaging the per-character accuracy scores.

4 Results and Analysis

The overall accuracy for each of the experiments is shown in Table 3. The results show that we were able to distinguish between characters with an accuracy superior to a random guess (which would yield an average accuracy of 2%, given there are a total of 50 classes, assuming balanced a class distribution). Precision of classification per character for the top 10 characters is shown in Table 2. The most successful feature were the content words, by far outperforming function words, which are usually successful in authorship problems. This shows that even though characters are indeed distinguishable, it may not be their style that differentiates them, at least not in the same way as it does for authors.

We take a closer look at the landscape of Shakespeare's characters as represented by our model, by reducing our bag-of-words representation to two dimensions using principal component analysis. Figure 1 illustrates this, showing that, even in this lower dimensional space, lines of the same character cluster together for some of the characters. Furthermore, it is interesting to see which characters are more similar by looking at their relative

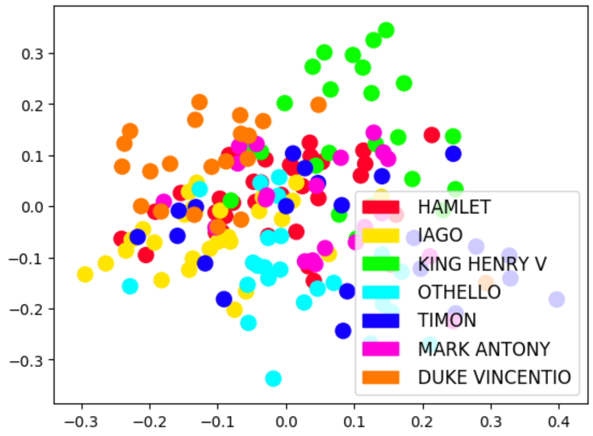

Figure 1: 2D view of character's lines (most frequent 7 characters)

Feature Set	Accuracy
SVM with all words	30%
SVM with K-best (100)	20%
SVM with content words	39%
SVM with stopwords	8%
SVM with character n-grams (2-10)	24%
Neural network with all words	20%

Table 4: Overall accuracy for each feature set for classifying plays

positions in this space.

Our results suggest lines spoken by different characters can be distinguished, especially through the content words used in them. A question raised by this is whether we are truly capturing features specific to the characters, or predicting something else, such as the play they belong to. To tackle this problem, we perform a second experiment where we try to predict the play a book belongs to, using the same models, features and experimental settings as in our character classification experiment.

The results for classifying texts by play are shown in Table 4. There are 32 plays in our dataset (32 classes), so the expected accuracy for a random classifier in the case of plays is around 3%. We can then conclude that results are comparable between the first and second classification experiments. Useful features tend to be the same as for the previous experiments as well. Content words perform best, and removing function words even adds an improvement to the results in the case of plays.

We also replicate the visualization experiment, plotting in 2 dimensions lines belonging to top 10 (most prolific) characters in the top 5 plays (longest), shown in Figure 2. Here too the distinction between lines in different plays is visible even in 2D, though less apparent than in the case of characters, which suggest characters may be more separable than plays.

The results of the classification experiments do suggest that identifying the play it belongs to is a factor in determining which character utters a line. Nevertheless, the classifier can still distinguish between characters of the same play, so other factors may contribute as well. We further try to understand how easy it is to classify between the characters to belonging the same play. Only 4 of the 32 plays have more than 2 characters in our class set: *The Tragedy of Othello, the Moor of Venice*, *The First Part of Henry the Fourth The Tragedy of Antony and Cleopatra* and *The History of Troilus and Cressida*. For each of the mentioned plays, we perform an experiment to classify between its characters, using the setting that performed best at both character and play classification: an SVM with content words as features. We average the accuracy per character for each play, then average the obtained accuracy per play, and get an average accuracy of 58.5% (almost double compared to the 30% accuracy that would be obtained by a random choice classifier). Table 6 shows the results per play, which seem to confirm that characters can be distinguished within plays as well.

Results also show that overall, content seems to be more predictive of the character, and that function words don't seem to capture a character's style in the same way they do an author's, in the case of Shakespeare. Nevertheless, the accuracy above chance obtained with function word features show they are not entirely unhelpful, confirming previous results in literary character classification (Dinu and Uban, 2017).

Finally, we perform a last experiment where we select only the 4 plays with more than 3 prolific characters and group them together into a set of 12 total characters that we try to classify. Looking at the errors the algorithm makes, whether or not it tends to mistake characters with other characters of the same play, should help us understand to what degree it learns to classify characters versus plays. Table 5 shows for each of the 12 characters, how many datapoints were classified correctly, how many were misclassified to a character in the same play, and how many were predicted to belong to a character in a different play.

Character	Same character	Diff character, same play	Diff character, diff play
Iago	20	6	2
Othello	18	2	4
Desdemona	3	5	4
Marc Antony	12	3	7
Cleopatra	5	6	7
Octavius Caesar	1	1	9
Falstaff	8	2	6
Prince Henry	3	5	7
Hotspur	5	4	5
Troilus	6	0	8
Ulysses	5	1	7
Pandarus	1	0	10

Table 5: Correct and mistaken classifications

Play	Accuracy
Othello	64%
Henry IV	62%
Antony and Cleopatra	51%
Trolius and Cressida	57%

Table 6: Average accuracies for character classification within plays

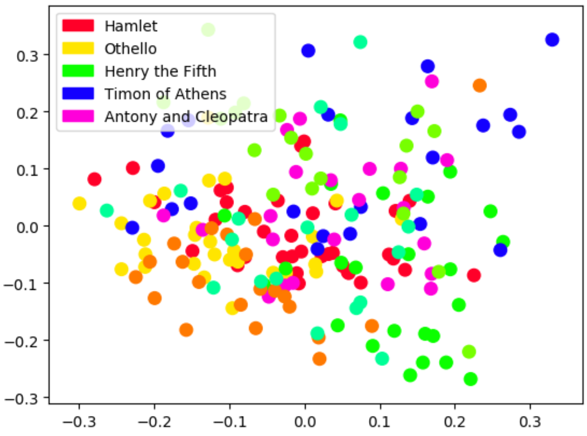

Figure 2: 2D view of character's lines grouped by play (most frequent 5 plays)

5 Conclusions and Future Directions

Our experiments have shown that it is possible to automatically distinguish between the characters of Shakespeare's plays using a machine learning model. The texts were most successfully classified using content words, not function words, that are known to capture the stylistic dimension of a text. This suggests the question Shakespeare's characters mostly differ in the topics they approach, and less in style, as defined in authorship attribution. We have also compared character classification to play classification, and have shown that, while the play a character belongs to is a useful indicator to its identity in classification, it is not the only factor which helps tell characters apart. It might be interesting to further explore other features such as sentiment or emotion features, or to use a more powerful classifier (such as a convolutional/recurrent neural network). Many of the challenges of this analysis stemmed from the scarceness of data (many characters were discarded, lines were grouped together), so a learning algorithm that would be able to better handle small data might help expand the set of possible experiments and give more insight into the issue.

In the future it may also be interesting to look at how various authors pertaining to different periods and literary currents compare in terms of their ability (and desire) to create individual, stylistically independent characters. Literary theory (Wellek et al., 1956) tells us that the practice of giving characters strongly individual voices is a rather modern idea, and that characters evolved with time and literary current from the classical figures, who represented a typology, to the realist characters, who are pictured with strong individualities. This would be interesting to confirm experimentally, by extending the study to perform a diachronic analysis of characters in literary works.

Further, the analogous problem to author profiling could be tackled with regard to literary characters. Separately of whether characters are easy to distinguish stylistically from one another, it may be interesting to see if an author managed to belivably build a character's style that is consistent with features of the character's personality: such as age or gender.

Source Code Plagiarism Detection with Pre-Trained Model Embeddings and Automated Machine Learning

Fahad Ebrahim
University of Warwick, UK
Fahad.Ebrahim@warwick.ac.uk

Mike Joy
University of Warwick, UK
M.S.Joy@warwick.ac.uk

Abstract

Source code plagiarism is a critical ethical issue in computer science education where students use someone else's work as their own. It can be treated as a binary classification problem where the output can be either 'yes' (plagiarism found) or 'no' (plagiarism not found).

In this research, we have taken the open-source dataset 'SOCO', which contains two programming languages (PLs), namely Java and C/C++ (although our method could be applied to any PL). Source codes should be converted to vector representations that capture both the syntax and semantics of the text, known as contextual embeddings. These embeddings would be generated using source code pre-trained models (CodePTMs). The cosine similarity scores of three different CodePTMs were selected as features. The classifier selection and parameter tuning were conducted with the assistance of Automated Machine Learning (AutoML). The selected classifiers were tested, initially on Java, and the proposed approach produced average to high results compared to other published research, and surpassed the baseline (the JPlag plagiarism detection tool). For C/C++, the approach outperformed other research work and produced the highest ranking score.

1 Introduction

Plagiarism is the ethical and educational issue of taking ideas from other sources and representing them as your own without acknowledgement. Plagiarism can be divided into text and source code. Academic source code plagiarism can be defined as "Source-code plagiarism in programming assignments can occur when a student reuses source code authored by someone else and, intentionally or unintentionally, fails to acknowledge it adequately, thus submitting it as his/her own work. This involves obtaining the source-code, either with or without the permission of the original author and reusing the source code produced as part of another assessment (in which academic credit was gained) without adequate acknowledgement" (Cosma and Joy, 2008). The words reuse, obtain, and acknowledge may also be defined on the basis of the academic requirements.

The detection of plagiarism is a lengthy and demanding process, so new technologies such as Artificial Intelligence (AI) might be used effectively. Plagiarism can be treated as a classification problem as the output can be considered a class of discrete values: 'yes' (plagiarised), 'no' (non-plagiarised), or potentially 'partial'. Source code plagiarism can be also considered to be an application of a source code similarity measurement task (Zakeri-Nasrabadi et al., 2023).

There are several ways to represent source codes (Hrkút et al., 2023) such as graphs, trees and tokens. The source codes must be converted into vectors known as embeddings before being fed into a classifier. Contextualized embeddings not only consider syntax but also the semantics of source codes. These embeddings can be created using pre-trained models. The emergence of pre-trained models has revolutionized the field of Natural Language Processing (NLP) and are being known for their robustness. They can be utilised in various ways such as re-training, fine-tuning and inference. Also, some domain-specific models have been created for certain areas and tasks.

This work inspects the robustness of the embeddings generated by source code pre-trained models (CodePTMs) for the task of source code plagiarism detection. Contextual embeddings are extracted using these CodePTMs and a classifier built on top of the embeddings. For classification, this work utilises the concept of Auto Machine Learning (AutoML) to determine the best classifier given certain training data. The training, testing, and evaluation are based on the SOurce COde reuse dataset

(SOCO) (Flores et al., 2014).

The paper is organized as follows: section 2 covers related work, section 3 covers the methodology, section 4 presents the results, and section 5 covers the conclusion and future work.

2 Related work

Several software tools have been used as source code plagiarism detectors. Novak compared several such tools, namely JPlag, MOSS, SIM, Splat, Marble, Plaggie, and Sherlock Warwick in his review paper (Novak, 2016).

Engels et al. introduced the idea of neural networks in source code plagiarism detection and reused the output of MOSS on a dataset containing 20,706 C++ introductory course assignments. The evaluation was performed on the basis of the classification evaluation metrics (precision, recall, and F1 scores) (Engels et al., 2007).

Ljubovic and Pajic tackled the issue of external plagiarism by using a cloud and applying an Artificial Neural Network (ANN) based on the output of the SIM's software and repository monitoring on a dataset containing 3,655 submissions from an introductory C course (Ljubovic and Pajic, 2020). Their setup was compared to JPlag, MOSS and SIM.

Abstract Syntax Trees (ASTs) along with code disassembly have been used by Viuginov et al. who considered the lexical, syntactic, layout, and structural characteristics of the source code on a dataset containing 90,000 C++ solutions (Viuginov et al., 2020). For the evaluation, they calculated the F1-score.

Manahi et al. used a combination of Siamese networks, Bidirectional Long Short-Term Memory (BLSTM), and character embeddings on a dataset including 16,800 introductory course C assignments (Manahi et al., 2022). Siamese networks are multiple similar neural networks with the same configurations and weights. They are mainly used for similarity detection. For their evaluation, they calculated the classification evaluation metrics.

Humayoun et al. used the concepts of tokenization, AST, and upsampling on their public dataset of 60 introductory C++ programming assignments (Humayoun et al., 2022). The features tested were N-gram overlap, Longest Common Substring (LCS), and greedy string tilling. Eight classifiers were implemented using Weka and the authors' model was evaluated based on the classification evaluation metrics.

In the first part of his master's thesis (Heres, 2017), Heres proposed a system using N-grams, term frequency–inverse document frequency (TF-IDF), and cosine similarity. The dataset used was the SOCO Java set and their own private dataset having 16,954 files. The evaluation was based on the average precision score.

Deep learning using char-Recurrent Neural Network (char-RNN) and Long Short-Term Memory (LSTM) was the basis of Katta's approach, which used general deep features that could be applied to any dataset (Katta, 2018). The dataset covered an introductory C course with a total of 4,700 submissions. The model was evaluated using classification evaluation metrics.

2.1 SOCO related works

This work uses the SOCO dataset and the approach followed will be compared to the other approaches based on the same dataset.

Garcia et al. used an approach (UAEM) consisting of four phases (Garcıa-Hernández and Lendeneva, 2014). The first phase was related to pre-processing, which was the tokenization of the source code, and the second phase was the similarity measurement, which was based on the longest common substrings. The third phase was related to extracting different parameters such as distance, ranking, gap, and relative difference, and the final phase was decision-making by using the obtained parameters.

Ramırez et al. in their approach (UAM-C) applied three different views to the source code: a lexical view utilising 3-grams, a structural view that utilizes the methods headers, and a stylistic view covering features such as the number of spaces and the number of uppercase or lowercase letters (Ramırez-de-la Cruz et al., 2014).

Ganguly and John developed an Information Retrieval (IR) model (DCU)(Ganguly and Jones, 2014). They built a Language Model (LM) based only on the Java dataset. A Java parser was utilized as a bag of words scheme, and an AST was constructed to capture the structure of the code.

Ganguly et al. proposed an improvement over DCU (Ganguly et al., 2018), where a supervised classifier (random forest) was added to an IR model based only on the Java dataset. The approach had three models: an IR Language Model (LM), LM with AST (LM_AST), and LM_AST with different index fields (FLM_AST).

Flores et al. used a text comparison approach (Flores et al., 2014). They searched for matching lines between two source codes and calculated the ratio between the number of these lines and the larger number of lines of the two files. The decision was based on a threshold value. Furthermore, Apoorv worked in a similar manner, but the decision was based on the maximum similarity value (ratio of matching lines).

We refer to JPlag (Prechelt et al., 2002) as "Baseline1". JPlag is a well-known tool used for source code plagiarism detection. Source codes are converted into tokens, and the similarity between these tokens is estimated using the 'greedy string tilling' algorithm (Wise, 1993).

The work of Flores et al. is referred to as "Baseline2" (Flores et al., 2011), which divides the activity into three stages: pre-processing, feature extraction, and similarity measurement. Spaces, line breaks, and tabs are eliminated. The features are based on 3-grams and term frequencies, and cosine similarity is used to measure the similarity of two source codes.

The recent work of Setoodeh et al. has developed a four-phased approach (Setoodeh et al., 2021). The first phase is pre-processing, such as removing comments and unnecessary code, and the second phase involves generating a sequence to capture the structure of the source codes. The third phase is similarity measurement by applying multiple methods such as comparing the sequence strings, trees, and edges. The final phase is related to the evaluation including the calculation of the precision, recall, and F1 score, and a comparison with other SOCO-related works.

The approach taken in this paper differs from existing approaches in three respects. Firstly, the dataset used is open source, accessible, and adequate in size containing two PLs (Java and C/C++). Secondly, the approach is language-independent and does not depend on tokenizers or specific language syntax, so could be applied to any PL. Thirdly, the approach utilises the state-of-art CodePTM contextualized embeddings.

3 Methodology

This work follows the typical process of applying supervised ML to a classification problem, as mentioned in (Schlegel and Sattler, 2023). The cycle starts with data collection and feature engineering, followed by model selection. The model needed to be trained and tested. Enhancements with parameter tuning could be applied, prior to the model being evaluated.

3.1 Dataset

There is a lack of a proper dataset related to source code plagiarism due to potential legal or social issues, and it was therefore difficult to have an open-source academic dataset of students' data which could be used for this research. Possible solutions included using a privately created dataset (as suggested by several related works) or applying a code reuse dataset such as SOCO.

The SOCO dataset contains training and testing data written in C++ and Java. The training set in C++ included 79 files with 26 reuse cases, while there were 259 files with 84 reuse cases written in Java. For the testing set, in C++, there were 19,895 files with 322 reuse cases, while in Java, there were 12,080 files with 222 reuse cases. There were six different scenarios per language, labelled A1, A2, B1, B2, C1, and C2.

There were a few assumptions in this dataset. First, the reuse occurred within the same programming language, therefore multi-programming reuse was not covered. Second, reuse occurred in the same scenario without overlapping the testing set. One challenge in the SOCO dataset was that the training set was smaller than the testing set. Another challenge was that the testing data were severely imbalanced, while the training set was less imbalanced.

3.2 Data Pre-processing and Encoding

The source code was written in different files and had to be arranged into a suitable data structure. Then, the code needed to be converted into a clean format that could be fed into a classifier that accepts only numbers. Embeddings are vector representations of source code that can be created with pre-trained models. The embeddings are created using Sentence Transformers (Reimers and Gurevych, 2019) with mean pooling.

3.2.1 Selection of Source Code Pre-Trained Models

Multiple surveys have been written for CodePTMs as in (Niu et al., 2022, 2023; Zeng et al., 2022; Xu and Zhu, 2022). CodePTMs are models trained on a large corpus of code.

The suitable models in this work would be selected based on the following criteria.

- The model should be accessible and could be found in Huggingface[1] for ease of use. The models available in Huggingface are CodeBert (Feng et al., 2020), GraphCodeBert (Guo et al., 2020), UnixCoder (Guo et al., 2022), CodeT5 (Wang et al., 2021), CodeGPT (Lu et al., 2021), PLBART (Ahmad et al., 2021), and CodeBERTa (Wolf et al., 2019).

- The model should pass a simple test. It will be given a pair of totally different source codes. For instance, the first Java program prints 'Hello World' and the other contains a function that calculates the average of two numbers. Then, the similarity of the generated embeddings will be calculated. If the score is above 0.8, it would not be used. Otherwise, the model passes this test. As these two programs are totally different, the similarity score should be low. If it is high, then the source code is not represented adequately. For example, the model GraphCodeBert generates a similarity score of 0.94 if given this pair of code fragments. Further experiments on this test results can be seen in Table 1.

Pre-Trained Model	**Similarity Score**
PLBART	0.0257
Unixcoder	0.2988
CodeBERTa	0.7868
CodeGPT	0.8899
GraphCodeBert	0.9442
CodeBert	0.9918

Table 1: Cosine Similarity Scores

The three pre-trained models that yielded acceptable similarity scores were UnixCoder, PLBART and CodeBERTa. Each of these captures different aspects of source codes, as UniXcoder considers AST and code comments in addition to the source code, while PLBART captures the style and data flow. The similarity being referred to is the cosine similarity which will be explained in the following subsection.

3.3 Similarity Measure and Feature Selection

Cosine similarity is a common measurement of similarity used in NLP. It represents the angle between two vectors, and the angle (θ) is equal to the dot product of the two vectors (A and B) over the product of their norms, as shown in Equation 1. The higher the similarity score, the more similar the vectors are.

$$Cosine\ Similarity = cos(\theta) = \frac{A.B}{||A||.||B||} \quad (1)$$

The three features of the model would be the cosine similarity scores between the three generated embeddings per source code. Using each model embeddings separately achieved acceptable results. However, the combination of the three of them would add more data to train at the expense of complexity. The classifier would figure out which combination of these three features would be better in terms of evaluation.

3.4 Classification Model Selection

The concept of AutoML utilises several algorithms and selects the best-performing models for certain training data automatically. The main reason behind using AutoML in this work is to reduce time consumption. The testing dataset is large and testing different classifiers and comparing them would take a substantial amount of time. Thus, AutoML would search for the most appropriate classifier in less time. The library selected for this work is AutoSklearn (Feurer et al., 2015, 2022) which chooses the leading algorithm given specific training data and certain time intervals. AutoSkLearn handles both the model selection and parameter tuning. There are other AutoML libraries surveyed by Elshawi et al. (Elshawi et al., 2019). AutoSklearn is selected for its familiar syntax to Sklearn[2] and simplicity.

The inputs of the classifiers were the three cosine similarity values between three different CodePTM embeddings. The parameters configured for AutoSklearn were the duration of 30 minutes with 10-fold cross-validation. The best classification model selected for Java with the configured parameters and Java training set was extra trees, while for C/C++, the best classification model selected was gradient boosting. These two classifiers are relevant in this task as both of them are ensemble

[1] https://huggingface.co/

[2] https://scikit-learn.org/

techniques based on decision trees. They perform well in case of imbalanced data as in the SOCO dataset. Also, both methods are known for their high performance in Kaggle[3] competitions. Ensemble methods are known for potential lower loss and less over-fitting.

For testing, the similarity scores are fed to the selected algorithms to create prediction probabilities that are compared to a dynamic threshold determining whether the files are plagiarised or not. Once pairs of plagiarism files are available, the models are evaluated per the next subsection.

3.5 Evaluation

Classification could be evaluated with several metrics (Joshi, 2020). The fundamental metrics were true positive (TP), false positive (FP), true negative (TN), and false negative (FN). TP is to predict the positive value correctly, and FP is to mispredict a positive value. FN is to mispredict a negative value, while TN correctly predicts a negative value. Applied to plagiarism, positive could indicate that plagiarism was found, and negative could indicate that plagiarism was not found. Some other metrics that use TP, FP, and FN in their calculation are as follows: precision, recall, and F1 score, as presented in equations 2, 3, 3, respectively (Joshi, 2020).

$$precision = \frac{TP}{TP + FP} \tag{2}$$

$$recall = \frac{TP}{TP + FN} \tag{3}$$

$$f1score = 2 * \frac{precision * recall}{precision + recall} \tag{4}$$

Furthermore, for the SOCO dataset evaluation (Flores et al., 2014), these three metrics, namely recall, precision, and F1 score, were utilized as a part of the model's standard evaluation, while for the ranking of the model, only the F1 score was used.

The detailed technical methodology illustrated in this section is represented in Figure 1. Following are the simplified summarized steps.

1. Extracting contextualised embeddings using three different CodePTMs using sentence transformers with mean pooling.
2. Calculating the cosine similarity scores between pair of embeddings of the source codes. These scores form the input to the automated machine-learning process.
3. Selecting the leading classifier using AutoML during the training phase.
4. Generating the prediction probabilities with the selected classifier.
5. Decision-making based on whether the probabilities are larger than a dynamic threshold.
6. Evaluating the model and calculating the classification accuracy metrics including the F1 score.

4 Results

4.1 Results and Discussion

The results of the Java scenarios are presented in Table 2. For the scenario of C2 of identical plagiarism files, the metrics values were 1. Scenarios B1 and B2 produced high metric values, but for scenarios A1 and A2, the scores are lower as the file sizes and number of files are high.

Parameter	F1	Precision	Recall
C2	1	1	1
B1	0.724	0.977	0.957
B2	0.772	0.957	0.647
A1	0.643	0.9	0.5
A2	0.623	0.8	0.511

Table 2: Java metrics

The results of the C/C++ scenarios are presented in Table 3. For C1, the scores were high. While for other scenarios, the metrics were similar, falling in a similar range.

Parameter	F1	Precision	Recall
C1	0.8	0.857	0.75
B1	0.458	0.4	0.535
B2	0.473	0.44	0.512
A1	0.521	0.491	0.556
A2	0.47	0.389	0.593

Table 3: C/C++ evaluation metrics

The overall results of the Java files are represented in Table 4. For the proposed work, the F1 score was 0.69, the precision was 0.908, and the

[3] https://www.kaggle.com/

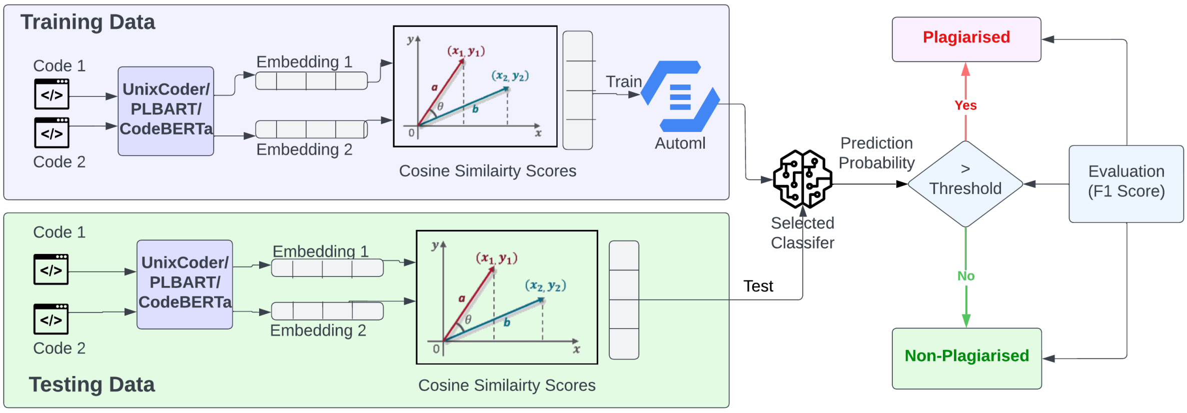

Figure 1: Detailed Methodology

recall was 0.559. For the F1 score, the minimum score was 0.031, the average was 0.54, and the maximum was 0.855. For the precision score, the minimum score was 0.016, the average score was 0.46, and the maximum score was 0.951. For the recall, the minimum score was 0.293, the average was 0.882, and the maximum score was 1. In our approach, the precision and F1 scores were between the average and the maximum values. The recall value was lower than the average value. The approach exceeded both baselines and ranked approximately third after Shiraz and UAM-C alongside DCU, LM_AST and FLM_AST in terms of F1 score and ranked second after Shiraz in terms of precision. The high value of precision indicates having fewer false positives, which means non-plagiarized cases are not detected as plagiarized. As the task of plagiarism is sensitive, then higher precision is more suitable. The lower value of recall means that some actual plagiarism cases were not detected. The main reason is due to having severely imbalanced data which can be fixed in future work. Therefore, the results related to the Java dataset were average to high.

The overall results of the C/C++ files can be seen in Table 5. The F1 score of our work was around 0.493, the precision was 0.443, and the recall was 0.561. For the F1 score, the minimum score was 0.01, the average was 0.2, and the maximum was 0.38. For the precision score, the minimum score was 0.005, the average score was 0.192, and the maximum score was 0.35. For the recall, the minimum score was 0.13, the average was 0.59, and the maximum score was 1. The approach taken in this work yielded the highest F1 and precision scores and outperformed both baselines. Recall was around the average values. Therefore, the results on the C/C++ dataset were competitive.

Table 4: Comparison with SOCO Java related works

The F1 score in C/C++ is lower than in Java (0.493 compared to 0.69) but compared to other works it is high. This is due to Java having more training data and a higher κ value than C/C++ which implies that the Java training set is more representative (Flores et al., 2014). The main limitation of this approach is the maximum input length to the pre-trained models, which is 512. If the input is larger than 512, it would be truncated. So, for larger files, the end of the files may not be captured. Therefore, if plagiarism occurs at the end of the

code files, it would not be captured.

The usage of contextual embeddings generated by CodePTMs is efficient in the task of source code plagiarism detection producing highly competitive results in the SOCO dataset.

5 Conclusion

Plagiarism in programming assignments is a critical issue in the field of computer science education. It can be treated as a machine learning binary classification problem. So, this research introduced a simple yet effective approach to the task of source code plagiarism detection. It started by selecting the open-source SOCO dataset with two PLs (Java and C/C++). Source code files were converted to embeddings to be part of any machine learning classifier. Three different CodePTMs (PLBART, UnixCoder, and CodeBERTa) were used to generate their own embeddings. Cosine similarity scores between these three models were calculated and considered to be the selected features. The classification models were selected using the concept of AutoML and the library AutoSklearn. The initial testing was conducted on Java, and the proposed model produced high metrics as compared to other approaches and exceeded both baselines. For C/C++, the model produced the highest F1 and precision scores as compared to other approaches and outperformed both baselines.

Exploring other CodePTMs that are not available on HuggingFace for source code plagiarism detection is an idea for future work, along with increasing the training time for AutoSklearn. The dataset is severely imbalanced, hence, different techniques could be used to tackle such issues. Also, chunking can be used to overcome the limited input size of the pre-trained models.

Abstract

Identifying semantic argument types in predication contexts is not a straightforward task for several reasons, such as inherent polysemy, coercion, and copredication phenomena. In this paper, we train monolingual and multilingual classifiers with a zero-shot cross-lingual approach to identify semantic argument types in predications using pre-trained language models as feature extractors. We train classifiers for different semantic argument types and for both verbal and adjectival predications. Furthermore, we propose a method to detect copredication using these classifiers through identifying the argument semantic type targeted in different predications over the same noun in a sentence. We evaluate the performance of the method on copredication test data with Food•Event nouns for 5 languages.

1 Introduction

This paper is concerned with the question of how to automatically decide which semantic type is targeted in predications over nouns. In our case, the predicate can be a verb or an adjective. This question is particularly interesting in cases where complex type nouns[1] are arguments of predications. But even with nouns that, lexically, have only a single type, the predication can target a different type and thereby trigger a coercion in the noun (Pustejovsky, 1991). Examples are given in (1). In both (1-a) as well as (1-b), the respective predicates target one of the two types of a complex type noun (a *dinner* is inherently both an Event and a Food item). In (1-c), the noun is a simple type noun (*soup* is only of type Food), and its type is targeted in the predication. The predication in (1-d) involves a coercion since it targets a type that is different from the lexical type of the noun. Finally, for complex type nouns, we can have cases where different component types of the same noun are targeted, either by different predicates as in (1-e) or by a single predicate as in (1-f) where *book* is a physical object and an informational content at the same time and the predicate targets both. The first case is an instance of copredication (see below).

(1) a. They chose the *vegetarian dinner*.
→ (target: *Food*)
b. I *organized* a *dinner* for them.
→ (target: *Event*)
c. I *ate* my *soup*.
→ (target: *Food*)
d. I *finished* my *soup*.
→ (target: *Event*, coercion)
e. They *organized* a *vegetarian dinner*.
→ (target: *Event* and *Food*)
f. He *wrote* a lot of *books*.
→ (target: *Phys_Obj•Information*)

Our main goal is to develop classifiers that, given a predicate and an argument noun in their sentential context, decide whether a specific type has been targeted. Furthermore, we exploit the cross-lingual transfer potential of multilingual *pre-trained language models* (LMs) in order to apply this task to different languages without the need of labelled data for all of them.

One interesting application of such classifiers is the detection of instances of copredication with complex type nouns. Copredication is a general term defining a "grammatical construction in which two predicates jointly apply to the same argument" (Asher, 2011, p. 11). We are interested in a specific type of copredication where two predicates that require different semantic types apply to the same noun (Pustejovsky, 1995; Pustejovsky and Jezek, 2008; Asher, 2011). For example, given the occur-

[1] Also "dot object" nouns (Pustejovsky, 1995), "nouns with facets" (Cruse, 1995), "dual aspect nouns" (Asher, 2011) in the literature.

Proceedings of Recent Advances in Natural Language Processing, pages 310–320

rence of a complex type noun such as *dinner* in a sentence where we have two (or more) predications over that noun, we want to decide whether these predications target different types, as for instance in (1-e). We will apply the classifiers developed in this paper to this task, using the complex type *Food•Event* as a test case.

We start by investigating whether it is possible to train classifiers for both verbal and adjectival predications for this purpose using LMs (BERT (Devlin et al., 2019), mBERT (Devlin et al., 2019), XLM-RoBERTa (Conneau et al., 2020a)) as feature extractors. In addition, we investigate whether it is possible to train multilingual classifiers with a zero-shot cross-lingual approach by training the classifiers on one language with the extracted embeddings of multilingual language models and applying them to other languages.

We train monolingual classifiers for Italian using the extracted embeddings of a monolingual BERT model[2] and the multilingual ones using the embeddings of the multilingual models mBERT and XLM-RoBERTa. We start with Italian as our source language due to the availability of annotated data in the T-PAS (Typed Predicate Argument Structures) resource (Jezek et al., 2014). We train classifiers for verbal predications for the semantic types *Human, Information, Event, Artifact,* and *Location* and adjectival predications for the semantic types *Event, Artifact,* and *Information*. The selection of these types is intended to capture the diversity of the semantic type hierarchy.

Finally, we apply the verbal and adjectival classifiers for *Artifact*[3] and *Event* semantic types to the sentences containing *Food•Event* nouns in order to detect certain copredication patterns, as in (1-e), in which a verb and an adjective predicate over the same noun. We evaluate the proposed model on test data for a set of typologically diverse languages; Chinese, English, German, Italian, and Turkish.[4]

2 Related Work

2.1 Selectional Preference and Semantic Type Knowledge of LMs

There is no study to our knowledge that aims at exploiting LMs for a selectional preference task, nor that investigates the transferability of selectional preference knowledge to other languages using multilingual LMs. However, there are studies that investigate the LMs' knowledge about selectional preferences of verbs and semantic types. Their findings suggest that contextual language models encode information about the selectional preferences of verbs (Metheniti et al., 2020; Chersoni et al., 2021; Li et al., 2021; Pedinotti et al., 2021) and the semantic type of the nouns in general (Zhao et al., 2020). Similar to our study, Zhao et al. (2020) and Chersoni et al. (2021) trained classifiers using the extracted representations of the BERT model for their tasks and these classifiers achieved high accuracy scores.

2.2 Zero-Shot Cross-Lingual Transfer using multilingual LMs

Several studies have investigated the performance of multilingual LMs for zero-shot cross-lingual transfer on a variety of tasks, e.g. NER, POS, NLI, QA. They show that these models are effective for this purpose (Pires et al., 2019; Conneau et al., 2020a; Wu and Dredze, 2020; Aghazadeh et al., 2022). It is also shown that these models perform well on multilingual benchmarks such as XTREME (Hu et al., 2020) and XGLUE (Liang et al., 2020). Additionally, these papers show that XLM-RoBERTa performs better than mBERT (Conneau et al., 2020a; Hu et al., 2020; Liang et al., 2020; Lauscher et al., 2020).

Recent research has also investigated the effects of language differences in cross-lingual transfer. It has been shown that structural similarity, such as word order or typological similarity affects the transfer (Pires et al., 2019; Conneau et al., 2020b; K et al., 2020; Lauscher et al., 2020; Deshpande et al., 2022). The difference in the language script is also shown to be important, but only when the word order differs as well (Pires et al., 2019; Deshpande et al., 2022).

2.3 Copredication Detection

Jezek and Vieu (2014) adopt a semi-automatic approach for extracting copredications of *Physical_Object•Information* nouns with a verb and an adjective in Italian. First, they manually select a list of predicates for both semantic types: Physical Object and Information. Then, they construct copredication contexts with different predicate combinations and extract examples by searching the corpus for these contexts. As an extension to the

[2] See Appendix A for information about the models, parameters and libraries used for the experiments.

[3] Artifact is the supertype of Food in the T-PAS semantic type hierarchy.

[4] Datasets and code are available at: `https://github.com/yavasde/predication-classification`

previous study, Vieu et al. (2015) use a latent semantic distributional model in order to select the predicates to avoid the manual process of predicate selection. Compared to these studies, our method is automatic and does not rely on the classification of each predicate, which can be problematic due to their polysemous nature, but relies on the classification of each predication instance. This also allows using this method cross-linguistically without knowledge specific to each language.

3 Method

3.1 Predication Classifiers

We first show that it is possible to train a classifier for the identification of the semantic argument type targeted by a predicate in a specific predication context using the extracted representations of LMs. Furthermore, we aim to investigate whether this knowledge is transferable from one language to another with a zero-shot cross-lingual approach by training classifiers on the source language using the multilingual representations of the multilingual LMs and applying the trained models to the target languages.

For all semantic types and predication types, we use LMs as feature extractors and train monolingual and multilingual classifiers with the SVM algorithm using the extracted embeddings of the models.[5] For monolingual Italian classifiers, we use a BERT model for Italian and for multilingual classifiers, we use the multilingual LMs mBERT and XLM-RoBERTa. We train binary classifiers for each of the semantic types *Artifact, Event, Human, Information* and *Location* for verbal predications and *Artifact, Event,* and *Information* for adjectival predications.[6]

We use the contextualized embeddings of the predicate and the argument in a specific sentence as input for the classifiers. First, we tokenize each sentence with the model tokenizer and give the tokenized sentence as input to the model. Then, we extract the embeddings of the predicate (verb/adj) and the argument (direct object/noun) from the last 4 layers of the model output and average them to create one representation for each item.[7] We use only the last 4 layers because higher layers are more specialized in semantics-related tasks (Liu et al., 2019; Tenney et al., 2019; Zhao et al., 2020). We formalize the task as a relation classification problem where we classify the relation between the predicate and its argument. For this purpose, we concatenate the embeddings of the predicate and the argument and use the final embedding as the input for the classifiers.[8]

3.2 Copredication Detection

In order to detect copredication, the classifiers are applied to the sentences with complex type nouns, where both syntactic types of predications are available for the same noun. First, sentences are parsed using the Stanza library (Qi et al., 2020) in order to identify the predications in sentences. Then, the embeddings of the predicate-argument pairs are extracted from the LM, concatenated and given to the relevant classifiers (verb/adj). Copredication is considered detected if both verbal and adjectival predication classifiers of different semantic types classify the predications as positive.

4 Training Classifiers

4.1 Data

4.1.1 Verbal Predication Classifiers

Training data. We use T-PAS (Typed Predicate Argument Structures; Jezek et al., 2014) as our primary resource. T-PAS provides corpus-derived argument structure patterns for Italian verbs with manually annotated semantic argument types; e.g [Human] mangiare [Food] (*Eng.: [Human] eat [Food]*). Each verb pattern has matching corpus instances extracted from the itWac corpus (Baroni et al., 2009).

In T-PAS, semantic types are organized in a hierarchy. For each semantic type (*Human, Event, Information, Artifact, Location*), we extract sentences whose verbs take direct objects with the target semantic type or a subtype of it.

The training negatives are also selected from T-PAS from the semantic types other than the target semantic type's supertypes, subtypes, or the semantic type itself. The negatives are downsized to make their size equal to the positive samples.

[5] Even though we tested several classification algorithms, we used SVM for the final experiments because it performed best. See Appendix B for the detailed comparison.

[6] We use binary classifiers instead of a multiclass one because there are predicates that can target both semantic types as in example (1-f).

[7] In the cases in which the target words are tokenized into subwords by the model tokenizer, only the first subword is taken into account.

[8] Fine-tuning is the most standard way to use LMs for token or sentence classification but it is not that straightforward to fine-tune the models for relation classification.

Table 1: The data size and the test results of each classifier. F1 scores are given. The results of the cross-linguistically best-performing classifiers are given in bold. *T-PAS+CT* results are given in parentheses.

To this end, the sentences are clustered with K-Means algorithm using the Scikit-learn library and an equal number of sentences are selected from each cluster. This undersampling method is chosen to have a balanced representation of the negatives.

The selected sentences for both positives and negatives are parsed with the spacy-udpipe Python library[9] in order to identify and annotate the verb and the direct object in each sentence.[10]

Cross-lingual test data. The test data is selected by splitting the data (test size %33) extracted from T-PAS. The data are then machine translated using DeepL API[11] to the other languages.

It is required that the verbs and objects are correctly identified in the translations. For this purpose, they are translated out-of-context and searched for in the sentences. Additionally, the translations are parsed using the Stanza library and all the verb-object pairs in the sentences are extracted through their dependency labels in order to find the correct pairs. However, sometimes, the pairs are not found automatically, in which case they are manually annotated.

In a final step, all translated sentences are manually checked and corrected by (near-)native speakers of the respective languages following the guideline presented in Appendix C. Sentences that can not be corrected are eliminated. Equal numbers of negatives and positives are selected for each dataset. The resulting data numbers for each language are given in Table 1.

4.1.2 Adjectival Predication Classifiers

Training data. The training data for the adjectival predication classifiers are generated using *Masked Language Modeling* (MLM) with BERT due to the unavailability of annotated data. We generate data for 3 semantic types *Artifact, Event* and *Information* using the verbal predication datasets for these types as the basis. We insert an adjective that is predicted by the model into the sentences in order to modify the direct object. The assumption is that in sentences where the verbal predication over the objects targets a certain type, the adjectives predicted by the model with a high probability score will do so as well.

First, a mask is inserted after the noun, and then the Italian BERT is made to predict a word instead of the mask. Only word predictions over a certain confidence score (0.15) are selected from the model predictions. For the final step, the predicted word is inserted in place of the mask and the resulting sentence is parsed with the spaCy library[12] to check

[9] Available at: https://spacy.io/universe/project/spacy-udpipe

[10] Sentence-level annotations are not provided in T-PAS.

[11] Available at: https://www.deepl.com/

[12] Available at: https://spacy.io/

if the relation between the noun and the predicted word is the desired one (*adjectival modification*). The sentences that meet these conditions are used for the training of the classifiers.[13]

Cross-lingual test data. Since the adjective data is generated, we do not test the performance of the classifiers on this data but on manually constructed data for Italian and English.

The test data for Italian are created by extracting corpus instances from the itWac corpus, identified through a concordance search for the most typical 5-10 lexical items that express each type in corpus instances and their respective most frequent adjective modifiers. The sentences are extracted for 3 semantic types (*Artifact, Event* and *Information*) and the negatives of the test data are selected from the sentences of the other 2 semantic types.

The test data for English are also constructed by extracting corpus examples. First, good representatives of each semantic type noun are selected based on their occurrence in the T-PAS data; these are the nouns that only occur in the target semantic type data and occur more than once. As the next step, we translate the selected nouns to English and extract sentences with these nouns from the ukWac corpus (Baroni et al., 2009) but only consider the ones where the noun is the direct object of a verb and also have a token size between 3 and 20. We parse the sentences using the Stanza library and select the ones where there is an adjective that modifies the noun. Finally, we manually select the sentences with good examples of adjectives. The semantic types are the same as for Italian and the negatives are constructed similarly.

Both the test and training data are balanced in terms of the number of positives and negatives. The data size for adjectival predication classifiers can be seen in Table 1.

4.2 Experiments and Results

We test the monolingual classifiers on Italian test data ('B' for monolingual Italian BERT based classifiers) and the multilingual classifiers on the cross-lingual test data ('XR' for XLM-RoBERTa and 'mB' for mBERT based classifiers). F1 score is used as the metric and cross-lingual performance is evaluated by comparing the average f1 score on cross-lingual test data, see Table 1 for the results. The detailed results with precision and recall scores can be found in the Appendix D. A language-specific evaluation is given in Appendix E.

Overall results. The monolingual classifiers perform very well on the task. Each monolingual verbal predication classifier achieves over 0.92 f1 score and each monolingual adjectival predication classifier achieves over 0.84 f1 score. Similarly, all multilingual verbal predication classifiers achieve over 0.85 average f1 scores for all languages and all multilingual adjectival predication classifiers achieve over 0.81 average f1 scores for English and Italian. Overall, XR-classifiers perform better than mB-classifiers (See Table 1).

Monolingual vs. multilingual. The comparison of the monolingual and multilingual classifiers' performances on Italian test data shows that on average, the monolingual classifiers perform better than the multilingual ones on the source language test data. However, for some semantic types, such as *Human* (verb) and *Artifact* (adj), XR-classifiers perform better than the monolingual classifiers. (See Table 1 for the individual results and Figure 1 for the average for verbs.)

Verbal vs. adjectival predications. Overall, the performance of the verbal predication classifiers is better than the adjectival predication classifiers. Contrary to verbal predication classifiers, mB-classifiers perform better than XR-classifiers for adjectives overall. However, the performance difference is smaller.

5 Copredication Detection

5.1 Classifiers for Complex Type Nouns

Even though T-PAS is not necessarily a resource with simple type nouns, the number of sentences with Food•Event nouns is low in our datasets.[14] Since our task is to detect copredication with complex type nouns, we require classifiers that can disambiguate the meanings of these nouns.

In order to address this, we add, to each classifier's training data, additional data with complex type nouns, in which only one type of the noun is targeted; Food or Event as in (1-a) and (1-b). We add the additional data to the training data of Artifact and Event classifiers for both verbs and adjectives. The original classifiers will be referred to as 'T-PAS' and the latter as 'T-PAS+CT'.

[13] The original adjectives in the sentences are replaced by model-predicted ones, in order to avoid copredication instances in the training data.

[14] There are 2 sentences in the Artifact and 3 in the Event dataset.

Training data with complex type nouns. Additional training is obtained by extracting the sentences of Food•Event nouns with Food or Event predications from corpus. First, we determine the best predicates for each type of predication; best food verbs, event adjectives, etc. For this, we use our datasets. We extract the predicates from each semantic type dataset (Artifact and Event) and select the predicates that occur more than once and that only occur in the target semantic type dataset. In the second step, we select 9 Food•Event nouns (see Appendix F for the selected nouns) and we extract the sentences of these nouns with the selected predicates from the itWac corpus. Finally, we add the complex type sentences both to the positives and negatives of Artifact and Event training data for verbs and adjectives with the amount of 20%.

Training results. The performance of the T-PAS+CT classifiers on the test data can be seen in Table 1. Their performance is close to the T-PAS classifiers overall, with some slight differences for some semantic types and languages.

5.2 Evaluation

We apply both semantic type classifiers (Artifact and Event) to classify the verbal and adjectival predications in the sentences of the test data. We investigate how often copredication is detected both in the positives and negatives of the test data. However, we do not consider the correct classification of individual predications in this evaluation method. We use an additional evaluation method to investigate how often the predications are identified correctly.

We test both T-PAS and T-PAS+CT classifiers on the cross-lingual copredication test data comprising 5 languages; Chinese, English, German, Italian, and Turkish. We use monolingual classifiers for Italian and XR-classifiers for other languages since they performed better on single predication classification overall.

Additionally, we investigate the effects of the complex type nouns on copredication detection. We do that by comparing the performance of the method on two types of negatives: negatives with simple type nouns and complex type nouns.

5.2.1 Evaluation Data

The test data is manually created for Italian and machine translated into Chinese, English, German, and Turkish. The translations are manually corrected by (near-)native speakers of the respective languages. A similar correction procedure is applied to the test data, following the data correction guidelines in Appendix C.

Lang.	Classifier	Scores		
		Sens.	Spec.	g
it	T-PAS	0.66	0.35 (0.79)	0.48
	T-PAS+CT	0.46	0.62 (0.87)	**0.53**
de	T-PAS	0.66	0.25 (0.83)	0.40
	T-PAS+CT	0.53	0.58 (0.91)	**0.55**
en	T-PAS	0.83	0.29 (0.79)	0.49
	T-PAS+CT	0.70	0.66 (0.83)	**0.67**
tr	T-PAS	0.76	0.25 (0.75)	0.43
	T-PAS+CT	0.53	0.45 (0.87)	**0.48**
zh	T-PAS	0.82	0.59 (0.83)	**0.69**
	T-PAS+CT	0.68	0.65 (0.83)	0.66
Random Baseline		*0.25*	*0.25*	*0.25*

Table 2: Performance on the cross-lingual copredication test data. g stands for the geometric mean of specificity and sensitivity. The results of the classifiers with the best overall performance are given in bold. The specificity scores in the parenthesis refer to the specificity over simple type nouns.

The test data contains 30 positive and 24 negative examples of copredication with different semantic types (for more details, see Appendix G). In the positives, verbs and adjectives target different types of Food•Event nouns, whereas in the negatives, both predicates target the same type of Food•Event nouns (either Event or Food). An example of positives is given in (1-e), where the verb 'organize' targets the Event type and the adjective 'vegetarian' targets the Food type. As an example of the negatives, in (2-a), both the verb 'eat' and the adjective 'cold' target the Food type.

We prepare additional data for negatives with simple type nouns. We do this by substituting the Food•Event nouns in the negatives with a Food or Event simple type noun as in (2-b) (see Appendix G for more details).

(2) a. It's depressing to *eat* a *cold lunch*.
    b. It's depressing to *eat* a *cold soup*.

5.2.2 Results

We evaluate the results using three metrics; *sensitivity* (recall), to measure the ability to detect the positives and *specificity*, to measure the ability to detect the negatives, and finally, the geometric mean of sensitivity and specificity, for the overall performance. The results can be seen in Table 2.

Overall. T-PAS classifiers achieve higher sensitivity scores compared to specificity scores for all languages. Even though the sensitivity scores achieve

0.80, specificity scores are around the random baseline for most of the languages. The difference between both scores is lower for Chinese and the specificity score is also good. With T-PAS+CT classifiers, there is an increase in specificity scores but also a drop in sensitivity scores for all languages. The scores for sensitivity and specificity are closer to each other. Overall, TPAS+CT classifiers perform better in terms of their overall performance for all languages except for Chinese.

Simple type nouns. The results of specificity scores on different types of negatives show that the low specificity score is much higher in the negatives with complex type nouns compared to the negatives with simple type nouns. The specificity scores increase with T-PAS+CT classifiers also for the second type of negatives however the difference between the two types of classifiers is much lower. For example, the increase for Italian is from 0.79 to 0.87 compared to 0.35 to 0.62.

6 Discussion

The findings of the previous studies suggest that LMs encode information about the selectional preferences of verbs (Metheniti et al., 2020; Chersoni et al., 2021; Li et al., 2021; Pedinotti et al., 2021) and semantic types of nouns (Zhao et al., 2020). Our study shows that it is possible to exploit this knowledge of LMs to train classifiers for the identification of the semantic types targeted by both verbs and adjectives.

From a cross-lingual point of view, our results show that it is possible to use the embeddings of the multilingual LMs to train classifiers in order to transfer knowledge from one language to another. Our results are in line with the previous studies in terms of the performance of individual models. XLM-RoBERTa yields better performance compared to other multilingual LMs (Conneau et al., 2020a; Hu et al., 2020; Liang et al., 2020; Lauscher et al., 2020) and its performance is comparable to monolingual models (Conneau et al., 2020a). Even though we have limited test data for adjectival predication classifiers, we expect the transfer to work similarly for both types of predications (verbal and adjectival) and the results for English show this is the case.

In the copredication detection task, our results show that classifiers that are trained only with data with simple type nouns are not able to disambiguate the meanings of complex type nouns. This is evident in the tendency of false positives (low specificity) with T-PAS classifiers. Even when both predications target the same semantic type in a sentence, i.e. in negatives, copredication is detected. This is because both semantic type classifiers tend to classify the predications as positive when a complex type noun is involved. However, this tendency is absent with simple type nouns, which is also evident in the specificity scores. We think that this tendency is due to the nature of complex type nouns and how they are represented by LMs, which is a topic we intend to investigate in the future. The false positive tendency is overcome by adding more data with complex type nouns and this improves the overall performance which shows that copredication detection is possible with the proposed model.

Cross-linguistically, the performance on copredication detection shows a similar pattern for all languages and for both monolingual and multilingual classifiers. In the future, we plan to use this method for building a cross-lingual collection of corpus-based copredication instances that includes also other complex types and copredication constructions.

7 Conclusion

In this study, we focused on training classifiers for the identification of the semantic argument types targeted by the predicates in a specific predication context using the extracted embeddings of LMs. We trained both monolingual and multilingual classifiers for different semantic types and for both verbal and adjectival predications. The training results for individual classifiers show that it is possible to train classifiers for this purpose using LMs and to train multilingual classifiers with zero-shot cross-lingual transfer using multilingual LMs . Furthermore, we proposed a method to detect copredications using these classifiers and evaluated the method's performance on cross-lingual copredication test data. Our results show that copredication detection is a more complicated task. However, the method achieves reasonable scores for all languages and good scores for English.

Acknowledgments

This study is a part of the project "Coercion and Copredication as Flexible Frame Composition" funded by DFG (Deutsche Forschungsgemeinschaft). We would like to thank Younes Samih for his invaluable insights and feedback.

A Models, Parameters and Libraries Used for the Experiments

The embeddings are extracted using the Transformers library (Wolf et al., 2020). The classifiers are trained using the Scikit-learn library (Pedregosa et al., 2011). The Scikit-learn library is also used for the clustering of the negative dataset.

For the SVM algorithm, the radial basis function kernel is used with a C value of 100 and a gamma value of 0.001. K-Means is used as the clustering algorithm for the negative dataset, and the number of clusters (k) is determined as 10.

We use the BERT model *dbmdz/bert-base-italian-base-cased* as feature extractor for monolingual Italian classifiers and multilingual LMs mBERT *bert-base-multilingual-cased* and XLM-RoBERTa *xlm-roberta-base* for multilingual classifiers. All models are available at `https://huggingface.co/`.

B Comparison of Classification Algorithms

The performance of several classification algorithms (*Logistic Regression, Naive Bayes, Random Forest, Support Vector Machine*) is compared for

Table 4: Performance of different classification algorithms on Italian verbal predication test data. Best performing classifiers for each semantic type are given in bold.

the monolingual verbal predication classification task. See Table 4 for the f1 scores of the classifiers trained with different algorithms. Overall, SVM is the best performing one.

C Data Correction Guideline

Please, follow these points for the manual correction of the translated test data:

- If the verb and the object are not identified correctly, they should be annotated manually.
- The sentences should be corrected if they sound unnatural or the predicate does not target the desired semantic type.
- For the correction, the sentences can be changed or the verb and the noun can be changed.
- The noun should be the object of the verb. If the verb takes a prepositional phrase instead, it should be changed with another verb.
- If any of the target words is a *multi-word expression*, the headword should be considered as the target word.
- If the sentence is passivized in translation, it should be turned into an active one.

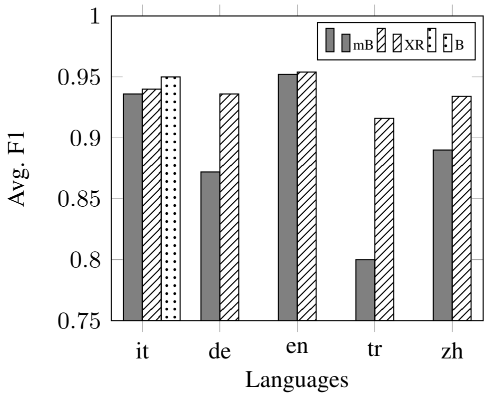

Figure 1: The average f1 score of different model-based classifiers on each language for verbal predication.

D Detailed Test Results

See Table 3 for the precision and recall scores of each classifier.

E Language-Specific Evaluation

The performance of the multilingual classifiers for verbal predication changes depending on the target language (See Figure 1). Similar to the studies that investigate the effects of structural differences of languages on cross-lingual transfer (Pires et al., 2019; K et al., 2020; Conneau et al., 2020b; Lauscher et al., 2020; Deshpande et al., 2022), our results show that the performance of the XR-classifiers on the typologically more distant languages Turkish and Chinese is worse. Similarly, the mB-classifiers perform worse on Turkish. We don't think the quality of the translations is the reason since native speakers manually checked the translations of these languages. However, even the worst performance is still good with over 0.8 f1 score.

The classifiers perform best on English test data, which is not the source language. One possible reason is that the Italian test data was not manually corrected, in contrast to the target languages. For this reason, the test data for the source language may contain more noise due to, e.g. parsing errors.

Even though XLM-RoBERTa improves the results for all languages, we see that the improvement changes depending on the language. One possible explanation is the larger size of training data for the XLM-RoBERTa model for these languages compared to mBERT.

F Food•Event Nouns

pranzo ('lunch'), *cena* ('dinner'), *colazione* ('breakfast'), *merenda* ('snack'), *aperitivo* ('aperitif'), *buffet* ('buffet'), *picnic* ('picnic'), *pasto* ('meal'), *spuntino* ('snack')

G Data Information for Copredication Test Data

The test data contains 30 positive and 24 negative examples of copredication with different semantic types targeting a Food•Event noun. There are both *Food verb-Event adj* and *Event verb-Food adj* combinations in the positives. Similarly, there are both *Food verb-Food adj* and *Event verb-Event adj* combinations in the negatives. The distributions of the types can be seen in Table 4. The cross-lingual copredication test data contains the same number of sentences and distribution for all languages, except for Chinese, which lacks one sentence for *Food verb-Event adj* and one sentence for *Event verb-Event adj.*

Positives	**Negatives**
Total: 30	Total: 24
food-event: 15	*food-food:* 15
event-food: 15	*event-event:* 9

Table 5: Data size and type distribution of copredication test data. The first semantic type refers to the verbal predication and the second one to the adjectival predication, e.g. *food-event*: Food verb-Event adj.

In addition to these data, another type of negative instances is created in order to test the effects of the complex type nouns in copredication detection. This data contains negative instances of copredication with simple type nouns, in which both a verb and an adjective targeting the same semantic type (also the same as the noun's semantic type) predicate over the noun. This type of negative instances are produced by substituting the Food•Event nouns in the negatives with a Food or Event simple type noun. However, in some cases, the sentences are also changed in order to make them more natural. In 24 sentences, 9 sentences are exactly the same except for the noun. However, 10 sentences are changed to some extent, leaving the predicates the same, and 5 sentences are changed completely.

A Review of Research-based Automatic Text Simplification Tools

Abstract

In the age of knowledge, the democratisation of information facilitated through the Internet may not be as pervasive if written language poses challenges to particular sectors of the population. The objective of this paper is to present an overview of research-based automatic text simplification tools. Consequently, we describe aspects such as the language, language phenomena, language levels simplified, approaches, specific target populations these tools are created for (e.g. individuals with cognitive impairment, attention deficit, elderly people, children, language learners), and accessibility and availability considerations. The review of existing studies covering automatic text simplification tools is undergone by searching two databases: Web of Science and Scopus. The eligibility criteria involve text simplification tools with a scientific background in order to ascertain how they operate. This methodology yielded 27 text simplification tools that are further analysed. Some of the main conclusions reached with this review are the lack of resources accessible to the public, the need for customisation to foster the individual's independence by allowing the user to select what s/he finds challenging to understand while not limiting the user's capabilities and the need for more simplification tools in languages other than English, to mention a few.

1 Introduction

In the age of knowledge and information, the democratisation of information facilitated through the Internet may not be as pervasive owing to potential challenges posed by written language, particularly among specific segments of the population. A great deal of the daily life processes are written and may produce lexical, syntactic and/or semantic difficulties in general, but particularly for those most vulnerable, such as people with cognitive disabilities, autism spectrum disorders, non-native speakers, children, and others. The guidelines provided by organisations like the Plain Language Association International (PLAIN)[1] and easy-to-read movement (AENOR, 2018) already highlight both the need for and the promotion of text understandability via the simplification of specific language phenomena. Therefore, enhancing text readability and comprehensibility becomes essential to uphold the right to cognitively accessible texts. Currently, these simplification tasks are laborious and time-consuming as they are conducted manually. Thus, Natural Language Processing (NLP) techniques, particularly Automatic Text Simplification (ATS), are demanded by society to address this issue.

The objective of this paper is to present the existing tools for ATS, paying particular attention to those whose target audience is a specific group of people with special needs. Consequently, an analysis of these tools is conducted to determine the specific languages, language phenomena and linguistic levels they simplify; the approaches followed; their intended target audience (i.e. individuals with cognitive impairment, language difficulties, attention deficit, and others); and other relevant aspects.

This study is framed as part of a larger project, the ClearText project[2], that aims at the creation of a text simplifying tool for the simplification of Spanish texts from the public administration to help people with mild to moderate cognitive impairment. In order to accomplish our goal, a preliminary assessment of the existing ATS tools is required to ascertain the advancements made, methodologies employed, and potential areas for refinement in our own simplification tool.

2 On the Right to Understand

The inherent difficulty in certain written texts has caused society to demand more transparent and accessible texts. This has resulted in several movements, like the plain language movement and the easy-to-read movement.

The plain language movement defends understandable language that ensures the fulfilment of the text's purpose. In fact, Eagleson (1997) even affirms that "[...] it is the writer's responsibility to be clear. It is not the reader's responsibility to understand". As this is not always the case, ATS tools provide citizens with the necessary means to access otherwise unreachable information.

While the plain language movement has the entire society as target audience, the easy-to-read movement is concerned with increasing both the reading and comprehension of texts for those more vulnerable. The individuals that may benefit from easy-to-read materials may be subsumed under two categories: (1) people with disabilities and (2) readers with a limited language proficiency (Nomura et al., 2010). The former category encompasses individuals with conditions such as aphasia, dementia, autism, intellectual disabilities (spanning mild to moderate and profound), neuropsychiatric disabilities (e.g., attention deficit hyperactivity disorder (ADHD)), deafblindness, deafness or hearing impairments (DHH), Asperger syndrome, Tourette syndrome, dyslexia, and other reading difficulties. The latter category comprises non-native speakers, individuals with limited reading abilities, and children.

3 Automatic Text Simplification

Automatic Text Simplification (ATS) can be defined as "a technology to produce adaptable text by reducing their syntactic and lexical complexity so that they become readable for a target user group" (Bott and Saggion, 2012).

3.1 Levels of Simplification According to Language Phenomena

Simplification tools primarily focus on addressing lexical and/or syntactic language phenomena to enhance readability and comprehensibility although, in some cases, stylistic modifications are also employed. According to Chen et al. (2017), ATS is composed of lexical, syntactic and discourse simplification levels.

Lexical simplification entails the identification of complex words i.e. infrequent, technical, abstract and others, and replacing them with simpler, more general, frequent and concrete synonyms. It can also be solved by enriching or enhancing the text by providing a definition, image or video, among others. Implicit in this step is the disambiguation task, which entails selecting the most prevalent meaning among the list of synonyms available. Presently, relying solely on the most frequent sense of a word can engender issues that require further solutions in future ATS research endeavors.

Syntactic simplification involves the reduction of sentence structure complexity i.e. passive constructions, long sentences, appositions, relative clauses. As a result, this process includes sentence structure reordering, splitting, and adjustment, as well as the reduction of grammar complexity and the elision of unnecessary information.

Discourse simplification is concerned with ascertaining that no information is lost in the previous lexical and syntactic simplifications, especially pronouns. Hence, discourse simplification is a step that tackles coreference and coherence aspects, like anaphora resolution, replacing new or repeated entities or making noun phrases more accessible (Todirascu et al., 2022).

Regarding **stylistic simplification** and interface design, in other words, how the textual elements are presented to the user, visual design and layout also affect text readability. Works covering font size and line spacing (Rello et al., 2016), highlighting paragraphs (Kobayashi and Kawashima, 2019), or having whitespace between paragraphs to enhance webpage readability (Yu and Miller, 2010), among others, support this view. Additionally, the guidelines provided by the entities and organisations mentioned in Section 2 also cover stylistic aspects. While we acknowledge that it is not the primary objective of ATS to perform this specific task, we have chosen to include it due to the availability of such stylistic options in certain tools.

3.2 Tool Approaches

As indicated by Al-Thanyyan and Azmi (2021), ATS has followed three different approaches:

(1) A rule-based approach (Siddharthan, 2006) involves a significant amount of handcrafted rules where certain linguistic phenomena are located and replaced. For instance, identifying complex words and replacing them with simpler, shorter, and more frequent synonyms; using active voice instead of passive voice, among others. This represents the conventional approach within ATS for languages lacking extensive parallel corpora comprising original text and its corresponding simplified version.

(2) A data-driven approach, also regarded as corpus-driven approach or machine learning-based approach, like in Zhu et al. (2010) and Kauchak (2013), is characterised by the use of large parallel data resources through the deployment of machine learning or deep learning techniques, such as neural networks and word embeddings. For instance, LexSiS is a lexical simplification algorithm for Spanish (Bott et al., 2012a).

(3) A hybrid approach, combines the previous two, like in Siddharthan and Mandya (2014) and Bott et al. (2012b).

3.3 Target Users

Several ATS projects have been created with the end user in mind, such as the PSET project (Practical Simplification of English Texts) (Carroll et al., 1998), intended for people with aphasia, which later resulted in the HAPPI project (Devlin and Unthank, 2006); the PorSimples Project (Aluisio et al., 2010), for low literacy individuals; the Simplext project (Saggion et al., 2015b) and the Able2Include project (Saggion et al., 2017) for people with intellectual disabilities; and the FIRST project (Valdivia et al., 2014) for people with autism. Although it must be pointed out that some of them do not offer a corresponding simplification tool.

4 Methodology

This tool review was carried out by following a five-step methodology detailed below. A systematic review of studies was undergone by searching two databases: Web of Science[3] and Scopus[4].

Step 0. Research scope definition and eligibility criteria. We are not concerned with an exhaustive analysis of ATS tools but rather with those tools which are (1) ATS tools with (2) a scientific background, in other words, the tool is supported by a research group. Thus, papers dealing with other simplification aspects, i.e. simplification tool metrics, datasets or corpora, tools for automatic assessment of conceptual text complexity, methods, individual parsers, paraphrasing, lexical resources, tools to enhance readability, etc., are not considered.

Step 1. Search method and bibliographic database query. This step entails the initial search of generic terms dealing with ATS until April of 2023. For this purpose, and as we previously mentioned, Scopus and Web of Science were the selected databases we used. The query utilised was "text simplification" AND "tool" for both databases, which yielded 115 papers: all fields included in case of Web of Science produced 31 results and only article title, abstract and keywords in Scopus provided 84 results.

Step 2. Result fine-grain filtering. This step consists of selecting the papers that are within our scope (i.e. papers presenting a simplification tool) and dismissing those beyond our scope. For instance, the paper dealing with the *Alector* parallel corpus (Gala et al., 2020) or *CoCo*, a tool for the assessment of conceptual complexity (Štajner et al., 2020), were discarded. In addition, preliminary studies where the tool is a prototype not yet developed (i.e. the tool is not named and the simplification levels are not explained) were also not taken into account, as for instance the case of Moen et al. (2018) or Kandula et al. (2010). Repeated papers in both databases and tools presented by several papers were considered only once. After this step, 8 papers were selected and 8 tools were obtained.

Step 3. Result checking and recovery. Finally, this step involves the addition of the papers dealing with ATS in general which were dismissed in the previous step because they do not present a simplification tool. Upon closer revision and examination, they mention one or several ATS tools, mainly in the state of the art section. This step added 19 more papers covering 19 tools. Given that these findings double the results of Step 2, we revisited the underlying cause for the absence of those papers in our query results: it is attributable to the omission of the term "tool" in the titles, abstracts or keywords in those papers. Consequently, our method, far from being erroneous, effectively captures and retrieves ATS tools that would have otherwise been overlooked.

Step 4. Tool analysis. In total, 27 tools were selected after this process. The list of selected tools yielded was analysed to determine the following: (1) the language simplified, the language phenomena tackled, the language level simplified and the

[3] https://www.webofscience.com

[4] https://www.scopus.com/

specific domain (if any); (2) the tool's approach; (3) the specific target audience of the tool; and (4) whether or not these tools are accessible and operative at the moment (i.e. the tool includes an interface and allows the text simplification process) and if they are open-source (i.e. made freely available for the rest of researchers).

5 Simplification Tools Review

As mentioned previously in Step 0, commercial tools were discarded. Although some deductions of what these tools are able to do can be ascertained, there is no way to know which operations (i.e. split, replace, reorder, etc.) the text has undergone in the simplification process. Nonetheless, we acknowledge the usefulness of such tools for the general population, regardless of the shortcomings these often might have: character limitation, payment access restrictions and others. As a way of example, some commercial tools that help users in text simplification without any character limitations are *SIMPLISH*[5] and *Rewordify*[6].

Next, we present the tools selected following the previously explained methodology and analyse the language, language levels and domains they simplify, as well as their respective approaches, intended target users, and accessibly and availability considerations.

5.1 Languages, Language Levels Simplified and Specific Domains

Efforts have been made to create monolingual text simplification tools, especially in English, with 12 out of 27 (44.44%) tools analysed being in English (see Table 1). Nevertheless, Romance languages like Spanish, French, Italian or Portuguese are also present. We can observe a lack of multilingual simplification tools, with only two exceptions: *MUSST*, for English, Spanish and Italian, and *Open Book*, for English, Spanish and Bulgarian.

Concerning the language level simplified by these tools, the vast majority (23, 85.19%) perform **lexical simplifications**, with 11 tools exclusively simplifying at this particular level. This is usually carried out by means of providing more frequent or accessible synonyms, but it may also be solved by enriching the text by offering a definition, a link to Wikipedia or similar sources, and audiovisual aids like pictures or videos. These simplifications are implemented by means of dictionaries of synonyms and databases with the most frequent word sense. For instance, *NavegaFácil* provides definitions, synonyms and antonyms, lemmatisations, images, Google search, Wikipedia, translation and text to voice.

Syntactic simplification is implemented in roughly half of the tools analysed (14, 51.85%). The fact that not all the tools simplify at this level undermines the overall quality of the simplified text. Some other tools only simplify at a syntactic level, like *MUSST*, *Split* and *EuTS*. In fact, *EuTS* tackles a superficial syntactic simplification but maintaining the general structure of the original text. In addition, *FACILITA* uses summarisation and simplification techniques and its syntactic simplification consists of sentence splitting, change of discourse markers, passive to active voice, inversion of clause order, SVO order (subject-verb -object) and (de)topicalisation.

Regarding **discourse simplification**, 5 tools (18.52%) tackle issues related to discourse. For instance, *ERNESTA* addresses anaphora resolution combined with syntactic simplification. *HECTOR* adjusts the coreference chains during the syntactic transformations and, in this way, replaces new or repeated entities, specifies entities, makes noun phrases more accessible. And *ArText* includes discourse-based recommendations, like varying discourse markers.

Lastly, **stylistic changes** are undergone by adapting the typography (e.g. font size, font and background colour, and others) to maximise the understanding of the message and minimise the effort made by the reader. Simplification tools that also modify the font and other stylistic-related aspects are *NavegaFácil*, *FRIENDLYREADER* and *DysWebsia*.

If we consider the entire palette of simplification levels (i.e. lexical, syntactic, discursive and stylistic), only *FRIENDLYREADER* covers all of these levels of simplification (3.70%), whereas *ArText*, *HECTOR* and *Open Book* incorporate 3 out of 4 levels (11.11%). The rest of the ATS tools examined either simplify at one level (14, 51.85%) or two levels (9, 33.33%).

With respect to the specific language domain, even though the majority of tools (22, 81.48%) have a generalist approach, there are tools devoted to the medical field (2, 7.41%), such as *Medical*

Table 1: Summary of the simplification tools analysed. In accordance with the column information, the first column includes the tools analysed. The ones that include an asterisk are also plug-ins. The language abbreviations in the third column "AR", "BG", "DA", "EN", "ES", "EU", "FR", "IT", "PT", and "SV" correspond to Arabic, Bulgarian, Danish, English, Spanish, Basque, French, Italian, Portuguese and, Swedish respectively, progressing from top to bottom. The abbreviations dealing with the language levels simplified that appear in the fourth column, "DIS", "LX", "SN", and "ST" stands for "discourse", "lexical", "syntactic", and "stylistic", respectively. The user abbreviations employed in the fifth column are "M" and "S", denoting "multiple" and "specific" correspondingly. Regarding the approaches, "DD", "RB", and "H" stands for data-driven, rule-based, and hybrid, respectively. Only one of the tools, *DysWebsia*, remains unknown. Lastly, in the final column assessing tool accessibility and their open-source code, "I" and "O" represent "inoperative" and "operative" in relation to the tool's access link, while a "+" symbol signifies open-source code.

Text Simplification Tool[7] and *SIMPLE*; for educational purposes (2, 7.41%), like *SALSA* and *Text Adaptation*; or for public administration users (1, 3.70%), such as *ArText*.

5.2 Technical Approach for Simplification

In this section, we analyse the approach taken for text simplification. In general, the automatic simplification process comprises two stages (Cripwell et al., 2023): (1) the simplification plan, which refers to the decision about what linguistic aspect to simplify, for instance, identifying complex words or sentences; and (2) the simplification stage, when the plan to produce the simplified content is applied, e.g., splitting long sentences. It is worth noting that a system may perform these tasks holistically without a clear distinction between stages, as in neural generative models (Ondov et al., 2022).

There are three common approaches to solving tasks at each step (Al-Thanyyan and Azmi, 2021). On the one hand, the **rule-based** approach relies on linguistic expertise that is algorithmised enabling the system to perform the task. One example is *SIMPLIFICA* where a set of rules involving PoS tagging, disambiguation algorithms, and dictionaries of complex words are used for lexical simplification. On the other hand, **data-driven** approaches may leverage different corpora to learn how to perform different tasks. Just to illustrate, Sheang and Saggion (2023) and Qiang et al. (2021) trained language models to generate substitution candidates for lexical simplification. Finally, **hybrid** systems may leverage both data-driven and rule-based approaches.

Table 1 shows the following findings regarding the tool approaches: the majority of tools are rule-based (12, 44.44%), whereas 7 are data-driven (25.93%), 7 are hybrid tools (25.93%) and one, *DysWebsia*, is not specified (3.70%). Most data-driven approaches focus on lexical simplification either for complex word identification, such as *Lexi* or *EASIER*, or substitution generation, as in the case of *Anita*. Another aspect worth discussing is the lack of tools leveraging recent advances in large language models (LLM), even for lexical simplification, although there are exceptions such as Rolin et al. (2021) using CamenBERT (Martin et al., 2020). Again, other proposals outside this review, such as Qiang et al. (2021), explored LLMs but without developing a tool.

5.3 Target Users

Regarding the target users of the analysed tools, these usually have either (1) a generalist approach with multiple target users or (2) a more specific or specialised approach, by targeting particular target groups like dyslexic people. However, some tools do not explicitly mention whether they were conceived with a target user in mind (see Table 1).

On the one hand, 12 tools (44.44%) have a **specific target audience**. For instance, *SALSA*, aimed at English as a second and foreign language students; *FACILITA*, intended for low literacy readers; *ERNESTA*, created for children with low reading skills; *Open Book*, designed for autistic people; or *DysWebsia*, developed for dyslexic individuals. In addition, under specific target audiences are also subsumed other personalised tools, like *Lexi* and *Medical Text Simplification Tool*, that are customised according to the individual's particular needs.

On the other hand, some other tools have **multiple target audiences** (8, 29.63%): those tools aimed at a wider audience and considered a one-size-fits-all approach by (Bingel et al., 2018), such as people with cognitive disabilities in general, like *NavegaFácil* or *EASIER*; or varied audiences like poor literate individuals, language learners and children (*AI-Baseet*); teachers, publishers, journalists, companies, and others (*SIMPLIFICA*); people with aphasia, dyslexia, intellectual disability, deaf or hard-of-hearing (DHH), second language learners and children (*FRIENDLYREADER*); or specialists, medicine and tourism university students, laypeople and public administration (*ArText*).

Lastly, there are 7 tools (25.93%) that **do not specify** whether they were conceived with a specific target in mind (see Table 1).

5.4 Accessibility and Availability

The vast majority of the simplification tools analysed (23 out of 27, 85.19%) are currently inaccessible either because (1) the link is not working and, therefore, they are inoperative[8] at the moment of the analysis or (2) the link to the tools is not provided and left unspecified[9] in the paper (see Table 1). This means that only four (14.81%) of the tools examined are currently functional and accessible for use[10]: *ArText*, which instead of out-

[7] Onwards referred to as MTST in Table 1 for brevity.

[8] Indicated with I in Table 1.

[9] Indicated with a hyphen in Table 1.

[10] Indicated with O in Table 1.

putting a simplified text, it identifies the complex language phenomena and recommends solutions; *EASIER*, which identifies complex words in a text and provides a definition; and *FRIENDLYREADER* and *Simplext*, which output simplified text. These results evidence the need to maintain these simplification resources, both technically and in financing terms, so that they fulfil their intended purpose.

Respecting the tool's open-source nature[11], less than half of the tools explicitly acknowledge the availability of their open-source code in their respective papers (see Table 1).

6 Conclusions and Future Work

In this paper we conducted a review of research-based ATS tools to determine which language they simplify, what simplifications are applied, which approaches are followed, who are the target users (e.g. people with disorders and disabilities, students, children, and others) and whether or not these tools are accessible to the public and available for researchers. From this analysis some general conclusions are reached concerning what these tools have to offer, what they are lacking and other future considerations in NLP:

- **Languages simplified and language level simplification.** ATS is an area with a promising future as many languages are still underrepresented in the results derived from this study. If the objective is to create a tool that truly helps people with written comprehension, all levels of simplification must be taken into consideration.

- **Multioption and customisation.** ATS tools should offer multiple options or solutions for the technical and/or complex vocabulary, such as synonyms, definitions, images, links to explanatory webpages, text-to-speech, and translation, to name a few, in order to enrich the text and cater to the different users' needs. A one-size-fits-all simplification approach is not the ideal way of creating simplification tools. These should foster the individual's independence by allowing the user to select what s/he finds challenging to understand and not limiting the user's capabilities.

- **Approaches.** There is a lack of tools based on neural or other data-driven holistic approaches, e.g. performing different types of simplifications at once, after learning from examples of complex/simple text (Ondov et al., 2022). Moreover, we did not detect any tool leveraging advances in LLMs —with some exceptions— but we expect this area to be explored in the future.

- **Target audience.** We understand that the targets' needs are different and, consequently, the text simplifications they require ought to be different as well. Evidently, tools that adopt a generalist approach, albeit targeting a broader range of population, do not refine the simplification depending on the user's needs to the same extent as individualist tools do.

- **Accessibility and availability**. While a substantial amount of research is dedicated to ATS, the full accessibility and functionality of ATS tools is crucial so that the valuable efforts made by the scientific community are effectively disseminated to society.

After this preliminary study, the results indicate different paths that research groups could improve upon, like simplifying more language levels, customising simplifications by having into account the user's needs, maintaining tool accessibility and including other languages that still require simplification tools, among others. Thus, we encourage to continue researching, implementing and providing robust ATS tools to facilitate access information to society at large.

In the context of the ClearText project, the goal is a two-fold simplification approach by addressing both disability-related and individual-specific language obstacles. In this way, we enable users to determine the extent to which they address the language obstacles associated with their specific disabilities, while considering that each individual exhibits unique idiosyncrasies and varying impairment degrees.

Acknowledgments

This research was conducted as part of the ClearText project (TED2021- 130707B-I00), funded by MCIN/AEI/10.13039/501100011033 and European Union NextGenerationEU/PRTR.

Abstract

In this paper, we propose VOCAB-EXPANDER at https://vocab-expander.com, an online tool that enables end-users (e.g., technology scouts) to create and expand a vocabulary of their domain of interest. It utilizes an ensemble of state-of-the-art word embedding techniques based on web text and ConceptNet, a common-sense knowledge base, to suggest related terms for already given terms. The system has an easy-to-use interface that allows users to quickly confirm or reject term suggestions. VOCAB-EXPANDER offers a variety of potential use cases, such as improving concept-based information retrieval in technology and innovation management, enhancing communication and collaboration within organizations or interdisciplinary projects, and creating vocabularies for specific courses in education.

1 Introduction

Motivation. In many scenarios, it is necessary to create an ontology or other formal model of a domain of interest from scratch. For instance, in the field of technology and innovation management, technology scouts and other end-users without technical skills often use a list of terms for continuously retrieving and scanning texts from different media sources (e.g., news articles, social media, publications, patents) in order to become aware of novel relevant technologies and to create and populate profiles of technologies and actors within a particular domain, such as Smart Cities. However, coming up with such a vocabulary is typically highly time-consuming and costly due to the domain-specificity (i.e., non-experts have no starting point what to add), the complexity of correctly defining the scope of the domain (e.g., Smart Cities can range from Smart Home to energy efficiency to security), the ambiguity of natural language (i.e., the meaning of terms may vary depending on the context in which they are used), and the emergence of new terms over time.

Current Situation. So far, domain experts (e.g., technology scouts in technology and innovation management) still rely heavily on domain expert knowledge (de Weck, 2022). Several tools for modeling a domain of interest exist, including Protegé (Musen, 2015) and D-Terminer (Rigouts Terryn et al., 2022). However, these tools are often considered as "too heavy" for creating only a domain-specific vocabulary instead of an ontology with a specific data model and standardizations (e.g., W3C RDF, OWL). Furthermore, these tools are typically designed to support the modeling process (e.g., based on an existing text corpus), but do not suggest directly related terms for given terms.

Contributions. In this paper, we propose the system VOCAB-EXPANDER, available online at https://vocab-expander.com, that enables end-users without technical skills to create and expand a vocabulary of their domain of interest. The system utilizes an ensemble of state-of-the-art word embedding techniques to suggest related terms for already given terms. In addition to word embedding models based on web text, the system also incorporates embeddings based on ConceptNet, a common-sense knowledge base. The system is equipped with an easy-to-use interface that allows end-users to quickly confirm or reject term suggestions. The ranking of the suggested terms is based on the number of links they possess to other terms within the vocabulary. The created vocabulary can be listed as a table and visualized as a graph (see Figures 1 and 2). We also provide an import and export functionality for the vocabularies.

Use Cases. Our tool offers a variety of potential use cases. For tasks such as technology and innovation management, it can be used to improve concept-based information retrieval by utilizing the created domain-specific vocabulary as search terms.

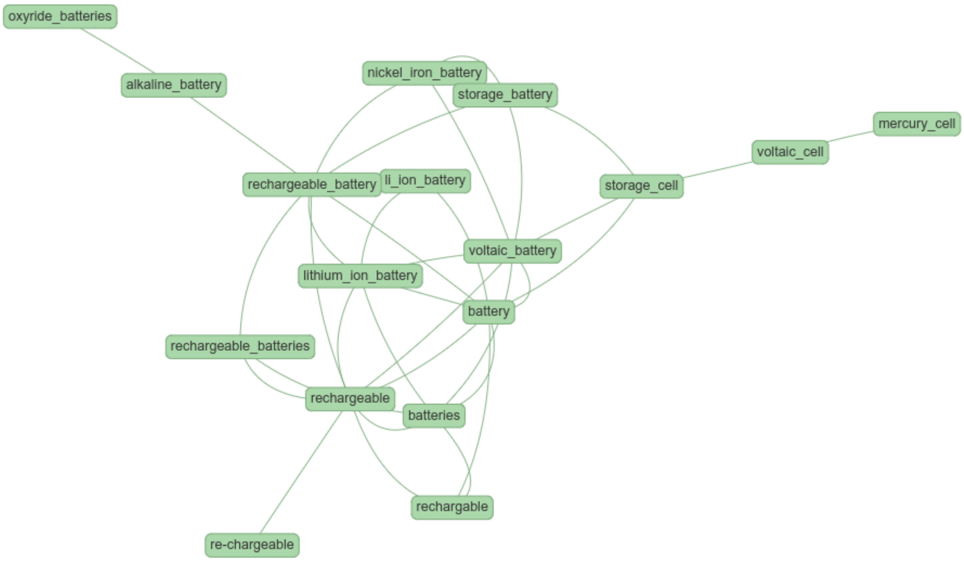

Figure 2: Screenshot

Additionally, the created vocabulary can serve as a basis to enhance communication and collaboration within organizations or interdisciplinary projects by ensuring the use of consistent terminology among all involved parties. In the field of education, our tool allows for the creation of vocabularies for specific courses or subjects, ensuring that all relevant terms within a field or subject are covered. Overall, our system provides a valuable solution for creating and maintaining domain-specific vocabularies, which can be used in various fields to improve information retrieval, human communication, and natural language processing.

Provisioning. The source code of our system is publicly available on GitHub (https://github.com/nicpopovic/VocabExpander) under the MIT License, making it easy to reuse and adapt for a wide range of use cases.

2 System Design

The system utilizes an ensemble E of state-of-the-art pre-trained word embedding models available in *gensim* (Řehůřek and Sojka, 2010) to suggest related terms for already given terms. Specifically, the user can choose one or several of the following models: (1) *word2vec-google-news-300* (Mikolov et al., 2013), (2) *glove-wiki-gigaword-300* (Pennington et al., 2014), (3) *fasttext-wiki-news-subwords-300* (Mikolov et al., 2018), (4) *conceptnet-numberbatch-17-06-300* (Speer et al., 2017).

Words $w \in W$ are categorized into 3 categories, accepted words W_a, rejected words W_r, and suggested words W_s. Initially, a user adds one or more words to W_a. For each word $w_a \in W_a$ the top k most similar words $w_{sim} \in W_{sim}$ according to each embedding model $e \in E$ are fetched along with the average pairwise similarity scores $P_{w_{sim,j},w_i}$ across E. $w_{sim} \notin W$ are added to W_s. Next, we calculate a score S_{w_s} for each suggested word $w_s \in W_s$ by aggregating similarity scores to accepted words and subtracting weighted similarity scores to rejected words:

$$S_{w_{s,i}} = \sum_{w_{a,j} \in W_a} P_{w_{s,i},w_{a,j}} - \lambda \sum_{w_{r,k} \in W_r} P_{w_{s,i},w_{r,k}}$$

where $\lambda = 0.5$. Suggested words are then associated with the accepted word with which they have the highest pairwise similarity and ordered according to their score $S_{w_{s,i}}$.

The system's frontend, presented in Figure 1, displays the list view of accepted words and the corresponding suggested words. The list view showcases the three highest-ranked suggestions for a selected accepted word. If the score of a suggested word falls below a pre-determined threshold, a lower opacity indicates this. Users can quickly accept a suggested word by clicking on it or reject it by clicking the ”x” button next to it. Additionally, a graph view is available as shown in Figure 2, allowing users to visualize the similarity scores between accepted words. The user interface also includes import and export buttons in the top left corner, enabling the import and export of vocabulary lists.

3 Related Work

Ontology Engineering and Ontology Learning. Various methods have been proposed for constructing an ontology for a specific domain in a manual, semi-automated, or automated way (Hazman et al., 2011). Automated methods typically involve extracting concepts and relations between them from domain-specific text corpora provided by the user (Elnagar et al., 2020). In contrast to them, our approach does not rely on the availability of a large text corpus; instead, we enable users (domain experts as well as newcomers) to independently explore and discover related concepts from scratch. Furthermore, ontology learning (Buitelaar et al., 2005) typically includes additional processing steps, which are out of our scope, such as clustering the concepts with identical or similar meanings and assigning unique identifiers to concepts.

Automated Term Extraction. Research on automatically extracting terms from text corpora, such as named entities, has been performed extensively. Early approaches on automatic term extraction combined linguistic hints, e.g., part-of-speech patterns, with statistical metrics for calculating the termhood and unithood (Kageura and Umino, 1996), which allows to quantify to which degree the candidate term is related to the domain. Rule-based approaches have been used through many years (e.g., Daille (1994); Drouin (2003)) and are still popular nowadays (Kosa et al., 2020). Machine learning-based approaches for automated term extraction utilize, among other things, external data sets and web search (Ramisch et al., 2010) and word embeddings (Wang et al., 2016; Amjadian et al., 2018). Newest approaches are also based on language models (e.g., (Gao and Yuan, 2019; Lang et al., 2021)), but require, as many other approaches, more context than a few keywords as input as for our system.

Demo Systems for Automated Term Extraction. Rigouts Terryn et al. (2022) proposed D-Terminer, a running system for monolignual and bilingual automatic term extraction. In contrast to us, they focus on multiple languages, and use a text corpus as input for the system. Additionally, TermoStat (Drouin, 2003) and TerMine (Frantzi et al., 2000) are examples of online systems for term extraction and rely on rule-based hybrid approaches. Finally, MultiTerm Extract[1] and SketchEngine[2] are available commercial systems.

4 Conclusion

In this paper, we proposed VOCAB-EXPANDER, an online tool that enables end-users to create and expand a vocabulary of their domain of interest. It uses state-of-the-art word embedding techniques based on web text as well as ConceptNet, a common-sense knowledge base, to suggest related terms for already given terms. The system can be used for a variety of purposes such as improving information retrieval, communication and collaboration, creating vocabularies for education, and fine-tuning language models in natural language processing.

For the future, we will allow for the integration of domain-specific text corpora (e.g., provided by the domain experts) and provide a functionality to see to which degree the suggested terms occur in the text corpora. Furthermore, we plan to evaluate the performance of VOCAB-EXPANDER by means of user studies in different domains and applications.

On the Generalization of Projection-Based Gender Debiasing in Word Embedding

Elisabetta Fersini, Antonio Candelieri, Lorenzo Pastore
University of Milano-Bicocca
Milan - Italy
{elisabetta.fersini, antonio.candelieri}@unimib.it
l.pastore6@campus.unimib.it

Abstract

Gender bias estimation and mitigation techniques in word embeddings lack an understanding of their generalization capabilities. In this work, we complement prior research by comparing in a systematic way four gender bias metrics (Word Embedding Association Test, Relative Negative Sentiment Bias, Embedding Coherence Test and Bias Analogy Test), two types of projection-based gender mitigation strategies (hard- and soft-debiasing) on three well-known word embedding representations (Word2Vec, FastText and Glove). The experiments have shown that the considered word embeddings are consistent between them but the debiasing techniques are inconsistent across the different metrics, also highlighting the potential risk of unintended bias after the mitigation strategies.

1 Introduction

A recent body of work in Natural Language Processing (NLP) has focused attention on quantifying different types of bias through various approaches, spanning from psychological tests and performance differences for various tasks to the geometry of vector spaces (Sun et al., 2019). Defining the type of bias is essential to estimate and mitigate it. Several forms of biases specific to NLP application have been introduced in the literature during the last 5 years (Nozza et al., 2019; Nissim et al., 2020; Goldfarb-Tarrant et al., 2021). In (Hitti et al., 2019) the authors defined ***gender bias*** *in a text as the use of words or syntactic constructs that connote or imply an inclination or prejudice against one gender*, highlighting that gender bias can evidence itself structurally, contextually, or in both forms. Structural bias occurs when the construction of sentences shows patterns closely tied to the presence of gender bias. On the other hand, contextual bias can happen in the tone, words, or context of a sentence. Unlike structural bias, this type of bias is not evident in grammatical structure but requires contextual background information and human perception. Therefore, gender bias can be discovered using both linguistic and extra-linguistic cues and can manifest itself in subtle or explicit ways, with differing degrees of intensity (Stanczak and Augenstein, 2021; Caliskan et al., 2022; Sen et al., 2022). Furthermore, gender bias can easily propagate to models and downstream tasks, causing harm to the end-users (Bolukbasi et al., 2016). These forms of bias can emerge as representational harms and gender gaps.

The current literature about gender bias estimation and mitigation related to word embeddings lacks an understanding of their generalization capabilities. Therefore, this work complements prior research by providing the first systematic evidence on the generalization of estimating gender bias and debiasing techniques, including comprehensive quantitative and qualitative analyses. In particular, we compared in a systematic way four gender bias metrics (Word Embedding Association Test (Caliskan et al., 2017), Relative Negative Sentiment Bias (Sweeney and Najafian, 2019), Embedding Coherence Test (Dev and Phillips, 2019) and Bias Analogy Test (Dev and Phillips, 2019)), two types of projection-based gender mitigation strategies (hard- and soft-debiasing (Bolukbasi et al., 2016)) on three well-known word embedding representations (Word2Vec (Mikolov et al., 2013), FastText (Bojanowski et al., 2017) and Glove (Pennington et al., 2014)). The main findings of the systematic comparison can be summarized as follows:

- The considered word embeddings are consistent between them but the debiasing techniques are inconsistent across the different bias estimation metrics, underlying controversial generalization capabilities;
- The investigated debiasing techniques, evalu-

Proceedings of Recent Advances in Natural Language Processing, pages 336–343
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_038

ated with respect to multiple points of view, have highlighted the potential risk of unintended bias after the mitigation strategies.

The paper is organized as follows. In Section 2, the most relevant bias estimation metrics are presented. In Section 3 hard and soft debiasing strategies are reported. In Section 4, a systematic comparison is performed, detailing the main findings about the generalization capabilities in debiasing word embeddings. Finally, in Section 5 conclusions are reported and future work is discussed.

2 Measuring Gender Bias

In recent years numerous investigations have been focused on the development of measures to estimate gender bias in embedding methods. The most widely used techniques are: Word Embedding Association Test (Caliskan et al., 2017), Relative Negative Sentiment Bias (Sweeney and Najafian, 2019), Embedding Coherence Test (Dev and Phillips, 2019) and Bias Analogy Test (Dev and Phillips, 2019).

Word Embedding Association Test (WEAT). The Word Embedding Association Test (Caliskan et al., 2017) exploits the Implicit Association Test (IAT) (Greenwald et al., 1998) in order to quantify gender bias in word embeddings through the difference in the strength of association of concepts. In psychology, the Implicit Association Test (IAT) is used to assess the presence of subconscious gender bias in humans. This can be defined as "the difference in time and accuracy that humans take to categorize words related to two concepts they find similar versus two concepts they find different". In detail, WEAT compares sets of identified concepts (i.e., male and female words), denoted as X and Y (each of equal size N, with two sets of biased attributes A and B of equal size N) in order to measure bias over social attributes and roles (i.e., career/family words). The association of a single word x with the bias attribute sets A and B is computed as:

$$f(x,A,B) = \frac{1}{N}\sum_{a\in A} cos(x,a) - \frac{1}{N}\sum_{b\in B} cos(x,b) \quad (1)$$

To estimate the bias in the sets X and Y, the effect sized d is estimated as follows:

$$d(X,Y,A,B) = \frac{\mu_{x\in X} f(x,A,B) - \mu_{y\in Y}(f(y,A,B)}{std_{t\in X\cup Y f(t,A,B)}} \quad (2)$$

where $\mu_{x\in X}(f(x,A,B)$ refers to the mean of $f(x,A,B)$ with x in X and $std_{t\in X\cup Y f(t,A,B)}$ to the standard deviation over all word biases of x in X. The null hypothesis suggests that there is no difference between X and Y in terms of their relative similarity to A and B. In other words, a positive value of $d(X,Y,A,B)$ confirms the hypothesis that words in X are stereotypical for the attributes in A and words in Y stereotypical for words in B, while a negative value of $d(X,Y,A,B)$ suggest that the stereotypes would be opposite. In Caliskan et al. [2017], the null hypothesis is tested through a permutation test, i.e., the probability that there is no difference between X and Y (in relation to A and B) and, therefore, that the word category is not biased.

Relative Negative Sentiment Bias (RNSB). Relative Negative Sentiment Bias (Sweeney and Najafian, 2019) measures the fairness in word embeddings through the relative negative sentiment associated with terms from various protected groups. The idea is to use the embedding model to initialize vectors for an unbiased positive/negative word sentiment dataset. Using this dataset, a logistic classification algorithm is trained to predict the probability of any word being a negative sentiment word. After training, a selected set of neutral identity terms from a protected group (i.e., national origin) is taken to predict the probability of negative sentiment for each word in the set. Neutral identity terms that are unfairly entangled with negative sentiment in the word embeddings will be classified like their neighboring sentiment words from the sentiment dataset.

Given a gold standard of labeled positive/negative sentiment words, (x_i, y_i), where x_i is a word vector from a possibly biased word embedding model, the goal is to minimize the learned weights w of a logistic loss L:

$$min_{w\in R^d} \sum_{i=0}^{n} L(y_i, w^T x_i) + \lambda\|w\|^2, \lambda > 0 \quad (3)$$

where λ is a scalar, known as regularization rate, aimed at reducing over-fitting.

Given a set $K = k_1, ..., k_t$ identity word vectors, we define a set P containing the predicted negative sentiment probability via the minimization of the logistic loss normalized to be one probability mass:

$$P = \left\{ \frac{f^*(k_1)}{\sum_{i=1}^{t} f^*(k_i)}, ..., \frac{f^*(k_t)}{\sum_{i=1}^{t} f^*(k_i)} \right\} \quad (4)$$

The metric $RNSB(P)$ is defined as the KL divergence of P from U, where U is the uniform distribution from the t identity word elements:

$$RNSB(P) = D_{KL}(P \| U) \tag{5}$$

The RNSB metric captures the distance, via KL divergence, between the current distribution of negative sentiment and the fair uniform distribution. The fairer is the word embedding model with respect to sentiment bias, and the lower is RNSB.

Embedding Coherence Test (ECT) Embedding Coherence Test (ECT) (Dev and Phillips, 2019) measures if groups of words have stereotypical associations by computing the Spearman Coefficient of lists of attribute embeddings sorted based on their similarity to target embeddings. In particular, ECT quantifies the amount of explicit bias by comparing vectors of target sets T_1 and T_2 (averaged over the constituent terms) with vectors from a single attribute set A. ECT first computes the mean vectors for the target sets T_1 and T_2:

$$\mu_1 = \frac{1}{|T_1|} \sum_{t_1 \in T_1} t_1 \tag{6}$$

$$\mu_2 = \frac{1}{|T_2|} \sum_{t_2 \in T_2} t_2 \tag{7}$$

Next, for both μ_1 and μ_2 it computes the (cosine) similarities with vectors of all $a \in A$. Finally, the two resultant vectors of similarity scores, $s1$ (for $T1$) and $s2$ (for $T2$), are used to obtain the final ECT score. ECT corresponds to the Spearman's rank correlation between the rank orders of $s1$ and $s2$. In our specific case of gender bias, ECT quantifies the amount of explicit bias by means of the Spearman's rank correlation between the vectors of similarity scores between the attribute words set and the gender target sets. In this case, the higher the correlation and the lower the bias.

Bias Analogy Test. The Bias Analogy Test (BAT) has been introduced in (Dev and Phillips, 2019) as a set of word analogy tests. The main goal is to find the word pair in the best analogy to the pair *(he, she)*. To evaluate the extent of gender bias in word embeddings, we used the SemBias dataset, where each sample contains four-word pairs: a gender-definition word pair (Definition; e.g., *gentleman - lady*), a gender-stereotype word pair (Stereotype; e.g., *doctor - nurse*); the two other pairs consist of words similar in meaning but irrelevant to gender (None; e.g., *cat - dog*, or *flour - sugar*). To quantify the correctness of the analogy of "he-she", for each set of word pairs (Definition, Stereotype, None) the percentage of times that each class of pair is on the top based on a word embedding model is computed. The relational similarity between *(he, she)* and *(a,b)* in SemBias is computed using the cosine similarity between the (*he-she)* gender directional vector and *(a-b)* using the word embeddings under evaluation. For the four-word pairs in each instance in SemBias, we select the word pair with the highest cosine similarity with *(he-she)* as the predicted answer. If the word embedding has been properly debiased, higher values in Definition and lower values in Stereotype and None are expected.

3 Debiasing Methods

Given the potential risk of using Machine Learning algorithms that amplify gender stereotypes contained in pre-trained word embeddings, the main challenge in debiasing tasks is to strike a balance between maintaining model performance on downstream tasks while reducing the encoded gender bias (de Vassimon Manela et al., 2021). To this purpose, projection-based debiasing methods are exploited and compared to determine their generalization capabilities. In this work, we consider two main mitigation strategies, hard- and soft-debiasing.

Hard-debiasing. Hard-debiasing (Bolukbasi et al., 2016; Cheng et al., 2022), also known as *Neutralize and Equalize*, ensures that gender-neutral words are zero in the gender subspace and equalizes sets of words outside the subspace. In order to accomplish this task, hard-debiasing has the goal to satisfy the constraint that any neutral word should be equidistant to all words in each equality set (i.e., a set of words which differ only in the gender component). For instance, taking (grandmother, grandfather) and (guy, gal) as two equality sets, after equalization, *babysit* would result to be equidistant from (*grandmother, grandfather*) and (*gal, guy)*, closer to *grandparent* and further away from the *gal* and *guy*. Instead of completely removing gender information, the approach is aimed at shifting word embeddings to be equally male and female in terms of their vector direction and proposes to modify the embedding space by removing the gender component only

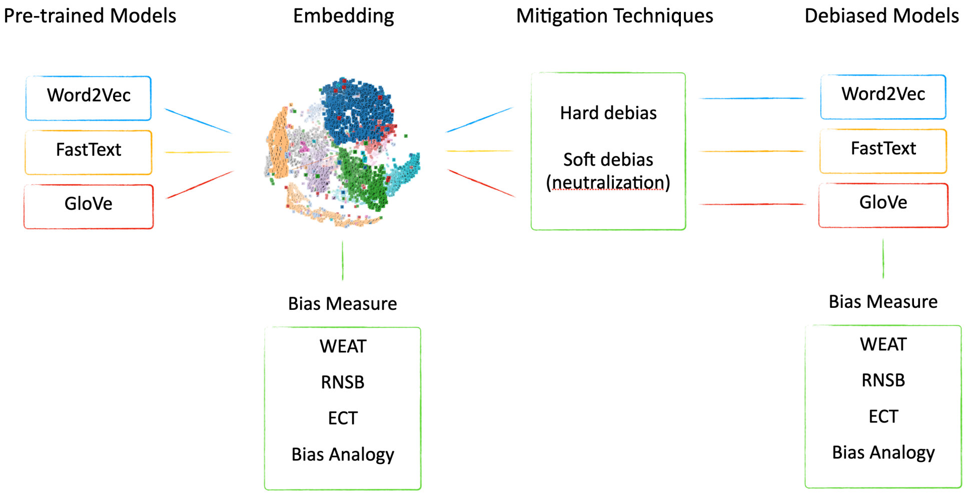

Figure 1: Proposed comparative framework

from gender-neutral words. This approach is appropriate for applications where one does not wish to display any bias in any such pair with respect to neutral words. The disadvantage of equalizing sets of words outside the subspace is that it removes certain specific distinctions that may be of value in specific applications. For instance, Bolukbasi et al. highlight that one may wish a language model to assign a higher probability to the phrase such as *grandfather a regulation* since it is an idiom, unlike *grandmother a regulation*.

Soft-debiasing. The soft-debiasing approach (Bolukbasi et al., 2016) reduces the differences between sets whilst maintaining as much similarity as possible to the original embedding, with a parameter that controls for this trade-off. More specifically, soft-debiasing applies a linear transformation that seeks to preserve pairwise inner products between all the word vectors while minimizing the projection of the gender-neutral words onto the gender subspace. In order to accomplish this task, soft-debiasing exploits a set of gender-definitional words to train a support vector machine and uses it to expand the initial set of gender-definitional words.

4 Generalization Capabilities: A Systematic Comparison

In order to perform a deep analysis of bias measures and mitigation techniques on word embeddings, we selected three of the most well-known and adopted models:

- **Word2Vec:** 300-dimensional embeddings for ca. 3M words learned from Google News corpus (Mikolov et al., 2013)

- **Glove:** 300-dimensional embeddings for ca. 2.2M words learned from the Common Crawl (Pennington et al., 2014)

- **FastText:** 300-dimensional embeddings for ca. 1M words learned from Wikipedia 2017, UMBC web base corpus, and statmt.org news (Bojanowski et al., 2017)

These three models belong to two different families. Both families learn the geometrical encoding (vectors) of words from their co-occurrence information. However, they differ because Word2Vec and FastText are *predictive* models, whereas GloVe is a *count-based* model.

In order to understand and evaluate unintentional gender bias in word embeddings from a comprehensive point of view, we adopted the framework reported in Figure 1. In particular, given the considered word embeddings, the systematic comparison for understanding the generalization capabilities of the examined gender-debiasing techniques is performed according to the following three main steps: (1) estimation of the gender-bias metrics, (2) exploiting both hard- and soft-debiasing methods and (3) evaluating the debiased embeddings using the same bias measures before and after the mitigation strategy. To evaluate the pre-trained word embeddings, we use the four metrics, comparing the results before and after the mitigation strategies.

We report in Tables 1, 2 and 3 the corresponding values according to seven sets of different target words and multiple male and female attribute words. For each metric, we computed the values obtained by the considered models according to the (**o**)original embedding, the (**s**)oft debiased, and the (**h**)ard debiased ones.

Table 1: WEAT values for target word groups with respect to male and female terms.

The first measure we evaluate is the Word Embedding Association Test (WEAT) where, for each target group we computed the association with the set of male and female attribute words (pronouns). In table 1 we highlight in **bold** the best results obtained by each model. At first glance, it seems that the considered debiasing operations have affected the WEAT value for all the embeddings. Compared to the original version, all three embeddings show a significant improvement in both soft and hard debiased embeddings. Nevertheless, ***Word2Vec and FastText have a noticeable tendency to the hard debiased embedding, while Glove has very similar values for the soft and hard embeddings***.

Regarding the Relative Negative Sentiment Bias (RNSB) metric, it can be interpreted as the distance between the current distribution of negative sentiment and the fair, uniform distribution. Therefore, the fairer a word embedding model is with respect to sentiment bias, the lower the RNSB metric should be. The results in Table 2, although RNSB is not directly comparable with WEAT, seem to be coherent.

Table 2: RNSB values for target word groups with respect to male and female terms.

For what concerns the Relative Negative Sentiment Bias metric, it can be interpreted as the distance between the current distribution of negative sentiment and the fair, uniform distribution. Therefore, the fairer a word embedding model is with respect to sentiment bias, the lower the RNSB metric should be. The results in table 2, although RNSB is not directly comparable with WEAT, seem to be coherent. All the models seem to be improving in the debiased embedding. However, it is necessary to make a few considerations about RNSB with respect to WEAT: 1) the relative improvement from the original to the hard debiased embeddings is much more moderate in RNSB than in WEAT and 2) ***in contrast to WEAT values, GloVe's best embeddings in terms on RNSB is the hard debiased one, while Word2Vec and FastText's best model seems to swing between soft and hard***.

Regarding the Embedding Coherence Test (ECT), it quantifies the amount of explicit bias and returns the Spearman's rank correlation between the vectors of similarity scores between the attribute word set and the gender target sets. The results in Table 3 seem to confirm the considerations related to WEAT and RNSB, denoting an improved representation (less biased) with respect to the original embedding. In particular, we found out that the best debiased embedding is the one generated with the hard debiased technique. Nevertheless, we noticed that ***ECT's values are extremely high in the soft or even the original embedding for some attribute words***. In fact, the Spearman correlations are close to 1, indicating that the two variables being compared are monotonically related, even if their relationship is not linear.

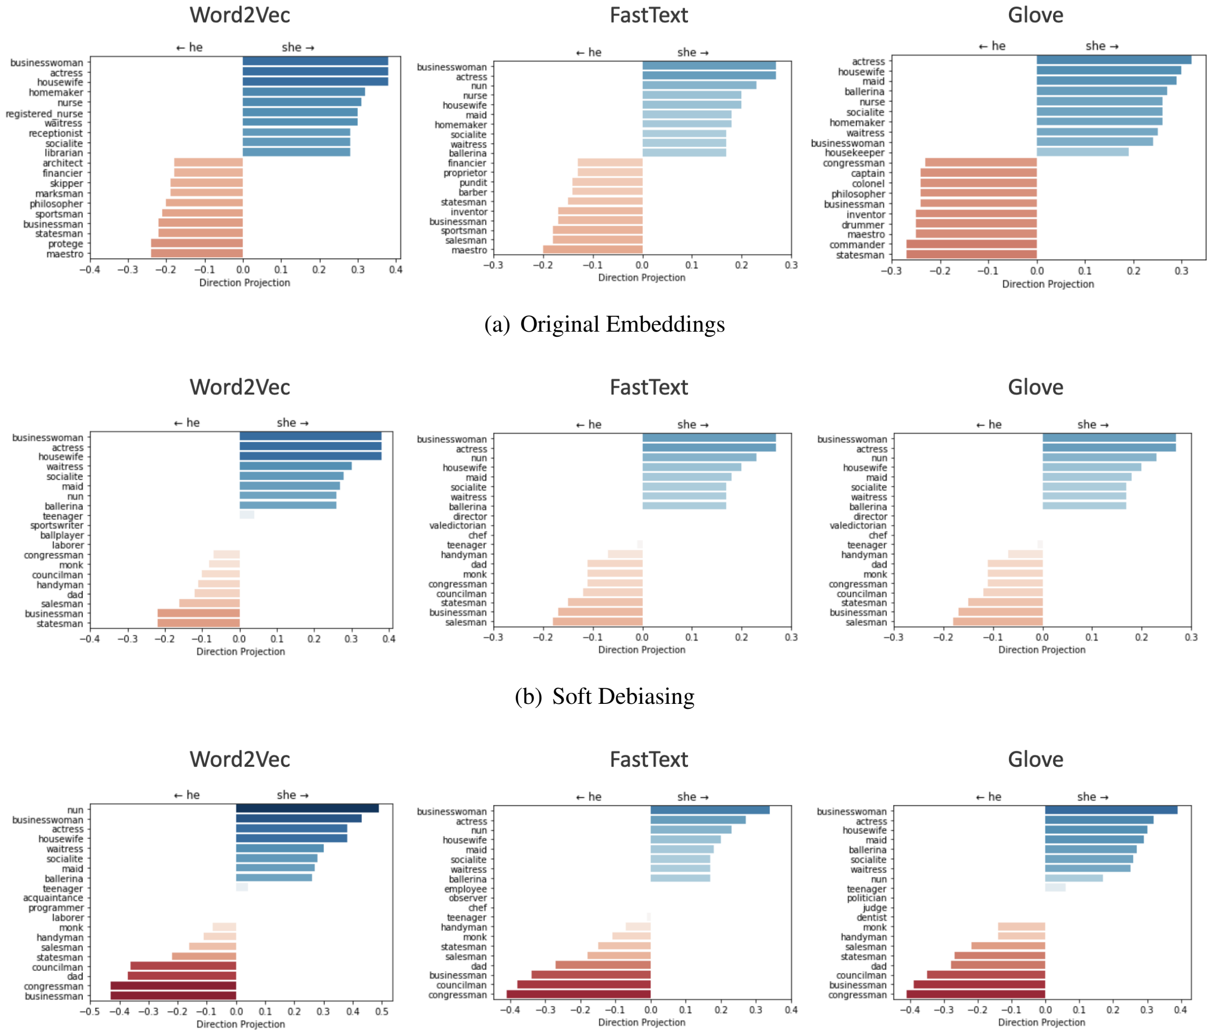
Table 3: ECT values for target word groups with respect to male and female terms.

We report in Figure 2(a), 2(b) and 2(c) the *Gender Direction* for different occupations for each pre-trained model according to the original embeddings and the two debiasing techniques. Although there is an improvement for all models from the



(a) Original Embeddings

(b) Soft Debiasing

(c) Hard Debiasing

Figure 2: Gender direction for occupations in Original embeddings, Soft and Hard Debiasing.

original to the hard debiased embedding, we can observe a few potentially biased representations in the *she* direction. In particular terms such as *maid*, *waitress* and *housewife* do not constitute a form of directly observable bias, but the absence of male equivalent terms is a potential warning.

Although the analysis carried out to this point seems to confirm that the embeddings have been successfully debiased, the qualitative evaluation of the results has brought out some concerns regarding the actual presence of bias. To this purpose, we evaluated the embeddings adopting the Bias Analogy Test reporting the results in Table 4. The debiased models show lower values in **Definition** than the original embedding, suggesting the presence of bias.

In particular, for the word pairs Definition, Stereotype and None, for each pre-trained model, the only improvement from the original embedding appears to be in the **Stereotype** values of the soft embedding.

	Word2Vec			FastText			GloVe		
	o	**s**	**h**	**o**	**s**	**h**	**o**	**s**	**h**
Definition	**.826**	.823	.795	**.911**	.777	.820	**.835**	.770	.809

None	**.039**	.075	.089	.023	.175	**.119**	**.050**	.152	.111
Sub-Definition	.600	**.700**	.500	**.825**	.500	.700	**.675**	.525	.500
Sub-Steretype	.300	**.200**	.275	.125	.125	**.100**	.275	**.125**	.225
Sub-None	**.100**	**.100**	.225	**.050**	.375	.200	**.050**	.350	.275

Table 4: BAT values for pre-trained models.

Regarding the sub-metrics reported in the bottom part of the table (Sub-Definition, Sub-Stereotype and Sub-None), they spotlight a bad generalization ability for all the embeddings when compared with their corresponding original metrics. The obtained results on the BAT metric coupled with the gender direction analysis, being inconsistent with the previous remarks on WEAT, RNSB and ECT, highlight the potential risk of unintended bias after the mitigation strategies.

5 Conclusions and Future Work

In this paper, a systematic comparison of different bias estimation metrics, mitigation strategies and word embeddings has been performed. The computational investigation highlighted analogies and dissimilarities among metrics, pointing out the importance of using different types of measures to have a wider overview of the generalization capabilities of the two most important debiasing techniques. The experiments have shown that the considered word embeddings are consistent between them but inconsistent across the different metrics. Although WEAT, RNSB and ECT values are coherent, the gender direction of occupations and the BAT values are signals reflecting the presence of bias in the supposed debiased models. A future research investigation relates to the evaluation of multiple bias metrics not only on word embeddings but also on transformer-based representations as contextualized word embeddings. Finally, a generalization of the proposed investigation should be pursued on generative language models.

Abstract

In this paper we propose a first empirical mapping between the RST-DT and the PDTB 3.0. We provide an original algorithm which allows the mapping of 6,510 (80.0%) explicit and implicit discourse relations between the overlapping articles of the RST-DT and PDTB 3.0 discourse annotated corpora. Results of the mapping show that while it is easier to align segments of implicit discourse relations, the mapping obtained between the aligned explicit discourse relations is more unambiguous.

1 Introduction

Different linguistic frameworks have been proposed to model the discourse relations that hold between textual segments. Two widely used frameworks are the Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) and the Penn Discourse Treebank (PDTB) (Miltsakaki et al., 2004; Prasad et al., 2008). Following these frameworks, several annotated corpora have been developed for a wide variety of NLP tasks, such as discourse parsing (Chi and Rudnicky, 2022), implicit discourse relation classification (Liu and Strube, 2023) and discourse generation (Stevens-Guille et al., 2022).

Since generating and manually annotating discourse corpora at the large scale required for fine-tuning large language models is prohibitively expensive and laborious, a viable alternative is to establish a mapping between already existing corpora so that they can be used seamlessly and interchangeably together. The two primary discourse annotated corpora are the RST-DT (Carlson et al., 2001) and the PDTB (PDTB 1.0, 2.0 and 3.0) (Prasad et al., 2006, 2007; Webber et al., 2019). However, since both corpora are annotated based on different frameworks, they differ in how they segment and label discourse relations. The resulting structural differences limit the extent to which they can be used together to train discourse models.

In this paper, we present a first empirical mapping between the RST-DT and the PDTB 3.0 based on the overlapping sections of the two annotated corpora. Previous work has addressed such a mapping between the RST-DT and PDTB 2.0. Sanders et al. (2021) proposed a theoretical mapping between both frameworks, while Demberg et al. (2019) established an empirical mapping based on the subset of the corpora that they share. However, to the best of our knowledge, no work has proposed a mapping between the RST-DT and the PDTB 3.0.

2 Background

The linguistic frameworks behind the RST-DT and the PDTB differ in how textual units are segmented and in how discourse relations are defined.

2.1 RST-DT

The RST-DT corpus (Carlson et al., 2001) is based on the RST theoretical framework (Mann and Thompson, 1988). In this framework, a text is first segmented into minimal non-overlapping units, referred to as elementary discourse units (EDUs). The grammatical clause is the starting point of the segmentation. After segmentation, relations between EDUs are identified using an open set of discourse relations. These relations are established recursively between adjacent EDUs until the entire text is connected, forming a single tree-like structure that encompasses multiple embedded relations (Taboada and Mann, 2006).

Consider the text in Example (1)[1] and its corresponding RST diagram in Figure 1.

(1) [There have been three days of hot, wind-swept rain,]^{edu1} [and now with the first sun we are after speckled sea trout,]^{edu2} [which with redfish provides most of the game fishing hereabouts.]^{edu3}

[1] Taken from the WSJ_1323 article in the RST-DT corpus.

Proceedings of Recent Advances in Natural Language Processing, pages 344–352
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_039

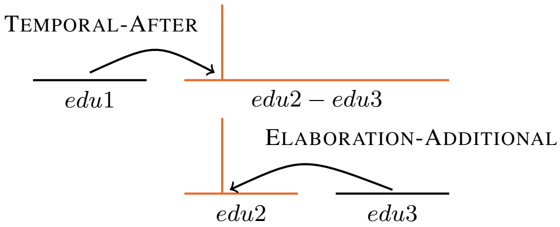

Figure 1: RST diagram of Example (1).

The leaves of the resulting RST diagram in Figure 1 correspond to the EDUs of Example (1) (i.e., $edu1$, $edu2$ and $edu3$), while the internal node of the tree correspond to multiple contiguous EDU segments (i.e., $\langle edu2 - edu3 \rangle$). Vertical lines in the diagram represent the nucleus of the discourse relation. All discourse relations in the RST framework hold between a nucleus and a satellite (mononuclear) or between two nuclei (multinuclear). The nucleus of a relation (depicted with a vertical line and shown in orange in Figure 1) represents an essential unit of information, while the satellite provides supporting information.

2.2 PDTB

The PDTB corpora (Prasad et al., 2006, 2007; Webber et al., 2019) are based on their namesake theoretical framework (Miltsakaki et al., 2004; Prasad et al., 2008). In the PDTB framework, discourse relations are annotated by first identifying discourse connectives (e.g., *but*, *however*) and then the arguments between which the relation holds. Unlike in the RST framework, in the PDTB framework arguments are not annotated for their nuclearity.

Discourse relations, in the PDTB, can be categorized as explicit or implicit[2]. An explicit discourse relation is marked by a discourse connective, while an implicit discourse relation holds between two arguments in the absence of a discourse connective. Explicit and implicit discourse relations are further differentiated based on their sense. Senses are organized hierarchically into three levels. The top level has four classes: Temporal, Contingency, Comparison, and Expansion, which are then further refined into second and third level senses. In this work, we consider only the second level of sense granularity in our mapping.

The release of PDTB 3.0 (Webber et al., 2019) has brought important changes to its predecessor PDTB 2.0. In particular, the second and third levels of the sense hierarchy have been revised and 13,000 additional discourse relations have been annotated. Similarly, the number of intra-sentential implicit discourse relations went from 530 instances in the PDTB 2.0 to 6,234 in the PDTB 3.0. Due to these, 19% of the discourse relations annotations in the PDTB 2.0 corpus were changed. Of these, around 56% correspond to explicit discourse relations, while around 40% correspond to implicit relations.

3 Previous Work

Previous work has attempted to establish a mapping between the RST-DT and the PDTB corpora. Most recently, Demberg et al. (2019) proposed an empirical mapping between the RST-DT and the PDTB 2.0. Their approach was able to map 76% of the PDTB explicit and implicit discourse relations (senses) to an RST-DT relation based on an analysis of the overlapping sections of the two corpora.

Additionaly, Demberg et al. (2019) compare the results of their empirical mapping with the theoretically mappings proposed by Chiarcos (2014), Bunt and Prasad (2016) and Sanders et al. (2021). They found that their empirical results matched the theoretical mappings in more than 70% of the explicit relations, but only in less than 50% of the implicit relations. Another empirical mapping between the RST-DT and the PDTB 2.0 corpora was conducted by Polakova et al. (2017). They focused only on implicit discourse relations where an exact segment span matching was possible, which included a total of 472 discourse relations.

However, previous work was based exclusively on the PDTB 2.0 corpus. Given the significant changes in the PDTB 3.0, it has become necessary to develop a new mapping algorithm to accommodate the new annotation guidelines and establish a first empirical mapping between the RST-DT and the PDTB 3.0.

4 Corpora

The RST-DT corpus (Carlson et al., 2002) consists of 385 Wall Street Journal articles annotated with 20,017 discourse relations, while the PDTB[3] corpus (Prasad et al., 2019) consists of 2162 Wall Street Journal articles with 53,631 discourse relation annotations.

Both corpora overlap on 365 articles, allowing us to establish a direct mapping between the two.

[2] Other PDTB discourse relations include AltLex, AltLexC, EntRel, NoRel and hypophora.

[3] We will simply refer to PDTB 3.0 as PDTB henceforth.

Table 1 shows the total number of individual segments[4] and discourse relations in both corpora over this overlap. Due to its non-hierarchical structure, the PDTB corpus contains far less discourse relations than the RST-DT (see Table 1). Note that out of the 9,369 PDTB relations in the overlapping section of the PDTB corpus, 4,169 (44.5%) are explicit and 3,965 (42.3%) are implicit discourse relations. This corresponds to a combined total of 8,134 (86.8%) discourse relations. The remaining 1,235 (13.2%) PDTB relations include other relations such as AltLex, AltLexC, EntRel, NoRel and hypophora, which we did not take into account.

	RST-DT	**PDTB**
Text Segments	21,789	18,738
Discourse Relations	20,017	9,369

Table 1: Number of segments and discourse relations in the RST-DT and the PDTB corpora over the overlapping set of 365 Wall Street Journal articles.

5 Aligning and Mapping Relations

Similarly to Demberg et al. (2019), and given the smaller number of PDTB relations compared to RST-DT relations (see Table 1), we used the PDTB as the starting point for the alignment and mapping of discourse relations.

5.1 Segment Alignment

The purpose of the alignment is to match PDTB segments to their closest RST-DT segment. RST-DT segments can be individual EDUs (e.g., $edu1$), or contiguous EDUs (e.g., $\langle edu2 - edu3 \rangle$). PDTB segments can either be continuous, as in Example (2), or discontinuous, as in Example (3), where $arg2$ is discontinuous and split into two constituents: $arg2a$ and $arg2b$.

(2) **PDTB:** [We've had a good relationship with GE]^{arg1} [which is the first time you could say that]^{arg2}

(3) **PDTB:** Mr. Carpenter notes [that these types of investors]^{arg2a} also [are "sophisticated" enough not to complain about Kidder's aggressive use of program trading]^{arg2b}

Continuous For each continuous PDTB segment, we find the RST-DT segment that maximizes the character overlap, while minimizing the number of additional characters in the RST-DT segment.

A PDTB segment is considered *perfectly* aligned if all of its characters overlap with the RST-DT segment, or if the extra characters in the RST-DT segment are punctuation or explicit connectives. We consider instances of the latter as perfect since PDTB segments systematically exclude terminal punctuation and explicit connectives contrary to RST-DT segments. In Example (4), $arg1$ of the PDTB relation is perfectly aligned with $edu67$ since only punctuation differs and $arg2$ is perfectly aligned with the RST-DT segment $\langle edu68 - edu69 \rangle$.

(4) **PDTB:** [We've had a good relationship with GE]^{arg1} [which is the first time you could say that]^{arg2}

RST-DT: ["We've had a good relationship with GE,]^{edu67} [which is the first time]^{edu68}[you could say that]^{edu69}

On the other hand, a PDTB segment is considered *imperfectly* aligned with an RST-DT segment, if that RST-DT segment has the longest overlap with the PDTB segment among all RST-DT segments, and either the RST-DT or the PDTB segment includes extra characters beyond punctuation or explicit connectives. In Example (5), $arg1$ is *imperfectly* aligned with $edu92$ since the PDTB segment includes the additional tokens 'of the opportunity'.

(5) **PDTB:** [of the opportunity to "rebuild a franchise" at Kidder]^{arg1}

RST-DT: [to "rebuild a franchise" at Kidder.]^{edu92}

Table 2 shows statistics of the alignment of continuous PDTB segments onto RST-DT segments. As the table shows, most of the alignments found (85%) are perfect alignments and 50% consist of one PDTB argument being perfectly aligned with a single RST-DT EDU (1 : 1 alignments).

Discontinuous If PDTB segments are discontinuous, we align each of its constituents to an RST-DT segment using the same method as for continuous arguments. In Example (6), $arg2$ is discontinuous and split into two constituents: $arg2a$, which is aligned with $edu110$, and $arg2b$, which is aligned

[4] We will refer to PDTB arguments and to RST-DT EDU segments simply as segments for the remainder of the paper.

Type	Arg : EDU	Count (%)	Total (%)
Perfect	1 : 1	7,621 (50%)	12,959 (85%)
	1 : n	5,338 (35%)	
Imperfect	1 : 1	1,705 (11%)	2,329 (15%)
	1 : n	624 (4%)	
	Total	**15,288 (100%)**	**15,288 (100%)**

Table 2: Statistics of the alignment of continuous PDTB segments onto RST-DT segments.

Type	Constituent : EDU	Count	Total
Perfect	1 : 1	762 (38%)	936 (47%)
	1 : n	174 (9%)	
Imperfect	1 : 1	818 (41%)	1053 (53%)
	1 : n	235 (12%)	
	Total	**1,989 (100%)**	**1,989 (100%)**

Table 3: Statistics of the alignment of discontinuous PDTB segment constituents onto RST-DT segments.

with the RST-DT segment $\langle edu110 - edu111\rangle$.

(6) **PDTB:** Mr. Carpenter notes [that these types of investors]^{arg2a} also [are "sophisticated" enough not to complain about Kidder's aggressive use of program trading]^{arg2b}

RST-DT: [Mr. Carpenter notes]^{edu109} [that these types of investors also are "sophisticated" enough]^{edu110} [not to complain about Kidder's aggressive use of program trading.]^{edu111}

Table 3 shows statistics of the alignment of discontinuous PDTB segments onto RST-DT segments. As the table shows, the ratio of perfect alignments is lower than in the case of continuous arguments (47% vs 85%, see Table 2). However, $1 : 1$ alignments (i.e., one PDTB argument constituent being perfectly aligned to a single RST-DT EDU) are still more frequent than $1 : n$ alignments.

5.2 Relation Mapping

After aligning PDTB segments onto RST-DT segments, we map the PDTB relations to their most likely RST-DT relations. To do so, we rely on the strong nuclearity principle (Marcu, 2000) and on the notion of nucleus path (Demberg et al., 2019). In the context of the RST, the strong nuclearity principle dictates that relations annotated between segments of multiple contiguous EDUs also hold between the nucleus of each of these contiguous segments. The nucleus path, in turn, identifies the single nuclear EDU that originated the entire complex segment by always following the segments annotated as nuclei. Five different mapping scenarios are considered.

Perfect Mapping If both PDTB segments are continuous and perfectly aligned with different RST-DT segments, we map the PDTB relation to the lowest RST-DT relation covering these RST-DT segments. In Figure 2, $arg1$ is perfectly aligned with $\langle edu13 - edu18\rangle$ and $arg2$ is perfectly aligned with $\langle edu19 - edu20\rangle$. Therefore, we map the PDTB relation between $arg1$ and $arg2$, Implicit.Expansion, to Elaboration-Additional, the lowest RST-DT relation covering $\langle edu13 - edu18\rangle$ and $\langle edu19 - edu20\rangle$.

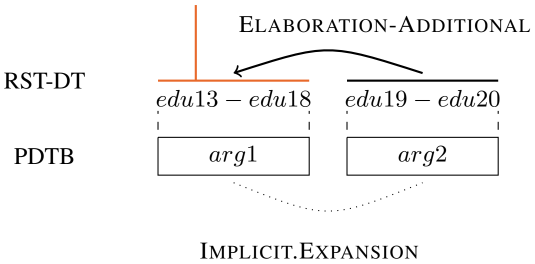

Figure 2: Example of a perfect relation mapping.

Imperfect Mapping If the nucleus paths of both RST-DT segments lead to an EDU that overlaps the aligned PDTB segment, then the potential mapping is retained. Figure 3 shows an example of an imperfect mapping. The lowest covering relation Explanation-Argumentative, is between $\langle edu91 - edu92\rangle$ and $\langle edu93 - edu96\rangle$. Following the nucleus path from $\langle edu91 - edu92\rangle$, the first nucleus found is $edu91$. Although $arg1$ is aligned with $edu92$, it overlaps with $edu91$ and is, therefore, in the nucleus path. The first nucleus in the nucleus path from $\langle edu93 - edu96\rangle$ is $\langle edu93 - edu95\rangle$. As $arg2$ overlaps perfectly with $\langle edu93 - edu95\rangle$ it is also in the nucleus path. As both PDTB segments are in the nucleus path, the PDTB relation between $arg1$ and $arg2$, Contingency.Cause, is mapped to the RST-DT Explanation-Argumentative relation.

Embedded Relation When both segments of a PDTB relation are aligned with the same RST-DT segment, the relation cannot be mapped. This occurs due to a difference in granularity across frameworks. In Example (7), illustrated in Figure 4, both $arg1$ and $arg2$ are aligned with $edu2$. The PDTB relation, Expansion.Manner, is more fine grained and does not have an equivalent RST-DT relation. In these cases, the PDTB relation cannot be mapped.

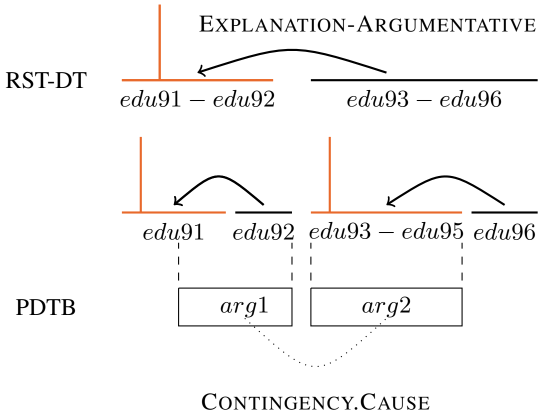

Figure 3: Example of an imperfect relation mapping.

(7) **PDTB:** [jump from murder to antitrust cases]^{arg1} [from arson to securities fraud]^{arg2}
RST-DT: [A judge must jump from murder to antitrust cases, from arson to securities fraud,]^{edu2}

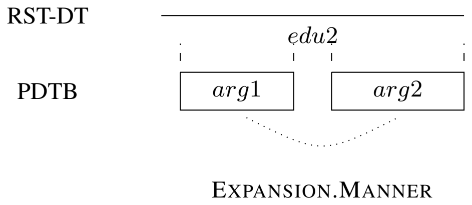

Figure 4: Example of an embedded relation which is not mapped.

If the mapping is neither perfect, imperfect or embedded, we identify the most immediate discourse relation between the aligned RST-DT segments as a potential map to the PDTB relation. We then follow the nucleus path from each of the RST-DT segments to their nuclear EDU and verify if it is included within the aligned PDTB segment. Three outcomes are possible.

Unclear Nucleus Path If at least one of the nucleus paths of the RST-DT segments leads to an EDU that does not overlap with the aligned PDTB segment, then we do not map the PDTB relation. In Figure 5, $arg1$ is aligned imperfectly with $edu101$, while $arg2$ is aligned perfectly with $edu104$. The closest covering RST-DT relation is CONSEQUENCE. As shown in Figure 5, the nucleus path from $\langle edu102 - edu104\rangle$ leads to $\langle edu102 - edu103\rangle$ which does not overlap with $arg2$. Therefore, the PDTB relation remains unmapped.

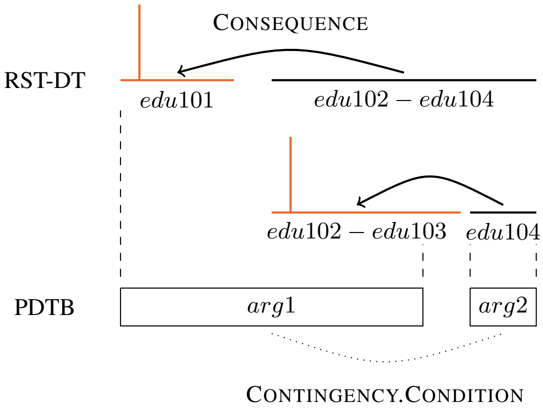

Figure 5: Example of an unclear nucleus path, which is not mapped.

Multinuclear Relation If at least one of the nucleus paths of the RST-DT segments leads to a multinuclear relation, it becomes impossible to identify a single nucleus to follow the nucleus path and we do not map the PDTB relation. In Figure 6, $arg1$ is aligned with $\langle edu139 - edu141\rangle$, while $arg2$ is aligned with $edu142$. As the figure shows, no single nucleus can be identified at the end of the nucleus path starting at $\langle edu138 - edu141\rangle$ because the following RST-DT relation, between $\langle edu138 - edu141\rangle$ and $\langle edu139 - edu141\rangle$, is a multinuclear relation and we cannot unambiguously trace it to $arg1$. As a consequence, the PDTB relation is not mapped.

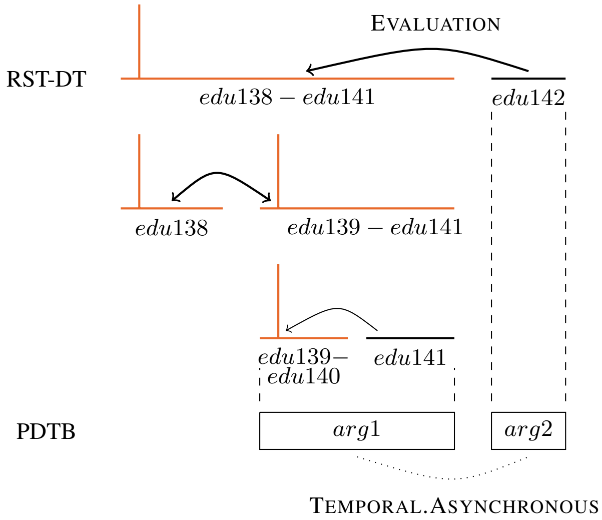

Figure 6: Example of a multinuclear relation, which is not mapped.

Discontinuous Relation If one segment of a PDTB relation is discontinuous and the other segment is embedded between its constituents, we attempt to map it. To do so, we verify if the RST-DT segments aligned with the constituents are related by a SAME-UNIT relation. If so, the PDTB relation is mapped to the RST-DT relation between the RST-DT segment aligned with the continuous PDTB segment and an RST-DT segment aligned with a PDTB constituent. An example is shown in Figure 7. As shown in the figure, $\langle edu96 - edu97 \rangle$ and $edu98$ have a SAME-UNIT relation, so we map the PDTB CONDITION relation, to the RST-DT CIRCUMSTANCE relation between $edu96$ and $edu97$.

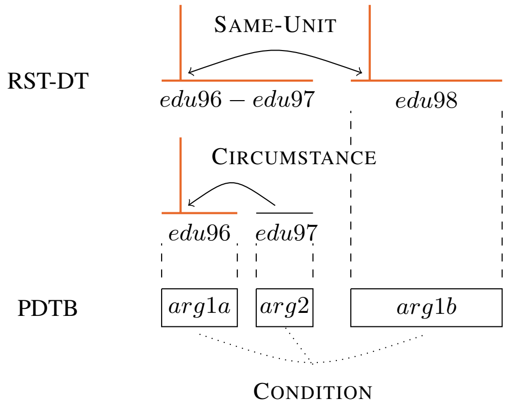

Figure 7: Example of a discontinuous relation mapping.

The five cases above illustrate how the mapping algorithm works in the different encountered scenarios. Based on it, we then established a mapping between the discourse relations that were successfully aligned in the overlapping articles of the RST-DT and the PDTB.

6 Results

We first present the results of the relation alignment (see Section 5.1) and then present the relation mapping results (see Section 5.2).

6.1 Relation Alignment

Table 4 shows the results of the relation alignment. Recall that to align a relation across frameworks both segments of the relation need to be aligned. As Table 4 shows, the approach was able to align 6,510 (80.0%) of the 8,134 explicit and implicit PDTB discourse relations in the overlapping articles of the RST-DT and the PDTB corpus. More precisely, our proposed algorithm was able to align 3,073 (73.7%) of the 4,169 explicit discourse relations and 3,437 (86.7%) of the 3,965 implicit relations.

As Table 4 shows, implicit relations have more successful alignments than explicit relations - 3,437 (86.7%) out of 3,965 vs 3,073 (73.7%) out of 4,169, respectively. This is because of the significantly higher number of discontinuous PDTB segments in explicit relations. In fact, 729 (17.5%) of all explicit discourse relations were impossible to align because at least one of the segments in the PDTB was discontinuous and no matching SAME-UNIT label was found in the RST-DT for the same segment spans. Whereas this only happened to 214 (5.4%) of all implicit discourse relations.

The higher number of discontinuous PDTB segments in explicit relations also comes as a consequence of the annotation style of the PDTB corpus. Because explicit relations are annotated based only on the presence of a connective, they are more permissive on the location and extent of their arguments. This creates a challenge when aligning the relations onto the RST-DT, where all adjacent text segments are connected. Conversely, for the implicit relations, given their more subjective interpretation, the PDTB only annotates instances where both arguments are adjacent to each other. Thus, leading to a clearer agreement with the annotation style of the RST-DT.

Another interesting result shown in Table 4 is the higher number of imperfect alignments among explicit relations (836/3,073) compared to implicit relations (375/3,437). A manual analysis shows that most of these imperfect alignments correspond to PDTB relations where the segments are not adjacent. This led to instances where the corresponding RST-DT text segments are made of multiple contiguous segments that do not exactly match the span of the PDTB segments. This, however, does not happen for implicit relations as they are only annotated in the PDTB between adjacent segments.

6.2 Relation Mapping

Once the relation segments were aligned, we mapped the relation labels (see Section 5.2). Table 5 shows the mapping of the 3,073 aligned explicit discourse relations, while Table 6 shows the mapping of the 3,437 aligned implicit discouse relations. To keep both tables readable, we show only discourse relations for which at least one mapping was found with at least 30 instances. Percentages and color gradients are calculated row-wise.

As Tables 5 and 6 show, and similarly to what Demberg et al. (2019) found, we obtain a clearer mapping for explicit discourse relations when compared to implicit discourse relations. If we consider relations that appear in both tables, such as

Relation Mapping	Discourse Relation	Type	Count	Sub-Total	Total
Possible	Explicit	Perfect Mapping	2,237 (28%)	3,073 (38%)	6,510 (80%)
		Imperfect Mapping	836 (10%)		
	Implicit	Perfect Mapping	3,062 (38%)	3,437 (42%)	
		Imperfect Mapping	375 (5%)		
Impossible	Explicit	Embedded Relation	106 (1%)	1,096 (14%)	1,624 (20%)
		Unclear Nucleus Path	64 (1%)		
		Multinuclear Relation	197 (2%)		
		Discontinuous Relation	729 (9%)		
	Implicit	Embedded Relation	50 (1%)	528 (6%)	
		Unclear Nucleus Path	81 (1%)		
		Multinuclear Relation	183 (2%)		
		Discontinuous Relation	214 (3%)		
Total			8,134 (100%)	8,134 (100%)	8,134 (100%)

Table 4: Alignment results between relations in the overlapping articles of the RST-DT and the PDTB corpus.

the RST-DT List relation, we observe a more predominant mapping to single explicit PDTB relations than what we observe for implicit relations. For instance, 664 (95.0%) out of the 699 RST-DT List relations in Table 5 are mapped to the PDTB Expansion.Conjunction relation. On the other hand, in Table 6, only 302 (63.0%) out of 479 List relations are mapped to the PDTB Expansion.Conjunction, while 92 (19.2%) are mapped to Contingency.Cause and 45 (9.4%) are mapped to Temporal.Asynchronous. The same is true for other discourse relations occurring in both tables.

Compared to the results obtained by Demberg et al. (2019), we observe other similar patterns. For instance, the PDTB Temporal class in Table 5 shows very clear mappings between the RST-DT Temporal-Same-Time and Temporal-After to the PDTB explicit Temporal.Synchronous and Temporal.Asynchronous, respectively. In addition, the explicit discourse relations in the PDTB Comparison and Contigency classes are harder to unambiguously map to individual RST-DT relations. Finally, for the discourse relations in the PDTB Expansion class in Table 6, we observe the same difficulties in establishing a mapping to their RST-DT counterparts.

The clearer mapping between explicit relations compared to implicit relations, contrasts with the alignment results presented in Section 6.1. However, this was expected, since the presence of an explicit discourse connective allows for a more objective interpretation of the discourse relation that holds between the text segments.

7 Conclusion

In this paper we have presented a first empirical mapping between the RST-DT and the PDTB 3.0 annotated corpora. Following our proposed algorithms we were able to map 6,510 (80.0%) of the explicit and implicit discourse relations in the 365 Wall Street Journal articles overlapping the RST-DT and the PDTB 3.0 corpora. Compared to the 76% successfully mapped relations obtained by Demberg et al. (2019) in their empirical mapping between the RST-DT and the PDTB 2.0, we were able to achieve a 4% improvement in mapping coverage.

Our alignment results show a clearer correspondence between segments of implicit discourse relations when compared to segments of explicit relations. This is a consequence of the difference in annotation between the two corpora. Since the RST-DT establishes discourse relations between all adjacent text segments, the PDTB often establishes explicit relations between text segments which are not adjacent. This creates a challenge for the alignment algorithm. However, when an alignment was found, we observed a clearer mapping between explicit discourse relations than between implicit discourse relations. This stems from the presence of discourse connectives which allow for a more objective interpretation of the relations.

8 Limitations and Future Work

The empirical mapping proposed was based exclusively on the 365 overlapping articles of both

PDTB / RST-DT	Comparison		Contingency		Expansion	Temporal		Total

Table 6: Mapping results for the aligned PDTB implicit discourse relations. The table shows only discourse relations for which there was at least one mapping with a total of at least 30 instances (i.e., 2,331 relations instead of 3,437). The percentages and the color grading were calculated row-wise.

annotated corpora. We did not consider the remaining non-overlapping articles in our mapping as we would not be able to find a correspondence to the existing discourse relations on the other corpora. Based on our findings we could extrapolate our mapping to the remaining articles within a certain degree of accuracy, but a such a mapping could not be afterwards used to attest the robustness of our approach. Therefore, we preferred to focus only on the articles for which an objective correspondence could be established between both corpora.

As future work, we would like to extend the work to include AltLex and AltLexC discourse relations to have a more complete mapping between both corpora. We would also like to develop automatic segmentation and discourse relation classifiers based on our results to then establish a mapping between the remaining Wall Street Journal articles that do not currently overlap the RST-DT and the PDTB 3.0. This would allow us to generate a more comprehensive set of discourse annotated data following two of the most widely used discourse frameworks for the fine-tuning of large language models.

Reproducibility

We used the Gate Embedded API and Java for the implementation. Our code can be found on GitHub[5].

Abstract

We investigate approaches to classifying texts into either conspiracy theory or mainstream using the Language Of Conspiracy (LOCO) corpus. Since conspiracy theories are not monolithic constructs, we need to identify approaches that robustly work in an out-of-domain setting (i.e., across conspiracy topics). We investigate whether optimal in-domain settings can be transferred to out-of-domain settings, and we investigate different methods for bleaching to steer classifiers away from words typical for an individual conspiracy theory. We find that BART works better than an SVM, that we can successfully classify out-of-domain, but there are no clear trends in how to choose the best source training domains. Additionally, bleaching only topic words works better than bleaching all content words or completely delexicalizing texts.

1 Introduction

With the rise of social media over the last 10 years, there has also been a rise in the uses of the internet to spread different types of information, some of it of a more questionable nature. We are interested in the spread of conspiracy theories, which have morphed from a fringe phenomenon to a more widely visible, mainstream phenomenon. Along with the increasing spread of misinformation, conspiracy theories have been shown to polarize opinions to extremes and to incite violence (Douglas and Sutton, 2018; Enders et al., 2022).

While conspiracy theories are often seen as monolithic belief systems, the truth is more complex: People who admit to believing a specific conspiracy theory tend to also believe in other conspiracy theories, but they may only believe different subsets of factoids associated with a specific conspiracy theory (Enders et al., 2021). For any computational approach to detecting conspiracy theories, this means that we cannot expect to have access to accurate training data. Instead, we will face novel mixes of factoids and conspiracy theories, which deviate from existing training data. For this reason, we investigate here whether it is possible to find out-of-domain conspiratorial texts. We use the Language Of Conspiracy (LOCO) corpus (Miani et al., 2021) to develop classifiers that label a text as either conspiratorial or mainstream, and we investigate under which conditions such classifiers work robustly out-of-domain. More specifically, we investigate bleaching methods to steer the classifiers away from words that are typical for a single conspiracy theory (e.g., 'global warming' for conspiracy theories revolving around climate change).

The remainder of this paper is structured as follows: Section 2 explains our research questions, section 3 describes related work, and section 4 describes our data and methodology. Section 5 describes our results for the in-domain setting (section 5.1), for the out-of-domain setting (section 5.2), and for the bleaching experiments (section 5.3). We conclude in section 6.

2 Research Questions

In this paper, we investigate the following research questions:

1. Which machine learning architectures are well suited for classifying texts into conspiracy theory and mainstream? Which feature types do we need? Does feature selection improve results for SVMs?

2. Can we classify out-of-domain texts? In other words, do we need training data from a specific conspiracy theory, or is it possible to reuse existing training data to detect novel conspiracy theories?

Proceedings of Recent Advances in Natural Language Processing, pages 353–363
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_040

3. Does bleaching specific words improve out-of-domain results? I.e., can we identify sets of words that are too specific for a single conspiracy theory but do not work well for classifying texts from another conspiracy theory?

3 Related Work

We restrict our review to work on conspiracy theories and their detection. We acknowledge work on propaganda detection and persuasive technology detection (e.g., Barrón-Cedeño et al., 2019; Da San Martino et al., 2019; Martino et al., 2019). There is overlap between these areas of research and the detection of conspiracy theories, given that both approaches work on the document level and examine how information is manipulated. However, propaganda detection primarily focuses on politically related events, whereas conspiracy beliefs tend to span a wide array of topics.

Although exact markers have proven difficult to identify for conspiracy theories, Wood et al. (2012) showed that conspiracy theory proponents often subscribe to multiple conspiracies, some contradictory, which led them to conclude that conspiracy theories are not stand-alone phenomena from individuals. Instead, conspiracies might come in clusters caused by general conspiratorial thinking.

Work by Klein and Hendler (2022) found that certain lexical items can be used to differentiate between some conspiratorial and non-conspiratorial texts in Reddit posts and a forum popular among anti-vaccine proponents. Examples of conspiracy-indicative lexical items include so-called thought-terminating cliches, such as 'agree to disagree', 'do [your/your own/the] research', and dysphemisms such as 'fraudulent', 'deceptive', and 'deceive' rather than 'lie.'

Attempts to identify linguistic characteristics used in conspiracy theories were explored by Klein et al. (2019). They used the Linguistic Inquiry and Word Count (LIWC) to analyze the conspiracy subreddit, in order to identify lexical categories based on a semantic knowledge base. In a majority of instances, conspiracy users exhibited a statistically relevant usage of words used to induce 'negative emotion' and 'anger' among others, making conspiracy texts more distinguishable.

Similar findings were noted within the Language Of Conspiracy (LOCO) corpus (Miani et al., 2021). The corpus was seeded using phrases related to conspiracy theories to collect close to 100 000 text documents taken from 150 websites, dividing texts into those containing conspiratorial content and mainstream documents. A lexical analysis of conspiracy based on LIWC categories and using Empath, a tool that generates new lexical associations in texts, showed that conspiracy theories contain more emotionally charged language, particularly language indicating negative emotions such as anger.

Mompelat et al. (2022) analyzed two conspiracy theories, Sandy Hook and Coronavirus, in the LOCO corpus, to establish a set of unique features (e.g., linguistic) by which mainstream and conspiracy documents could be differentiated. They noted that a significant portion of conspiracy documents did not contain unique identifiable features, suggesting automatic classification would be difficult. They also found that mainstream documents were frequently irrelevant regarding the topic of the conspiracy theory for which they were retrieved.

As new conspiracy theory corpora have been assembled, the capabilities of models to detect novel conspiracy theories have been explored. Phillips et al. (2022) created a Twitter data set covering four conspiracy topics: climate change, COVID-19 origin, COVID-19 vaccine, and the Epstein-Maxwell trial. They used several BERT variants to classify tweets as conspiracy theory vs. non-CT, to identify the tweets' stance towards a conspiracy theory, and to detect the topic of the conspiracy theory. While they suggest that successful models can be built with relatively small data sets, they also note that annotator disagreement and class imbalance can contribute to difficulties in reliable classification.

4 Methodology

4.1 Data Set

We use the Language Of Conspiracy (LOCO) corpus (Miani et al., 2021) and select five conspiracies that fall across a spectrum of political and social associations: vaccines, climate change, pizzagate, flat earth, and bigfoot. Given the uneven distribution of these conspiracies in the LOCO corpus, ranging from approx. 1 300 to 7 000, we randomly select a subsample of 1 330 texts from each conspiracy, while maintaining a relative balance between the mainstream and conspiracy labels across the conspiracy theories. We then randomize the data and create an 80/10/10 split of training/development/test data. The final numbers of documents per set are shown in Table 1.

	Train		Develpment		Test	
Topic	Mainstream	Conspiracy	Mainstream	Conspiracy	Mainstream	Conspiracy
vaccine	796	268	104	29	100	33
climate change	799	265	99	34	102	31
pizza gate	808	256	95	38	97	36
flat earth	802	262	100	33	98	35
bigfoot	816	248	93	40	91	42

Table 1: Data split per conspiracy theory.

4.2 Classifiers

SVM We train a model using an SVM (Cortes and Vapnik, 1995) with a linear kernel using different feature sets including word n-grams, character n-grams, and POS tags. We set the minimum frequency to 1; word n-grams include unigrams, bigrams, and trigrams while character n-grams are between 3-7 in length. All experiments are performed using scikit-learn (Pedregosa et al., 2011). We perform a grid search to find the best parameters of our SVM models by evaluating on the development set on in-domain experiments and then use these parameters for all other experiments.

Feature selection For the feature selection experiments, we use the built-in χ^2 metric in scikit-learn.

Transformer We use BART (Lewis et al., 2020), a pre-trained transformer-based seq2seq model with a bidirectional encoder, but a left-to-right autoregressive decoder. Rather than optimizing on next sentence prediction, the model is trained by restoring corrupted documents to their original form. One advantage of this is that the model is thus learning larger structures and context within a document rather than a more localized neighboring sentence. We view this as preferential given the longer length of documents and irregular information ordering. Additionally, the maximum tokenized input is 1024, which is double the maximum input to standard BERT models (Devlin et al., 2019). Both aspects should benefit our use-case given the relatively long length of individual documents within the corpus (see section 5.4). Despite this, most documents are still too long to be embedded. We choose to embed the first and last 512 subtokens in order to attempt to capture more information on a document level[1]. We experiment with one, three, and five epochs on the dev set for in-domain experiments and select the epoch (5) with the highest average across all conspiracy theories for all additional experiments.

The best hyperparameters for both models are listed in Table 8 in the Appendix A.

4.3 POS Tagging and Topic Modeling

POS tagging We use Stanza (Qi et al., 2020) and extract POS unigrams, bigrams, and trigrams; using a minimum frequency of 1 and absolute counts across our datasets.

Topic modeling To determine the most important words for a conspiracy theory, topics were extracted via topic modeling. We use LDA (Blei et al., 2003), set $N = 5$ (to represent the five conspiracies), and exclude stopwords[2] since a first run including stopwords showed a high number of stopwords in the topics word, most of them repeated among different topics.

We then extract the 20 highest ranked words (see Table 2). We can see that some of the conspiracies are clearly represented in a certain cluster, such as cluster one heavily containing words associated with vaccines while clusters three and five represent climate change. We assume that these highly associated words can hinder the ability to identify more in-domain conspiracies and use these words as a basis for bleaching experiments (see Section 5.3).

4.4 Evaluation

We report the F1 score on the test sets.

5 Results

5.1 In-Domain Experiments

We first experiment with an in-domain setting, i.e., we train and test on the same domain. This provides us with an upper bound in terms of how difficult the problem is and how much variation we can expect across the five conspiracy theories. We also use

[1] Prior experiments with BERT or using the first 1024 subtokens in BART resulted in lower scores.

[2] We use NLTK (Bird et al., 2009) stopwords and an additional set of common words not present in that base list.

cluster	topic words
1	vaccine vaccines health people children may virus also disease said one autism coronavirus 19 covid medical study vaccination cases flu
2	it people like that one think going re know we get said would you time there ve want go they
3	earth climate change years one warming global water could scientists also would world ice like planet sea time science new
4	trump one said news people us media it also world conspiracy would new like president time many clinton the state
5	climate change said world global new countries emissions also would health government year states energy china people economic public united

Table 2: Words associated with each LDA topic.

classifier	features	vaccine	climate change	pizzagate	flat earth	bigfoot
SVM	word	82.33	85.84	91.19	84.57	81.41
	char	88.30	84.05	92.38	85.28	83.67
	word+char	88.30	84.05	92.38	85.28	83.67
BART	word	**96.88**	**93.39**	**95.20**	**93.02**	**95.56**

Table 3: Results (F1) of in-domain experiments across 5 conspiracy theories.

these experiments to determine which classifiers work well for the problem and which features are useful, results of which are in Table 3.

For the SVM, word n-grams provide strong baselines, but most domains benefit from character embeddings, with vaccine seeing an almost 6% absolute increase, and only climate change showing a decrease about 1.8%. Interestingly, we see that character only and word+character features yield the same results. We assume that this indicates that character n-grams are more useful, as they are higher in frequency and capture many words at the subword level. BART has the highest overall performance, with bigfoot increasing almost 12% absolute over the word+char SVM experiment, and the variation across domains is reduced.

It is also obvious that different conspiracy theories provide various levels of difficulty, with vaccine generally being the easiest and climate change and flat earth being the most difficult ones for BART. However, we also see differences between the different classifiers and features. For the word-based SVM, for example, bigfoot seems to be the most difficult and pizzagate the easiest.

We experiment with feature selection for the word model as we assume that many n-grams will be of little use or misleading. We chose the word setting since this is the most explainable setting, and the setting that has the highest potential of improvement. Table 4 presents results for the feature selection experiments, with the 'all' setting containing all word features from Table 3 (approximately one million).

Results for feature selection do not show any clear tendencies, as three different trends emerge as the number of features are reduced: a trend towards a slight increase in performance (vaccine), a general decrease in performance (climate change and flat earth) and then a slight buoy effect with an increase then decrease (bigfoot). This suggests the optimal number of features for each domain is unique and we cannot generalize feature thresholds effectively.

5.2 Out of Domain: Comparing Source Domains

Table 5 shows the results when we train on one domain and classify out-of-domain texts. For ease of comparison, we repeat the in-domain results (underlined). In this setting, we either use a single conspiracy theory as training set, or we use a mix of the four conspiracy theories and test on the fifth. We assume that a mix of conspiracy theories may provide a more general basis in an out-of-domain setting. In order to avoid effects of training set size, we use quarter of the texts per conspiracy theory so that the mixed training set is similar in size to the individual sets.

no. features	vaccine	climate change	pizzagate	flat earth	bigfoot
all	82.33	**85.84**	91.19	**84.57**	81.41
3000	79.79	82.78	**91.50**	83.54	82.64
2000	83.18	80.16	87.73	76.33	**82.86**
1000	83.18	82.32	89.62	75.93	81.58
500	**83.54**	79.79	90.31	76.33	79.74

Table 4: Results (F1) of feature selection experiments using SVMs and word n-grams.

For most conspiracies, out-of-domain detection yields poorer performance compared to in-domain results, with some pairs exhibiting extreme drops of performance. For example, training on climate change and testing on pizzagate using word-based features in the SVM results in an F score of 53.17, as compared to 91.19 when testing on pizzagate in-domain. In general, the decrease is less pronounced for BART, with some exceptions. For example, when training on bigfoot and testing on pizzagate, the F score only reaches 69.00 while we reach 95.20 in-domain[3].

The best results overall are reached by BART. However, for climate change, flat earth, and bigfoot, we reach the best results when training on a single conspiracy theory. For vaccine, using a mix of conspiracy theories for training works better, and for pizzagate, both settings work equally well.

Overall, there is no clear trend concerning which conspiracy theory is best suited as training set in an out-of-domain setting. Even for a specific target domain, the best training domain varies based on the choice of classifier and features. For example, when testing on vaccine, the word-based SVM and BART prefer a mixed training set, while the character-based and char+word SVM prefer bigfoot.

For out-of-domain feature selection results, we see the same general trend as in Table 4 as performance not only drops across domains, but, in the majority of cases, a reduction of features yields even worse performance (for details see Table 9 in the Appendix B). Single out-of-domain conspiracy detection may simply not be highly detectable with small subsets of features due to the specific lexical co-occurrences within a specific domain. The mixed setting mostly gives the best results, either with all features (vaccine, pizzagate) or with 2000 features (climate change, flat earth); for bigfoot, the mixed results using all features are very close to the results using all features when training on vaccine. However, even in the mixed setting, we see a degradation in performance, even though this set should include a higher degree of lexical variation. This vocabulary seems to be specific to the source conspiracies, not a potentially evolving conspiracy.

5.3 Bleaching Features for Domain Adaptation

A classifier's generalizing ability in an out-of-domain setting can be affected by words that are good predictors for individual conspiracy theories. For example, the word 'Sasquatch' will be especially useful in identifying bigfoot conspiracy theory texts, but it will not be useful for pizzagate. For this reason, we need to create more abstract feature representations abstracting away from lexical information. One approach is bleaching, which aims to abstract meaning away from specific word features and to create more robust abstract features that may capture more meta or abstract characteristics of a text. While some bleaching techniques are focused on generating meta characteristics of words (e.g., how many alphanumeric characters) and have helped in cross-lingual gender prediction (van der Goot et al., 2018), we are more interested in lexical bleaching, similar to work by Tian and Kübler (2021), who bleached proper nouns for period classification of Chinese texts, by replacing them by their POS tags.

We chose to apply various levels of word bleaching: complete delexicalization (POS), content word bleaching, and topic word bleaching. In the delexicalization process, we utilized POS unigrams, bigrams, and trigrams instead of word n-grams. However, we assume that this form of bleaching will be too extensive, and that the POS features will not retain enough information for our task. Thus, for content word bleaching, we substituted nouns, verbs, adjectives, adverbs, and foreign words by their re-

[3] We acknowledge that overfitting may play a role in performance drops in out-of-domain settings. This is due to our experimental setting where we optimize the parameters in-domain, assuming it is infeasible to optimize for every test domain.

classifier	features	source	vaccine	climate change	pizzagate	flat earth	bigfoot

		climate change	95.01	93.39	80.26	88.57	90.36
		pizzagate	91.94	87.04	95.20	90.84	**93.70**
		flat earth	92.87	89.40	89.27	93.01	90.37
		bigfoot	94.91	**92.19**	69.00	86.50	95.56
	word	mix	**95.49**	88.05	**90.79**	89.71	91.90

Table 5: Results (F1) for out-of-domain experiments across 5 test CTs. In-domain results are underlined; best out-of-domain results are bolded.

spective POS tags. Again, this form of bleaching is less extreme than complete delexicalization, but it may still delete too many important lexical items. Thus, we investigate a third form of bleaching where we identify words that are typical for a conspiracy theory, and then only substitute those. For topic word bleaching, we use topic modeling to identify these CT specific words and substitute the words from Table 2.

Table 6 presents results for all bleaching experiments. For delexicalization, SVM results for in-domain experiments are substantially lower than the baseline word n-grams seen in Table 3. BART experiments show a more severe degradation, with F-scores ranging from 42.42 (flat earth) to 68.44 (climate change). This may be anticipated as an input of POS tags instead of words leads to a misalignment with the training words used to train the contextual embeddings. Then, the generated embeddings from the POS representations are most likely lower in quality and information. Our results suggest that the model cannot be fine-tuned on a more coarse-grained representation, which contradicts findings for cross-lingual zero-shot parsing using a multilingual language model (Zhou and Kübler, 2021).

For the out-of-domain experiments, in most cases, the POS setting still yields worse performance than the equivalent baseline experiments (Table 5), there is one exception: When training on pizzagate and testing on climate change, abstracting away from the lexical level can potentially help. Thus, overall, we conclude that POS tagging removes too much lexical content and leaves the classifier unable to distinguish conspiracy and mainstream texts.

For content word bleaching, we also see mixed results across settings in comparison to POS bleaching. For some domains, there is an increased performance across all settings (e.g., vaccine) while for others, there are mostly negative trends (e.g., pizzagate), and other domains show volatility in both directions (e.g., climate change). For BART, almost all settings show increased performance compared to POS representations, but they are all still substantially lower than their word experiment coun-

class.	features	source	vaccine	climate change	pizzagate	flat earth	bigfoot

terparts.

Topic word bleaching shows some increased performances for SVM in in-domain settings not only over content words, but over the initial word n-gram SVM models, specifically for vaccine, climate change, and pizzagate. However, the words in Table 2 are heavily representative of these three conspiracies, not seemingly including words more associated with flat earth and bigfoot. It is an open question whether including more words associated with the latter CTs could yield improvements, or whether those CTs are less specific and do not have any clear topic words.

5.4 Text Length Distributions

One factor that may influence both in-domain and out-of-domain results is text length. Table 7 presents the means and standard deviations for both conspiracy and mainstream texts across domains. Some domains show rather large variations. For

	mainstream		conspiracy	
source	mean	stdev	mean	stdev
vaccine	836.89	879.80	1079.87	1112.09
climate change	949.67	1080.65	1085.83	1150.55
pizzagate	1031.49	1421.66	1504.92	1637.73
flat earth	849.93	985.01	1644.65	1622.10
bigfoot	886.80	1095.04	1693.90	1805.82

Table 7: Average length and standard deviation of the number of words per data set.

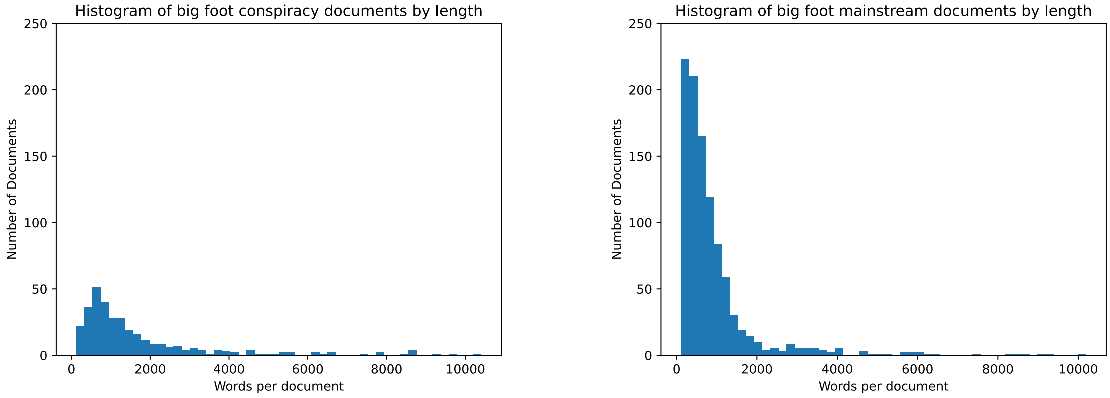

Figure 1: Text length distributions for bigfoot conspiracy (left) and mainstream (right) documents.

example, Figure 1 shows the text distributions for bigfoot between conspiracy and mainstream texts: The distribution of mainstream texts is heavily right skewed and of shorter lengths, while the bigfoot conspiracy texts are not as heavily right skewed and reflect a high average of text lengths: The average bigfoot conspiracy texts are almost twice as long as their mainstream counterparts.

Across domains, both mainstream and conspiracy texts also vary substantially, with vaccine texts having the shortest average length, pizzagate exhibiting longer mainstream texts, and bigfoot longer conspiracy texts. Similar trends are seen across the domains. One side effect of such distributions is that more information is contained in the conspiracy texts that may be relevant for identification than their mainstream counterparts, which, while shorter, are more frequent. This means we have data imbalance in both directions, both in the number of texts labeled conspiracy, and in the length of the texts, with conspiracy texts presumably containing more relevant information but spanning over longer contexts.

6 Conclusion

We presented a systematic set of experiments into how successfully we can classify conspiracy theories in both an in-domain and out-of-domain settings using different features and classifiers. Results showed, unsurprisingly, that while an SVM model presents strong baselines, a transformer-based model yields superior performance in both in-domain and out-of-domain settings. Of more interest though is that determining good source topics for detecting out-of-domain conspiracy theories is extremely difficult and not intuitive. It remains unclear what exactly the core semantic and structural relationships between conspiracies and mainstream texts are. While bleaching too much content (replacing all words or content words by POS tags) yields poor performance, bleaching typical words per conspiracy theory is promising.

One inherent difficulty that makes further in-depth analysis difficult is data quality of the automatically retrieved LOCO documents (Mompelat et al., 2022), which may hinder the efficacy of the resulting models. However, it is also clear that conspiracy theories are not as monolithic as assumed here. Research into the spread of conspiracy theories shows that people who believe in one conspiracy theory are also likely to believe in others, but not everybody believing in a CT will believe the same subset of factoids (Enders et al., 2021). This may also mean that the texts collected per CT are less homogeneous than necessary for classification.

Further research will need to investigate in more detail the inter-relatedness between different conspiracy theories. A better understanding of how they relate content-wise may allow us a better understanding of how to create a robust training set that can be used to detect conspiracy theories out of domain. Additionally, we are planning to investigate better bleaching methods, along with having a closer look at the SVM features that show the highest correlation with conspiracy theories, to determine defining characteristics of conspiratorial language across different domains.

7 Ethics Statement

Creating automated methods for detecting conspiratorial content in texts is always associated with the risk that the machine learner will learn and potentially amplify biases present in the training data. The LOCO corpus, which serves as the basis for our investigation, was collected automatically, using seed phrases. For this reason, it is unknown how well the data collection worked, and which biases the corpus contains. Mompelat et al. (2022) have shown that for at least one conspiracy theory, the mainstream collection of texts contains a non-trivial number of irrelevant texts. This can lead to a classifier that is more topics-based than focused on separating conspiracy theories from factual texts concerning similar topics. However, at this point of time, this corpus is the most extensive collection of texts that contains a range of conspiracy theories along with mainstream documents covering the same topics.

Abstract

For school teachers and Designated Safeguarding Leads (DSLs), computers and other school-owned communication devices are both indispensable and deeply worrisome. For their education, children require access to the internet, as well as a standard institutional ICT infrastructure, including e-mail and other forms of online communication technology. Given the sheer volume of data being generated and shared on a daily basis within schools, most teachers and DSLs can no longer monitor the safety and wellbeing of their students without the use of specialist safeguarding software. In this paper, we experiment with the use of state-of-the-art neural network models on the modelling of a dataset of almost 9,000 anonymised child-generated chat messages on the Microsoft Teams platform. The dataset was manually annotated into two binary classes: true positives (real safeguarding concerns) and false positives (false alarms) that a monitoring program would be interested in. These classes were then further annotated into eight fine-grained classes of safeguarding concerns (or false alarms). For the binary classification, we achieved a macro F1 score of 87.32, while for the fine-grained classification, our models achieved a macro F1 score of 73.56. This first experiment into the use of Deep Learning for detecting safeguarding concerns represents an important step towards achieving high-accuracy and reliable monitoring information for busy teachers and safeguarding leads.

1 Introduction

As our lives become ever more digital, traditionally "offline" activities are steadily moving online, and child safeguarding is no exception. In simpler times, it might have been enough for a schoolteacher to walk up and down a classroom to cast an eye over their pupils, or for a member of staff to oversee breaks in the playground to ensure that no bullying takes place. These days, however, children are often to be found online: when they aren't using school computers to do their work, they are reading news and social websites, watching videos, messaging one another, and sharing content. As a result, schools are now reliant on specific safeguarding technology to help monitor the online activities of their pupils.

So necessary is this technology that the UK's statutory guidance for schools and colleges on safeguarding children, *Keeping Children Safe in Education* (KCSIE)[1], heavily emphasises the dangers posed by the internet in schools and outlines the obligations of staff to ensure that appropriate web filtering and monitoring systems are in place. As a result, such systems are commonplace and are used in schools and colleges across the UK as well as abroad. KCSIE points to a range of online risks to which schools must be vigilant, ranging from harmful web content (e.g. pornography, fake news, extremism) to problematic forms of contact (e.g. online grooming, child exploitation), bad behaviour (e.g. cyberbullying, sharing of explicit images), and financial traps (e.g. online gambling, inappropriate advertising, phishing).

Given that no digital monitoring system can be perfect, and given the seriousness of child safety, human discernment is still required even for the most sophisticated risk-detecting algorithms. The output of a school's online monitoring system is typically reviewed by a Designated Safeguarding Lead (DSL) or other trusted member of staff before incidents can be triaged and acted upon. As such, it is a priority that such systems capture as many true positive cases as possible while minimising

WARNING: This paper contains offensive examples.

the number of false positives (i.e. noise). For a sensitively tuned safeguarding system that's geared more towards recall than precision, false positives are unavoidable, but they also represent a burden on the DSL in that they require time and energy to review and discard before real safeguarding concerns can be acted upon.

While much progress is being made in online safeguarding technology, most products are still bedevilled by the same NLP challenges faced in every other sector that utilises computational linguistics: word-sense disambiguation, parsing, coreference resolution, and sentiment analysis, just to name a few. Meanwhile, we have witnessed huge strides in NLP applications with the assistance of neural networks and other advanced machine learning techniques, the likes of which are only very recently becoming visible in the educational technology and child safeguarding sectors.

In this paper, we describe some initial experiments into applying Deep Learning (DL) techniques to the problem of online safeguarding for schoolchildren. We carry out these experiments in the hope of developing more useful and accurate safeguarding technology that will save schools time and effort and ultimately help to protect children better. In this particular case, we focus on messages sent between children on school-owned devices, specifically on the chat platform of Microsoft Teams, as captured by a keylogging cloud-based safeguarding tool, Senso.cloud. A safeguarding concern in such chat messages might be anything from bullying and discriminatory language to disclosures of self-harm and other indications of mental health risks.

The remainder of the paper is structured as follows. In Section 2, we explore some of the related work that has already been carried out, as well as the gap that we aim to address with our ongoing work. Section 3 describes the process of data collection and data annotation, followed by Section 4, which explains the use of machine learning models in our experiments. Section 5 reports on the results of our experiments, and in Section 6, we conclude the paper with a brief discussion and some comments on future work.

2 Related Work

While there is not, to our knowledge, a safeguarding study that is directly comparable with this one, we discuss in this section some examples of machine learning and deep learning in NLP generally, as well as the use of NLP for various safeguarding applications.

2.1 Machine Learning and Deep Learning in NLP

Over the years, machine learning has been widely used in NLP tasks including text classification, which we utilise in this study. Early approaches relied heavily on feature engineering combined with traditional machine learning classifiers such as Naive Bayes and support vector machines (Dadvar et al., 2013; Xu et al., 2012). More recently, neural networks such as LSTMs, bidirectional LSTMs, and GRUs combined with word embeddings have proved to outperform traditional machine learning methods in text classification (Aroyehun and Gelbukh, 2018; Modha et al., 2018).

With the recent introduction of transformer models such as BERT (Devlin et al., 2019), deep learning methods have been applied to various text classification tasks and achieved state-of-the-art results in many benchmarks. The transformer models have a transfer learning approach in which the model is pre-trained on a large number of documents and then fine-tuned to a downstream task such as text classification (Ranasinghe et al., 2019). This transfer learning strategy has provided excellent results and, consequently, the NLP community has successfully applied transformers to many tasks (Ranasinghe and Zampieri, 2020).

2.2 NLP for Safeguarding

Hatespeech, trolling, cyberaggression and cyberbullying have become the focal areas of regular shared tasks, conferences and special issues (Zampieri et al., 2020, 2019b; Satapara et al., 2023; Modha et al., 2022). There have also been recent works dedicated to the detection of mental health problems online, such as on social media (Bucur et al., 2021; Bannink et al., 2014). All of these represent useful and timely applications of machine learning methods to certain specific aspects of online safety.

Promising work has also been undertaken in automatic online grooming detection, such as Cano et al. (2014), Zuo et al. (2018) and Anderson et al. (2019); see also Borj et al. (2022). Building on this body of research, the DRAGON-S project at Swansea University seeks to utilise machine learning to identify the conversational stages that characterise an online grooming interaction and then develop an automatic groomer "spotter" tool

(Lorenzo-Dus et al., 2023). Meanwhile, the detection of online sexual predatory behaviour using DL has become the subject of an edited volume published this year (Kesavamoorthy et al., 2023).

SafeChat, a system developed by researchers at the University of Sunderland (MacFarlane and Holmes (2018); Seedall et al. (2019)), is a DL-driven chat moderation app for children that specifically seeks to prevent children from sharing inappropriate personal information (e.g. home address, or a meeting place) to mitigate threats to physical safety. Similarly, SafeToWatch is a visual threat detection solution for mobile phones, developed by SafeToNet and the Internet Watch Foundation, which utilises machine learning to recognise the generation of child sexual abuse material in real time and proactively prevent the material from being created or sent (IWF, 2023).

All of these represent important contributions to data-driven, intelligent child protection. However, each of these is focused on achieving one specific safeguarding goal, such as detecting depression or identifying conversations with online predators. Research and development that applies deep learning to generalised safeguarding, i.e. seeks to detect a range of safeguarding concerns for the benefit of teachers and DSLs, is thin on the ground. While there are commercial safeguarding systems that claim to utilise AI technology to this end, details of such systems are not (to our knowledge) made available in public-facing documents or publications.

3 Data

In this section we outline our data collection and annotation as well as ethical considerations.

3.1 Data Collection

Senso.cloud[2] is proprietary, cloud-based software used to help monitor and protect children using computers in schools. It primarily employs a key-logging approach to violation detection, which essentially matches a user's keystrokes against a set of *a priori* keyword "libraries", each one centred around a particular safeguarding concern. For example, the word *porn* will trigger a "violation" against the keyword library related to inappropriate adult content. The violation, along with its surrounding textual context, will then be logged within the Senso.cloud portal for manual review by the designated member of staff responsible for safeguarding the user who typed it.

Because Senso.cloud only logs typing activity when a violation is triggered, the only data that is available for research purposes is that which has been deemed a potential safeguarding threat. For this experiment, we drew on roughly one year's worth of historical Microsoft Teams violation log entries (student-generated messages containing one or more strings matching a Senso.cloud violation keyword), and from this secure repository took a random anonymised sample of 10,000 messages. Of these 10,000, it was found that 1,148 were not analysable as they contained only empty HTML tags (from e.g. redacted GIFs and other images); these were discarded. The remaining 8,852 were manually annotated by a safeguarding specialist according to eight fine-grained labels:

- **TP1**: an unambiguous true positive violation that requires the attention of a safeguarder, e.g. *I feel suicidal*
- **TP2**: a somewhat ambiguous true positive violation that may require the attention of a safeguarder, e.g. *I will beat u*
- **FP1**: a false positive in the sense that it is copy-pasted media rather than self-generated, e.g. explicit song lyrics, or an unfortunate news story
- **FP2**: a false positive generated by discussion of problematic or adult themes within schoolwork assignments, e.g. a debate on gun control laws
- **FP3**: a false positive as a result of sentiment polarity, e.g. *you're fucking awesome*
- **FP4**: a false positive as a result of polysemy, e.g. *I'm hardcore*
- **FP5**: a false positive as a result of foreign language interference, e.g. *je vais être en retard*
- **FP6**: a false positive as a result of violations within other words, e.g. *gunna*

A portion of the dataset underwent annotation by two annotators. We measured the inter-annotator agreement with Cohen's kappa, which was 0.83. The high inter-annotator agreement suggests that the labels are straightforward and the annotation guidelines are clear.

[2] https://senso.cloud/gb/

It should be noted that the violation data used in this paper was captured by an older version of Senso.cloud's safeguarding module, and that the figures in Table 1 do not reflect Senso.cloud's current performance on Microsoft Teams chat monitoring. This historical data was used for our machine-learning purposes only.

Binary classes	Fine-grained classes	Totals	
True Positive	TP1	3,071	4,258
	TP2	1,187	
False Positive	FP1	157	4,594
	FP2	409	
	FP3	992	
	FP4	1,252	
	FP5	194	
	FP6	1,590	

Table 1: Number of Instances in Each Class

As shown in Table 1, the eight fine-grained classes can be grouped into two binary classes: true positive and false positive. From a safeguarder's point of view, the binary classification is the one that matters the most, as it determines whether or not further action is required. The fine-grained classes are there to provide more detailed distinctions between different kinds of textual messages, so that a monitoring program might better understand the nature of a keyword violation. The classes were not predetermined, but emerged during the course of the annotation process. It is also worth noting that the classes do not each relate to a different kind of safeguarding concern (e.g. bullying, mental health), but rather the question of whether or not a safeguarding concern of any kind is suggested in the text (binary), and, further to that, the nature of the keyword violation as captured by the keylogging system (fine-grained).

In a safeguarding system, the emphasis is always on safety over precision and so it will inevitably be sensitive enough to capture false positives as well as true positives. In child protection, it is better to err on the side of caution and then filter – usually manually – the output of the software for genuine safeguarding concerns. For this reason, we expect a high number of false positives in any safeguarding system, and it is to this end that a machine-learning-assisted approach could potentially help to create a more streamlined process for teachers and DSLs.

3.2 Ethical Considerations

Any research involving input from children is inherently sensitive from an ethical standpoint. In our case, there is a considered and lawful basis, rooted in safety and the public interest, to capture only the online activities of schoolchildren that indicate a reasonable likelihood of a safeguarding risk. To protect those children's privacy, we do not analyse this data in the context of usernames, device names, or school locations.

For ethical and data protection reasons, we do not have full access to, nor can we share, the metadata of the messages in our dataset. The sensitivity of child safeguarding data is one of the key reasons that such research is difficult to conduct and to replicate, and could explain why so little of it exists in the literature for us to compare our work against.

4 Methodology

Our methodology mainly consists of two steps: data preprocessing and machine learning, which we describe in the following subsections.

4.1 Data Preprocessing

For data preprocessing, we performed data cleaning, in which we removed HTML tags related to text formatting as they do not contribute to the machine learning models. After this simple data cleaning step, we fed the data into different machine learning models, which we describe below.

4.2 Machine Learning Models

During our experimentation, we explored a range of machine learning models, spanning from simple to more sophisticated ones. For instance, we tested models like BiLSTM, which offer efficient solutions for the task at hand. We also examined complex models like transformers, which will deliver superior results but come with a trade-off in terms of computational efficiency.

SVC Our simplest machine learning model is a linear Support Vector Classifier (SVC) trained on word unigrams. Prior to the emergence of neural networks, SVCs achieved state-of-the-art results for many text classification tasks (Schwarm and Ostendorf, 2005; Goudjil et al., 2018) including offensive language identification (Zampieri et al., 2019a; Alakrot et al., 2018). Even in the neural network era, SVCs produce an efficient and effective baseline.

BiLSTM As the first embedding-based neural model, we experimented with a bidirectional Long Short-Term Memory (BiLSTM) model, which we adopted from a pre-existing model for Greek offensive language identification (Pitenis et al., 2020). The model consists of (i) an input embedding layer, (ii) two bidirectional LSTM layers, and (iii) two dense layers. The output of the final dense layer is ultimately passed through a softmax layer to produce the final prediction. The architecture diagram of the BiLSTM model is shown in Figure 1. Our BiLSTM layer has 64 units, while the first dense layer has 256 units.

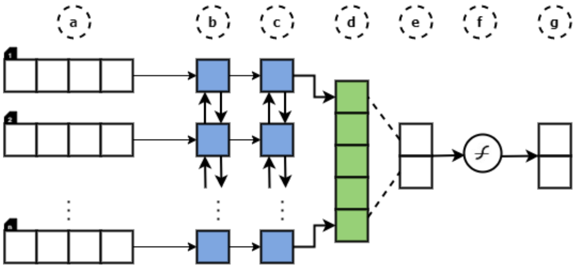

Figure 1: The BiLSTM model for sentence-level Sinhala offensive language identification. The labels are **(a)** input embeddings, **(b,c)** two BiLSTM layers, **(d, e)** fully-connected layers; **(f)** softmax activation, and **(g)** final probabilities (Ranasinghe and Zampieri, 2023)

CNN We also experimented with a convolutional neural network (CNN), which we adopted from a pre-existing model for English sentiment classification (Kim, 2014). The model consists of (i) an input embedding layer, (ii) 1 dimensional CNN layer (1DCNN), (iii) a max pooling layer and (iv) two dense layers. The output of the final dense layer is ultimately passed through a softmax layer to produce the final prediction.

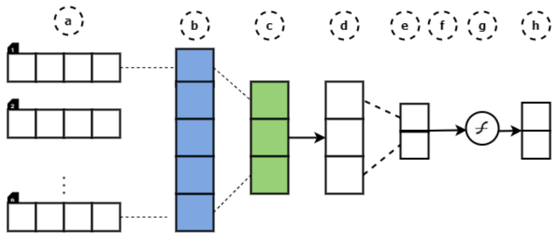

Figure 2: CNN model for sentence-level Sinhala offensive language identification. The labels are **(a)** input embeddings, **(b)** 1DCNN, **(c)** max pooling, **(d, e)** fully-connected layer; **(f)** with dropout, **(g)** softmax activation, and **(h)** final probabilities (Ranasinghe and Zampieri, 2023)

For the BiLSTM and CNN models presented above, we set three input channels for the input embedding layers: pre-trained word2vec embeddings, pre-trained fastText embeddings, and updatable embeddings learned by the model during training. For both models, we used the implementation provided in the *OffensiveNN* Python library[3].

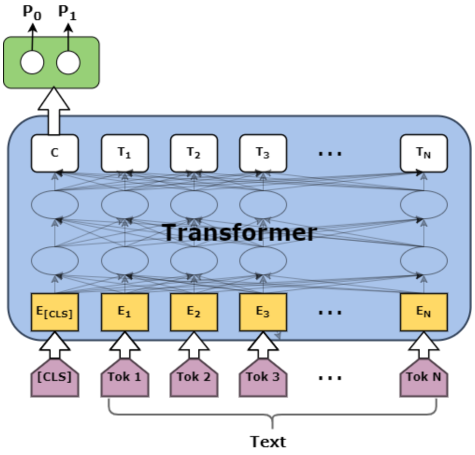

Figure 3: A schematic representation of the transformer models in classification (Uyangodage et al., 2021).

Transformers From an input sentence, transformers compute a feature vector $\boldsymbol{h} \in \mathbb{R}^d$, upon which we build a classifier for the task. For this task, we implemented a softmax layer, i.e., the predicted probabilities are $\boldsymbol{y}^{(B)} = \text{softmax}(W\boldsymbol{h})$, where $W \in \mathbb{R}^{k \times d}$ is the softmax weight matrix, and k is the number of labels, which in our case is two. This architecture is depicted in Figure 3. We employed a batch size of 32, Adam optimiser with learning rate $2\text{e}{-5}$, and a linear learning rate warm-up over 10% of the training data. During the training process, the parameters of the transformer model, as well as the parameters of the subsequent layers, were updated. The models were evaluated while training using an evaluation set that had one-fifth of the rows in data. We performed early stopping if the evaluation loss did not improve over three evaluation steps. All the models were trained for three epochs. We experimented with BERT-BASE-CASED (Devlin et al., 2019), ROBERTA-BASE (Liu et al., 2019) and ELECTRA-BASE (Clark et al., 2020). All the pre-trained transformer models we used for the experiments are available in HuggingFace (Wolf et al., 2020).

5 Results

We show our results in two levels: binary classification in Section 5.1 and fine-grained classification in Section 5.2. For each level, we experiment with the machine learning models described in Section 4 to see how they perform. All the models were trained on the training set and then evaluated by predicting the labels for the held-out test set. As the label distribution is highly imbalanced, we evaluate and compare the performance of the different models using macro-averaged F1 score. We further report per-class Precision (P), Recall (R), and F1 score (F1) for the binary classification. We also experimented with several resampling methods to balance the classes, such as upsampling and downsampling. However, we did not see a significant improvement in the results. Therefore, we continued the experiments with the original training set distribution.

5.1 Level A - Binary Classification

As shown in Table 2, neural models outperform the traditional machine learning model, SVC. From the experimented word embedding models, fastText performed best, providing a macro F1 score of 0.82 with CNN architectures. The results suggests that the character embedding approach in fastText is effective at classifying user-generated content that contains unrecognised or improvised words, i.e. text-speak. The transformer models provided the best results. The best transformer model was RoBERTa which provided a macro F1 score of 0.87, closely followed by BERT, which provided a macro F1 score of 0.86.

The results clearly show that transformer models can successfully be used for a classification task such as this one.

5.2 Level B - Fine-grained Classification

The results for fine-grained classification are given in Table 3. Similar to the binary classification, neural models outperformed the traditional SVC model. Furthermore, transformer models produced the best macro F1 scores. As with the binary classification task, RoBERTa performed the best out of all models in the fine-grained classification.

The results of the fine-grained classification were not as good as those of the binary classification.

At the best of times, multi-class classification is a challenging task. Previous research (Zampieri et al., 2019a) has shown that multi-class classification usually performs worse than binary classification. Furthermore, in this sample, the number of instances available for some of the classes in the fine-grained classification was low, which can affect the machine learning models when predicting for that class. This can result in a low macro F1 score.

Considering both levels, we can conclude that deep learning architectures provided satisfactory results and they can be successfully utilised to detect generalised safeguarding concerns in schoolchildren's online conversations.

6 Conclusions

We have presented the first study using deep learning to detect generalised safeguarding concerns in schoolchildren's online conversations. We have developed and employed a new and highly relevant dataset consisting of more than 8,850 instances annotated on binary labels as well as fine-grained labels. We employed ten machine learning models, including state-of-the-art transformer models, on the two tasks. We showed that deep learning architectures provided the best results, and among them, the RoBERTa transformer model provided the best result. With this study, we show that machine learning and, particularly, deep-learning-based models can be employed to detect safeguarding concerns in schoolchildren's online conversations.

As for limitations, we acknowledge that the dataset is imperfect on a few fronts. For one, it is limited to the English language, and it is captured from just one app, which is Microsoft Teams chat. As a result of the data collection method via the Senso.cloud software, which nonetheless gains us access to a high volume of primary data generated by our target demographic, the data we receive is pre-filtered. That is to say, we only have access to messages that have been captured according to Senso.cloud's *a priori* safeguarding keyword libraries (an important limitation for personal data protection purposes), and as such we cannot comment on recall. It also means that there is an imbalance of data and this imbalance is reflected in the distribution across the classes. The classes themselves emerged in response to the nature of the data, and as such, they are fitted to our specific software and set of keywords. Finally, we acknowledge that the dataset is necessarily opaque, for sensitivity and proprietary reasons, as are the models developed during this industry research. At this very early stage in the work, we are not yet able to make these resources public or provide the level of detail that one would find with open-access resources. In future endeavours, we hope to find a safe and satisfactory way of doing so.

This initial study opens many exciting avenues in detecting safeguarding concerns in online conversation. In this research, we focused on English, and given that the dataset is anonymised, we cannot safely attribute each instance to a specific variety of English (e.g. British English, American English). However, the machine learning models that we explored are language-independent. In the future, we hope to evaluate these machine learning approaches in multilingual conversations. While the transformer models provided the best results, these models are large in size and computationally expensive. Therefore, it can be difficult to use them in real time. Recent work has shown that knowledge distillation can transfer knowledge from large models to computationally light models such as SVCs. In future work, we hope to build more practical models to detect safeguarding concerns in online conversations in real time.

In terms of direct, practical applications, the present research demonstrates the usefulness of pre-trained deep learning architectures in reliably identifying a concerning online message from a child, even without the wider context of the conversation. For teachers and DSLs, this translates to an intelligent system that can support them in processing the safeguarding alerts they receive daily via their school's safeguarding software. With more data and experiments, this vein of research promises to produce real-world benefits for those faced with high volumes of student safeguarding data in their day-to-day work.

Abstract

Spotting hate speech in social media posts is crucial to increase the civility of the Web and has been thoroughly explored in the NLP community. For the first time, we introduce a multilingual corpus for the analysis and identification of hate speech in the domain of inceldom, built from incel Web forums in English and Italian, including expert annotation at the post level for two kinds of hate speech: misogyny and racism. This resource paves the way for the development of mono- and cross-lingual models for (a) the identification of hateful (misogynous and racist) posts and (b) the forecasting of the amount of hateful responses that a post is likely to trigger. Our experiments aim at improving the performance of Transformer-based models using masked language modeling pre-training and dataset merging. The results show that these strategies boost the models' performance in all settings (binary classification, multi-label classification and forecasting), especially in the cross-lingual scenarios.

Disclaimer: Due to the nature of the topic, this paper contains offensive words.

1 Introduction

Hate speech can be generally defined as "language that is used to express hatred towards a targeted group or is intended to be derogatory, to humiliate, or to insult the members of the group" (Davidson et al., 2017). Detecting hate speech can be challenging as there is a lack of consensus on its definition, while the use of offensive neologisms makes the task even more arduous (Fortuna et al., 2020). This is even more critical in environments frequented by incels, short for *involuntary celibates*, which pertain to the so-called *manosphere* (Nagle, 2017, p. 75-86) and mainly comprise men unsuccessful in finding a sexual partner or significant other. Some of these individuals tend to engage in the spread of various forms of hate speech —in particular racism and misogyny— and recurrently adopt novel lexicon in doing so (Blommaert, 2018). Such dynamic jargon causes models trained on hate speech to fail to recognize incel-specific instances of hate speech.

Our contributions are the following:

(*i*) Corpora. We introduce two unsupervised corpora on the inceldom domain, one in English and one in Italian. A subset of each corpus includes manual annotations for different kinds of hate speech (cf. Section 3).[1] The raw data can be used for domain adaptation and language modeling, among other applications. The annotation allows addressing three tasks. *Binary:* determine whether a post p conveys hate speech or not. *Multi-label:* determine whether p is misogynous and/or racist. *Forecasting:* Given an original post p' (the first post in a thread), forecast the amount of hateful posts that it is likely to trigger in future responses.

(*ii*) Masked language modeling. We perform mono- and cross-lingual masked language modeling (MLM) to adapt BERT and mBERT models to the inceldom domain for the first time. We release the best configurations according to their impact in the identification of hate speech (Section 4).[2]

(*iii*) Hate speech identification. We show the impact of domain-adapted Transformers and the downstream training of models for hate speech identification, in the niche context of incel hate speech. We combine new incel-specific and existing supervised corpora within and across languages in three settings: binary classification, multi-label classification and forecasting (Section 5).

Our experiments show that MLM pre-training is effective, particularly in cross-lingual scenarios, resulting in a 17-point absolute improvement in

https://doi.org/10.26615/978-954-452-092-2_042

terms of F$_1$-measure in the binary task, and a 34- and 18-point increase in the misogyny and racism detection tasks, respectively. Combining Italian and English datasets leads to a large performance increase of 22 points in terms of F$_1$-measure, for the best MLM pre-trained model. In the forecasting setting, our regression model effectively predicts the number of hateful responses a post may generate in the following replies, surpassing the mean squared error (MSE) baseline by 37%.

2 Related Work

Corpora built from incel platforms are rare and not necessarily applicable to the use-case of this study, either due to the source of the data only being partially compatible with the linguistic domain presently tackled (Pelzer et al., 2021) or because of the criteria according to which it was annotated (Zhou et al., 2022). Most studies have focused on the linguistic properties of incel corpora, predominantly adopting qualitative approaches. For example, Tranchese and Sugiura (2021) compared incel discourse from Reddit forums to the language used in pornography and highlighted its misogynistic implications. Papadamou et al. (2020) conducted a cross-platform study on incel profiling, by collecting $6.5k$ YouTube videos shared by users in Incel forums within Reddit, while also examining the YouTube recommendation algorithm. Their findings show that incel activity on YouTube is increasing, stirring towards the dissemination of incel views. Jaki et al. (2019) adopted a mixed approach, mainly focusing on text profiling, with their discourse analysis suggesting that incel language is not as coherent as previously assumed, while also employing a multichannel CNN, using $50k$ Incels.me messages, $50k$ neutral texts composed of $40k$ paragraphs from random English Wikipedia articles, and $10k$ random English tweets. Past studies have relied on the Pushshift Reddit API to build a corpus within the linguistic domain of inceldom (Farrell et al., 2020; Mollas et al., 2022). Zampieri et al. (2019) build a dataset from English tweets which can be used to train models to identify and categorize offensive posts, with information on whether the target is a group or individual.

Recently, more hate speech studies turn towards a new approach: *forecasting*. Zhang et al. (2018) extract politeness strategies and rhetorical prompts to predict whether a conversation will turn uncivil. Meng et al. (2023) predict the intensity of hate that a tweet might carry through its reply chain by exploiting tweet threads and their semantic and propagating structures. Dahiya et al. (2021), compiled a dataset of $4.5k$ tweets and their reply threads, confirming that longitudinal patterns of hate intensity among reply threads are diverse, with no significant correlation with the source tweet. Their approach differs from ours in that they calculate hate intensity for chunks of a thread, not for the whole thread at once. Almerekhi et al. (2020) proposed a model for toxicity triggering prediction by integrating text-based features as well as features that are related to shifts in sentiment, topic flow, and discussion context, proving that toxicity triggers contain detectable features. Lin et al. (2021) proposed a model that uses a post's semantic, propagation structure, and temporal features to predict hateful propagation in social media.

3 Incel Corpora

We performed a *modern diachronic* study (Partington, 2010) on incel forums, shedding light on the way the language of inceldom evolves. We consider two forums: *Incels.is*,[3] in English, and *Il forum dei brutti*,[4] in Italian. Studying such niche communities, as opposed to those hosted for example on Reddit, allows us to study a language which is representative of the incel speech community. This is because moderation is more lax,[5] which allows users to express themselves more genuinely.

The study, discussed at length in Appendix A, shows that excessively outdated resources might not be entirely representative of the discourse currently produced by the speech communities being scrutinized. More worthy of notice is that incel language differs from general Internet language, especially when hate speech is expressed. Such findings show that building new corpora from scratch is a worthwhile effort, as having an accurate representation of current language is a priority.

We retrieved dumps of posts from the two forums. The metadata for each post includes: author id, the position of the post in the thread, URL, timestamp and both post and thread unique ids.

We refer to the unsupervised dataset obtained from the dump of the *Incels.is* forum as IFU-22-EN

[3] https://incels.is (Last access: 11 August 2023)

[4] https://ilforumdeibrutti.forumfree.it (Last access: 11 August 2023)

[5] The /r/incels and /r/braincels subreddits, the most popular to date, were respectively shutdown in 2017 and 2018 because of the hatefulness of their contents.

Dataset	Posts	Threads	Length
IFU-22-EN	4,7M	223k	31.07±70.01
IFU-22-IT	627k	30k	52.78±80.77

Table 1: Statistics of the IFU-22-EN and the IFU-22-IT unsupervised corpora (length computed in tokens).

Please identify whether each post is categorized as misogynous, racist, or falls into another category:
A post is deemed **misogynous** if it:

- Objectifies or stereotypes women;
- Claims that men are superior to women;
- Derails the conversation to defend the abuse of women, deny male responsibility, or redirect the conversation in favor of men;
- Contains sexual advances, solicits sexual favors, sexually harasses the recipient, or threatens women with physical violence to assert power; or
- Uses slurs against women purposelessly.

A post is considered **racist** if it:

- Uses a racial slur;
- Stereotypes, attacks, or seeks to silence a minority without a valid argument;
- Promotes violent crime against minorities;
- Misrepresents the truth or distorts views on a minority with baseless claims; or
- Shows support for problematic ideologies, such as xenophobia, homophobia, or sexism.

Figure 1: Guidelines for the corpus annotation, derived from (Fersini et al., 2018) for misogyny and (Waseem and Hovy, 2016) for racism.

(Incel Forum Unsupervised, 2022, English). The posts it contains come from the “Inceldom Discussion” section. The dataset extracted from *Il forum dei brutti*, which we refer to as IFU-22-IT (Incel Forum Unsupervised, 2022, Italian), comes from the “Una vita da brutto” section. Table 1 shows the statistics of the two datasets. The average length of the posts is much longer in Italian than in English. The median posting time difference between an original post and its first response is also much higher in IFU-22-IT, with a median of 540 against only 155 seconds. This could hint that threads in *Il forum dei brutti* are less active as far as the frequency of replies is concerned, but hosting conversations which are more akin to actual discussions, rather than the more chaotic back-and-forths which seem to take place in *Incels.is*.

We annotated a subset of the posts from both collections with two independent binary labels: one for misogyny and one for racism. We refer to the resulting datasets as IFS-EN and IFS-IT, which stand for Incel Forum Supervised in English (with 5,203 instances) and Italian (with 500 instances).

Corpus	Mis	Rac	Both	Neither
IFS-EN$_{\mathrm{tr}}$	806	630	46	2,160
IFS-EN$_{\mathrm{de}}$	173	130	13	464
IFS-EN$_{\mathrm{te}}$	160	125	7	489
IFS-IT$_{\mathtt{te}}$	187	8	5	300

Table 2: Class distribution for the IFS-EN and IFS-IT supervised datasets. Mis=misogynous, Rac=racist.

IFS-EN was initially sampled with two constraints: 50% of the posts had to include at least one term characteristic of incel jargon[6] and instances had to be longer than five words. The former constraint sought to balance the occurrence of instances with and without incel jargon to prevent models from overly relying on it, while the second aimed at excluding instances which would not be useful during training. For IFS-IT, only a 5-word minimum length constraint was applied. Figure 1 shows the annotation guidelines.

With relation to English, a pilot annotation was first carried out by three annotators on a subset of 50 instances. All annotators have a C2 CEFR level of English and are experts in the subject, with a strong foundation in linguistics and gender studies, as well as knowledge of NLP and data annotation. The obtained Cohen’s Kappa inter-annotator agreement (IAA) (Bobicev and Sokolova, 2017) was of 0.77, considered *substantial* (with 0.81 being the threshold for *almost perfect*). The rest of the instances were annotated by a single annotator. As for Italian, two annotators, native speakers of Italian and with the same background as above, obtained an IAA of 0.69 over 50 instances. As the IAA was deemed acceptable, the 450 other instances were all labeled by a single annotator.

We split IFS-EN into training, development and testing partitions with a ratio of 70/15/15, while we use IFS-IT only for cross-lingual testing. Table 2 shows the statistics of the two supervised corpora. About 1.2% of the instances are judged as both misogynous and racist.

4 MLM Pre-Training

We build upon BERT base for monolingual English scenarios and mBERT base (Devlin et al., 2019) for cross-lingual scenarios in English and Italian. Based on Caselli et al. (2021), we attempt

to improve the models' understanding of the incel language by training them on the MLM task, producing what we refer to as in-domain *Incel BERT* and *Incel mBERT* versions.

In the monolingual scenario, three samples from the IFU-22-EN unsupervised dataset are used, considering randomly-selected splits of $10k$, $100k$, and $1M$ posts. We adopt a similar approach in the cross-lingual scenario, where we consider (i) the same English subsamples alone; (ii) subsamples of $10k$, $100k$, and $627k$ instances in Italian from IFU-22-IT (the full corpus contains $627k$ instances); and (iii) 50–50% splits from both IFU-22-EN and IFU-22-IT of $10k$, $100k$, and $1M$ instances. None of the instances used for MLM pre-training include data from IFS-EN and IFS-IT.

In all cases, MLM pre-training is carried out by tokenizing posts with AutoTokenizer[7] and masking tokens with a probability of 15%. We use a batch size of 32 and train the models for one epoch on a single Tesla P100 GPU with 16 GB of VRAM.

In order to assess the impact of the MLM pre-training, we perform preliminary experiments on the binary classification task: hate speech or not. We fine-tune each model version using IFS-EN$_{tr}$ for training and IFS-EN$_{de}$ for development.[8] We then test on IFS-EN$_{te}$ in the monolingual scenario and on IFS-IT in the cross-lingual scenario. Our baseline for monolingual scenarios is BERT, while we use mBERT in cross-lingual ones.

Table 3 reports the results. The experiments are repeated ten times in order to make our results more reliable and diminish the effect of random initializations. As it is common (e.g., Pelicon et al. (2021); Muti and Barrón-Cedeño (2022)), mBERT achieves inferior results in the monolingual scenario compared to BERT. Pre-training BERT on $1M$ monolingual instances on the MLM task improves model performance and yields the best results. The performance improves linearly but subtly as more data is introduced, reaching a 3-point absolute difference: from 0.845 to 0.872. When zooming into posts which do not contain incel terminology, the performance of the models is lower, but pre-training on $1M$ monolingual instances still provides a performance boost over BERT$_{base}$ (0.727 vs 0.671). When looking at posts which contain incel terminology, both models obtain an F$_1$ of 0.934, showing that explicit hate is much easier to detect.

In the cross-lingual scenario, MLM also has a positive impact, but the improvement is not linear with the amount of data. When performing MLM with monolingual data, be it in English or Italian,

[7] https://huggingface.co/docs/transformers/model_doc/auto

[8] For all classification experiments, the number of epochs is set based on the performance achieved on IFS-EN$_{de}$.

Table 5: Impact of incorporating additional datasets in English (Italian) when fine-tuning BERT (mBERT) and Incel BERT (Incel mBERT) on the mono- (top) and cross-lingual (bottom) hate speech detection task.

the testing performance on both languages is better than vanilla mBERT, when using $10k$ instances, but drops with additional monolingual training material. Using a bilingual combination of MLM material produces the best model when using $1M$ instances. This configuration boosts the performance: (*i*) by 39 points on Italian, with respect to adding $1M$ of all-English instances (0.503 vs 0.112) and (*ii*) by 1 point on the English one (0.845 vs 0.835). With respect to the mBERT baseline, training on $1M$ bilingual instances provides a performance boost of 17 points (0.503 vs. 0.333).

Going forward, we use the best post-MLM models: Incel BERT trained on $1M$ English instances in monolingual experiments and Incel mBERT trained on $1M$ bilingual instances in cross-lingual ones.

5 Downstream Tasks

This section discusses our three experimental settings: (*i*) binary hate speech classification, (*ii*) multi-label misogyny and racism classification, and (*iii*) hate speech forecasting. In all settings we tokenize input sentences with AutoTokenizer, padding to a maximum of 256 tokens, including [CLS] tokens, and returning attention masks. All models are trained with a batch size of 16, using the AdamW optimizer with $lr = 10^{-5}$ and $\epsilon = 10^{-8}$.

Both classification tasks are evaluated on the basis of F_1-measure. The forecasting (regression) task is evaluated using mean squared error (MSE) and mean absolute error (MAE).

5.1 Binary Hate Speech Classification

Following the approach of Pelicon et al. (2021), we enrich the models while training them on the downstream binary task by using various combinations of existing datasets labeled for hate speech, summarized in Table 4. The Davidson dataset is subsampled to the size of IFS-EN_{tr} because doing so performed better in preliminary experiments. For HatEval, we only use the part pertaining to misogyny, as the instances annotated for hate speech against migrants were not relevant with relation to incel speech. Table 5 displays the results for the dataset combinations which performed the best.

Monolingual scenario. Combining IFS-EN_{tr} with the Stormfront, Davidson, and Stormfront+HatEval datasets slightly improves BERT's performance, respectively yielding an improvement of 1, 0.6 and 0.4 points on the test set. Neither HatEval nor HateXplain contribute positively. In the case of HatEval, this is probably due to the fact that it focuses only on misogynous hate speech, which is not entirely representative of the problem at hand. As

	Label	Model	Validation (English)			Test (English)		
			F_1	Rec	Prec	F_1	Rec	Prec
Monoling.	M	BERT	0.759±0.009	0.737	0.783	0.804±0.014	0.800	0.808
		Incel BERT	0.786±0.005	0.786	0.786	0.803±0.005	0.826	0.782
	R	BERT	0.831±0.006	0.874	0.791	0.796±0.012	0.838	0.759
		Incel BERT	0.854±0.012	0.838	0.872	0.821±0.012	0.818	0.823
						Test (Italian)		
Cross-ling.	M	mBERT	0.764±0.022	0.749	0.781	0.214±0.102	0.127	0.813
		Incel mBERT	0.773±0.008	0.757	0.790	0.552±0.049	0.404	0.886
	R	mBERT	0.818±0.010	0.859	0.781	0.393±0.015	0.354	0.459
		Incel mBERT	0.828±0.007	0.876	0.786	0.577±0.045	0.523	0.644

Table 6: Results for the mono- and cross-lingual scenarios of the misogyny (M) and racism (R) classification setting.

regards HateXplain, it likely failed to improve the performance of the model because it was built to be used jointly with the attention arrays it contains and because its sentences are already tokenized and stripped of punctuation, which means the model has less syntactical information to work with.

As for Incel BERT, all combinations yielded worse results than the baseline. This could be because the model became too biased toward IFS-EN$_{\text{tr}}$, making it unable to learn effectively from other datasets. That said, Incel BERT's results on IFS-EN$_{\text{te}}$ are still better than the ones BERT achieves when merging IFS-EN$_{\text{tr}}$ with Stormfront, Davidson, or Stormfront+HatEval.

Cross-lingual scenario. As expected, despite the annotation schema of our datasets and the ones we add to them being different, providing mBERT with extra training material in Italian (HSD$_{\text{fb}}$ and HSD$_{\text{tw}}$) improves the model, compared to only fine-tuning on IFS-EN. All models improve over the baseline, reflecting the importance of adding training material in the target language, even if no MLM pre-training is carried out at all. The best performance is achieved when adding HSD$_{\text{fb}}$ alone, with a performance on par with that obtained when adding both datasets. The difference of 36.1 points hints at a high affinity between the annotation schemes of HSD$_{\text{fb}}$ and IFS-IT.

A similar trend can be observed when training Incel mBERT by also adding both HSD$_{\text{fb}}$ and HSD$_{\text{tw}}$ to the training data, with a 22-point increase (from 0.503 to 0.721). When evaluating on Italian, using both English and Italian for MLM training and merging both HSD$_{\text{fb}}$ and HSD$_{\text{tw}}$ to IFS-EN for fine-tuning outperforms the rest of the alternatives. This is the case even if departing from vanilla Incel mBERT, which performs the worst before adding Italian fine-tuning data.

In general, in both mono- and cross-lingual scenarios, a lower standard deviation is observed for Incel BERT and Incel mBERT when additional training material is added, reflecting that the models gain substantially in stability thanks to it.

5.2 Multi-Label Hate Speech Classification

In this case, we fine-tune for the multi-label problem of identifying misogynous and/or racist posts, again in mono- and cross-lingual scenarios.[9] In both cases, only IFS-EN is used for training and development. In the monolingual scenario, testing is done on IFS-EN$_{\text{te}}$, while in the cross-lingual scenario IFS-IT is used. Table 6 shows the results for each individual class.

Monolingual scenario. The misogyny detection performance obtained by BERT and Incel BERT 1M on the Italian test set is essentially the same: 0.803 vs 0.804 F_1-measure. Incel BERT's recall is better than vanilla BERT's, which could reflect that MLM pre-training is indeed helping the model identify misogyny more effectively, but at the same time turning it more permissive.

Regarding racism, Incel BERT performs slightly better than BERT, with an absolute difference of 2.5 points: 0.821 vs 0.796. Just like in the binary setting, the performance boost obtained by Incel BERT is the result of the model already being familiar with the novel racist language used by incels.

Cross-lingual scenario. Both with relation to misogyny and racism identification, the performance of Incel mBERT is far higher compared to vanilla mBERT's. As far as misogyny identification is concerned, Incel mBERT outperforms the baseline mBERT model by 33.8 points, while in the racism detection task it outperforms the baseline by 18.4 points. These results suggest that using target

[9] In this setting, each model is fine-tuned five times.

Corpus	HS (%)	No HS
IFU-22-EN	836,974 (17.59)	3,919,908
IFU-22-IT	282,724 (44.30)	355,419

Table 7: Class distribution of the predicted labels on IFU-22-EN and IFU-22-IT, showing the number of posts judged as being hate speech (HS) or not (No HS).

language data for MLM pre-training can greatly increase the performance of a model even without using any target language (Italian, in this case) data for fine-tuning on the downstream task.

As opposed to the monolingual scenario, in this case the greater performance boost is also an indication that exposing the model to the target language domain is highly effective. This shows that the language of inceldom in *Il forum dei brutti* is indeed very different from general Italian language, in line with the diachronic study of Appendix A, and that the model benefits from learning its features.

5.3 Hate Speech Forecasting

In the context of an Internet forum, we define forecasting as the capability of predicting how many posts will contain hateful content following an original post p' as soon as it has been posted. We conceptualize the amount of hate generated in a thread as the ratio between the number of hateful posts following p' and the total number of posts contained in the thread it has started. Based on this rationale, we build two corpora, one in Italian and the other in English, in which each p' is paired to a *hate score* in the range $[0, 100]$, indicating how much hate it has generated, with the extremes representing that none or all of the thread's posts are considered hateful.

To produce the data for this setting, we first generate automatic binary predictions for all the posts in IFU-22-EN and IFU-22-IT using the top models from Section 5.1: Incel BERT trained on IFS-EN alone for the former and Incel mBERT trained on IFS-EN$_{\text{tr}}$ plus HSD$_{\text{fb}}$ and HSD$_{\text{tw}}$ for the latter. Table 7 shows the resulting class distribution, which is in line with the training material's. We use these binary decisions to compute a silver hate score for each p' in the corpora. The resulting collection of p'–hate score pairs in English includes $223k$ instances, while the Italian one has $30k$.

Figure 2 shows histograms of the hate score distributions in both languages. The distribution for English is skewed to the left, with a median of 13.89, indicating that most original posts tend to trigger a small amount of hateful responses. The Italian distribution resembles a Gaussian with a median of 42.86, except for the outliers at the extremes. This reflects a uniform range in the amount of hate triggered by comments in the Italian forum.

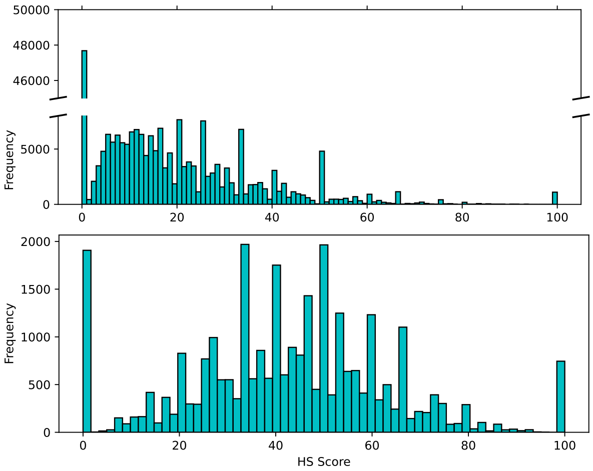

Figure 2: Hate score distribution associated to the original posts for English (top) and Italian (bott.) forecasting.

It is clear that many of the original posts in both forums trigger no hate, while a smaller number triggers a plethora of hateful responses. The number of completely non-hateful threads is much higher in the English OP–score corpus while, comparatively, the number is much lower in the Italian one, where it is on par with the center of the distribution. As regards the number of threads with a hate score of 100, the opposite is true: *Il forum dei brutti* has a much higher percentage of hate, because in most of its threads which only have one reply, that reply is hateful (515 out of 921 single-reply threads).

We address forecasting as a regression problem and train Incel BERT and Incel mBERT to output continuous $[0, 100]$ hate scores. We do this by adding a 1D linear output layer on top of them. Unlike previous experiments, here we train the models only on original posts p' and for a different objective. We split both English and Italian corpora into training, development and test sets with ratios of 70/15/15 and use them to train and evaluate mono- and cross-lingual models. Following the approach of Kang et al. (2018), our baselines are the means of the scores contained in the development and test partitions of the produced hate score datasets.

Table 8 shows the results, recorded over four epochs. We set the maximum number of epochs at four because in the cross-lingual scenario the tuning converges on the fourth epoch.

Monolingual scenario. The model performs better

e	Monolingual			Cross-lingual		
	MSE$_{va}$	MSE$_{te}$	MAE	MSE$_{va}$	MSE$_{te}$	MAE
1	**188.63**	**181.19**	9.95	590.98	586.65	19.37
2	192.71	186.28	10.36	466.27	462.58	16.71
3	195.50	188.51	9.94	436.57	432.68	16.12
4	203.52	196.25	10.24	**425.13**	**421.70**	15.95
b	296.18	286.44	13.17	461.84	457.47	16.56

Table 8: Performance in terms of MSE (val. and test) and MAE (test) for the forecasting task, for the mono- and cross-lingual scenarios; e=epoch, b=baseline.

than the baseline right from the first epoch, on which it achieves its top performance with an MSE of 181.19, 36.74% lower than the baseline. This indicates that the model is reasonably effective at forecasting the amount of hate that an original post is going to generate. This is also supported by the fact that, for instance, the mean absolute error (MAE) on the English test set after one epoch is 9.95, compared to 13.17 for the baseline.

Cross-lingual scenario. Incel mBERT struggles more at forecasting, with the best MSE on the Italian test set being 421.70, which corresponds to a MAE of 15.95. Compared to the monolingual scenario, the performance gap from the baseline is also not as significant (7.82%). Other than the difficulty added by the cross-lingual component, the noisier silver data produced by a lower-performing single-post classification model makes effective forecasting more challenging, which is also reflected by the slow convergence after additional epochs.

These results, particularly those in the monolingual setting, hint that it would be possible to estimate the amount of hate that a post is likely to trigger —just by looking at its textual content— as soon as it has been posted, although the prediction quality has room for improvement.

6 Conclusions

In this paper, we have explored the creation of models for the automatic identification of hate speech in incel forums: binary hate speech identification, multi-label misogyny and racism identification, and forecasting of the level of hate that the first post of a thread is likely to trigger.

Our experimentation on the three problems, in monolingual and cross-lingual scenarios, shows that (*i*) pre-training on the masked language modeling task to make BERT-based models more aware of incel language is a key factor to aspire to produce good predictions; (*ii*) the inclusion of supervised material extracted from sources external to incel forums can help boost models further, also across languages; and (*iii*) it is feasible to forecast the amount of hate that an original post will likely trigger prior to any replies, although further improvements are still required.

In future work, we plan to delve further into forecasting by implementing temporal and propagation features (e.g., Meng et al. (2023); Dahiya et al. (2021); Lin et al. (2021); Almerekhi et al. (2020); Jaki et al. (2019)). Based on Pelicon et al. (2021), we also plan to expand language coverage, with German- (Mandl et al., 2019) and Spanish-language (Basile et al., 2019) hate speech datasets being two of the most prominent candidates due to their similarity to English and Italian, respectively.

Limitations

The large amount of explicit hate in the training data might lead the models to prioritize detecting overtly offensive language while potentially overlooking more subtle forms of implicit hate. Consequently, instances of implicit hate within threads might be misclassified, affecting both the classification and regression-based evaluation.

We attempted to assess our models' generalizability with preliminary cross-domain tests on the Contextual Abuse Dataset (Vidgen et al., 2021). This was the only relevant thread dataset available, but its abusive language labels did not align with ours. The limited availability of thread datasets hindered further cross-domain and cross-lingual experiments, rendering further research timely.

The forecasting setting, built on top of post-level silver data as a proxy, could benefit from human annotation at the thread level. Still, making this task practical at scale is complex and expensive.

Ethical Considerations

All data used to compile our corpora is publicly available. Forum users accept a legal disclaimer before posting and are kept anonymous.

The paper covers sensitive topics which could be subject to bias and human supervision is necessary to assess the quality of the results, especially during the annotation process. Therefore, the annotated posts were evaluated as objectively as possible.

Although we reckon freedom of speech as a fundamental right, we advocate for online content moderation, given the real-world violence triggered by hate speech, as discussed in the introduction.

Appendix

A Analysis of Keyness in Incel Forums

We can investigate the difference of relative frequency in word usage between general language and the language used in a specific speech community by building corpora representative of the two groups of speakers. That is, we can use a large *reference corpus*, representing general language usage, and compare its frequencies to a *focus corpus* (Kilgarriff, 2009), built only from texts pertaining to a specific communicative context.

We show the evolution of incel language by studying the change in *keyness* (Kilgarriff, 2009) of specific terms, showing how the lexical features of incel speakers of English and Italian change rapidly over time. Keyness indicates which words in a focus corpus are highly frequent compared to a reference corpus. The keyness of a word w is defined as (Lexical Computing Ltd., 2015):

$$keyness(w) = \frac{fpm_f(w) + n}{fpm_r(w) + n} \quad (1)$$

where $fpm_f(w)$ represents the normalized frequency of a focus corpus word per million words, $fpm_r(w)$ refers to the word in the reference corpus, and n is a smoothing parameter (here, $n = 1$).

To study the English-speaking *Incels.is* forum, we consider all of its contents, for a total of 104M words (collected up to 18 October 2022). We do the same for the Italian *Il forum dei brutti*, for a total of 30M words (up to 4 December 2022). For English, we calculate the keyness by using enTenTen20 as the reference corpus, while for Italian we use itTenTen20 (Jakubíček et al., 2013).

As far as *Incels.is* is concerned, in order to compile a list of characteristic incel lexicon, the keyness of lexical items was calculated across the entirety of the forum, up to October 2022. Preliminary candidates were selected by collecting single- and multi-word items that ranked in the top 500 for keyness, for a total of 1k analyzed items. Racism and misogyny are very characteristic elements of the language of incels (Silva et al., 2016; Ging and Siapera, 2018; Jaki et al., 2019). Therefore, we manually selected characteristic hateful terminology for this speech community by considering racist and misogynous terms that are not typically found in general language, i.e. having high keyness scores.

In order to conduct the diachronic study, the subset was divided into 22 chronological partitions, one for each 100 pages[10] of the forum from 2017 to 2022. The keyness of each selected term was measured for every partition, calculating the slope of its regression line across all 22 partitions. For each term, the slope was divided by the average keyness over the 22 partitions, thus obtaining its normalized slope. For each partition, only the terms having the top 500 keyness scores were recorded. Zero values (7.16% in total), produced whenever the item's keyness was not high enough to appear among the top 500 terms of the partition, were ignored both for the calculation of the slope and for the average keyness. The 10 terms with the highest and lowest normalized slope, 20 in total, were thus grouped, calculating their mean normalized slope.

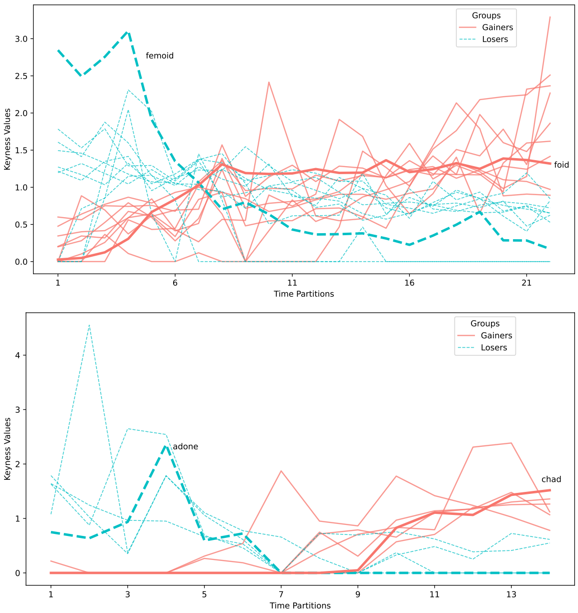

Figure 3: Keyness over time for the characteristic incel terms extracted from *Incels.is* (top) and *Il forum dei brutti* (bottom). Red (blue) lines represent the terms that gained (lost) keyness over time.

As regards *Il forum dei brutti*, the forum contents were divided chronologically by grouping posts by year of creation, from 2009 to 2022, for a total of 14 partitions. In this case, we carry out a study on 10 terms we deem to be characteristic of the forum's incel language, used to describe other men in negative or positive ways. The amount of zero values for these 10 terms is 44.44% of the total.

Figure 3 shows the over-time trend of the keyness of the terms extracted from *Il forum dei brutti* and *Incels.is* over the partitions of the two forums. The curves show clear opposite trends for the two groups, which we refer to as "gainers" and "losers" of keyness, based on whether their mean normalized slope is positive or negative, respectively. The plots help visualize a widening over-time difference in lexicon, which may cause models trained on dated texts to become increasingly worse at evaluating more recent data. The highlighted terms in the figure also show that certain terms seem to substitute each other over time, although not all of them can be paired in this manner. For example, "adone" is a close synonym of "chad", while "foid" is a contraction of "femoid", and for both pairs we can observe opposite trends with a specific point in time in which one overtakes the other.

Table 9 reports the normalized slopes of the

[10] Each page contains 10 threads.

	Gainer	**Slope**	**Loser**	**Slope**
Incels.is	shitskin	0.093	racepill	-0.019
	deathnic	0.081	stacie	-0.022
	cumskin	0.079	jb	-0.027
	noodlewhore	0.077	chadlite	-0.029
	slav	0.068	whitecels	-0.032
	foid	0.058	cunt	-0.036
	curryland	0.051	slut	-0.046
	aryan	0.048	deathnik	-0.047
	ricecel	0.047	roastie	-0.051
	whore	0.025	femoid	-0.124
	Mean	**0.063**	**Mean**	**-0.043**
FdB	zerbini	0.104	reietto	-0.142
	normie	0.121	strafigo	-0.122
	bv	0.125	figaccione	-0.122
	chad	0.126	attraente	-0.113
	subumano	0.158	adone	-0.103
	Mean	**0.127**	**Mean**	**-0.120**

Table 9: Keyness normalized slopes for *Incels.is* and *Il forum dei brutti* (FdB).

terms obtained from the two forums. In both cases, the mean normalized slopes of the two data series, compared side by side, quantitatively display a clear trend according to which certain terms gain popularity over time, while others become less popular. With regard to *Il forum dei brutti*, the difference is 0.247, while for *Incels.is* the difference between the mean normalized slopes is smaller, 0.106, which points at a slower lexical evolution. For both forums, the shift in lexicon needs to be taken into account in order to have a clear picture of the language adopted by each speech community.

As regards *Il forum dei brutti*, we can observe that the way users refer to men changes in a rather clear way. Positive words that are commonly used in general language, such as “strafigo” (meaning “extremely handsome”), are substituted by specialized terms that are more specific to the forum’s speech community, e.g., “chad”. [11] Conversely, we can see the same phenomenon for negative words, where “reietto” (“outcast”) loses popularity, leaving space to terms with more specialized uses. An example of this is “bv”, meaning “brutto vero” (lit. “truly ugly”), which, being an acronym, is more opaque to outsiders.

With relation to *Incels.is*, as already anticipated through Figure 3, although terms like “foid” and “femoid” have the same meaning (both are used to dehumanize women by associating them to insentient androids), [12] the shorter form has become more popular, while the use of the full form has decreased. This might seem like a minor detail, but the sheer amount of misogyny that is expressed in the forum through this term alone makes it important to point out a shift in its use.

The same conclusions can be drawn for both forums: the presented terms are arguably characteristic of the incel language used within the two platforms and the change in their usage over time is non-negligible. This implies that language models could become progressively worse at predicting over these domains, were their training resources not be periodically updated. Therefore, if the material used to train models is outdated, their understanding of the discourse currently produced by a specific community could become suboptimal.

In both scenarios, it is thus arguably desirable, if not necessary, to periodically update corpora to have accurate terminological representations. In some cases, it would arguably make sense to even rebuild resources from scratch, were they too outdated. In our case, given the observed changes in keyness, we estimate that the hereby analyzed time frame could be taken as a reference for how long resources can be considered up-to-date.

Abstract

The large amount of textual information, in digital format available today, makes the knowledge extraction task unfeasible by manual means. It is therefore necessary to develop automatic tools that allow us to integrate this knowledge into a structure that is easy to use by both machines and humans. This paper presents T2KG, a framework that can incorporate the relevant information from several structured or unstructured documents into a semantic network. Structured documents are processed based on their annotation scheme. For unstructured documents, T2KG uses a set of Natural Language Processing sensors that identify relevant information to enrich the semantic network created by linking all the knowledge from different documents.

1 Introduction

Nowadays, the amount of information available on the web is available in multiple formats. Leveraging this data requires the design of software systems that can exploit the information, obtain relevant data, structure it in a specific format, and generate reports that help to evaluate this information. Software systems focused on performing all these actions are currently oriented to apply different natural language processing techniques. Many early developments were domain-dependent, so domain-specific resources, although costly in terms of time and expertise, were relatively easy to obtain. But recently, general-purpose, domain-independent systems are being developed. However, it would be difficult to imagine a system like ChatGPT incorporating a multi-domain ontology in real time. The trend in Natural Language Processing (NLP) today is text-to-text development that does not use manually curated semantic resources such as semantic networks. In other words, text-to-text oriented systems use self-generated resources without the need for external semantic resources. However, systems must take into account that the software created must be maintainable and extensible, using processes and methodologies that make all these aspects possible.

This work aims to present a framework capable of extracting knowledge from heterogeneous sources, structured such as comma-separated volumes or relational databases, or unstructured such as plain text from Wikipedia. Knowledge from different sources is integrated into an ontology. It also allows the user to query the knowledge in natural language while results are analyzed automatically to generate custom graphics or visualizations to ease its interpretation.

2 State of the Art

Knowledge representation is the process of modeling information in a way that enables effective reasoning, communication, and decision-making by computers. Given the increasing amount of digital data available, it has become more important than ever to conceive ways to represent it in a meaningful way to add knowledge to NLP systems. This knowledge has been used to improve the accuracy of tasks such as sentiment analysis, named entity recognition, and text classification (Gao et al., 2019; Peng et al., 2023). Two main tasks are involved in this process: knowledge extraction and knowledge integration from different sources. For knowledge extraction, it's necessary the development of sensors to extract pieces of relevant information (e.g. entities and relations) from unstructured documents. Knowledge integration needs to deal with linking entities, modeling uncertainty, or solving inconsistencies.

One of the challenges of multimodal representation is integrating information from different sources in a meaningful way. This requires the

Proceedings of Recent Advances in Natural Language Processing, pages 385–391
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_043

development of novel algorithms and techniques that can effectively capture the relationships between different types of data. Several approaches have been proposed for integrating text and image data, including deep neural networks for image and text (Gao et al., 2020; Zhang et al., 2020a).

In recent years, there has been significant progress in the field of knowledge representation from unstructured textual data, for example, processing scientific articles. Scientific articles contain a wealth of information, including structured data such as references and citations, as well as unstructured data such as text and figures. By representing this information in a structured way, it is possible to create a comprehensive knowledge graph that captures the relationships between different concepts and entities. One common approach is to use natural language processing techniques to extract structured data from the text of scientific articles (Zhang et al., 2020b; Dunn et al., 2022). For example, named entity recognition can be used to identify entities such as proteins, genes, and diseases in the text, while relationship extraction can be used to identify the relationships between these entities. Another approach is to use machine learning techniques to learn representations of entities and relationships in a knowledge graph directly from the text and image data (Liu et al., 2020). Also, it is possible to use image processing techniques to extract information from figures and tables (Zulkarnain et al., 2022). For example, optical character recognition (OCR) can be used to extract text from figures, while computer vision techniques can be used to identify patterns and relationships in the data.

There are different techniques for knowledge extraction:

1. Rule-based approaches involve the use of domain-specific expert-crafted rules that are designed to capture relevant information. Rule-based approaches can be effective in extracting structured information from scientific articles, but they are limited by the difficulty of designing rules that capture all the relevant knowledge or that apply to other domains (Atzmüller et al., 2008).

2. Statistical approaches use statistical models to identify and extract knowledge from scientific articles. These models are trained on large datasets of annotated texts to identify patterns corresponding to different types of knowledge. Statistical approaches can be effective in extracting knowledge from large volumes of unstructured data, but they can be limited by the quality of the training data (Momtazi and Moradiannasab, 2019).

3. Machine learning-based approaches involve using machine learning algorithms to automatically learn patterns in the data that correspond to different types of knowledge. These algorithms are typically trained on large datasets of annotated scientific articles to identify complex patterns in the data that are difficult to capture using rule-based or statistical approaches. Machine learning-based approaches can be highly effective in extracting knowledge from texts but require large amounts of high-quality training data (Tiddi and Schlobach, 2022).

Knowledge graph construction involves the creation of a structured representation. A knowledge graph consists of a set of entities representing objects or concepts and a set of relationships between them. There are different techniques for constructing knowledge graphs:

- Ontology-based approaches use pre-defined ontologies to structure knowledge extracted from scientific articles. These approaches typically involve mapping entities and relationships from the text to concepts defined in the ontology. They can be effective for building knowledge graphs consistent with domain-specific knowledge, but they can be limited by the availability and quality of the ontology (Krötzsch, 2017).

- Co-occurrence-based approaches leverage statistical techniques to identify relationships between entities. Typically they compute the frequency of entities appearing together, connecting them based on this information. These approaches can be adequate for constructing knowledge graphs that capture the co-occurrence relationships between entities, but not for more complex relationships (Heist, 2018).

- Machine learning-based approaches use large annotated corpora to learn to identify entities and relationships from the text. They can spot complex patterns. Machine learning-based approaches can be highly effective in constructing knowledge graphs that capture complex relationships between entities, but they require large amounts of high-quality training data (Neelakantan, 2017).

Multimodal knowledge extraction and representation have promising applications in healthcare and biomedicine. By representing medical data in a structured way, it is possible to create a more comprehensive understanding of diseases and to develop more effective treatments. For example, knowledge graphs have been used to identify new drug targets for diseases (Sang et al., 2018; Gao et al., 2022).

In healthcare, knowledge representation techniques are being used to extract valuable insights from electronic health records (EHRs). EHRs contain a wealth of information, including patient demographics, diagnoses, and treatments. By applying knowledge representation techniques to EHRs, researchers can extract valuable insights into disease risk factors, treatment efficacy, and patient outcomes (Liao et al., 2010). In biomedicine, knowledge representation techniques are being used to extract knowledge from large volumes of scientific literature. The aim is to create a comprehensive biomedical knowledge graph that can be used to facilitate drug discovery, disease diagnosis and personalised medicine. Knowledge graphs constructed from the biomedical literature can thus capture complex relationships between genes, proteins and diseases, which can be used to identify potential drug targets. (Yuan, 2020).

3 T2KG Framework

We present T2GK, a framework for managing (i.e., extracting, storing and retrieving) knowledge from heterogeneous sources. Section 3.1 describes how align structured and unstructured data into an unified schema. Next, the data mining process is described in the section 3.2. Subsequently, in section 3.3 the extracted pieces of information are integrated into the Knowledge Graph. Finally, the section 3.4 presents the retrieval and visualisation of the data, as well as the evaluation of the platform.

3.1 Standard Annotation

The system works with both structured and unstructured data. The structured data follows an internal organization that can be used to label the information it contains. For example, an Excel sheet with a column called ”city” will label the rest of the elements in that column with that label or as the database name field. There are many different structured formats, the first action is to manage and standardize these representations for internal use. We use subject-verb-predicate triples to link the relevant information, according to the scheme shown in Figure 1.

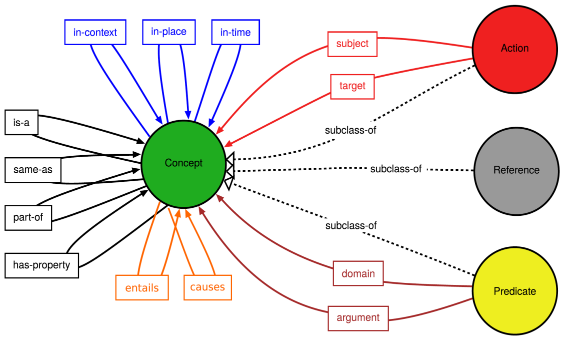

Figure 1: Conceptual schema

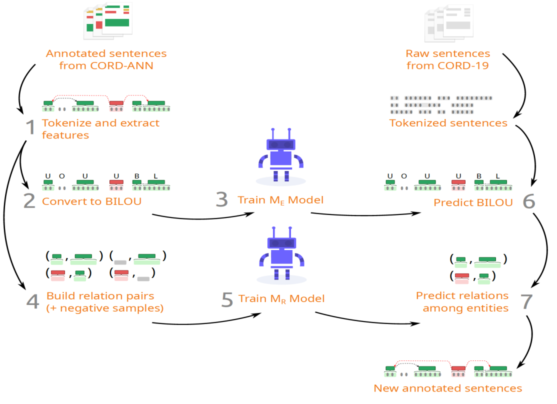
On the other hand, unstructured content lacks a predefined structure of concepts and relations. Hence, the stage for processing unstructured data is designed as a text-mining pipeline through which simple concepts are processed and transformed into more complex ones.

3.2 Knowledge Discovery

This stage presents a machine-learning pipeline for the automatic annotation of entities and relations in raw text. This pipeline is trained on manually annotated sentences and applied to the remaining corpus. Figure 2 shows a high-level overview of the pipeline, which comprises the following steps:



Annotated sentences from CORD-ANN
Raw sentences from CORD-19
1 Tokenize and extract features
Tokenized sentences
U O U U B L
2 Convert to BILOU
3 Train M$_E$ Model
U O U U B L
Predict BILOU 6
4 Build relation pairs (+ negative samples)
5 Train M$_R$ Model
Predict relations among entities 7
New annotated sentences

Figure 2: Illustrative representation of the text-mining pipeline used

1. Sentences are tokenized, computing syntactic and morphological features for each token (using the spaCy [1] library).

2. Training data is manually annotated for entities using BRAT [2]. Then BRAT format is converted to BILOUV encoding (i.e., Begin, Inside, Last, Out, Unit, and oVerlap) for entities.

3. An Entity Model (EM) is trained on the token features to predict the BILOUV encoding. For experiments, we use a Conditional Random Fields (CRF) [3] model.

4. Training data is manually annotated for relations. Each relation pair is converted to a set of aggregated features, and negative relation pairs are randomly sampled.

5. A Relation Model (RM) is trained using the relation features. We use a logistic regression model [4].

6. The EM is applied to unlabeled sentences.

7. The RM is executed on the pairs of entities predicted in the previous step.

For the entity model, the syntactic and morphological features include lemma, coarse and fine-grained part-of-speech, dependency labels, general purpose entity labels (e.g., PERSON, LOCATION, etc.), word shape, and several flags for specific patterns such as emails, numbers, and URLs. For the relation model, the aggregated features correspond to those from the tokens that comprise the two entities that participate in the relation, as well as the features of all the tokens in the smallest sub-tree of the dependency tree that contains both entities.

The ultimate purpose of these models is to automatically extract relevant knowledge from the unlabeled pool of sentences. Taking into account the complexity of this natural language processing task, there is always a trade-off between extracting as much knowledge as possible (i.e. maximizing recall) versus extracting knowledge as accurately as possible (i.e., maximizing precision). However, this trade-off can be explicitly controlled by measuring a degree of uncertainty in the model predictions, and only outputting the elements (i.e., entities and relations) whose uncertainty is below a given threshold. For the EM, the raw marginal probabilities provided by the CRF model are a possible measure of uncertainty. In the case of the RM, the logits provided by the logistic regression model can be used.

3.3 Knowledge Graph Integration

The knowledge graph discovered from each input document should be merged with the knowledge previously extracted by the system. Each of these knowledge graphs represents a collection of knowledge assets from a particular domain or a general domain. Some of them may overlap, containing the same knowledge facts, even if labeled as different entities or relations. Others may have contradictions or inconsistencies, either within themselves or with one another. For that reason, this stage is required to be able to undertake a matching among entities, relations, and instances in two or more graphs that are deemed similar. The result of this process is a unified knowledge graph integrating knowledge from different sources.

3.4 Case Study and Evaluation

After the new knowledge graph is created, this step provides quality evaluation metrics that assert the reliability, completeness, or soundness of the new knowledge. These metrics are based on comparing the new knowledge graphs with the existing knowledge.

This section shows the use of the T2KG system through a practical scenario that involves the processing of both unstructured and structured data sources. We use publicly available data, being the main reason for not designing this experiment with biomedical and health content.

The case study includes data about the geolocations of schools, hotels, restaurants, and bars in the province of Alicante, Spain. Also, structured population data from the Spanish Institute of Statistics (INE) was used. Unstructured data contains comments on social networks. The first step consists of obtaining the statistics data in CSV format and mapping it to a knowledge graph. The CSV file[5] contains information about Alicante's neighborhoods and their residents. The next step involves the processing of a continuous stream of Twitter messages. These are obtained through the standard Twitter query API.

Table 1: Results of the knowledge discovery process

Processing the structured data, the location of different entities can be matched to the neighborhoods where they are located. From the unstructured data, we can know the emotions conveyed by the comments mentioning the entities.

A total of 532 instances were matched, which indicates a 41.95% of accuracy for the Twitter entity extractor. A manual review of the 1268 recognized instances was performed, to evaluate the reasons for the mistakes. All entities appearing on Twitter were searched in Google and the first result was used as ground truth. Table 1 summarizes these results.

The following figures show a set of screenshots of the application that visualizes the knowledge extracted. Figure 3 shows information related to the neighborhoods of Alicante. Figure 4 shows how the knowledge extracted from comments on social networks about hotels, restaurants, and bars in Alicante is incorporated. It is possible to see the distribution by each hotel or by stars. Finally, Figure 5 shows the graph of the knowledge retrieved by a query about the hotels in Alicante.

4 Conclusions

The manual construction of ontologies involves a human effort that sometimes cannot be tackled in domains that need to incorporate knowledge immediately. The use of knowledge graphs can alleviate this lack of resources that hinder the development of tools based on general-purpose knowledge resources. In this work, the aim was to design and implement a framework for automatic knowledge discovery from different data sources. This framework has been designed as a modular set of stages that perform specific tasks that communicate with each other. In future lines of development, we will pursue the implementation of health domain sensors (e.g. medicines, diseases, treatments, substances, etc.), and more complex mechanisms for knowledge integration (e.g., ontology merging and mapping processes). Another line for future research is related to context mismatch and recognition. This process is necessary for accurately matching portions of unstructured text to sections of an already stored ontology. We also aim to develop a full application for the analysis of scientific articles from the biomedical and health domain.

Abstract

In the domain of cuisine, both dishes and ingredients tend to be heavily rooted in the local context they belong to. As a result, the associated terms are often *realia* tied to specific cultures and languages. This causes difficulties for non-speakers of the local language and machine translation (MT) systems alike, as it implies a lack of the concept and/or of a plausible translation. MT typically opts for one of two alternatives: keeping the source language terms untranslated or relying on a hyperonym/near-synonym in the target language, provided one exists. !Translate proposes a better alternative: explaining. Given a cuisine entry such as a restaurant menu item, we identify culture-specific terms and enrich the output of the MT system with automatically retrieved definitions of the non-translatable terms in the target language, making the translation more actionable for the final user.

1 Introduction

National and regional cuisines are heavily tied to their historical and socio-cultural background (Civitello, 2011). Ingredients are often used differently within different cultures (e.g., whereas *hibiscus* represents a spice for chicken soup in the Philippines, it is the main ingredient for a fresh drink in Mexico[1]). Sometimes, an ingredient is widely present, but is used only in a specific region (e.g., *stridoli*[2] grow across Europe, but only some varieties are edible and are used primarily in Italian cuisine). Geographical and cultural diversity have led to the creation of unique local recipes that have no equivalents elsewhere; e.g., *strozzapreti* (an Italian pasta type) and *shish kebab* (a Middle East grilled meat dish) are not available in other cultures and, as a result, are not translated into other languages. In translation studies, such cases fall under *realia*, words referring to objects of the local material culture associated with a lack of the relevant concept and/or of a plausible translation in other languages (Vlakhov and Florin, 1970). In human translation, realia are often left untranslated (transcribed, transliterated or adapted according to the norm of the target language), and can in addition be explained by the translator, in notes or directly in the text (Florin, 1993). In MT, the problem of untranslatable items is solved either by keeping the realia untranslated, or by translating them with a hyperonym or a near-synonym in the target language.

In this demo, we focus on realia in Italian cuisine. This is one of the most widespread cuisines in the world (Capatti and Montanari, 2005), whose most dishes lack a translation in other languages, and are instead denoted by the original Italian vocabulary. Leaving aside items turned international, such as *pizza* or *cappuccino*, this phenomenon can produce a negative effect on non-Italian speakers, who might struggle to understand the meaning of most dishes and ingredients.

Our !Translate system (a) prevents a machine translation system from attempting to translate non-translatable terms, and (b) enriches the resulting partial translation with definitions of such non-translatable items, which are automatically identified and extracted from encyclopedic articles, in order to increase overall text comprehensibility.[3]

The paper is organised as follows. Section 2 introduces our approach to the identification of non-translatable fragments. Section 3 describes our method for the supervised retrieval of definitions. Section 4 outlines the architecture of the !Trans-

late system. Section 5 overviews related work. Section 6 closes with conclusions and further work.

2 Identification of Non-Translatable Fragments

Sentences that contain terms or phrases that are out of vocabulary for an MT engine typically yield low-quality MT output. Hence, we can use a list of entries (glossary) for regional dish names and ingredients, and adopt a brute force approach to identify non-translatable fragments. We iterate through the glossary in the source language and find the longest match in the input sentence. By using the longest match, we take advantage of glossary entries that may contain the full name of a traditional dish, as opposed to single words for a specific ingredient.

The matching algorithm considers variants of a term, i.e. aliases that are contained in each glossary entry, since it is common for regional dishes to have more than one name (usually because the original name was in a local dialect and has since been ‘italianised’, taking a slightly different form), and either variant can appear in restaurant menus or recipes. While more sophisticated entity-linking models could be used (cf. Section 5), this brute-force approach proved to be enough in the cuisine setting.

Our glossary is built from Wikipedia entries that belong to categories associated with the Italian cuisine and from an in-house parallel collection of regional-cuisine menu entries prepared by professional translators.[4] To select the subset of relevant Wikipedia articles both in Italian and English, we rely on the categorisation of the Wikipedia itself and select those entries that belong to, at least, one of the relevant categories. Table 1 shows the categories used for the two languages. As expected, there are very few parallel categories for the cuisine domain (*dolci* and *Italian desserts*), which reflects the standpoint of the Wikipedia editions in the two languages.

	P	**R**	**F$_1$**
Wikifier	23.44	**54.05**	32.70
Brute force	**88.06**	53.15	**66.29**

Table 2: Performance of the alternatives for the identification of non-translatable fragments.

In order to assess the performance of the alternative approaches to non-translatable fragments identification, three annotators labelled 120 instances —one native speaker of Italian and two advanced non-native speakers. After consolidation, 111 text spans were identified as non-translatable. Table 2 shows the performance of two alternative models: our brute-force approach and a standard entity linking approach (Brank et al., 2017). Whereas the recall values are comparable for both models, the precision of our approach is more than three times better, boosting the F$_1$-measure. This is thanks to the applied glossary, which prevents the model from greedily identifying all (pseudo-)terms.

3 Acquisition of Definitions

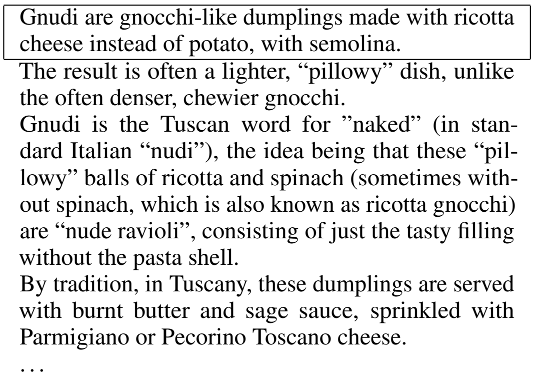
In order to obtain the necessary definitions, we aim at automatically extracting definitional contexts from the Wikipedia, the largest multilingual collection of copyright-free encyclopedic content. We use the Italian and English Wikipedia dumps from July 2021 and keep only the articles that belong to the Italian cuisine, according to their associated categories (cf. Table 1 for the whole list of categories). Table 3 shows statistics of the resulting dataset, which displays the expected distribution: more articles in Italian about the Italian cuisine, even if the articles tend to be longer in English.

Our objective is extracting definitional contexts that can explain non-translatable cuisine terms

[4] Professional translations from Italian into English of the menus from the 2021 edition of the *Festa Artusiana*, a regional cuisine festival (`http://www.festartusiana.it`).

	it	en
articles	2,054	1,923
tokens	780,996	1,170,360
avg. length	380	608

Table 3: Statistics of the articles associated to the Italian cuisine identified in the Italian and English editions of the Wikipedia (avg. article length computed in tokens).



Gnudi are gnocchi-like dumplings made with ricotta cheese instead of potato, with semolina.
The result is often a lighter, "pillowy" dish, unlike the often denser, chewier gnocchi.
Gnudi is the Tuscan word for "naked" (in standard Italian "nudi"), the idea being that these "pillowy" balls of ricotta and spinach (sometimes without spinach, which is also known as ricotta gnocchi) are "nude ravioli", consisting of just the tasty filling without the pasta shell.
By tradition, in Tuscany, these dumplings are served with burnt butter and sage sauce, sprinkled with Parmigiano or Pecorino Toscano cheese.
. . .

Figure 1: A Wikipedia article (input) with its definitional context framed (output), as identified by the BERT-based model.

across languages. Aristotle formulated definitional contexts as sequences of type

$$X = Y + C \ , \tag{1}$$

where X is the *definiendum* (the term), $=$ is the *definitor* (a connective verb such as 'to be' or 'consist'), Y is the *definiens* (the genus phrase, or nearest superconcept), and C are the *differentiæ specificæ*, the distinguishing characteristics that specify the distinction between one definiendum and another (Del Gaudio et al., 2014). For example, the definitional context for *gnudi* is as follows:

$$\overbrace{\text{Gnudi}}^{X}\ \overbrace{\textit{are}}^{=}\ \overbrace{\text{gnocchi-like dumplings}}^{Y}$$

$$\underbrace{\text{made with ricotta cheese instead of potato}}_{C}$$

In order to train the model to identify such definitional contexts, we use the corpus produced by Navigli et al. (2010). It is a collection of 4,719 items, each containing the opening sentences of a Wikipedia article in English. Definitional contexts in this collection were manually identified, resulting in 1,872 positive instances. Figure 1 shows an example of the input —a full Wikipedia article— with the expected output.

	F$_1$	Acc
Navigli and Velardi (2010)*	75.23	83.84
bert-base-cased	96.08	96.82
bert-base-multilingual-cased	**97.66**	**98.09**

*No official testing partition has been published; hence these numbers are not directly comparable against ours.

Table 4: Performance of the two model variations for the identification of definitional contexts.

We experimented with two models based on BERT (Devlin et al., 2019) to classify sentences as definitional context or not: `bert-base-cased` and `bert-base-multilingual-cased`. The former is intended for the extraction of definitions when the target language is English, whereas the latter is intended to give an estimation of the performance when requiring definitions in Italian. We split the dataset into 80% for training, 10% for validation and 10% for testing. Table 4 shows the performance obtained on the testing partition. The performance of both the monolingual and the multilingual alternatives is remarkable, landing close to a perfect accuracy.

Table 5 shows some examples of definitional-context candidates that our model identifies in Wikipedia articles, both in English and Italian. Both instances 1 and 3 represent proper definitional contexts that would help a user to understand a dish. Instance 2 is a proper definitional context, but with a clear encyclopedic spirit. Instance 4 refers to the story of fish fingers rather than a proper definition.

4 The !Translate Components

Figure 2 illustrates the architecture of the !Translate system, which is composed of the backend and the frontend.

Backend The *backend* website allows project contributors to manage glossaries and their entries. The *multilingual glossary* itself is a database that is accessed through APIs by the backend website and the *definition extractor* component. Not all cuisine-related entries in the Italian Wikipedia have a corresponding page in English. For those, we use MT to translate the best definition extracted from the Italian page.

Frontend The *frontend user interface* is a website that accepts user input and displays enhanced translations in the desired language. The input is a free text (e.g., a recipe, a restaurant menu) which is

definitional context	**op**
English	
1. **Picada** is a type of tapas eaten in Argentina and Uruguay, usually involving only cold dishes, such as olives, ham, salami, mortadella, bologna, different types of cheese, marinated eggplants and red pimentos, sardines, nuts, corn puffs, fried wheat flour sticks, potato chips, and sliced baguette	♣
2. **Sucrose** is a disaccharide made up of glucose and fructose.	
Italian	
3. I **canéderli** (in tedesco Semmelknödel) sono degli Knödel (grossi gnocchi) composti di un impasto a composizione variabile di pane raffermo.[a]	♣
4. Le **"dita di pesce"** (fish fingers) furono una ricetta di inizio Novecento pubblicata su una popolare rivista britannica ed è tuttora considerato spesso un piatto-simbolo della cucina del Regno Unito.[b]	

[a] Canérdeli (in German Semmelknödel) are Knödel (large gnocchi) made of a dough with diverse mixtures of sourdough bread.

[b] Fish fingers were a recipe from the early 20th century published on a popular British magazine and is still often considered a signature dish of UK cuisine.

Table 5: Examples of extracted definitional contexts in English (top) and Italian (bottom; English translations included for comprehensibility). Column **op** flags definitions considered operational for the !Translate explanation purposes.

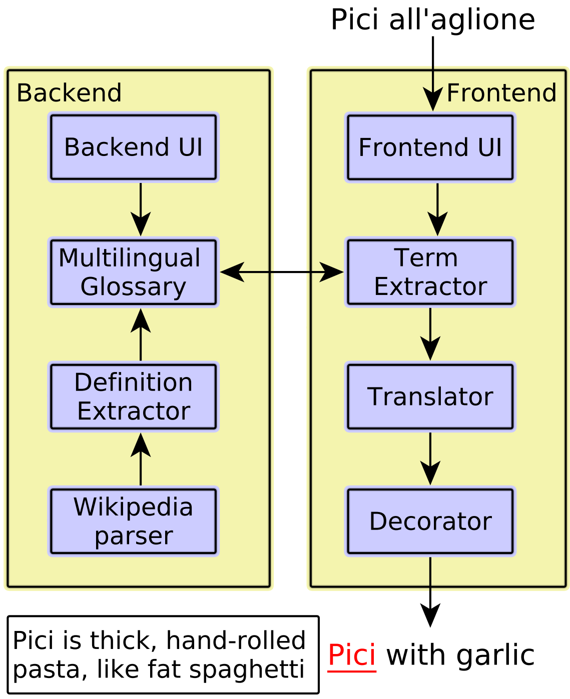


Figure 2: The !Translate system architecture

passed through a *segmentation* or sentence-breaker component to divide input text into individual sentences. A *term extractor* matches non-translatable fragments against the *multilingual glossary* and replaces them with special do-not-translate XML tags, with attributes to encapsulate the desired substitution terms. This step produces an out-of-vocabulary, preventing an MT system from attempting to translate literally certain terms and contains metadata to inform further components in the pipeline about the non-translatable items found. The *translator* component handles calls to a cloud MT engine, such as ModernMT;[5] this is a simple proxy for an online MT, with no customization or adaptation. The post-processing *decorator* component takes the MT output and, by looking at the metadata in each do-not-translate tag, substitutes these tags with a hyperlink to a definition, and their content (the fragment within do-not-translate tags) with the proper translation taken from the glossary.

As observed in the example of Figure 2, given the input *Pici all'aglione*, the system matches **Pici** with a non-translatable entry from the glossary, retrieves the pre-obtained definition, and plugs it in next it in the enhanced translated output.

Figure 3 shows a snapshot from our system.

Original text:

zuppa inglese

Translated text

Zuppa Inglese

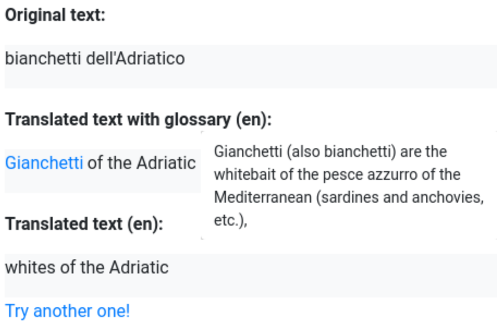
Zuppa Inglese (, Italian: [ˈdzuppa iŋ ˈgleːze, ˈtsuppa iŋˈgleːse]; Italian for "English soup") is an Italian dessert layering custard and sponge cake, perhaps derived from trifle.

Figure 3: A snapshopt of the system interface showing *zuppa inglese* —which is not English and is not a soup— and its augmented (no) translation.

Rather than translating the entry and providing a useless "accurate" translation ('English soup'), our system opts for keeping the entry untranslated and providing a definition instead, which properly describes the concept. Figure 4 shows another example. This time, part of the item is translated whereas another part is not, and it is explained instead: *bianchetti* are not *little whites*, but young blue fish, such as sardines.

5 Related Work

Entity linking aims at identifying the unique identity of an entry. This kind of technology is commonly supported on linking text to encyclopedic entries. Such a process is also known as wikification, in which the entities are linked to the Wikipedia in order to augment the comprehensibility of a text. One of the first approaches was Wikify! (Mihalcea and Csomai, 2007), which relied on a combination of steps to perform keyword-matching and disambiguation independently. Babelfy (Moro et al., 2014) is another alternative, but its approach to word disambiguation targets to identify all concepts which, for our purposes, results in over-identification. In recent approaches, entity linking is modeled with neural models that perform the task of entity finding and linking at once (Kolitsas et al., 2018). Through a dual encoder, the model proposed by Botha et al. (2020) can link entities in multiple languages. We do not opt for any of these models because the texts we deals with are brief (e.g., menu entries) and rather than performing an open search, we only need to find matches.



Original text:

bianchetti dell'Adriatico

Translated text with glossary (en):

Gianchetti of the Adriatic

Gianchetti (also bianchetti) are the whitebait of the pesce azzurro of the Mediterranean (sardines and anchovies, etc.),

Translated text (en):

whites of the Adriatic

Try another one!

Figure 4: A snapshopt of the system interface showing *bianchetti dell'Adriatico*. At the bottom the default (wrong translation). In the middle, the correct and augmented partial translation: 'Gianchetti of the Adriatic'.

The task of extracting definitional contexts is not limited to glossaries and encyclopaediae, but extended to other fields such as ontology learning (Gangemi et al., 2003), question answering (Saggion, 2004; Cui et al., 2007) and eLearning (Westerhout and Monachesi, 2007). Most approaches rely on lexico–syntactic patterns (Saggion, 2004; Cui et al., 2007; Fahmi and Bouma, 2006; Degórski et al., 2008) that require manual annotation and/or manually written rules. A different approach has been taken with the use of Word Lattices, directed acyclic graphs that represent a segment. (Navigli and Velardi, 2010) introduced Word-Class Lattices to model textual definitions.

6 Conclusions and Future Work

We have presented !Translate , an application that automatically produces translations combining machine translation, entity linking, and supervised definition retrieval to provide informative translations to users in settings in which machine translation alone is not enough. We have focused on the domain of cuisine, in which terms often lack in the target language and require further descriptions (definitions) to become operational.

As part of our ongoing work, we are experimenting with a MT Quality Estimation (QE) component to optionally direct the translation request to a notification queue component that will post a request to a crowdsourcing-based translation component for those sentences that are deemed difficult to translate automatically, even with the help of a glossary.

Ethics/Broader Impact

This paper presents a system that enhances machine translation via automatic identification of untranslatable terms and automatic extraction of definitions for these terms, which are then added to the MT output. Our focus is on culture-specific items in restaurant menus written in Italian, but our pipeline may benefit applications dealing with other specialised domains. On a wider societal plan, our work concerns intangible cultural heritage and aims to help protect local traditions by using local names while at the same time explaining their meaning to those who might not be familiar with them. We do not see any potential for malicious usage of our framework.

Abstract

We explore the use of source factors in context-aware neural machine translation, specifically concatenation-based models, to improve the translation quality of inter-sentential phenomena. Context sentences are typically concatenated to the sentence to be translated, with string-based markers to separate the latter from the former. Although previous studies have measured the impact of prefixes to identify and mark context information, the use of learnable factors has only been marginally explored. In this study, we evaluate the impact of single and multiple source context factors in English-German and Basque-Spanish contextual translation. We show that this type of factors can significantly enhance translation accuracy for phenomena such as gender and register coherence in Basque-Spanish, while also improving BLEU results in some scenarios. These results demonstrate the potential of factor-based context identification as a research path in context-aware machine translation.

1 Introduction

Machine translation typically operates at the sentence level, leaving aside larger context information. This mode of operation remains dominant within the Neural Machine Translation (NMT) framework (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017), although it limits accurate translation for linguistic phenomena that depend on context information, such as cohesion, discourse coherence or intersentential anaphora resolution (Bawden et al., 2018; Läubli et al., 2018; Voita et al., 2019b; Lopes et al., 2020; Post and Junczys-Dowmunt, 2023).

Addressing discourse-related phenomena in translation requires extending the scope of the translation models to address the relevant information present in the context sentences, in addition to that of the sentence to be translated. Several approaches have been proposed within NMT to extend the modelling window beyond isolated sentences, extending the input by including context sentences (Tiedemann and Scherrer, 2017) or modifying the NMT architecture to model context information (Jean et al., 2017; Zhang et al., 2018; Voita et al., 2019b; Li et al., 2020).

Despite the marked improvements achievable with the aforementioned approaches, the identification of the relevant contextual information to improve the translation of a given sentence is still an open research topic. Within concatenation-based approaches (Tiedemann and Scherrer, 2017), a simple yet strong document-level NMT baseline, context sentences are typically prepended to the sentence to be translated, and separated from it by a simple marker. Further identification of what belongs to the context or to the sentence to be translated is typically discarded, following in part initial results by Tiedemann and Scherrer (2017) where the use of prefixes to identify context tokens led to degraded results at best. An alternative method that may provide better context identification is the utilization of factors as context markers. Factors are learnable embeddings associated to input tokens that provide supplementary information about the token. Different approaches, such as addition or concatenation, can be employed to combine token embeddings with factor embeddings. Within the context identification process, this supplementary information may serve to indicate whether the token belongs to the context or not. To our knowledge, the use of these markers for context aware NMT has only been partially explored, and the results obtained so far have been inconclusive (Rikters et al., 2020; Lupo et al., 2023).

In this work, we present extended results on the use of factors for context-aware NMT, centred on using source factors and measuring their impact on both standard and contrastive datasets. We re-

Proceedings of Recent Advances in Natural Language Processing, pages 399–407

port results on English-German pronoun translation using the ContraPro test set (Müller et al., 2018), and on Basque-Spanish gender selection and register coherence with the TANDO test sets (Gete et al., 2022). We show that source factors can significantly enhance translation accuracy for phenomena such as gender and register coherence in Basque-Spanish, while also improving BLEU results in some cases. These results demonstrate the potential of factor-based context identification as a research path to improve context-aware machine translation.

2 Related Work

The inclusion of contextual information to improve machine translation is a long-standing topic of interest in the field (Mitkov, 1999; Tiedemann and Scherrer, 2017). Within the NMT paradigm in particular, an increasing number of studies have centred on context-aware NMT approaches and the improvements that these models may provide over non-contextual baselines (Li et al., 2020; Ma et al., 2020; Lopes et al., 2020; Fernandes et al., 2021; Majumde et al., 2022; Sun et al., 2022).

One of the first methods proposed for the task is the concatenation of context sentences to the sentence to be translated (Tiedemann and Scherrer, 2017), a simple approach which provides a robust baseline that often matches or outperforms more sophisticated methods (Lopes et al., 2020; Sun et al., 2022; Post and Junczys-Dowmunt, 2023). Variants of this approach include discounting the loss generated by the context (Lupo et al., 2022), extending model capacity (Majumder et al., 2022; Post and Junczys-Dowmunt, 2023) or encoding the specific position of the context sentences (Lupo et al., 2023). The latter in particular includes the use of learned embeddings for each sentence position, for which they report mixed results with improvements in English-Russian and a negative impact in English-German, using three context sentences. We include a variant of this approach in the form of separate factors for each context sentence, without discounting context loss and applying it to a larger context on English-German and Basque-Spanish datasets.

Alternative approaches to input extension notably include refining context-agnostic translations (Voita et al., 2019a) and modelling context information with specific NMT architectures (Jean et al., 2017; Li et al., 2020).

Since context-aware models are particularly suited to improve the translation of phenomena that directly depend on context information, several challenge test sets have been created specifically to evaluate the ability of models to adequately translate these phenomena in context (Guillou and Hardmeier, 2016; Bawden et al., 2018; Guillou et al., 2018; Müller et al., 2018; Lopes et al., 2020; Gete et al., 2022).

The use of factors was introduced in Statistical Machine Translation as a means to incorporate additional linguistic information (Koehn and Hoang, 2007). For NMT, the concurrent work of Sennrich and Haddow (2016) and Hoang et al. (2016) explored how sentence-level NMT models could benefit from incorporating additional linguistic information via factors in the source language. They thus added morphological features, part-of-speech tags, and syntactic dependency labels as input features, obtaining promising results in terms of perplexity reduction and higher BLEU (Papineni et al., 2002) scores.

Source factors have only been partially explored for context-aware NMT. In addition to the previously cited work of Lupo et al. (2023) on learnable context sentence position embeddings, Rikters et al. (2020) also employ factors to identify tokens as pertaining to the context or to the sentence to be translated. In their experimental results on Japanese–English translation, using one context sentence, the use of factors provided only minimal absolute improvements in terms of BLEU over simple input concatenation. Our work differs from theirs in several respects: we used larger contexts of 5 sentences, evaluated them on two language pairs, used contrastive evaluations on context phenomena in addition to BLEU scores, and measured the impact of both unique and multiple context factors.

3 Experimental Setup

3.1 Data

We describe in turn below the parallel and contrastive data used to train and test our NMT models in Basque-Spanish and English-German.

Parallel Data For Basque–Spanish, we selected the TANDO corpus (Gete et al., 2022), which contains parallel data from subtitles, news and literary documents, and includes validation and test sets. For English–German, we followed the approach of Müller et al. (2018) and the data was obtained from the WMT 2017 news translation task, using newstest2017 and newstest2018 as test sets, and the union of newstest2014, newstest2015 and newstest2016 for validation. Table 1 summarises parallel corpora statistics.

	EU-ES	EN-DE
TRAIN	1,753,726	5,852,458
DEV	3,051	2,999
TEST	6,078	6,002

Table 1: Parallel corpora statistics (number of sentences)

Contrastive Test Data For Basque–Spanish, we used the contrastive test set included in TANDO, a set created from collected books, TED talks, and proceedings of the Basque Parliament. It is designed to assess a model's ability to select the correct translation in terms of the choice of gender (feminine or masculine) or register (formal or informal) of certain words and it is composed of 600 instances, divided into two subsets: GDR-SRC+TGT, where the disambiguating information to predict the gender is present in both the source and target languages and COH-TGT, which evaluates the contextual coherence of the translation despite the absence of necessary information in the source language to make a correct selection of gender or register. All instances require contextual knowledge to select the correct translation.

For English–German, we used ContraPro (Müller et al., 2018) a contrastive test created from OpenSubtitles2018[1] (Lison et al., 2018) excerpts aiming to test the ability of a model to identify the correct German translation of the English anaphoric pronoun *it* as *es*, *sie* or *er*. It contains 12,000 instances, 4,000 per category, and requires knowledge of the context in 80% of the cases to select the correct translation.

All selected datasets were normalised, tokenised and truecased using Moses scripts (Koehn et al., 2007) and segmented with BPE (Sennrich et al., 2016), using 32,000 operations.

3.2 Models

We trained sentence-level baselines and concatenation-based context-aware models, which extend the input by concatenating the previous sentences to the current one to be translated (Tiedemann and Scherrer, 2017). This approach was selected for its simplicity and robustness, as it typically obtains competitive results without any modification of the NMT architecture (Tiedemann and Scherrer, 2017; Lopes et al., 2020; Majumde et al., 2022). We opted to use 5 context sentences, since for the two selected contrastive tests, the disambiguation information is always found within this context window.

Gete et al. (2022) noted that, although they provide marked improvements in terms of contrastive evaluations, models trained on concatenated context can worsen translation quality in terms of BLEU, especially with longer contexts. This might be due to increasing difficulties in identifying which parts of the information provided to the model are actually relevant to properly translate the current sentence. For larger contexts in particular, factors may help discriminate the different parts of the input provided to the model, at least in terms of separating context tokens from those of the sentence to be translated.[2]

To explore this hypothesis, we trained three variants of concatenation-based models, along with a sentence-level baseline, based on the Transformer-base architecture (Vaswani et al., 2017):

- SENTENCE-LEVEL: a standard Transformer-base model without input context.
- CONTEXT-AWARE: a standard Transformer-base model with concatenated input context, separated from the input sentence with a BREAK marker.
- CONTEXT-AWARE+FACTOR: a concatenation-based model that includes source factors with two different values to differentiate the sentence to be translated (S) from the context sentences (C). The factors are added at the token level and we eliminate the BREAK marker, as the factors serve to delimit which tokens are part of the context.
- CONTEXT-AWARE+MULTIFACTOR: This approach is similar to the previous one, but uses different values for the factor of each sentence in the context (C1, ..., C5). This approach is

[1] https://www.opensubtitles.org/

[2] Note that this differs from the use of prefixes attached to context subwords, as in Tiedemann and Scherrer (2017). In preliminary experiments, we also experimented with inline annotations to indicate if an input token pertained to the context. This method was discarded as it resulted in losses in terms of both BLEU scores and accuracy on the contrastive test sets.

similar to the learned sentence position embeddings of Lupo et al. (2023), although we removed the context separation token and did not use context loss discarding.[3].

Factor and token embeddings can be combined using addition or concatenation. We opted for addition since this approach maintains the dimension of the original embeddings, whereas concatenation leads to larger embeddings overall. We left an exploration of the concatenation approach for future work.

An example of input data for each of the context-aware methods is shown in Table 2. Factors were only used on the source language side in this study. The target side includes a context separation BREAK marker between context sentences and the translated source sentence. All 5 source context sentences are translated along with the non-context source sentence, and all translated context target sentences that occur before the target break marker are discarded.

Factor embeddings were added for each source token and summed to the token embeddings, as is typically done with positional encodings in Transformer models. Thus, each token vector contains information about the token itself, its position in the input, and its belonging or not to the context.[4]

The embeddings for source, target and output layers were tied and optimisation was performed with Adam (Kingma and Ba, 2015), with $\alpha = 0.0003$, $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-9}$. The learning rate was set to increase linearly for the first 16,000 training steps and then decrease proportionally to the inverse square root of the corresponding step. Validation data were evaluated every 5,000 training steps, and the process ended if there was no improvement in the perplexity of 10 consecutive checkpoints. All models were trained with the MarianNMT toolkit (Junczys-Dowmunt et al., 2018) and context-aware models were initialised with the weights of the baseline sentence-level models.

[3] Our experimental setup also differs, notably in terms of training corpora.

[4] An alternative approach would have involved concatenating the factor embeddings instead of summing them. We left variants of this type for future experiments.

4 Results and Analysis

4.1 BLEU Results

We first assessed the sentence- and context-level models in terms of BLEU (Papineni et al., 2002) using the SacreBLEU toolkit (Post, 2018)[5] on cased detokenised output. To determine whether differences in scores between models actually reflect differences in overall quality, we determined the statistical significance of our findings using paired bootstrap resampling (Koehn, 2004).

The results are presented in Table 3. In both language pairs, context-aware models obtained higher scores than the sentence-level baselines, which is not always the case with context-aware models on the BLEU metric (Gete et al., 2022). Turning to factor-based models, in Basque-Spanish the use of factors resulted in higher absolute values but none of these apparent improvements were statistically significant. In English-German similar results were obtained on the wmt2018 test set. However, both factored models obtained significantly better results than the context-aware baseline on the ContraPro test set. Additionally, the multi-factor variant also improved over the alternatives on the wmt2017 test set.

Overall, the improvements that had statistical significance ranged from .4 to .8 BLEU points. Although relatively minor, these gains indicate that the use of source factors has the potential to enhance translation outcomes in certain scenarios, and did not worsen them in any of the cases in our experiments.

4.2 Contrastive Results

Accuracy results for the contrastive test sets described above are shown in Tables 4 and 5, for Basque–Spanish and English-German, respectively.

Regarding coherence, the use of factors clearly enhanced the performance of Basque-Spanish translation models for both gender and register tests. Notably, models that incorporate multiple context factors exhibited marked improvements, with gains of 10 and 17 percentage points on gender and register, respectively. For the GDR-SRC+TGT test, however, the outcomes remained practically unchanged with respect to those of the non-factored model.

In the case of English-German models, the use of factors led to lesser differences, with an overall increased accuracy of only 3 percentage points for both single and multiple factors. Looking at the different pronominal categories, the improvements were mostly based on increased accuracy for the translation of pronouns *er* and *sie*, with improvements of 6 and 4 percentage points, respectively, when using single factors in the first case and multiple factors in the second case. This is not totally unexpected considering the already high accuracy for the translation of *es* by all models, including the sentence-level baseline.

For both language pairs, it is worth noting that the most substantial improvements are observed in cases with initially lower results, while those with high initial scores (GDR-SRC+TGT for Basque-Spanish and the subset corresponding to *es* in English-German) remain similar overall.

4.3 Impact of Factors Beyond Metrics

To complement the results in terms of BLEU and accuracy on contrastive test sets, we examined two different aspects regarding the use of factors.

First, we aimed to evaluate the extent to which the use of factors impacted translation results, even when the final score remained almost identical. To gain further understanding on this question, we computed the percentage of predictions that differed in each contrastive test between factored models and baseline context-aware models. The results in Table 6 indicate that, for Basque-Spanish, even for models where results were identical, as between the context-aware baseline and the single factor model (78% in this case), or almost identical as with the multi-factor model (77%), the predictions between models differed by 17%. A similar figure was obtained for English-German, where the difference amounted to 15% for the single factor model, and 14% when using multiple factors. The latter model featured the largest differences on the two coherence test sets in Basque-Spanish, which is in line with the larger metrics improvements obtained for the gender and register coherence contextual categories. Determining the specific conditions where the use of factors resulted in accuracy loss, thus negatively balancing the cases where factors resulted in gains, would require a more specific analysis which we leave for future work.

Additionally, we measured the average distance to the context sentence in all cases where the models made an incorrect contrastive prediction, with the results shown in Table 7. In English-German, the differences were minor overall, in line with the relatively close results in terms of metrics described in the previous sections. In Basque-Spanish, the model with the largest improvements, using multi-factors, was associated with increased distances, i.e. an extended context window over which the model could provide more accurate results. In this case as well, a more precise analysis of the contrastive predictions would be needed to further establish the strengths and weaknesses in the use of context factors.

5 Conclusions

In this work, we explored the use of factors in context-aware neural machine translation to improve the translation quality of inter-sentential phenomena. Specifically, we evaluated the impact of source factors in concatenation-based models, using both single factors for all context sentences, and multi-factors, where separate factors are assigned for each context sentence.

We conducted our experiments on parallel and contrastive test sets in English-German and Basque-Spanish, using larger contexts than in previous related studies, and targeting different phenomena such as pronoun translation, gender selection, and coherence in both register and gender.

Overall, both of the evaluated factor-based approaches improved over the concatenation-based baseline. In terms of BLEU, these approaches either matched or improved over the baseline, although the gains were relatively minor and only statistically significant on two test sets in English-German. On the contrastive sets, the largest gains were obtained in Basque-Spanish on the coherence-related tests, achieving gains of 10 and 17 percentage points in accuracy. On the gender selection test, no improvements were observed in this language pair, however. In English-German, the factor approach improved over the baseline overall, but with comparatively smaller gains.

The multi-factor approach provided the most consistent benefits across metrics, with additional results showing its increased accuracy in context-based predictions at a larger distance than the baseline and the single factor approach. This approach might thus be worth exploring further in different contexts or in combination with other approaches.

Our study mainly aimed to measure the potential of context factors in NMT, on a diverse set of test sets with relatively large contexts. In future work, we will further investigate factor-based context-aware NMT variants, notably by measuring the impact of target-side factors, evaluating the use of factors in combination with other context identification markers, and extending the analyses to more language pairs and contextual phenomena.

Abstract

Recent works on linear text segmentation have shown new state-of-the-art results nearly every year. Most times, however, these recent advances include a variety of different elements which makes it difficult to evaluate which individual components of the proposed methods bring about improvements for the task and, more generally, what actually works for linear text segmentation. Moreover, evaluating text segmentation is notoriously difficult and the use of a metric such as P_k, which is widely used in existing literature, presents specific problems that complicates a fair comparison between segmentation models. In this work, then, we draw from a number of existing works to assess which is the state-of-the-art in linear text segmentation, investigating what architectures and features work best for the task. For doing so, we present three models representative of a variety of approaches, we compare them to existing methods and we inspect elements composing them, so as to give a more complete picture of which technique is more successful and why that might be the case. At the same time, we highlight a specific feature of P_k which can bias the results and we report our results using different settings, so as to give future literature a more comprehensive set of baseline results for future developments. We then hope that this work can serve as a solid foundation to foster research in the area, overcoming task-specific difficulties such as evaluation setting and providing new state-of-the-art results[1].

1 Introduction

Linear text segmentation, also known as topic segmentation, is a well known problem in natural language processing, and the first step for a number of downstream applications. The task consists in the automatic segmentation of a text into topically coherent units and this has many use cases: a long transcript from a news show, e.g., could be divided into single news stories so as to help an end user in retrieving more relevant and specific information (Reynar, 1999) or a long article could be divided into subsections to aid its reading (Hearst, 1997).

Recent works have presented a series of advancements in the field, from which a number of conclusions could be drawn, such as the fact that Transformer architectures work better than traditional recurrent models (Lo et al., 2021) and that fine-tuned LLMs need no additional contextual information to perform the task (Lee et al., 2023).

The results of different recent works, however, can be contradictory and not pointing towards a clear direction forward in terms of what works and what does not in text segmentation. Part of the reason for this, we show, is the fact that existing and popular metrics such as P_k (Beeferman et al., 1999) might lead to very different results under different conditions and, therefore, the final results from which to draw our conclusions are unstable.

Based on this, we draw on existing literature to present our own topic segmentation models. We show that carefully designed recurrent neural networks are still relevant in the field as they can obtain state-of-the-art results in most occasions given a fixed and fair evaluation setting. We draw conclusions on why this might be the case and we show

that this evidence makes sense given previous literature on the subject.

2 Related Work

2.1 Models for Topic Segmentation

Traditionally, text segmentation involves the segmentation of text like books or articles (Beeferman et al., 1999; Koshorek et al., 2018), business meeting or TV news transcripts (Misra et al., 2010; Purver et al., 2006; Sehikh et al., 2018).

An early text segmentation system, TextTiling, used two adjacent sliding windows over sentences and compared the two by means of cosine similarity between the relative bag-of-words vector representations (Hearst, 1994). The same algorithm was then successfully used with different, more informative sentence representations, such as Term-Frequency Inverse-Document-Frequency (TF-IDF) rescoring of bag-of-words (Galley et al., 2003) and features derived from generative topic models like Latent Dirichlet Allocation (LDA, Riedl and Biemann, 2012). More recently, these topic features have been replaced with sentence representations extracted from large language models, again apparently showing improvements (Ghinassi, 2021; Harrando and Troncy, 2021; Solbiati et al., 2021).

Recent research has also seen a surge of large annotated datasets for the task, usually exploiting the headers of Wikipedia articles to obtain large datasets without requiring human annotation. The first such dataset was proposed by Koshorek et al. (2018), but the most popular datasets in this category are the two Wikisection datasets proposed by Arnold et al. (2019), as their smaller sizes allow for faster experimentation.

With the availability of such larger, publicly available datasets, supervised methods became the preferred approach for the task. Koshorek et al. (2018) trained a hierarchical, Bidirectional Long-Short Term Memory (BiLSTM) neural network to segment paragraphs in a large Wikipedia corpus, showing good improvements over non-neural and unsupervised methods. Since then, most of the literature has focused on using hierarchical recurrent neural networks (Tsunoo et al., 2017; Lukasik et al., 2020a; Sehikh et al., 2018) or, more recently, hierarchical transformers (Lukasik et al., 2020b; Glavaš and Somasundaran, 2020). In recent works, BERT used as a sentence encoder has been included either to instill additional general knowledge to end-to-end systems (Xing et al., 2020) or to extract standalone features (Lo et al., 2021).

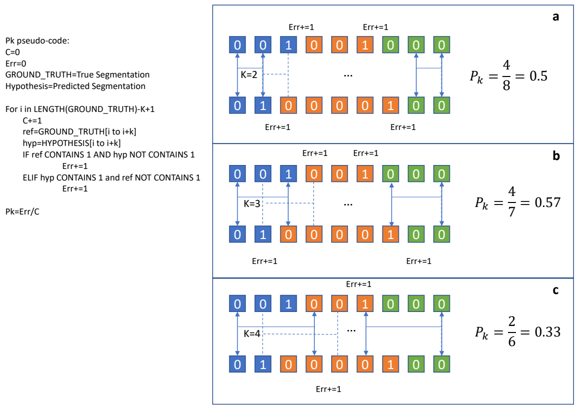
Transformer-based Large Language Models (LLMs) like BERT are extremely popular for many NLP tasks, often reaching state-of-the-art results. The same seemed to apply to text segmentation and recent literature has focused on the use of such models to perform text segmentation based only on local context, such as pairs of sentences, showing state-of-the-art results (Lee et al., 2023). In particular, the use of LLMs which were previously fine-tuned for sentence similarity together with additional fine-tuning of these models on the text segmentation task itself seemed to lead to best results, while the inclusion of additional context is, according to the authors, detrimental.

However, these last findings run counter to previous research, where the use of (limited) context was observed as generally beneficial (Lukasik et al., 2020a; Lo et al., 2021; Xing and Carenini, 2021; Xia et al., 2022) and the use of LLMs fine-tuned for sentence similarity did not lead to significant improvements (Solbiati et al., 2021). A more in depth exploration of state-of-the-art models shows further apparent contradictions. For example, the current second best model on Wikisection datasets shows significant improvements via the use of hierarchical transformers (Lo et al., 2021), while other sources have shown that, at least for certain datasets, BiLSTM networks can outperform transformers on this task (Lukasik et al., 2020a); this would be theoretically justified by the fact that recurrent neural networks such as BiLSTMs do give more importance to closer context, shown to be more relevant for the task (Xing and Carenini, 2021).

The current situation is therefore confusing, with different results suggesting quite different conclusions about the best choice of model architecture and settings. In this work, therefore, we focus on systematic comparison, and show that some of these discrepancies are explainable by the evaluation settings. When using a fixed evaluation setting, we can instead assess more convincingly what works best for the task and, as we show, this is indeed in line with our understanding of text segmentation as a task drawing from local coherence.

2.2 Evaluating Text Segmentation

Evaluating topic segmentation systems is itself an open problem. Classification metrics such as F1 score are not necessarily a good choice for topic segmentation: they consider a false positive boundary predicted just next to a true boundary, and one



```
Pk pseudo-code:
C=0
Err=0
GROUND_TRUTH=True Segmentation
Hypothesis=Predicted Segmentation

For i in LENGTH(GROUND_TRUTH)-K+1
    C+=1
    ref=GROUND_TRUTH[i to i+k]
    hyp=HYPOTHESIS[i to i+k]
    IF ref CONTAINS 1 AND hyp NOT CONTAINS 1
            Err+=1
    ELIF hyp CONTAINS 1 and ref NOT CONTAINS 1
            Err+=1

Pk=Err/C
```

Figure 1: Pseudo-code and examples of P_k. Sub-figures a, b and c show the P_k result for the same ground truth and predicted boundaries but using $k = 2$, $k = 3$ and $k = 4$ respectively. It can be noticed how the P_k results vary greatly according to the parameter.

predicted ten sentences away, as equally bad misses. To overcome this problem Beeferman et al. (1999) proposed the P_k metric, which assesses how likely it is for two points a distance k apart (usually set to half the average true segment length) to be incorrectly separated by the hypothesized boundaries. However, P_k also has many reported problems (Pevzner and Hearst, 2002), failing to penalize incorrect separation by multiple boundaries more than single ones, and favouring false positives over true positives (Georgescul et al., 2006). Many other metrics have been proposed to overcome the limitations of P_k (Pevzner and Hearst, 2002; Scaiano and Inkpen, 2012; Fournier and Inkpen, 2012) but none of them has ever been widely adopted, and most literature still uses the P_k metric, notwithstanding its limitations.

Among the shortcomings of P_k is also the high sensitivity of the metric to its parameter k (see figure 1). This, as we will show, makes misunderstandings in the evaluation more likely, as the k parameter can be set in ways that are different from other evaluation settings, leading to differences in results that do not reflect actual meaningful differences in segmentation.

3 Methodology

3.1 Our Models

Here we describe our proposed models, which are chosen to represent the main state-of-the-art approaches in the literature and aim to find which architectural and feature factors determine a good text segmentation performance.

3.1.1 Architectures

We experiment with three different architectures (see their visual representation in figure 2):

BiLSTM: This architecture was first proposed for topic segmentation by Koshorek et al. (2018) and it has been widely used by following literature with various modifications (Xing and Carenini, 2021; Barrow et al., 2020; Badjatiya et al., 2018). In its original form, this model consists of n layers of Bidirectional Long-Short Memory (BiLSTM) recurrent neural network modelling the word-level features, a pooling layer to obtain sentence representations and n additional BiLSTM layers modelling the sentence-level features, followed by a linear layer and a Softmax activation yielding a series of probabilities $\hat{Y}$. In our case, we follow recent literature (Lukasik et al., 2020a; Xing and Carenini, 2021) and we substitute the word-level BiLSTM with embeddings extracted from sentence encoders during pre-processing. Schematically, if we define $BiLSTM$ as a series of n BiLSTM layers each having h hidden units, $W \in (R)^{h\times 1}$ as the final linear layer and $Softmax$ as the softmax activation function, our BiLSTM model predicts

$$\hat{Y} = Softmax(W^T(BiLSTM(E))) \quad (1)$$

where $E := \{e_0, e_1, ..., e_n\}$ is the collection of all the sentence embeddings $e_i \in \mathbb{R}^d$ extracted from the given document's sentences.

At test time, we choose a threshold th by searching values between 0.05 to 0.95 with a step of 0.05 and choosing the one yielding best results on validation set. Threshold th is employed such that a topic boundary is placed after each sentence s_i for which $\hat{y}_i > th$.

Dot-BiLSTM: this architecture is similar to that of Sehikh et al. (2018) and Arnold et al. (2019), both having the intuition of separating the forward and the backward directions of the last BiLSTM layer in a network similar to the BiLSTM model described above, so as to directly compute a similarity score between the two, therefore forcing the model to exploit notions of semantic similarities more closely related to the downstream task. Having a stack of n $BiLSTM$ layers we obtain

$$H = BiLSTM(E) \quad (2)$$

Then, we separate H's forward direction $\overrightarrow{H}$ and backward direction $\overleftarrow{H}$, which are used to predict

$$\hat{Y} = 1 - Sigmoid(W^T_{for}\overrightarrow{H} \cdot W^T_{bac}\overleftarrow{H}) \quad (3)$$

with $Sigmoid$ being the sigmoid activation function, $\cdot$ being dot product and $W_{for} \in \mathbb{R}^h$ and $W_{for} \in \mathbb{R}^h$ both learnable parameters. The sigmoid-activated score is subtracted from 1, as we want the model to make sentences from two different topic segments further apart in the hidden space, thus closer to 0, while our objective labels define the identification of a topic boundary as 1.

We employ the same strategy as BiLSTM model to search the optimal threshold th.

Transformer: This architecture substitutes the BiLSTM to model sentences' context with a Transformer network (Vaswani et al., 2017). Similarly to above, we predict

$$\hat{Y} = Softmax(W^T(Transformer(E))) \quad (4)$$

where $Transformer$ represents the stack of n transformer layers substituting $BiLSTM$ from above and, in this case, $W \in \mathbb{R}^{d\times 2}$ reflecting the specific transformer architecture.

In this case, we set the threshold th to 0.5, as searching the threshold as described above consistently led to worse results.

3.1.2 Sentence Encoders

We experiment with two different sentence encoders further fine-tuned for topic segmentation.

RoBERTa last-mean (RoB): the popular RoBERTa architecture (Liu et al., 2019) consists of a 12-layer transformer encoder that was pre-trained on the masked language task in a more robust way than the original BERT architecture (Devlin et al., 2019), leading to considerable improvements on several benchmarks. Here we use the pre-trained model[2] and we obtain a single representation for each input sentence by averaging the last layer, shown to be an effective pooling strategy for sentence-level tasks (Huang et al., 2021).

All-MiniLM-L12-v2 (miniLM): this model is a version of the portable MiniLM language model, a comparatively smaller transformer encoder that is trained to mimic the last self-attention module of its larger counter-part, a process known as knowledge distillation (Wang et al., 2020). The version we use was further fine-tuned with a contrastive objective using cosine similarity between pairs of sentences that should be closer in space; it was used by Lee et al. (2023) as the backbone of their model, and here we compare it against larger, more popular transformer LLMs such as RoBERTa. Again, the sentence representation is obtained by averaging the last layer.

Both the above encoders were further fine-tuned on the topic segmentation task with this loss:

$$\mathcal{L} = ||label_{(i;i+1)} - \frac{e_i \cdot e_{i+1}}{||e_i||_2 \cdot ||e_{i+1}||_2}||_2 \quad (5)$$

where e_i and e_{i+1} are the sentence embeddings for sentences i and $i+1$, extracted by the sentence encoders. The corresponding $label_{(i;i+1)} = 1$ if they belong to the same segment, otherwise $label_{(i;i+1)} = -1$.

3.2 Other Baselines

We also report results from other baseline models for which existing implementations were available, so that the evaluation setting could be verified for each baseline. In our baseline comparisons we include $Transformer^2_{BERT}$[3] (Lo et al., 2021), $PairSeg_{MTL}$[4] (Lee et al., 2023), TextSeg[5] (Koshorek et al., 2018), BiLSTM-BERT[6] (Xing and Carenini, 2021), SECTOR[7] (Arnold et al., 2019) and TopicTiling[8] (Riedl and Biemann, 2012).

We also include NoPred, a baseline consisting in always predicting the majority class (i.e. no topic boundary): this simple baseline, in fact, can highlight how different k can determine very different results when using P_k, even when the predictions are just a constant value.

Other models have been variously proposed during the years and especially the ones proposed by Lukasik et al. (2020a) and Barrow et al. (2020) have been often used for baseline comparisons. As an official implementation for the two models is missing, however, we leave them out of our analysis, for the moment, leaving their inclusion in the revised ranking for future research.

3.3 Evaluation Setting

In evaluation, we used the mentioned P_k metric.

Most literature already settled on the use of half the average segment lengths when choosing k. Something that is not often specified is whether the average segment length should be computed based on the entire corpus or on single documents (therefore possibly leading to a different k for each test

[8] github.com/riedlma/topictiling

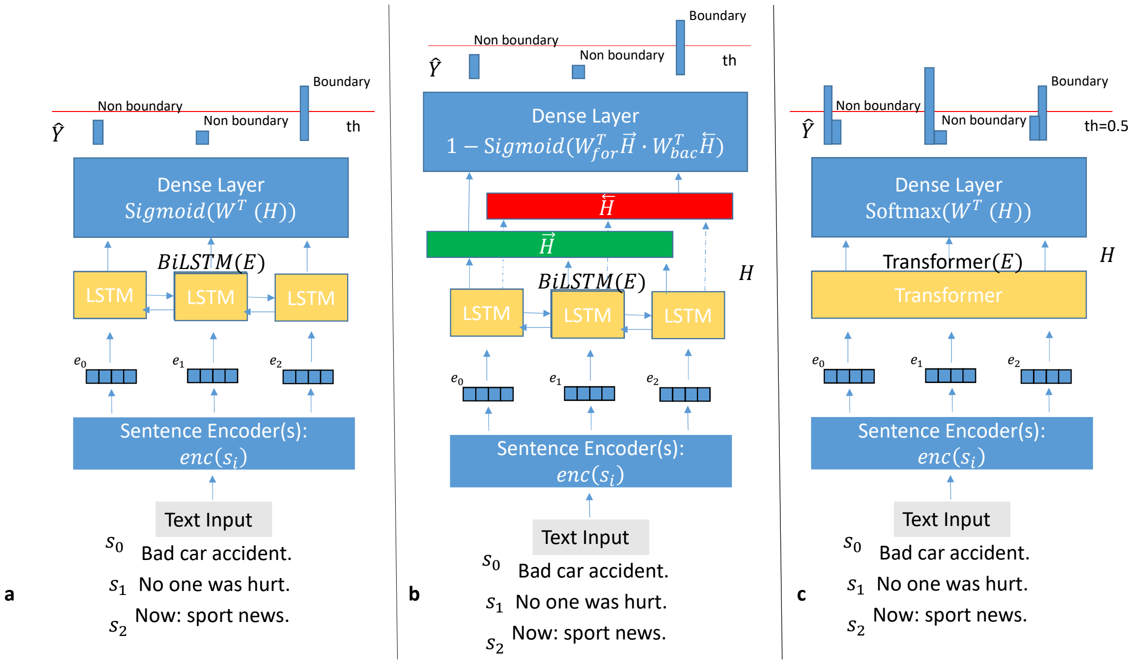

Figure 2: The three models we present: **a** BiLSTM; **b** Dot-BiLSTM; **c** Transformer.

document), but considering the existing implementations listed above it can be inferred that usually k is computed separately for each test document: this is also our default setting. Formally, given an input document doc having N segments, we compute:

$$k = \frac{\sum_{i=1}^{N} seglength_i}{2} \tag{6}$$

with $seglength_i$ being the length of the i_{th} segment in the document.

We also report results for different k to highlight how this can lead to divergent results.

3.4 Data

We use the Wikisection dataset proposed by Arnold et al. (2019). The dataset was obtained by scraping Wikipedia articles concerning specific macro-topics and using the existing headers to obtain ground truth labels for segmentation. The dataset is considerably smaller than the Wiki-757 dataset proposed by Koshorek et al. (2018) and it is therefore more popular in recent literature, as it allows for quicker experimentation. The dataset is divided in two languages, English and German, and two macro-topics for each language, cities and diseases. In our setting we follow recent literature and separate languages and macro-topics, therefore we obtain four separate datasets each having their predefined training, test and validation sets. Table 1 shows datasets statistics and general information.

Language	Macro-Topic	Abbrev.	Documents
English	Disease	en_disease	3900
English	City	en_city	19539
German	Disease	de_disease	2323
German	City	de_city	12537

Table 1: Wikisection datasets details: for more in-details information see the original paper (Arnold et al., 2019).

3.5 Experimental Setup

In our experiments we used the original parameters for all the baseline models, including the two state-of-the-art models described in section 3.1.

For BiLSTM and Dot-BiLSTM we followed the conventional setting of Koshorek et al. (2018) using 2 bidirectional LSTM layers, each direction having 128 hidden units. In training we minimised a binary cross entropy loss and we used a learning rate of 0.001 and Adam optimizer (Kingma and Ba, 2015). We applied dropout between input features and the first hidden layer, as well as between hidden layers, using for both probability values in the range

$\{0.2, 0.5\}$, where the optimal dropout probability was chosen based on validation results.

For our Transformer model, we followed the setting of Lo et al. (2021) using 5 transformer layers and a hidden dimension for the feedforward layer of 1024 hidden units. We have kept the dropout probability value to 0.2 as we observed no improvement in changing it and in training we minimised the cross entropy loss between the no-boundary and boundary class (where in our BiLSTM model we had a single output probability), using a learning rate of 0.0001 and Adam optimizer.

4 Results

4.1 Baseline Comparison with Standard P_k

Table 2 shows our results for the baselines and our models on the English Wikisection datasets.

A first look immediately shows that different k values affect not only absolute performance but the ranking of models; we discuss this in more detail in Section 4.2 below. However, even by looking just at the P_k^{def} columns (containing the results with the k we defined as standard), we can see that previous rankings do not hold in this consistent evaluation setting. Specifically, $Transformer^2_{BERT}$ does not seem to perform better than Bi-LSTM+BERT for en_city, and performs worse than all the other supervised baselines for en_disease; we discuss this in more detail later when analysing the influence of the Transformer architecture. The same holds for Pair_MTL, but in this case the model also underperforms with respect to SECTOR. Both these results contradict existing literature, suggesting that in fact the improvements that were noted in this case were due to a difference in evaluation setting, rather than in actual segmentation performance.[9]

Our BiLSTM-based models all perform better than most other baselines in both datasets, while our Transformer-based model shows extremely poor performance.

4.2 Sensitivity of P_k to k

The results using different k show conflicting results. By looking at the best performing models for P_k^{10}, it is evident that changing k does not influence the results in the same way for all models: if we set $k = 10$, $Transformer^2_{BERT}$ figures as the best model, while PairSeg_MTL under-performs; when changing to $k = 2$, the Transformer-based models

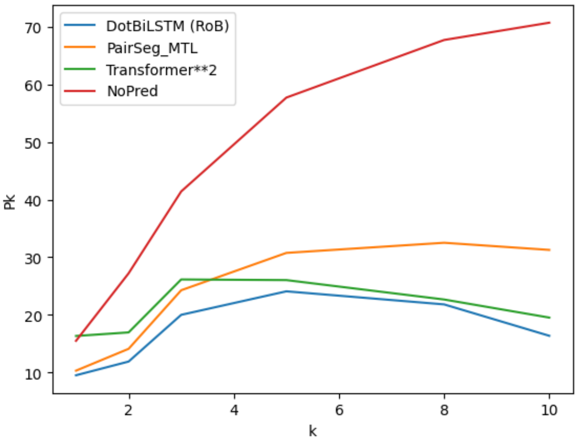

Figure 3: P_k results for different values of k and different models on en_disease test set.

are instead the worst performing ones. Even just never predicting a topic boundary produces very different P_k values according to which k we use, as shown in the first row of the table. The non-linear variation of results according to k is visually exemplified by figure 3.

4.3 Comparison of Different Architectures

Our results show that the Dot-BiLSTM architecture consistently outperforms other architectures; especially the Transformer-based model, which is consistently the worst.

The difference between Dot-BiLSTM and BiLSTM models is quite small, but this could be expected given the similarity of these two architectures. Still, Dot-BiLSTM always outperforms BiLSTM on both datasets, showing that the intuition of Sehikh et al. (2018) and of Arnold et al. (2019) was correct in the sense that forcing the model to directly modelling the similarity between adjacent units of text helps in the task of text segmentation. This was variously observed by including auxiliary losses during training (Xing and Carenini, 2021; Glavaš and Somasundaran, 2020), but here we observe how using this approach directly for segmentation works as well.

Given the consistent failure of the Transformer architecture, the relative success of $Transformer^2_{BERT}$ is more likely attributable to the use of pairwise embeddings from BERT, rather than some advantage of Transformer over BiLSTM on these datasets. If improvements using Transformer have previously been shown (Glavaš and Somasundaran, 2020; Lukasik et al., 2020a), such improvements were obtained on the much bigger

[9] By looking at the implementations listed above, Lo et al. (2021) set $k = 10$ and Lee et al. (2023) set $k = 2$.

	en_city			en_disease

Table 2: Results for all the presented models on en_city and en_disease datasets. For $Transformer^2_{BERT}$, $PairSeg_{M}TL$ and our models we present P_k results with the fixed k we established in section 3.3 (P_k^{def}), with $k = 10$ as used by Lo et al. (2021) (P_k^{10}) and with $k = 2$ as used by Lee et al. (2023)(P_k^2). In all cases, the lower the better. Best results for each dataset are highlighted in bold.

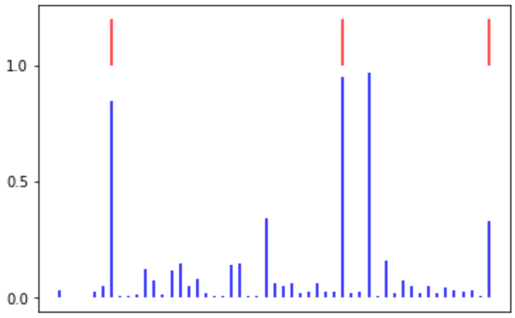

Figure 4: Probability of topic boundary output by Dot-$BiLSTM_{RoB}$ model for a test document. True boundaries are marked by the fixed-length vertical red lines at the top of the plot, while the output probabilities are represented by the variable-length blue lines.

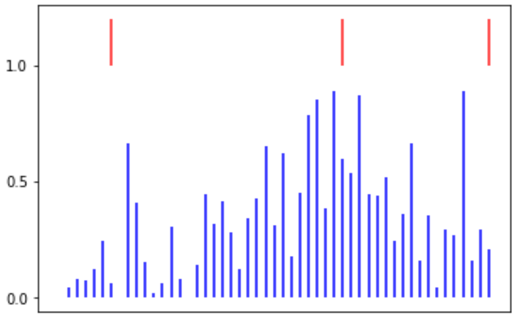

Figure 5: Probability of topic boundary output by $Transformer_{RoB}$ model for the same test document of figure 4. True boundaries are marked by the fixed-length vertical red lines at the top of the plot. The blue lines are the output probabilities.

Wiki-727 dataset. We hypothesise that the Wikisection datasets are too small to effectively train a Transformer model, especially considering that the setting by Lo et al. (2021) is considerably deeper and bigger than the BiLSTM setting.

However, preliminary experiments with reducing the size of the Transformer model did not show any improvement either, and there could be some additional explanation to this. The role of local context in text segmentation is well known and has been exploited by much previous literature (Xia et al., 2022; Hearst, 1997; Choi et al., 2001). In this context, the advantage of the Transformer architecture in capturing long-distance dependencies (Vaswani et al., 2017) may not add any useful information for the task at hand, but instead potentially add noise, making the learning more difficult especially on small datasets.

This intuition is also confirmed by a qualitative comparison of the output from the best performing architecture shown in figure 4 against the output from the Transformer model using the same encoder (figure 5). In the first case, in fact, probabilities appear to be quite low everywhere but for the places in which the model is confident in outputting a boundary (which is mostly correct). The Transformer model clearly outputs noisier probabilities, with clusters of high probabilities rather than isolated peaks. Following the above reasoning, we hypothesise that this is an effect of the global self attention module introducing noise in the form of similarities between far away sentences, which are irrelevant for the task.

We further tested this hypothesis by re-training our Transformer models for all our settings, but restricting the context window of the self-attention

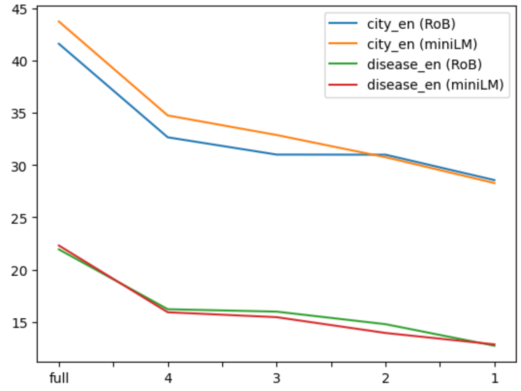

Figure 6: Effect of restricting the window of the self attention in our Transformer model. Y axis includes P_k values, while x axis includes the n parameter, representing the left and right context in the self attention module.

module to n sentences: at each time step, each sentence will have the information just from the n adjacent sentences. Figure 6 shows the results: for the Transformer architecture, restricting the available context always leads to better segmentation results, confirming our intuition. Still, the BiLSTM models outperform even the best performing Transformer setting, which might suggest that some characteristic of the BiLSTM architecture makes it more suitable for capturing the type of local context required for this task. Whether this is an effect of dataset size being too small for properly training a Transformer, or there is indeed some specific characteristic giving an edge to recurrent networks in this task, is an interesting question that we leave for future research.

4.4 Comparison of Different Encoders

Figure 7 shows the differences between encoders when using Dot-BiLSTM on the two English datasets. In the figure we also included the results for using the encoders without fine-tuning them, so as to isolate the effect of fine-tuning.

The differences between fine-tuned RoB and miniLM are small for en_city, while RoB performs more convincingly better on en_disease, even though the bigger difference could be an effect of bigger variation due to the dataset's smaller size.

In general, the choice of encoders does not seem to be extremely important when fine-tuning the encoders on the task. However, this changes when we do not fine-tune the encoders: in this case RoB outperforms miniLM by a larger margin on both datasets.

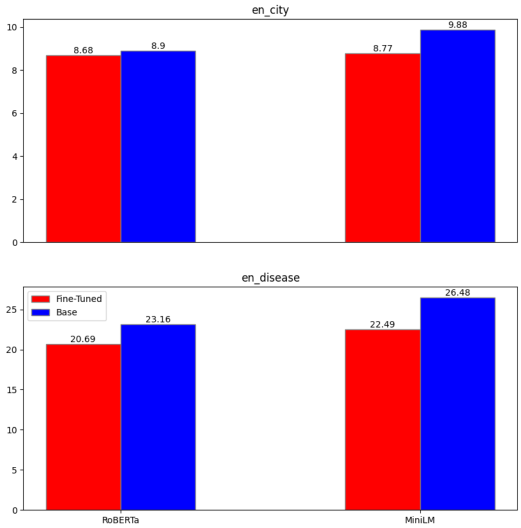

Figure 7: Comparison of results in terms of Pk_{def} for the DotBiLSTM model using RoB and miniLM encoders on en_city (top) and en_disease (bottom). We include results for both fine-tuned and base version of the encoders to evaluate the effect of fine-tuning.

The two versions of RoB (i.e. fine-tuned and base model) do not seem to present relevant differences for en_city, while fine-tuning seems to have a bigger effect on en_disease. When looking at miniLM, instead, the differences between fine-tuned and base models are much more noticeable for both datasets and this adds to the evidence from the comparison between RoB and miniLM in suggesting that RoB is probably a better encoder for text segmentation on these datasets.

Fine-tuning the encoders for text segmentation confirms itself as somewhat useful, but not at the level previously suggested by Lee et al. (2023).

4.5 Results on German Dataset

Model	de_city	de_disease
TopicTiling	41.3	45.4
TextSeg	27.5	35.7
SECTOR	16.2	27.5
Bi-LSTM+BERT	11.3	28
$Transformer^2_{DeBERT}$	13.30	27.89
PairSeg_MTL	41.08	33.40
$BiLSTM_{DeBERT}$	10.35	**22.61**
$Transformer_{DeBERT}$	26.11	37.46
Dot-$BiLSTM_{DeBERT}$	**10.27**	23.69

Table 3: Results using P_k^{def} for all the presented models on de_city and de_disease datasets. In all cases, the lower the better. Best results for each dataset are highlighted in bold.

Here we include the results obtained on de_city and de_disease. In carrying out these experiments we used the German version of BERT, DEBERT,[10] so as to match the setting in Lo et al. (2021). For our models, we previously fine-tuned the base model on each training set as previously described.

The results on the German subsets of Wikisection (table 3) mostly confirm the observations from their English counterparts. Particularly, we also see here that the BiLSTM models are better than the Transformer-based ones, including the reported state-of-the-art, $Transformer^2_{DeBERT}$.

It is interesting to notice how in this case the PairSeg_MTL model seems to fail completely. This might be caused by more specific characteristics of these datasets rather than the difference in language, but it is an effect that could be investigated further in future. Finally, the simple BiLSTM model in this case outperforms the Dot-BiLSTM for de_disease; the results from the two models are always very similar given the similarity in the architecture and it is likely that this difference is not significant.

5 Conclusion

In this work, we have given a systematic, fair comparison of three state-of-the-art models for linear text segmentation with two fine-tuned sentence encoders as feature extractors for the task, so as to highlight what techniques proposed by recent literature work in a fair setting.

Consistent with existing literature, we have shown that the popular P_k metric is not very stable. Specifically, the influence of different k used in the metric is noticeable; with the result that if models are compared under different evaluation settings, the conclusions that could be drawn are very different and potentially misleading.

By keeping the evaluation setting fixed, however, we show that BiLSTM-based models actually outperform Transformers, at least on the current datasets, and that fine-tuning the sentence encoders does bring improvements but not necessarily as big as previously suggested. Restricting the context available to Transformer models leads to performance gains, as previously noticed by Lukasik et al. (2020a) and Lee et al. (2023); but Bi-LSTM-based systems always outperform even the best performing Transformer models, perhaps suggesting that some architectural element of LSTMs makes them more apt for the task at hand. This is indeed interesting evidence, which we aim to develop further in future work.

Student's *t*-Distribution: On Measuring the Inter-Rater Reliability When the Observations are Scarce

Abstract

In natural language processing (NLP) we always rely on human judgement as the golden quality evaluation method. However, there has been an ongoing debate on how to better evaluate inter-rater reliability (IRR) levels for certain evaluation tasks, such as translation quality evaluation (TQE), especially when the data samples (observations) are very scarce. In reality, practitioners need to be able to assess the reliability of human MT quality evaluation based on one, two, or maximum three human linguists' judgements. In this work, we first introduce the little-known method to estimate the confidence interval for the measurement value when only one data (evaluation) point is available. This leads to our example with two human-generated observational scores, for which we describe "Student's *t*-Distribution", and explain how to use it to measure the IRR score using only these two data points, and calculate the confidence interval (CI) of the quality evaluation. We give a quantitative analysis of how the evaluation confidence can be greatly improved by introducing more observations, even if only one extra observation. We encourage practitioners and researchers to report their IRR scores and confidence intervals in all evaluations, e.g. using Student's *t*-Distribution method whenever possible; thus making the NLP evaluation more meaningful, transparent, and trustworthy.

1 Introduction

Human evaluations have been always the gold standard to judge the quality of natural language processing (NLP) system's outputs (Han et al., 2021; Freitag et al., 2021; Gladkoff and Han, 2022). This applies to many sub-tasks including machine translation (MT) (Han et al., 2020; Han, 2022a; Charalampidou and Gladkoff, 2022; MILAD, 2022), text summarisation (Bhandari et al., 2020; Latif et al., 2009), question answering (Alrdahi et al., 2020), information extraction (Wu et al., 2022; Nenadic et al., 2004), and prediction (Yang et al., 2009), as well as domain applications such as social media, biomedical and clinical domains knowledge representation (Milošević et al., 2019; Yang et al., 2021; Krauthammer and Nenadic, 2004). Nonetheless, human evaluations have been subject to criticisms and debates about their reliability, particularly when conducted without strictly defined procedures. (Han, 2022b; Han and Gladkoff, 2022; Graham et al., 2017). Despite the inclusion of factors such as quality controls and clear guidelines, human evaluation results can vary greatly among different individuals due to subjective judgements influenced by factors such as backgrounds, personalities, cultures, and so on.

Naturally, the confidence levels of human evaluation become the key point to the validity of such work. There have been some efforts made on how to measure the confidence level of human evaluations from a statistical point of view, such as very recent work using Monte Carlo Sampling Simulations by Gladkoff et al. (2022). However, this kind of statistical measurement still needs a good amount of data points, or *observations*, to be based upon. When there are a limited amount of observations obtained from the experiments, *how to measure the confidence level properly* is still a challenging question. One of the solutions to address this is to calculate the inter-rater agreement level and inter-rater reliability (IRR) scores. There are some historical IRR measurement metrics including Cohen's Kappa (Cohen, 1960) and Krippendorff's Alpha (Krippendorff, 1987, 2011). How-

Proceedings of Recent Advances in Natural Language Processing, pages 419–428
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_047

ever, as the last issue with statistical sampling, both Cohen's Kappa and Krippendorff's Alpha need a certain amount of samples data for probability calculation, which becomes troublesome when the observations are really *scarce*, e.g. only one, two, or a few data points. In addition, there are existing criticisms regarding the undesired prediction of Cohen's Kappa, e.g. Delgado and Tibau (2019) gave examples about how Kappa produced better scores for worse classifiers.

In this study, we examine scenarios in which observations from human evaluations are extremely scarce (e.g., limited to one or two values) and explore potential solutions. This endeavor is motivated by the realities of the translation and localization industry. Practitioners often need to determine the reliability of human machine translation (MT) quality evaluations based on the judgments of a single linguist, or at most, two to three linguist evaluations.

We start from one observation and introduce a confidence estimation method borrowed from Abbott and Rosenblatt (1962); Furnival et al. (1989) which was applied to forest study by Valentine et al. (1991). Then we discuss how this one observation-based confidence estimation is problematic and not much reliable. Following this, we bring an example of MT evaluation where two observations are obtained from the human assessment. In this case study, we introduce how to apply **Student's *t*-Distribution** to measure IRR with detailed formula interpretation and guidance. We also further give instructions on how to measure confidence intervals (CIs) using this method. We discuss the much improvement achieved by using two observational data points and Student's *t*-Distribution regarding narrowed-down CIs. Finally, we suggest that researchers also apply Student's *t*-Distribution to other NLP tasks and even beyond, i.e. outside of NLP tasks.

The rest of the paper is organised as below: Section 2 surveys the related work to ours on measuring IRR and confidence intervals from different fields, Section 3 presents a case study with a single observation, Section 4 follows up with two and more observations where we introduce Student's *t*-Distribution, and Section 5 concludes the paper with discussion and future work.

2 Related Work

Regarding agreement measurement, Cohen's Kappa metric was defined by Cohen (1960) as below:

$$\mathrm{K} = \frac{p_o - p_e}{1 - p_e} \tag{1}$$

where p_o is used to represent the ratio (proportion of units) when the raters agree with each other, while p_e is the agreement expected by chance. In the expression of frequencies, the Kappa value can be calculated by:

$$\mathrm{K} = \frac{f_o - f_e}{N - f_e} \tag{2}$$

In other words, the Kappa value reflects the agreement level (or proportion of agreement) after deducting the chance agreement. In the perfect situation, when the raters all agree with each other, i.e. the p_o value equals 1, the Kappa value will be 1 (Cantor, 1996). However, if the raters totally disagree with each other, i.e. the value of p_o is almost the same value of agreement by chance p_e, the Kappa value will be close or equal to 0. However, Kappa's value can be a negative number, when the agreement exhibition level is even smaller than by chance, e.g. using the above equations when the value of $p_o - p_e$ or $f_o - f_e$ is negative. As mentioned in the earlier section, the Kappa value requires a certain number of observations to properly estimate the metric scores.

Looking into the IRR measurement in crowdsourcing human evaluation domain, Wong et al. (2021) argued that the traditional Krippendorff's alpha or Cohen's kappa threshold values, e.g. above 0.6, are not ideal due to the ignorance of cultural and individual differences from crowdsource workers. They proposed a cross-replication reliability method based on Cohen's kappa and tested the methods on human judgements of facial expressions using a large amount of 4 million data points.

From NLP and MT field, Alekseeva et al. (2021); Gladkoff et al. (2022) applied Monte Carlo Simulation Analysis method to generate more samples for statistically estimating the confidence intervals of judgements when the samples presented for the human evaluation are small. Their experimental outputs demonstrate that not less than 100, and ideally 200 segments are necessary for the test set to produce an unbiased, statistically significant quality evaluation of the MT system output.

Outside of NLP fields, there are also some efforts made to address similar issues in measuring reliability and confidence intervals. For instance, Hallgren (2012) gave a tutorial on measuring IRR for the psychology domain when multiple coders are involved using case studies using commonly used Cohen's kappa and intra-class correlation (ICC). Similarly in the educational and psychological domain, Walker and Göçer Şahin (2020) carried out a study on applying differential item functioning (DIF) analysis to measure IRR, in comparison to the inter-class correlation coefficient and Cohen's kappa statistics.

From animal behaviour studies, Harvey (2021) raised the issues on inter-rater and intra-rater reliability and made a discussion on Cohen's Kappa and Krippendorff's Alpha values. From the sociological domain, Belur et al. (2021) reported a systematic survey on reporting IRR values from crime studies on multiple coders. They made further discussion on how human factors affect decision-making and how important it is to report accuracy, precision and reliability from screening/coding.

There is some existing business software integrating IRR into their statistical tools such as SPSS that has been used in different sectors including medical training assessment (Beck et al., 2016). The IBM SPSS uses interclass correlation coefficient (ICC) to measure the IRR values among different groups of raters [1].

However, to the best of our knowledge, there is no existing work on applying Student's *t*-Distribution for measuring IRR in NLP applications, especially in translation quality evaluation (TQE) field.

3 On Single Judgement

When observational data is very scarce, more than half a century ago, Abbott and Rosenblatt (1962) proved the possibility of measuring confidence intervals on *a single data point* from a mathematical point of view, and the later work from Furnival et al. (1989) further elaborated Abbott and Rosenblatt's formula with a more narrowed interval generation. We name it the **ARF** Interval by taking the initial letters of their names. [2]

This method may appear statistically counterintuitive, but it is certainly worth mentioning here, particularly as production decisions are frequently based on a single quality measurement. An intriguing paradox arises: while many statisticians would argue it's impossible to determine a confidence interval from one measurement, project managers often rely on a single TQE (Translation Quality Evaluation) value to make their decisions. In actuality, conclusions about the reliability of a single measurement can be made, but they require supplemental information, e.g., for translation industy, known vendor's past performance. Within the ARF interval calculation method, this additional data is also derived from an experimentally-based prior knowledge or theoretically-based value that, while external to the measurement, arises from the project context. Interestingly, project managers who use a single measurement's value to make their decisions apply a similar intuition. Consequently, it's fascinating to explore what mathematical principles can elucidate within this context.

The width of the confidence intervals reflects the uncertainty of the experiments, i.e., the wider it is, the less knowledge is available about the setup.

A relatively narrowed confidence interval indicates the controlled situations, for instance, the normal distribution in the following formula of standardised transformation:

$$\mathrm{z} = \frac{y-\mu}{\sigma} \tag{3}$$

of which, y, μ, and σ are the variables of the *variate*, *mean value*, and *standard deviation*. The parameter z represents the *standardised variate*.

For the situation with one observation, let $\hat{\mu}$ be the independent and fixed value that is known before and outside of the measurement, and y be the experimental measurement value. Furnival et al. (1989) gives the following calculation intervals:

$$ARF = \frac{y+\hat{\mu}}{2} \pm k|y-\hat{\mu}| \tag{4}$$

[1] https://www.ibm.com/uk-en/spss

[2] In another study by Rodriguez (1996) on confidence intervals (CIs) from one single observation, Herbert Robbins non-parametric CI was obtained and another technique was introduced for obtaining CI for the "scale parameter of finite length in the logarithmic metric".

This ARF interval contains the probability of μ that is larger than or equal to $1-\alpha$, and α meets the following equation with k:

$$k = \frac{1-\alpha+\sqrt{1-2\alpha}}{2\alpha}\ ,\ 0 < \alpha \leq 0.5 \tag{5}$$

The pair value of (k, α) was given by Furnival et al. (1989) as in Table 1.

3.1 Case Study using ARF Intervals

Let's have a case study on using ARF intervals for MT evaluation. Assuming that a translation vendor has been evaluated earlier on certain lines of projects and the average result was a score of 96.3 ($\hat{\mu}$). The next translation quality measurement produced by another vendor is a lower rating of 85.2 (y). How reliable is this measurement by itself purely from the statistical point of view? and what does it tell us? If we assume the quality measurements are distributed normally, it is logical to take the average value of the prior history evaluations as the predicted value for future outcomes. Below we give two practices using ARF intervals.

1) If we construct a 75% confidence interval for the true quality rating, we need to use k=1.8 from the instruction by Table 1, and the corresponding α value is 0.25. Using the ARF interval formula, it gives:

$$ARF = \frac{96.3+85.2}{2} \pm 1.8 \times |96.3-85.2| \tag{6}$$

which is 90.75±19.98. Therefore, the ARF interval for the true value of quality rating is [70.77, 100]. As we can see from this example, the 75% confidence interval is almost half of the measured value itself, i.e. the maximum deviation of 19.98 is 22% of the measurement result (90.75). Although the mathematical precision of the single quality measurement is limited to this level, it can be beneficial to define these limits.

2) Similarly, for an 80% CI ($\alpha = 0.2$) for the true quality rating, the corresponding k value from the Table 1 is 2.31 and the above formula gives the following ARF value:

$$ARF = \frac{96.3+85.2}{2} \pm 2.31 \times |96.3-85.2| \tag{7}$$

which is 90.75±25.64. In other words, the interval for the true value of quality rating is [65.1, 100]. From this, we can see that with 80% CI, the maximum deviation of 25.64 is 25% of the measurement result (90.75).

From these two case studies, what is probably more interesting in the context of translation quality evaluation is that "the middle of the CI lies halfway between an earlier average result and the recent lower measurement". We can spell a good rule of thumb: *if the single measurement deviates from the average, the true value is likely halfway between the average and the new measurement.* Knowledge of this would help not to overreact to unusually low single scores newly generated.

Even though it is possible to measure the confidence levels, this ARF interval is very wide and the worse thing is that it can not be improved by the choice of α. As shown in Table 1, 0.5 is the narrowest option of choice for intervals. However, this value is considered not high enough to make a significant impact. To the right side of the table, the smaller value the α is, the wider the resulting intervals will be. Therefore, choosing α value between (0.2, 0.25) is probably the compromise to make when there is only one observation or judgement available. From this case study, our finding is that evaluations consisting of only a single measurement are not recommended as there will be a higher chance of bias as illustrated by our translation evaluation example. Such measurements have only rough and indicative values, so the data collection and analysis approaches must be invoked to improve the quality of measurement itself with the data science apparatus. This will lead to our next section when we recommend that a second quality measurement is very necessary, how to measure it in the new situation, and how much difference it will make.

4 On Observations of More Than One

Following the last section, we **call on more measurement points** for NLP evaluation tasks, especially in the language service provider sector where the single observation value is still very common in practice due to the cost concern. [3]

For instance, when a single translation quality measurement is not satisfactory for one of the parties, second quality measurement can be made to validate the first measurement. Then, how much improvement to the confidence interval can be ob-

[3] e.g. referring to the R&D report from Language Service Provider https://logrusglobal.com/

	value (α)						
Distribution	0.50	1/3	0.25	0.2	0.1	0.05	0.01
Normal (k)	0.05	1.26	1.8	2.31	4.79	9.66	48.39
Unknown (k)	0.5	1.87	2.91	3.94	8.97	18.99	99

Table 1: The Value Matching of (k, α) for both Normal Distribution and Unknown Ones by Furnival et al. (1989).

tained by introducing extra observational data? To answer this, the obvious problem, of course, is that at least 20-30 data points are required to calculate the mathematical variance for a normal distribution. In settings where the sample size is less than 30, and the standard deviation of the entire population is unknown, *Student's t-Distribution* can be used to evaluate standard deviation based only on the number of measurements between one and 30, e.g. 2, 3, etc.

4.1 On Student's *t*-Distribution

When the sample size (*aka* observations) is very small in comparison to the entire population, Student (1908) designed Student's t-distribution to measure the mean errors and the confidence intervals of estimation.

When there is one degree of freedom, the critical values for Student's t-Distribution are shown in Figure 1 including the confidence level, one tail, and two tail scores. [4] The full list of critical values with more degrees of freedom is shown in Figure 2.[5] There are many researchers who proposed different algorithms to calculate these critical values by hand and using computers, for instance, the work from Cheng and Fu (1983) and comparison studies by Blair and Higgins (1980).

The notation of Student's t-Distribution is defined as below if we use T as the random variable:

- $T \sim t_{df}$ where $df = n - 1$

where df is the degree of freedom and n is the number of observations. For instance, if we have a sample size $n = 2$, we calculate the $df = 2 - 1 = 1$ and write the distribution as $T \sim t_1$.

For the situation when the standard deviation is unknown, the error bound for the sample mean is defined as:

$$E = (t_{\alpha/2})(\frac{s}{\sqrt{n}}) \tag{8}$$

where $t_{\alpha/2}$ is the critical value of t-score with the area to the right equal to $\alpha/2$ (Figure 2), s is the standard deviation of observations (samples):

$$s = \sqrt{\frac{\sum(x_i - \overline{\mathrm{x}})^2}{n-1}} \tag{9}$$

where $\overline{\mathrm{x}}$ is the mean value of n samples:

$$\overline{\mathrm{x}} = (1/n)\sum x_i \tag{10}$$

The resulting confidence interval (CI) is then the following span:

$$CI = (\overline{\mathrm{x}} - E, \overline{\mathrm{x}} + E) \tag{11}$$

4.2 Deploying *t*-Distribution to IRR

Looking back to our MT evaluation experiments, from a practical industry project on language service, we have an example to demonstrate how to deploy Student's t-Distribution to measure IRR value. Assume we have used the Multidimensional Quality Metric (MQM) initialised by Lommel et al. (2014) [6] and professional translators for a translation evaluation project and got two numbers of overall quality scores: QS1=76.85 and QS2=81.99 on a scale from 0 to 100.[7] We can immediately see that the QS2 81.99 is 6.7% greater than the QS1 76.85, and oppositely QS1 76.85 is 6.3% less than QS2 81.99. Therefore QS2 agrees with 93.3% of QS1, and QS1 agrees with 93.7% of QS2. This is almost 95% agreement, so it looks good for most cases. However, if the PASS/FAIL threshold is 80, the difference may be crucial for

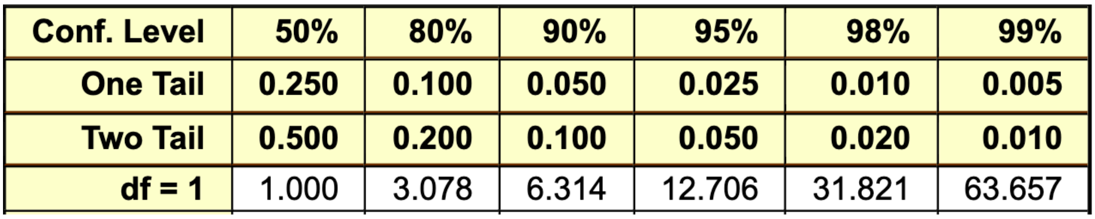
[5] https://www.stat.purdue.edu/~lfindsen/stat503/t-Dist.pdf

[6] open source project https://themqm.org/

[7] This is a real example from an industrial project on TQE called "Whale".



Conf. Level	50%	80%	90%	95%	98%	99%
One Tail	0.250	0.100	0.050	0.025	0.010	0.005
Two Tail	0.500	0.200	0.100	0.050	0.020	0.010
df = 1	1.000	3.078	6.314	12.706	31.821	63.657

Figure 1: Critical Values for Student's *t*-Distribution with One Degree of Freedom (from people.richland.edu)

the translator. Then, *what is the reliability of this evaluation result*?

The Sample Mean $\overline{\mathrm{x}}$ of QS1 and QS2 is $(QS1 + QS2)/2 = 79.42$ for this sample of two measurements. The Sample Standard Deviation s for this sample of two values is $\sqrt{(QS1 - \overline{\mathrm{x}})^2 + (QS2 - \overline{\mathrm{x}})^2} = \sqrt{6.6049 \times 2}$ which is 3.6345.

The Confidence Interval depends on the desired Confidence Level, which, in turn, depends on the subject matter area of the content which was translated. For most fields, the confidence level should be at least 80%. The critical number $t_{\alpha/2}$ for that level (0.1 which is 20% divided by 2 for one tail of the graph, $\alpha = 0.2$) and two measurements (one degree of freedom, *df*=1) is 3.078, as shown in Figure 1 and 2.

Therefore, the margin of error for these measurements is:

$$E = \frac{3.078 \times 3.6345}{\sqrt{2}} = 7.91 \qquad (12)$$

This means that the confidence interval for these two measurements is 7.91×2=15.8, which indicates that with an 80% degree of confidence, the true quality score lies on this interval: [79.42 – 7.91, 79.42 + 7.91], or [71.51, 87.33].

As we can see from this result, given the second measurement, we can significantly improve the confidence interval as compared to the single measurement. The two different judgements (observations) that we obtained reduce variance from 25% of a single judgement (Section 3) to 9.96% (7.91/79.42), i.e. more than two times narrower with an 80% confidence setting.

However, as in the previous example, this confidence interval is still relatively large. Can we tell anything about the translator passing or failing the 89% PASS/FAIL threshold? The answer is that since the sample mean is below 80% and equals 79.42, the evaluation result is borderline FAIL.

Ideally, we need a third measurement or even more observations to further improve this interval, but in a production setting, the additional data points are rarely obtained by repeated evaluations, due to the cost and time constraints required for such a process.

The good news is that we already have reliable information for translation quality evaluation (TQE) purposes: this is a borderline FAIL, becasue the Sample Mean is lower than the threshold, and therefore more than half of possible values are below the PASS threshold. This is not bad for the measurement of such a subtle, almost intangible object as the human perception of quality. But you can only obtain a history of performance based on multiple evaluations for different content pieces and apply data science approaches.

5 Conclusion and Future Work

When it comes to evaluating translation quality, the ability to measure alone is not sufficient; we also need to know how reliable the measurement is. Automatic evaluation of quality quickly produces the same scores if repeated a number of times, which creates an illusion of precision. Unfortunately, the results of automatic quality measurement not only depend on the language pair, the Machine Learning system, the decoder, and the content type, but also vary from dataset to dataset, depending on the way the data have been cleaned and formatted. Given these factors, automatic measurement can be very fast and "reliable", but it may be (and often is) invalid, as well as inconsistent. Human translation quality evaluation (TQE) is currently the only way to obtain valid measurements of human perception of quality, and considered to be the golden standard of TQE. However, human measurement's inter-rater reliability (IRR) should be assessed, even if evaluation has been carried out correctly. Even if evaluators are experienced linguists, trained to do evaluation according to proper system, and client specifications are clearly defined, the evaluators would still produce close but not the same evaluation results due to the very nature of human perception of quality, which is by definition the function of personal perception. This problem is exacerbated by the fact that in real life production setting there is no time or budget to validate the translation quality measurement even with the second reviewer, and even if there is a second reviewer, the low IRR of such measurement makes it difficult to confirm the first measurement.

In this paper, we first studied the typical production setting of gold standard human quality measurement, where TQE is performed by only one experienced, trained linguist, according to clearly defined customer specifications, producing a single measurement, and make conclusions about the reliability of such measurement. We then illustrated the results with the case of *Student's t-Distribution analysis of two measurements* made by two different reviewers.

From the first and second experiments, we can conclude that a single measurement has very low reliability and only has an indicative value. The confidence interval for one measurement is (as shown in Section 3) as wide as 25%, and therefore one evaluation cannot be taken as a basis for process decisions, more measurements are required. For instance, the second measurement can narrow down this interval and render it two times smaller, to around 10% (Section 4).

Yet we can say that the middle of the confidence interval lies halfway between the earlier average result and the lower recent measurement. *A good rule of thumb is born:* **if the single measurement deviates from the average, the true value sits, in all probability, halfway between the average and the new measurement**. Consequently, the recommendation is: please do not over-react on an unusually low new single score, take a middle ground between the older average and the new score, and think about it as the most probable result.

The second measurement may improve the confidence interval significantly but is rarely done unless during the arbitration. Therefore, it is more practical to obtain additional data points from other evaluations of different samples, in the course of the translation process.

Subsequent evaluations effectively are placed into two categories: (a) mostly PASS with only rare occasional FAIL, (b) all other cases (mostly FAIL, or many FAILs). This strategy is caused by the desire to ensure that a system is reliably well above the PASS/FAIL threshold and thus ensures quality results. Multiple evaluations also confirm the validity of quality measurements and allow the application of well-known maths of statistics of normal distribution.

However, it is worth noting that proper methods of data analysis are required to analyse *quality evaluation data-sets*, such as:

- Removal of outliers, which are caused by irrelevant causes.
- Evaluations made on very small or very large samples.
- Evaluations that are incorrect due to the improper application of metrics such as counting repeated errors, for example.
- Evaluations made by reviewers who were not trained, subjective, or had in mind different customer requirements.

It should be remembered, that data science only allows obtaining good results if you clean the data properly. Incorrect, biased, not properly calibrated, or imprecise conclusions and inferences may result from using uncleaned data.

Limitations

In this work, we discussed how to calculate confidence intervals and evaluation reliability when there are only one or two assessment scores from annotators, such as translation quality assessors. For the first case when there is only one new observation score, we assume there is a pre-estimated/expected score ready to use, i.e. for ARF interval. However, this might not be the case in some situations, or it might cost some time and money to get this value, for instance, for a newly established task without much prior knowledge. In the second case considered, we introduced Student's *t*-distribution method and gave two human judgement scores for estimation. This is expected to be helpful for the small number of observations; however, it does require some mathematical calculations using guided formulas and parameter tables, which might be not instantly convenient to translators or project managers who do not have much statistical knowledge, and requires manual calculations from educated AI researchers anyway. For real world applications preliminary setup and additional clear and crisp guidance for practitioners may be required.

Ethical Statement

There are no ethical concerns in this work since it is only about introducing alternative methodologies for calculating the confidence and reliability of human evaluations.

Acknowledgements

We thank the Whale project for sharing their real TQE examples with us to deploy the discussed methods. We thank Dr. Leonore Findsen at Purdue University Statistics Department and Prof. James Jones of Mathematics at Richland Community College for their open-source lecture notes. We are grateful to the anonymous reviewers for their valuable comments on our work. This work has been partially supported by grant EP/V047949/1 "Integrating hospital outpatient letters into the healthcare data space" (funder: UKRI/EPSRC).

Data Augmentation for Fake News Detection by Combining Seq2seq and NLI

Anna Glazkova
University of Tyumen
Tyumen, Russia
a.v.glazkova@utmn.ru

Abstract

State-of-the-art data augmentation methods help improve the generalization of deep learning models. However, these methods often generate examples that contradict the preserving class labels. This is crucial for some natural language processing tasks, such as fake news detection. In this work, we combine sequence-to-sequence and natural language inference models for data augmentation in the fake news detection domain using short news texts, such as tweets and news titles. This approach allows us to generate new training examples that do not contradict facts from the original texts. We use non-entailment probability for the original and generated texts as a loss function for a transformer-based sequence-to-sequence model. The proposed approach has demonstrated the effectiveness on three classification benchmarks in fake news detection in terms of the F1-score macro and ROC AUC. Moreover, we showed that our approach retains the class label of the original text more accurately than other transformer-based methods.

1 Introduction

The modern world provides great opportunities for news spreading. News travels fast, and it is difficult to expeditiously confirm or deny its credibility. In this regard, there is evidence that the tools for detecting fake news play a crucial role in the regulation of information flows.

Although machine learning models are widely used in fighting fake news, their performance depends on the size and quality of training data. Collection and annotation of text corpora require significant time costs. As an interim solution, augmented data obtained from a small number of annotated texts can be used while training.

Data augmentation (DA) is the artificial creation of training data for machine learning by transformations (Bayer et al., 2022). Even though the current state-of-the-art DA methods show impressive results, they are still ill-suited for some natural language processing tasks, such as fake news detection. The bottleneck is non-conditional DA that contradicts the preserving class labels. Thus, the generated news seems to be untruthful. Neither rule-based nor model-based approaches guarantee the factual consistency of the original and generated text. This can be a challenge for practical applications because the system will input fakes as examples of real news, and vice versa.

In this paper, we propose a DA approach that enables the generation of training examples flowing logically from the original texts. To that end, we combine pre-trained sequence-to-sequence (seq2seq) models showing SoTA results in DA, with natural language inference (NLI) models estimating textual entailment information. The task of NLI is to predict an entailment relation label (output) given a premise-hypothesis pair (input) (Poliak et al., 2018).

The contribution of this paper is two-fold: a) we built a model to augment data in the field of fake news detection by combining seq2seq and NLI. The model allows us to generate coherent outputs for original data; b) we evaluated and compared several approaches to DA on three datasets for fake news detection.

The paper is organized as follows. Section 2 contains a brief review of related work. Section 3 describes the proposed approach. In Section 4, we provide the details of the experimental setup. We report the results in Section 5. Section 6 concludes this paper.

2 Related Work

2.1 Fake News Detection

In recent years, the task of detecting fake news and rumours is extremely relevant. False infor-

Proceedings of Recent Advances in Natural Language Processing, pages 429–439

mation spreading involves various research tasks, including fact-checking (Atanasova et al., 2019), rumor detection (Chernyaev et al., 2020), topic credibility (Kim et al., 2019), fake news spreaders profiling (Rangel et al., 2020), and manipulation techniques detection (Da San Martino et al., 2020). An overview of fake news detection approaches and challenges has been discussed in Oshikawa et al. (2020). Surveys such as those provided in Parikh and Atrey (2018); Zhou et al. (2019) have shown that the concept of fake news combines differential content types of a news story. Previous research has also established that dynamic knowledge bases reflecting the changes occurring in a fast-paced world would be a universal solution for fake news detection tasks (Meel and Vishwakarma, 2020; Sharma et al., 2019). However, current studies focus on linguistic features determining the truthfulness of the text due to the greater availability and realizability of this approach.

There are different types of labelling or scoring strategies for detecting fake news. In most studies, fake news detection is formulated as a classification or regression problem and classification represents the most common way. Sometimes it is difficult to categorize all the news into two classes (fake or real) and scholars use fine-grained categorization including partially real and partially fake classes or other degrees. In this case, the problem can be formulated as a multi-label classification task (Rasool et al., 2019; de Morais et al., 2019). Baly et al. (2018) addressed the problem of fake news detection as a regression task. Therefore, the output of the classifier is a measure of the trustworthiness of news. Some authors have used the regression approach to obtain ground truth scores for texts (Baly et al., 2019; Esteves et al., 2018).

A lot of fake news detection methods are based on linguistic feature extraction, including grammar (Choudhary and Arora, 2021), punctuation (Shrestha et al., 2020), readability (Santos et al., 2020), term frequency (Jiang et al., 2021), and topic modelling features (Xu et al., 2019). The majority of existing research uses supervised methods. Various machine learning approaches in this field range from traditional methods to SoTA transformers. To date, transformer-based approaches show the highest results for fake news detection in various domains (Vijjali et al., 2020; Glazkova et al., 2021; Song et al., 2021). However, a number of studies have focused on unsupervised (Hosseinimotlagh and Papalexakis, 2018; Gangireddy et al., 2020) or semi-supervised approaches (Dong et al., 2019; Benamira et al., 2019).

2.2 Data Augmentation

Data augmentation is a widely used technique to increase the size of training data without directly collecting more data (Feng et al., 2021). Shorten et al. (2021) presented a review of text DA methods for deep learning. The authors grouped all DA methods into two classes: symbolic augmentation, such as rule-based and feature-based approaches, and neural augmentation, including generative approaches.

In natural language processing research, various studies have focused on token replacement methods for DA. For example, Wei and Zou (2019) proposed Easy Data Augmentation (EDA) performing a set of token-level operations including random insertion, deletion, and swap. Min et al. (2020) explored several methods to augment training sets using syntactic transformations including inversion, passivisation, and random shuffling.

Language models and seq2seq models are also widely used in DA. One of the most common methods is back translation (Sennrich et al., 2016). In this case, a pre-trained target-to-source translation model is used to generate source text from unpaired target text (Hayashi et al., 2018). Since transformer-based models show SoTA results in many natural language processing tasks, researchers attempted to adapt this methodology to DA. Thus, Wu et al. (2019) proposed a conditional BERT (CBERT) model extending BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2019) masked language modelling tasks by using class labels for predicting masked tokens. Anaby-Tavor et al. (2020) used a label-conditioned generator by fine-tuning GPT-2 (Radford et al., 2019) utilized this to generate new data. Kumar et al. (2020) compared several types of transformer-based pre-trained models, such as auto-encoder, auto-regressive, and seq2seq models for DA. The best result on three classification benchmarks was obtained using the BART model (Lewis et al., 2020). BART uses a standard seq2seq architecture with a bidirectional encoder (like BERT) and a left-to-right decoder (like GPT).

In recent years, there has been an increasing amount of studies on DA for the task of detecting fake news. Some studies suggested word replacement approaches to generate training examples (Suyanto et al., 2020; Ashraf et al., 2021). Amjad et al. (2020); Saghayan et al. (2021) used back translation to generate new data translating texts into English and back into the target language for fake news detection. Jindal et al. (2020) proposed an approach to generate a new text combining two fake news articles having a large intersection of their bag-of-words representations. Saikh et al. (2019) proposed an ML-based system where different text entailment features were employed. Moreover, Janicka et al. (2019); Glazkova et al. (2021) experimentally demonstrated that the models for fake news detection frequently do not benefit from using cross-domain additional datasets. This leads to the conclusion that DA may be the only source of additional texts in data-poor settings.

Some authors address the problem of coherent generated texts in DA. Martinc et al. (2022) utilized the NLI model to estimate the probability of the entailment between a true and a generated text as a measure of generation quality. In Rajagopal et al. (2022), a DA approach to generating coherent and factually inconsistent sentences based on WordNet was proposed. Li et al. (2018) jointly trained their model's encoder on summarization and NLI tasks to make the generated text more likely to be entailed by the source input. As far as is known to the author of this paper, there are no studies that directly use NLI in the process of DA. This study aims to overcome this gap.

3 Method

3.1 Problem of Coherent Outputs

In many cases, the current DA methods improve the performance of ML models. However, in the case of fake news detection, DA methods are required to produce new texts in line with the meaning of the original texts. It is a challenging task even for SoTA DA methods because abstractive models often make mistakes in facts (Kryscinski et al., 2020; Matsumaru et al., 2020).

For example, the BART-based model for DA (Kumar et al., 2020) produced the following outputs:

- **Original text**: Chinese converting to Islam after realising that no Muslim was affected by #coronavirus #covid19 in the country.
  Generated text: Chinese converting to Buddhism after realising there are no people affected by #coronavirus #covid19 in the country.

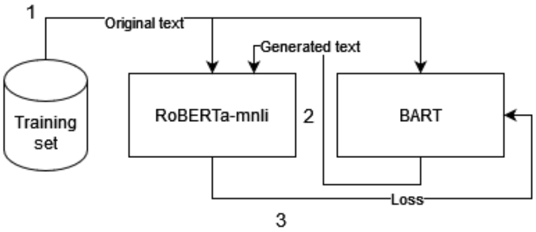

Figure 1: Training step.

- **Original text**: Syrian Coalition Condemns Horrific Massacre by Russian Air Force in Town of Atareb Aleppo Province.
  Generated text: Syrian Coalition Kills Russian Air Force in Battle of Eastern Aleppo Province.

Despite the topical proximity, the original and generated texts are very different in terms of fact-matching. In some cases, the generated text makes the opposite sense while having the same class label. Thus, we regularly see that the model generates unexpected words and produces untruthful examples.

3.2 Proposed Approach

Let N denote the set of news, where N_F and N_R are the subsets of fake and real news respectively, and I denote the output class space, $I = \{F, R\}$. During the DA process, we should generate a new text G_i for each $T_i \in N, i = \overline{1, n}$, where n is the size of N. It should be noted that $T_i \in N_I \rightarrow G_i \in N_I$. In other words, G_i and T_i refer to the same class from I.

To generate a text related to the same class as a source text, we must consider the consistency of the source and generated texts. Therefore, during the training process, we can estimate the probability that the generated text is a logical consequence of the original text. To quantify the problem of contradictory outputs that are untruthful to source news, we measure the likelihood that a generated text is an entailment of an original text. We train a seq2seq model optimizing the following loss function:

$$L = 1 - Pr[T_i \models G_i], \tag{1}$$

where $Pr[T_i \models G_i]$ is the probability of the original text T_i entailing a generated text G_i. Similar to (Trivedi et al., 2019), we utilized $\models$ to denote textual entailment. In our work, this loss function is used instead of the classical cross-entropy loss.

For each training example, we perform the following procedure:

1. Run the current model to generate the output G_i for the current example T_i.
2. Encode the original and generated texts and use them as a sentence-pair input for the NLI text classification model.
3. Calculate the probability that the original text is entailed by the generated text ($Pr[T_i \models G_i]$).
4. Calculate the loss function using the formula (1).
5. Go to the next training example.

The training objective of our model is to produce a logical consequence for an original text. In that way, we can generate texts that do not contradict facts from the original texts.

4 Experiments

4.1 Datasets

In this work, we used three datasets for fake news detection.

FA-KES (Salem et al., 2019). The dataset contains articles reporting on events from the Syrian war. We used the titles of the articles from the dataset.

COVID-19 Healthcare Misinformation Dataset (CoAID) (Cui and Lee, 2020). The dataset includes COVID-related fake news posted on websites and social platforms. The peculiarity of this dataset is the collection of real news from the websites of reputable medical organizations. In our study, we used a part of the news and claims obtained from websites. This limitation is because a significant part of the CoAID dataset contains tweet IDs instead of full texts, which is related to Twitter's security policy.

LIAR (Wang, 2017). The dataset consists of short statements collected from PolitiFact.com and evaluated for truthfulness. The LIAR dataset contains six fine-grained labels for truthfulness rating: pants-fire, false, barely-true, half-true, mostly-true, and true. In our study, we used only samples labelled with ”true” or ”false” categories as in other datasets.

The data statistics are presented in Table 1. The number of tokens was obtained using NLTK (Bird and Loper, 2004). A notable feature of the datasets under consideration is a short text length. Given the continuous development of social media, short-form text formats became popular. However, the sparsity and shortness of texts restrict the performance of text classification (Hu et al., 2022).

4.2 Data Augmentation Models

We considered four DA methods as our baselines and compared their results with the results obtained using our approach.

EDA (Wei and Zou, 2019), is a word-replacement technique that performs the following operations for the given text: a) replacing randomly chosen n words with their synonyms, b) inserting n synonyms into a random position in the text, c) randomly swapping n word pairs in the text, d) randomly deleting words with a given probability. In our experiments, we used the default parameters for EDA: 10% of the words in each sentence are to be replaced by synonyms, inserted, swapped, and deleted.

Back Translation (BT) (Sennrich et al., 2016), a method using back translating phrases between any two languages. We utilized the BackTranslation library[1] based on googletrans and zh-CN as a target language.

CBERT (Wu et al., 2019), a conditional BERT contextual augmentation model. We fine-tuned CBERT for two epochs for each dataset.

BART (Kumar et al., 2020), a seq2seq DA model based on BART. We applied token level masking replacing a continuous chunk of k tokens $w_i, w_{i+1}..w_{i+k}$ with a single mask token $< mask >$. The masking strategy was applied to 40% of the tokens. Similar to the original paper, we used $k = 3$. Next, we fine-tuned the BART-base (Lewis et al., 2020) for two epochs using a maximum sequence length equal to 64 and with a denoising objective where the goal is to regenerate the original text from a masked sequence. BART-base contains 12 layers (six for the encoder and six for the decoder), the hidden size is 768, the number of attention heads is 16 per layer, the number of parameters is 139M. The model was implemented using PyTorch Lightning (Falcon et al., 2019)

BART-NLI (ours), a model combining seq2seq

[1] `https://pypi.org/project/BackTranslation`

Avg number of tokens	10.49	11.96	19.48
Avg number of symbols	62.94	69.78	103.28

Table 1: Data statistics.

DA and NLI. As a base seq2seq model, we used the BART-based model for DA outperforming other models on several benchmarks (Kumar et al., 2020). We used the same implementation as for the previous model, but the non-entailment probability was utilized as a loss function for BART instead of the classical cross-entropy loss. Inspired by Matsumaru et al. (2020), we used the pre-trained RoBERTa-large (Liu et al., 2019) fine-tuned on the Multi-Genre NLI dataset (RoBERTa-mnli)[2] (Williams et al., 2018) to estimate an inference between the original and generated texts. We utilized RoBERTa-mnli in zero-shot settings and did not update its parameters, just producing inferences while training. RoBERTa-mnli was implemented with fairseq (Ott et al., 2019). Figure 1 presents the scheme of the training step for our model.

4.3 Classification Model

As a classifier, we used BERT-base-uncased[3] which is a version of BERT (Devlin et al., 2019). We fine-tuned BERT for two epochs with a maximum sequence length equal to 64 tokens and a batch size equal to eight. The models were implemented using Transformers (Wolf et al., 2020).

5 Results and Discussion

We report the results for all classifiers in terms of the F1-score macro (F1) and ROC AUC (ROC). For all corpora, we used five-fold cross-validation to obtain more reliable scores.

First, we evaluated the classification performance for the models trained on original corpora. During cross-validation, we consistently split the original corpus into training and test subsets five times. We added generated data to the training subset and shuffled the extended training subset. For each dataset, we generated n texts (n is the training subset size). Therefore, the training subset size increased to $(2 \times n)$ after DA. The model was evaluated on the test subset. Table 2 shows the results for all corpora (arithmetic mean values for all folds). The highest scores for each dataset are highlighted. Box plots for these results are presented in Figure 2.

As can be seen from the table, in the majority of cases, DA methods increase the classification performance. The results of transformer-based methods are mostly higher than the results of EDA and BT. The best result for the CoAID dataset in terms of F1 was shown using the original corpus. Probably, the effect of transformer-based data augmentation for this dataset could be improved using the models pre-trained on medical corpora. Although several DA models show close results, BART-NLI outperforms other methods on FA-KES (F1), CoAID (ROC), and LIAR (F1). CBERT shows the best scores on FA-KES (ROC) and LIAR (ROC). Hence, the proposed model outperforms other methods in three of the six cases. In two of the six cases, it demonstrates the second best results (FA-KES, ROC and LIAR, ROC). For CoAID and F1-score, BART-NLI demonstrated only a fifth result out of six, probably because of the absence of domain-adaptive pretraining of RoBERTa-mnli. Compared to BART, BART-NLI increased the results for all datasets in terms of both the F1-score and ROC AUC.

Further, we evaluated the semantic fidelity of the generated texts (Kumar et al., 2020). We trained a classifier on each corpus and used the trained classifier to predict the label of the generated output (Table 3). Higher performance means that the model retains the class label of the original text more accurately. The best semantic fidelity results were obtained by EDA (FA-KES, ROC and LIAR, ROC), BT (FA-KES, F1), and BART-NLI (COAID, both metrics and LIAR, F1). The results show the superiority of these models in terms of preserving the language semantics. It should be noted that

the scores obtained by BART-NLI are significantly higher than the results of other transformer-based methods.

5.1 Error Analysis

Table 4 shows some examples of successes and failures of our method compared to the BART DA model. In parentheses, we provide the classification results obtained using the pre-trained RoBERTa-mnli for the pair of original and generated texts. The factual inconsistencies are underlined.

In the first example in Table 4, BART generates the contradictory output while BART-NLI produces the textual entailment. Meanwhile, the text generated by BART-NLI looks more abstractive than the original text. In the second and third examples, BART generates contradictions because of the use of different concepts and named entities. In the fourth case, both models produce contradictions that completely change the meaning of the original texts. In the last example, the original and BART-generated texts are semantically close. The BART-NLI output is very abstractive and it was classified as a contradiction.

6 Conclusion

In this paper, we propose an approach to combine seq2seq and NLI models to improve the coherence of generated texts in DA. The approach showed relatively high results on three datasets for fake news detection. For all considered datasets and both metrics, the proposed approach improved the results of BART for DA in fake news detection. We compared the results with several common baselines and demonstrated that our approach preserves the language semantics compared to other transformer-based DA methods. In general, our results show the effectiveness of the use of NLI models to generate new training data to detect fake news.

General limitations of the study include increasing time and memory costs in comparison with using BART separately. Moreover, for some datasets, the performance of the approach is much lower than for others. An important feature of the study is the use of short texts. The effectiveness of the approach for longer texts requires further investigation.

The proposed approach probably can be applied in other subject areas where augmented data should be coherent with original texts. In the future, we will explore how to perform text DA using seq2seq and NLI for different natural language processing tasks, various models, and longer texts. In addition, the effect of domain-specific pre-training can be explored.

Abstract

In the 21st century, the proliferation of fake information has emerged as a significant threat to society. Particularly, healthcare medical reporters face challenges when verifying claims related to treatment effects, side effects, and risks mentioned in news articles, relying on scientific publications for accuracy. The accurate communication of scientific information in news articles has long been a crucial concern in the scientific community, as the dissemination of misinformation can have dire consequences in the healthcare domain. This paper delves into the application of unsupervised semantic similarity models to facilitate claim verification for medical reporters, thereby expediting the process. We explore unsupervised multilingual evidence retrieval techniques aimed at reducing the time required to obtain evidence from scientific studies. Instead of employing content classification, we propose an approach that retrieves relevant evidence from scientific publications for claim verification within the healthcare domain. Given a claim and a set of scientific publications, our system generates a list of the most similar paragraphs containing supporting evidence. Furthermore, we evaluate the performance of state-of-the-art unsupervised semantic similarity methods in this task. As the claim and evidence are present in a cross-lingual space, we find that the XML-RoBERTa model exhibits high accuracy in achieving our objective.

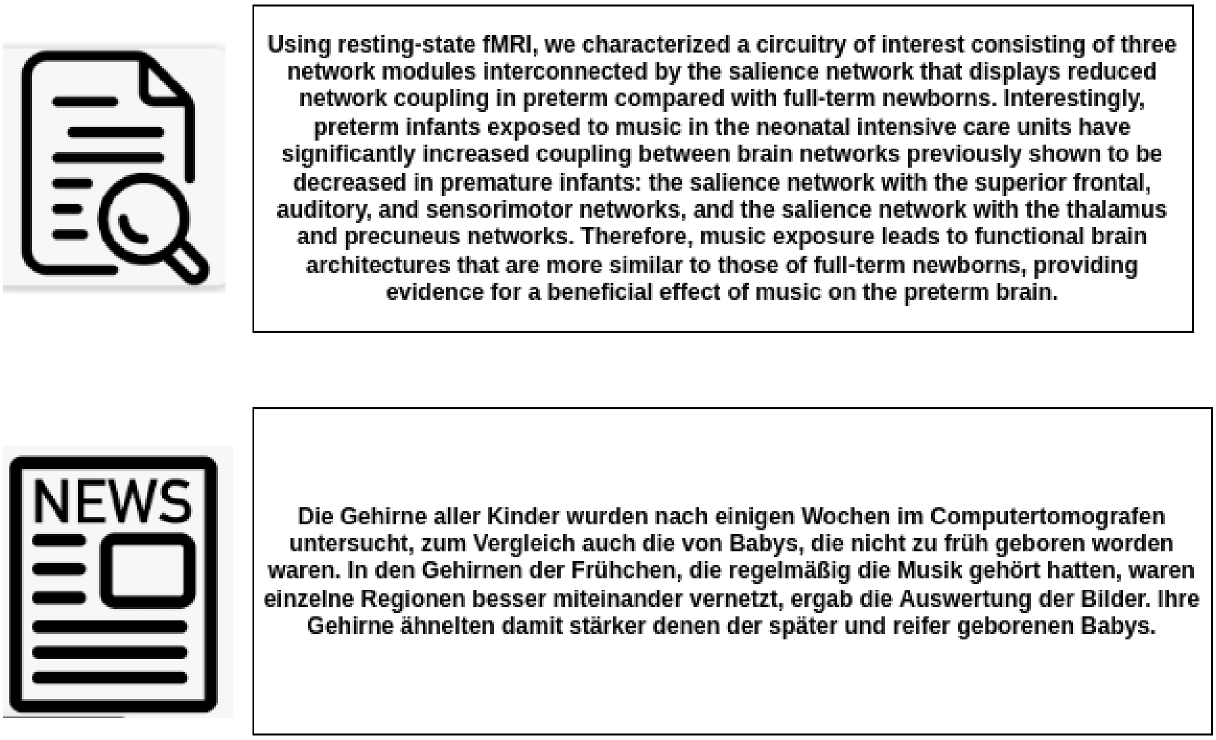
1 Introduction

The rise of misinformation has been greatly amplified by the advent of social media, primarily due to its increased dissemination and influence. One prominent manifestation of this issue is vaccine hesitancy, which has had significant societal repercussions. To illustrate this, a web-based survey (Neely et al., 2022) was conducted in June 2021 among 600 adults in Florida, revealing substantial exposure to COVID-19 vaccine misinformation among participants. Approximately 73% reported encountering misinformation in the past six months. An overview of current fake news research is given by (Kim et al., 2021). Through the convergence of computational and social science research, they delve into the significance and trajectory of enhancing ”digital media literacy” in diverse contexts of news generation and consumption.

Detecting misinformation has emerged as a critical challenge due to the rapid dissemination of news and the potentially severe consequences associated with false information. However, only a limited number of approaches have been developed to address the dynamic, versatile, and fast-spreading nature of fake news editorials. This challenge becomes even more pronounced in the healthcare domain, where the availability of training data is scarce, and pre-trained models may not be readily applicable. While supervised models rely on manually annotated training data, an unsupervised evidence retrieval and verification approach proves more suitable for quick response and works effectively with low-resource languages and domains.

The German HealthNewsReview project medien-doktor.de at TU Dortmund University evaluates the quality of medical reporting in German-speaking countries. In this paper, we aim to develop a semi-automated tool that will support journalists in their daily work by evaluating the quality of their ongoing reporting and, also, by finding scientific claims in research papers and journalistic articles with a team of highly renowned medical reporters. The medical reporters evaluate the quality of medical reporting in German-speaking countries and assess the quality of print, radio, online, and TV contributions by applying a catalog of criteria in a journalistic peer review process as explained by (Anhäuser et al., 2020). The detailed criteria have

Proceedings of Recent Advances in Natural Language Processing, pages 440–447
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_049



Using resting-state fMRI, we characterized a circuitry of interest consisting of three network modules interconnected by the salience network that displays reduced network coupling in preterm compared with full-term newborns. Interestingly, preterm infants exposed to music in the neonatal intensive care units have significantly increased coupling between brain networks previously shown to be decreased in premature infants: the salience network with the superior frontal, auditory, and sensorimotor networks, and the salience network with the thalamus and precuneus networks. Therefore, music exposure leads to functional brain architectures that are more similar to those of full-term newborns, providing evidence for a beneficial effect of music on the preterm brain.

Die Gehirne aller Kinder wurden nach einigen Wochen im Computertomografen untersucht, zum Vergleich auch die von Babys, die nicht zu früh geboren worden waren. In den Gehirnen der Frühchen, die regelmäßig die Musik gehört hatten, waren einzelne Regionen besser miteinander vernetzt, ergab die Auswertung der Bilder. Ihre Gehirne ähnelten damit stärker denen der später und reifer geborenen Babys.

Figure 1: We are interested in measuring the information similarity of statements in the scientific findings and news, shown here with real examples.

been developed following the example of international research projects such as healthnewsreview.org in the USA as discussed by (Schwitzer, 2008). The detailed evaluations are published on the website medien-doktor.de, along with advice on scientific reporting, media analyses, and blog posts on selected topics. Target groups are not only journalists, but also communication officers at research institutions, teachers, and lay citizens interested in improving their media and scientific literacy. In some newsrooms (among others German Press Agency, WDR, ZDF), these criteria of Medien-Doktor have already been taught as a possible standard for early-career reporters. Nevertheless, many non-specialized newsrooms still lack quality standards in science and medical reporting, particularly among regional media. In contrast to large national media with well-established science sections, regional newspapers often lack editors with scientific backgrounds. As analyses of evaluated articles have shown over the past years, the quality of medical reporting in local journalism usually lags behind the standards of national media. Nevertheless, especially in the German media landscape regional media still contribute significantly to opinion-forming and decision-making in wide circles of the population, while at the same time suffering the most from the loss of advertising income and structural upheaval in the time of changing habits of media usage. We, therefore, propose here the first steps towards quality-assuring tools that will help regional but also other media with their daily health reporting by economizing editorial resources.

As an initial step towards developing a semi-automated tool, we focus on the ”positive effects” criteria from the criteria catalog, which assesses how the potential benefits of therapies, tests, products, or procedures are presented. Journalists need to find evidence supporting claims made in scientific publications, a manual and time-consuming process. This presents a major challenge for healthcare reporters, as they rely on scientific publications to verify claims in news articles.

Healthcare news reporting is further complicated by the fact that journalists often need to translate highly technical language into layperson-friendly terms, as they disseminate scholarly information to audiences outside the research community, including the general public and policymakers. The public relies on the media to learn about new scientific findings, and media portrayals of science significantly influence people’s trust in science and their subsequent actions. However, there is a risk of inadvertently spreading misinformation in this process.

In this paper, we leverage recent advancements in Natural Language Processing, specifically the Transformer architecture, to develop a semantic-aware multilingual Transformer-based architecture for unsupervised evidence retrieval in healthcare claims. We propose an evidence retrieval approach instead of treating the issue as a simple classification task, thus aiding journalists by providing a list of supporting evidence and reducing their manual workload.

We present an architecture that assists fact-checking journalists in verifying the veracity of claims by contextually comparing them against evidence found in scientific publications. This paper addresses the following challenges:

- Finding similarity between scientific evidence and paraphrased scientific findings.
- Extracting evidence across different languages in news articles, considering that most scientific journals and evidence sources publish in English while we work with German news articles.

Both these challenges are demonstrated by an example showcased in Fig,1.

2 Related Work

The state-of-the-art methods for misinformation detection deal with claim verification in news articles and involve supervised methods, e.g., (Luken et al., 2018; Rawat and Kanojia, 2021). A good survey is (Guo et al., 2022). Most authors treat evidence retrieval and claim verification as a single task referred to as factual verification, e.g., (Nie et al., 2018). To overcome the main challenge of supervised approaches, i.e., the time and labor-intensive construction of reliably annotated datasets to train supervised models, some groups explore the potential of unsupervised models for misinformation detection, e.g., (Yang et al., 2019; Li et al., 2014). Independent of the modeling approach, the reliability of a source plays an important role in evidence retrieval and the verification process. Some work has been done to explicitly compute the reliability of a source, e.g., (Yan et al., 2022). In this section, we will briefly present representative results for each category.

The authors of (Nie et al., 2018) present a connected system consisting of three homogeneous neural semantic matching models that conduct document retrieval, sentence selection, and claim verification jointly for fact extraction and verification.

In (Luken et al., 2018), the authors break down the process into three modules: potentially relevant documents are gathered based on key phrases in the claim, then sentences relevant to the claim are extracted as evidence from these documents, and finally, the classifier discards any evidence deemed irrelevant and uses the remaining to classify the claim's veracity. An approach in which the evidence is gathered automatically for each claim is proposed in (Rawat and Kanojia, 2021). The approach extracts supporting evidence from the web articles and then selects appropriate text to be treated as evidence sets. A pre-trained model is used to summarize these evidence sets and then these extracted summaries are used as supporting evidence to aid the classification task. The approach collects evidence and prunes to top-k-related news items based on semantic similarity via BERTScore.

In (Wu et al., 2020) the authors proposed integrating credibility assessment as a part of the fact-checking task. The model first strengthens the interaction between claims and relevant articles to discover key evidence fragments, and then incorporates source features of articles and mitigates the interference of extreme semantics to explore more credible evidence discussing the questionable parts of claims.

In (Li et al., 2014), authors worked on the problem of automatically identifying trustworthy information and sources from multiple conflicting data sources. The authors propose to model the conflict resolution problem on data of heterogeneous types using a general optimization framework called CRH that integrates the truth-finding process on various data types seamlessly. They model the problem using an optimization framework where truths and source reliability are defined as two sets of unknown variables. The objective is to minimize the overall weighted deviation between the truths and the multi-source observations where each source is weighted by its reliability. In (Yin et al., 2008), authors designed a general framework for the Veracity problem and invent an algorithm, called TRUTHFlNDER, which utilizes the relationships between websites and their information, i.e., a website is trustworthy if it provides many pieces of true information, and a piece of information is likely to be true if it is provided by many trustworthy websites. An iterative method is used to infer the trustworthiness of websites and the correctness of information from each other. In (Yang et al., 2019), the authors follow an unsupervised approach by leveraging a Bayesian network model to capture the conditional dependencies among the truths of news, the users' opinions, and the users' credibility and proposed an efficient collapsed Gibbs sampling approach to infer the truths of news and the users' credibility without any labeled data.

In (Yan et al., 2022), authors propose a novel reputation model to quantify the newly defined source reliability, which will be accumulated as the long-term source quality. They propose a reputation-based truth discovery model, where initial weights are assigned based on source reputations. In (Baly et al., 2018), the authors presented a study on predicting the factuality of reporting and bias of news media. The models use a rich set of features derived from the content of the articles from the target news medium, its Wikipedia page, its Twitter account, and information about the web traffic it attracted. In (Mukherjee and Weikum, 2015) the authors analyzed the effect of different factors like language, topics, and perspectives on the credibility rating of articles in a news community. These factors and their mutual interactions are the features of a novel model for jointly capturing the credibility of news articles, the trustworthiness of news sources, and the expertise of users.

Most of the state-of-the-art methods make use of supervised-based models. This will be a challenge when we don't have annotated data to train large models. In this work, we explored unsupervised based semantic models since in our use case, we have only 20 manually annotated articles. Instead of tackling the problem of claim verification as a classification problem, we propose supporting the journalists with a list of evidence from scientific journals for that given claim. The unsupervised approaches in the literature depend on the characteristics of the news source and the features extracted from the article. These approaches do not consider the semantics and context of the text in the article.

3 Dataset

This paper investigates the correlation between claims made in health news articles and the supporting evidence found in scientific publications. The claims and evidence were manually annotated by medical reporters due to the labor-intensive nature of this task. Our dataset comprises 20 meticulously annotated articles from prominent German news sources, including Focus Online, Berliner Zeitung, Bild, and Welt. These healthcare news articles encompass a range of topics, such as the positive effects of different treatments/medications, including vaccines for COVID-19, and the relationship between aspirin and the coronavirus.

To substantiate these claims, medical reporters typically refer to scientific publications published in esteemed journals like Nature, PubMed, and Lancet. However, our particular use case presents a multilingual challenge as the news articles are in German, while the scientific studies are in English. The annotated claims consist of a collection of sentences, and correspondingly, the evidence paragraphs in the scientific publications are annotated by the journalists. As part of this ongoing project, we are curating this dataset, which will be made available for future publication.

4 Background

The assessment of text similarity has garnered significant attention from researchers in the fields of natural language processing and information retrieval. This longstanding problem is inherently complex, leading to the development of diverse approaches aimed at capturing a wide range of characteristics. The evaluation of semantic similarity can be categorized into two primary methods: sentence-embedding-based approaches and word-alignment-based approaches.

4.1 Word-Alignment-Based Methods

Alignment-based methods measure the word matching degree for sentence similarity evaluation. WMD is a popular alignment-based method. Its extensions are widely used in text similarity tasks.

4.1.1 Word Mover's Distance

Earth mover's distance (EMD), also known as the Wasserstein distance, is a distance measure between two probability distributions. Kusner et al. (Kusner et al., 2015) proposed a version of EMD applicable to language models, the Word mover's distance (WMD) which evaluates the distance between two documents represented in a continuous space using word embeddings such as the Word2Vec and fastText embeddings. For any two documents A and B, WMD is defined as the minimum cost of transforming document A into document *B*. Each document is represented by the relative frequencies of its words relative to the total number of words of the document, i.e., for the *j*th word in the document,

$$d_{A,j} = count(j)/ \mid A \mid \tag{1}$$

where $\mid A \mid$ is the total word count of document A and $count(j)$ is number of occurrences of the word with vocabulary index j. The *j*th word is represented by its corresponding word embedding, say $\mathbf{v}_j \in \mathbb{R}^n$. The n-dimensional word embeddings are obtained from a pre-trained model, e.g. Word2Vec or fastText. The distance between two words can easily be measured using Euclidean distance,

$$\delta(i, j) = \|\mathbf{v}_i - \mathbf{v}_j\| \tag{2}$$

Based on this choice, the Word mover's distance is defined to be the solution of the following linear program,

$$\begin{aligned} WMD(A, B) = & \min_{\mathbf{T}\geq 0} \sum_{i=1}^{V} \sum_{j=1}^{V} \mathbf{T}_{i,j}\delta(i, j) \\ \text{such that} & \sum_{i=1}^{V} \mathbf{T}_{i,j} = d_{A,j} \\ \text{and} & \sum_{j=1}^{V} \mathbf{T}_{i,j} = d_{A,i} \end{aligned} \tag{3}$$

Here, $\mathbf{T} \in \mathbb{R}^{V\times V}$ is a non-negative matrix, where $\mathbf{T}_{i,j}$ denotes how much of word *i* in document *A* is assigned to tokens of the word *j* in document *B*. Empirically, WMD has reported improved performance on many real-world classification tasks as demonstrated in (Kusner et al., 2015). The WMD has intriguing properties. The distance between two documents can be broken down and represented as the sparse distances between a few individual words. The distance metric is also hyperparameter-free. The most important feature is that it incorporates the semantic information encoded in the word embedding space and is agnostic to arbitrary word embedding models.

4.2 Text Embedding Methods

In such approaches, the aim is to extract a numerical representation of a sentence to encapsulate its meanings. In these methods, we generate embeddings for both claim and the evidence paragraph. The semantic similarity score is calculated using cosine similarity between claim and evidence embeddings.

4.2.1 TF-IDF

The TF-IDF algorithm is a commonly used technique in the extraction of text feature words based on statistical methods. It mainly evaluates the importance of a word-to-text and text sets by word frequency. It is mainly composed of two parts: word frequency and inverse text word frequency. In a document, the term frequency (TF) is the frequency at which a word appears in the text, and the result is usually normalized to prevent it from being biased toward longer text. Inverse Document Frequency (IDF) indicates the importance of a word in a text set.

4.2.2 FastText Based Embeddings

(Bojanowski et al., 2016) proposed an approach that is based on the skip-gram model, where each word is represented as a bag of character n-grams. A vector representation is associated with each character n-gram; words are represented as the sum of these representations. We obtain claim and evidence paragraphs' representations from a pre-trained fastText model which is based on the average of N-gram features.

4.2.3 BERT-Based Embeddings

Bidirectional Encoder Representations from Transformers (Devlin et al., 2019) is one of the most powerful context and word representations. BERT is based on the methodology of transformers and uses an attention mechanism. It employs the bidirectional training of the transformer architecture and applies it to language modeling. Unsupervised objectives, including the masked language model and the next sentence prediction, are incorporated. Word-piece tokenization is performed on the text from both the claim and scientific publication and then used as input to a pre-trained BERT model. The BERT model provides contextual embedding for these word pieces.

- **Sentence-BERT:** (S-BERT) proposed by (Reimers and Gurevych, 2019), is a modification of the pre-trained BERT network that uses siamese and triplet network structures to derive semantically meaningful sentence embeddings that can be compared using cosine similarity.

- **Sci-BERT:** A transformer model proposed by (Beltagy et al., 2019), is trained using masked language modeling on a large corpus of scientific text. It leverages unsupervised pretrain-

ing on a large multi-domain corpus of scientific publications to improve performance on downstream scientific NLP tasks.

- **XML-RoBERTa:** XLM-R (XLM-RoBERTa, Unsupervised Cross-lingual Representation Learning at Scale) proposed by (Conneau et al., 2020) is a scaled cross-lingual sentence encoder. It is trained on 2.5T of data across 100 languages data filtered from Common Crawl.

5 Proposed Approach

In this section, we describe the architecture of our Semantic Matching component as illustrated in Fig.2. Given a claim in a healthcare news article, we need to find paragraphs in the scientific publication where the evidence for the claim are present. The news article for our use case is in German and the scientific publications are in English, introducing a cross-lingual aspect to the problem. A claim annotated by the medical reporters is a set of sentences in which the positive effects of a medicine or a therapy are explained. As a first step, we extract all the paragraphs from the scientific publication and preprocess the text. Preprocessing in the case of the models trained on English corpus, we translate the claim in English using DeepL translate [1]. The semantic match component takes a claim and the union of the paragraph set from the scientific publication as inputs and outputs a subset of paragraphs. Evidence paragraph selection can also be formulated as semantic matching between each paragraph and the claim to select the most plausible evidence set. The selection is done via these steps:

- Calculating the semantic similarity score, s_i, for all the paragraphs in the scientific publication.
- Sorting sentences by their s_i values and adding the top k-paragraphs to the resulting list.

Our proposed pipeline generates a collection of the top k most similar paragraphs, which serve as evidence in the context of fake news detection. Unlike traditional approaches that treat fake news as a classification problem, our pipeline introduces an evidence retrieval approach. This approach effectively assists journalists in locating relevant supporting evidence, thereby reducing the need for manual search efforts. The advantages of our system include: (i) its unsupervised nature, allowing it to adapt to concept drifts without relying on labeled data, and (ii) empowering users with decision-making capabilities while minimizing manual workload.

6 Evaluation and Discussion

In this paper, we employed manual annotation by medical reporters to annotate the evidence for

Word Movers distance	Yes	65%	30%	10%
Sentence BERT	Yes	65%	40%	10%
SciBERT	Yes	70%	40%	20%
XML-RoBERTa	No	90%	50%	30%

Table 1: Accuracies score for different semantic similarity-based models for 20 annotated articles.

claims in healthcare news articles, which were predominantly in German. To bridge the language gap, we utilized DeepL, a translation tool, to translate German claims into English. For the experiments, we explored both monolingual and multilingual semantic similarity models. The monolingual models utilized DeepL translations, while the multilingual models, such as XML-RoBERTa, enabled us to handle both English and German texts.

To measure the semantic distance between sentences, we developed a component that searches for semantically similar evidence in scientific studies once a new claim is received. This component employs transformer models to generate representation embeddings for each claim and the paragraphs in the scientific publications. By calculating the similarity distance, we identify the most similar evidence, aiming to provide users with semantically related evidence.

During the evaluation, we considered partial evidence matches within the extracted ”k”-nearest neighbors as valid matches. This approach supports journalists in finding additional evidence to supplement partial matches. We evaluated various methods, including word alignment-based approaches and sentence embedding methods, for unsupervised evidence retrieval. The models extracted the ”k”-nearest neighbors that exhibited the highest similarity to the given paraphrased claim.

From our results presented in Table 1, XML-RoBERTa demonstrated the best performance in extracting evidence for the given paraphrased claims. Classical semantic similarity approaches using tf-idf and fastText embeddings did not perform well, as these approaches struggle to capture contextual information effectively. Among the embedding approaches, word movers distance with fastText embeddings outperformed cosine similarity measures using tf-idf or fastText. Word movers distance treats text similarity as a transportation problem, utilizing word embeddings to determine shared meanings or contextual usage, thereby achieving superior performance compared to cosine similarity models.

In terms of transformer-based models, semantic similarity using XML-RoBERTa embeddings performed the best. Additionally, cross-lingual models outperformed monolingual models, highlighting the benefits of leveraging multilingual capabilities in our approach.

7 Conclusion and Future Work

In this paper, we tackled the challenge of claim verification by employing evidence retrieval techniques from scientific studies. Our approach involved developing a semantic matching method capable of retrieving the most similar evidence from a given scientific report. Through the evaluation of various semantic similarity methods, including text representations and word alignment techniques, we demonstrated the effectiveness of using a multilingual model like XML-RoBERTa to calculate semantic similarity and identify relevant paragraphs containing the evidence. By approaching this as an evidence retrieval rather than a classification problem, our proposed approach aims to support medical reporters and journalists in efficiently locating supporting evidence for paraphrased claims, thereby reducing the need for manual searching.

Moving forward, we will focus on retrieving the most relevant scientific papers from a pool of documents that encompass the supporting evidence for a given claim in healthcare news articles. Additionally, we recognize the need for improvement in the k-nearest neighbors within our models. To achieve this, we plan to target specific sections within scientific publications, such as the results or conclusion section, where there is a higher probability of finding pertinent evidence. These advancements will further enhance the efficacy and precision of our evidence retrieval approach, paving the way for more accurate claim verification.

Acknowledgments

We would like to thank Tobias Kreutzer and Paul Klammer for their contribution in the project and feedback.

Abstract

Multiword Expressions (MWEs) have been a bottleneck for Natural Language Understanding (NLU) and Natural Language Generation (NLG) tasks due to their idiomaticity, ambiguity, and non-compositionality. Bilingual parallel corpora introducing MWE annotations are very scarce which set another challenge for current Natural Language Processing (NLP) systems, especially in a multilingual setting. This work presents AlphaMWE-Arabic, an Arabic edition of the AlphaMWE parallel corpus with MWE annotations. We introduce how we created this corpus including machine translation (MT), post-editing, and annotations for both standard and dialectal varieties, i.e. Tunisian and Egyptian Arabic. We analyse the MT errors when they meet MWEs-related content, both quantitatively using the human-in-the-loop metric HOPE and qualitatively. We report the current state-of-the-art MT systems are far from reaching human parity performances. We expect our bilingual English-Arabic corpus will be an asset for multilingual research on MWEs such as translation and localisation, as well as for monolingual settings including the study of Arabic-specific lexicography and phrasal verbs on MWEs. Our corpus and experimental data are available at `https://github.com/aaronlifenghan/AlphaMWE`

1 Introduction

Multiword Expressions (MWEs), such as “a cheap shot” (a cruel verbal attack) or “take it with a grain of salt” (regard something as exaggerated), are combinations of words that function as a single unit and have a specific meaning (Baldwin and Kim, 2010), typically regarded as a *‘pain in the neck’* to Natural Language Processing (NLP) tasks, particularly in the field of machine translation (MT) (Sag et al., 2002) and information extraction (Kovačević et al., 2013; Maldonado et al., 2017). Translating MWEs accurately poses a significant challenge for statistical and neural MT systems (Han, 2022b; Han et al., 2021, 2020b). The difficulty lies in the idiomatic, colloquial or culture-specific nature of MWEs, which requires a deep understanding of their meaning, context, and cultural references (Moreau et al., 2018). Additionally, MWEs can be interpreted into multiple possible meanings, further complicating their translation. Therefore, a parallel corpus that incorporates MWE annotation is expected to be useful for improving the MT quality via system fine-tuning and error analysis. However, Arabic seems to lack a satisfactory corpus for such use. The literature describes several English–Arabic parallel corpora. However, to the best of our knowledge, none of these corpora includes the MWEs annotation.

In this paper, we describe our ongoing effort to extend AlphaMWE coordinated by Han et al. (2020a), a multilingual parallel corpus with annotation of MWEs, to the Arabic language including both standard and dialectal ones, i.e. the Egyptian and Tunisian Arabic. Arabic is a morphologically rich language and has been challenging for state-of-the-art MT systems (MILAD, 2022). Fol-

lowing AlphaMWE, our study primarily focused on Verbal MWEs (VMWEs). A VMWE is defined as a MWE whose canonical form has a verb as its syntactic head (Markantonatou et al., 2017; Ramisch et al., 2018, 2020) with popular examples "kick the bucket", "take ... for granted", and "swallow someone's pride". We used state-of-the-art MT engines to facilitate the standard Arabic corpus creation and we will discuss the pros and cons of different MT models on MWE-related translation errors. We carried out manual post-editing and annotations by native Arabic speakers for this. Regarding dialectal Arabic corpus, we translated them from English from scratch, since the current MT models do not cover dialectal Arabic translations and the quality from MT output is too low to be useful, which also indicated the value of our corpus creation. Overall, in this work, we not only contribute to a series of parallel corpus on English-Arabic with MWE annotations but also give qualitative and quantitative analysis on MT errors facing MWEs, which we hope will be valuable for future MT research on this language pair.

The rest of this paper is organised as follows: Section 2 describes previous work dedicated to parallel Arabic corpora and compares our contribution to the state of the art. Section 3 is a brief introduction to the Arabic language. Section 4 explains the construction of the AlphaMWE-Arabic corpus and the qualitative evaluation using examples from MT outputs. In Section 5, we offer more quantitative and statistical analyses of the data annotation process using the human-in-the-loop metric HOPE (Gladkoff and Han, 2022). Finally, Section 6 concludes our paper and discusses perspectives for future work.

2 Related Work

The development of machine translation for low-resource languages is a widely studied challenge in NLP (Ortega et al., 2021). Many efforts have been made to create effective MT models. To train these models, various parallel resources have been proposed.

Ziemski et al. (2016) created the United Nations Parallel Corpus, which consists of over 2 million words of parallel texts in 6 official languages, including English and Arabic. Another work that includes Arabic is the multilingual parallel corpus MultiUN (Chen and Eisele, 2012). It extends the United Nations Parallel Corpus by including texts from various sources such as the United Nations and other international organisations.

In addition, several researchers have undertaken efforts to construct resources for Arabic dialects. Boujelbane et al. (2013) built a bilingual dictionary that utilised explicit knowledge about the relationship between Tunisian Arabic and Modern Standard Arabic (MSA). Wael and Nizar (2012) translated dialectal Arabic to MSA as a bridge to translate to English. Bouamor et al. (2014) created a multi-dialectal Arabic parallel corpus that contains 2000 sentences in MSA, Egyptian, Tunisian, Jordanian, Palestinian, and Syrian Arabic.

However, this previous work mainly focused on the creation of lexical and grammatical parallel resources using either manual or automatic methods, without *annotation* of linguistic phenomena such as MWEs.

To address this, there have been numerous studies aiming at creating monolingual corpora annotated with verbal MWEs, such as the PARSEME shared task corpora (Ramisch et al., 2020). PARSEME is a multilingual initiative that targets the parsing of MWEs in over 26 different languages, including MSA (Hadj Mohamed et al., 2022), but they are not parallel data. To extend this effort, AlphaMWE (Han et al., 2020a) not only focuses on the creation of *multilingual parallel* corpora but also incorporates the *annotation of MWEs* in both the source and target languages. So far, 4 languages are covered in AlphaMWE, namely English, Chinese, Polish, and German. However, as we discussed earlier, there is a lack of such parallel corpora for Arabic, even though it is one of the most spoken and used languages. In this work, we develop an Arabic edition of AlphaMWE including both the standard language and dialectal varieties.

3 On Arabic Language

The term "Arabic language" today can refer to either Modern Standard Arabic (MSA) or various spoken vernaculars referred to as Arabic dialects. The classical form of MSA is used in religious texts, poetry, and formal writing, whereas the dialectal form is used in everyday and colloquial conversation. We give in this section a brief overview of MSA specificities.

Firstly, in MSA, there are no capital letters and the use of punctuation marks is not widely adopted in current Arabic texts (at least not regularly). Secondly, Arabic tends to use long and complex sentences with *right-to-left* writing, making it common to find an entire paragraph without any punctuation. Thirdly, as a Semitic language, Arabic has a complex morphology. Indeed, it uses *concatenative morphology (agglutinated or compound words)*, where words are formed via a sequential concatenation process[1]. For example, the sentence *'then they will write it'* is presented in Arabic as one word فسيكتبونها. In addition, the Arabic language has some words that can add diacritical marks on top or below them to form new words that have new pronunciations and meanings, of which the new pronunciation is similar to the ones from the original word. As a result, texts without diacritical marks are highly susceptible to ambiguity. For instance, the word/symbol علم (pronunciation: Alam) can be diacritised in 9 different forms (Maamouri et al., 2006) including عِلم ("science", pronunciation: Elm), عَلم ("flag", pronunciation: Alam), and علَّم ("he taught", pronunciation: Ellem), etc. Finally, another special aspect of Arabic is its flexible word order, where the rearrangement of certain words in a sentence does not affect its meaning. This is because the language uses case markers, particles, and other linguistic tools to clarify the connections between words, resulting in a more flexible syntax compared to languages with a more rigid word order. For example, *"the boy went to the school"* can be written in Arabic in three forms: الولد ذهب إلى المدرسة (the boy went to the school), ذهب الولد إلى المدرسة (went the boy to the school), and إلى المدرسة ذهب الولد (to the school went the boy). These unique features make Arabic a challenging language for NLP tasks.

4 AlphaMWE-Arabic

Following AlphaMWE (Han et al., 2020a), we used the PARSEME corpus for English as the source language. The PARSEME corpus is well established and provides a clear process of tagging and categorisation. The English corpus used in the PARSEME shared task was created by Walsh et al. (2018), where 832 VMWEs were manually annotated across 7,437 sentences taken from various topics and domains, such as news, literature, and IT documents[2]. Overall there are around 750 sentences extracted from the source PARSEME English corpus that include VMWE tags by AlphaMWE[3]. Furthermore, AlphaMWE divided these 750 sentences into 5 portions (by files) with the same size, i.e. around 150 sentences each for cross-validation and system-tuning purposes. We followed this process for the creation of our three corpora: Modern Standard Arabic, Tunisian Arabic, and Egyptian Arabic. We will first introduce the workflow for creating standard Arabic MSA including the usage of MT; then we introduce the ones for the dialectal varieties.

4.1 AlphaMWE-MSA

For MSA, we translated the English source using a MT system in the loop of our process. We favoured the use of the "MT plus post-editing (MT+PE)" as the preferred option, rather than translating from scratch via native speakers. Henceforth, the translation process is more efficient and the creation of the Arabic corpus was made more easily. This, in turn, allowed us to quantitatively evaluate the results and then finally, post-edit the output to obtain our human gold standard. This pipeline will be further elaborated in the next subsections. Our MSA corpus yielded 2,700 tokens. Our two native Arabic speakers who carried out the post-editing work include one Masters student from Egypt and one Ph.D. student from Tunisia both studying NLP abroad for their degrees as fluent English speakers. Following the AlphaMWE creation workflow (Han et al., 2020a), the post-editing was cross-validated by having them double-check on each other's first edit edition. The amount of annotation, translation, and evaluation work measured by time is around 15+ hours each.

4.1.1 MT Systems Comparison

We compared different MT systems on the English-to-Arabic translation including GoogleMT (Vaswani et al., 2017; Johnson et al., 2017) and Systran Translate[4]. We give some examples of our comparisons in Figure 4.1.1, where we used the colours green, red, yellow, and magenta to indicate that categories of well-translated,

[1] Agglutination is the process, common in Arabic, of adjoining clitics from simple word forms to create more complex forms.

[2] `https://gitlab.com/parseme/parseme_corpus_en` PARSEME English corpus

[3] `https://github.com/poethan/AlphaMWE` It includes parallel Chinese, German, and Polish ↔ English

[4] `https://www.systran.net/en/translate/`

wrong, correct but unnatural and skipped. We qualitatively evaluated the translation samples and from which, we have the following findings:

- 1) when Systran MT output makes mistakes, the errors are very severe, such as adding context out of the blue, while GoogleMT's output still makes some sense when it is wrong. For instance, in sentence 2 (Figure 4.1.1), the phrase "jerked the paper out of view" was translated by Systran MT into a completely different context أزاغ الورقة خجلاً (azāgh al-w̄arakah khajalan / lit. 'deflected the paper shyness') 'he deflected the paper with shyness'.

- 2) Systran has more correct translations on entities. For example, the word *"copyright"* in sentence 5 (Figure 4.1.1) is correctly translated by Systran MT to حقوق النشر و التأليف while Google MT translated it as حقوق المؤلف ("the right of the author"). Although Systran MT performs reasonably well on some translations, as shown in the previous example, Google MT still performs better in terms of semantic accuracy overall.

Our thought is that we want to reduce the workload for the professional post-editing step, and we are keen to know more about how MT makes errors and mistakes when translating MWEs and verbal idioms. Therefore, we choose GoogleMT as our engine with the following rationale: a) entity errors can be fixed more easily than out-of-the-blue errors; b) we can get more examples of how MT fails in translating MWE-related content and these examples can be valuable for future research such as on guiding MT development.

4.1.2 Workflow Examples

We illustrate our workflow process with the following example sentence (Sentence 1). Firstly, we carried out the automatic translation for the Arabic target direction using Google Translate (output in Sentence 2). Then, we post-edited the output with annotation of the relevant target side VMWEs that are in line with the source English ones as shown in the example (Sentence 3). Finally, we evaluated the Google translation quality using the HOPE metric (Gladkoff and Han, 2022). The HOPE methodology is used to assess the quality of the Google Translation, taking into account expert post-editing annotations and a scoring model that assigns error penalty points based on error severity and category (Charalampidou and Gladkoff, 2022). In our example, Google Translate was unable to preserve the idiom of the original statement. As a result, the sentence's idiomatic meaning is lost in some cases.

(1) (*Source*)
But she did not **give me any time of day**.
lit.[5] 'But she did not pay me any attention' || 'she ignored me'

(2) (*Google Translation*)

ihtemām	aī	**ta'īrnī**	lm	lakenn-hā
attention	any	pay.3.FEM.PAST	not	but-her

lit. 'But she did not pay me any attention' || 'she ignored me'

The different types of MT errors in HOPE are described in (Gladkoff and Han, 2022) as follows:
Mistranslation (MIS): Translation distorts the meaning of the source, and presents mistranslation or accuracy error.
Style (STL): Translation has poor style, but is not necessarily ungrammatical or formally incorrect.
Terminology (TRM): Incorrect terminology, inconsistency of translation of entities (forms, sections, etc.)
Impact (IMP): The translation falls short in clearly conveying the intended message (even if it may be accurate word-for-word, a good translation should not rely solely on literal equivalence and should have a clear expression of the central idea).
Missing Required Adaptation (RAM): The source has errors and needs correction, or requires significant adaptations for the target but the translator failed to make these changes.
Ungrammatical (UGR): Translation is ungrammatical - needs to be fixed to convey the meaning

[5] We follow the PARSEME corpus format, using 'lit.' as starting mark followed by literal translation and meaning equivalent translation.

Figure 1: MT Output Comparisons between GoogleMT and Systran. Green: well translated, Red: wrong translation, Yellow: correct but unnatural and Magenta: skipped.

properly.

Proofreading Error (PRF): Linguistic error which does not affect the accuracy or meaning transfer, but needs to be fixed.

Proper Name (PRN): Named entity translation error.

We added two new error types to accommodate our post-editing and evaluation tasks on English-to-Arabic MT output:

MWE Missed Chance (MMC): Indicate when the MT output on source MWEs is either wrong semantically or correct translation but without using the corresponding correct MWEs in the target (in the situation when there is indeed such MWE in target).[6]

Skipped Word (SKP): Highlight when the MT system failed to translate a certain word that was important to the context.

In the scoring calculation of HOPE, there are score ranges from 0 to 16 (0, 1, 2, 4, 8, 16) indicating none, minor, medium, major, severe, and critical errors assigned to each error type. Then the overall penalty score of a segment or sentence (PSS) is used to classify the MT output into - correct (unchanged): PSS score 0, good enough: PSS score 1-to-4, or with major errors (requiring fixing): PSS score 5+.

Table 1 gives an example of evaluating these error types and their scores using our Source (1), MT output (2), towards the correct translation (3). In this example, the existing error types include MMC and IMP, with their severity level of 8 and 16 and the overall sentence level penalty point is 24. This indicates that the MT output sentence belongs to sentences with a Major error category.

In Section 5, we will report the statistical errors over all 150 segments.

4.2 Dialectal Arabic

As we previously mentioned, dialectal Arabic is used in everyday conversation, and with the explosion of social media it is inevitable that a great amount of the linguistic data digitally available is Dialectal. MWEs are also more prevalent in dialectal Arabic due to the idiomatic nature of informal speech. However, there are a few challenges with Dialectal Arabic. Firstly, it is not standardised, meaning there is no standard spelling which may incur multiple readable spelling variations of the same word. Secondly, very little work has been done on dialects in the context of MWEs. Thirdly, and perhaps most importantly, there is a large number of different dialects when it comes to Arabic. We focus in our work on both Egyptian and Tunisian Arabic.

Since there is no MT system that translates into Dialectal Arabic we opted to translate the source from scratch. Our Tunisian Arabic corpus contains 2,495 tokens and our Egyptian Arabic corpus contains 2,055 tokens.

Error type	score	severity
MMC	8	Severe
MIS	0	None
STL	0	None
TRM	0	None
IMP	16	Critical
UGR	0	None
PRF	0	None
SKP	0	None
Sum	24	Major

Table 1: An Evaluation Example using Source Sentence (1) and MT Output Sentence (2) Toward the Correct Translation (3) using HOPE Metric (including each error type and overall sentence level)

5 Statistical MT Error Analysis

Evaluation of HOPE tasks can be carried out both with and without a final human-generated reference translation. Regardless, the evaluator assesses errors based on the HOPE quality metrics and assigns a score based on the severity of the errors using a penalty points system. In this task, we will generate a gold standard translation for the purpose of our open-source parallel corpus creation. Figure 2 shows the statistics from the HOPE metric on the 'aa' portion, one of the five files (*aa* to *ae*) included in the AlphaMWE corpus, on the percentage of MT output sentences that falls into 'un-changed (correct)', 'minor errors', and 'major errors'. The scoreboard shows that only 35% of MT output sentences are correct, and there are 44% and 21% of sentences having minor and major errors.

Table 2 shows more details and statistics of each error type from the HOPE metric evaluation. From Table 2, we can see that the largest ratio of error type is IMP, i.e. the "Impact" error. Then the

[6] In the situation when there is no corresponding MWE in the target, we add the literal translation in place of no real MWE.

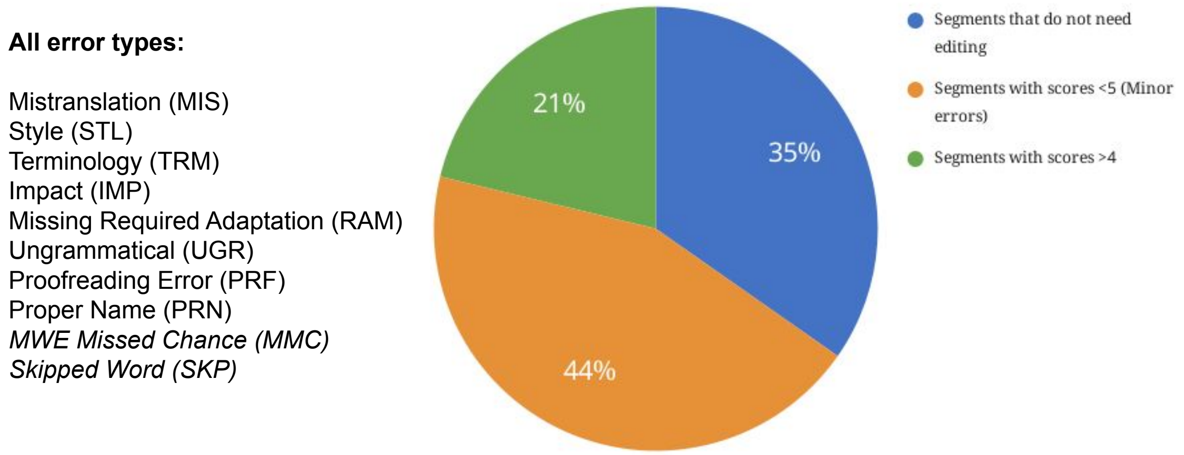

Figure 2: Evaluation Results using HOPE Metric on 150 Segments including Correct Translations (blue, PSS score = 0), Minor Errors (orange, 1 < PSS < 5), and Major Errors (green, PSS > 5).

Error type	MMC	MIS	STL	TRM	IMP	UGR	PRF	SKP	All	PPS
Total Penalty Scores	76	68	69	39	114	37	46	6	455	
Ratio out of total segments	17%	15%	15%	9%	25%	8%	10%	1%		3.03

Table 2: Penalty Score Ratios of Each Error Type and Average Penalty Scores of Each Segment from 150 Segments using HOPE Metric. The 'total penalty score' is the sum of all penalty score values from the same specific error type across all 150 segments. The 'Ratio out of total segments' values are calculated by the specific penalty scores divided by the All sum (455), except for the last value in the bottom right corner PPS (Penalty Points per Segment) which is calculated by all Penalty scores divided by all segment numbers, i.e. 455/150. The Average Penalty Point per Segment is 3.03 overall for all tested segments.

newly added error type MMC, i.e. "MWE Missed Chance", has 17% of all error weight. The next most common error types are followed by MIS, STL, and PRF representing "Mistranslation, Style, and Proofreading Error". On average, each segment received 3.03 penalty points.

6 Discussion and Future Work

To bridge the gap in the parallel corpus of English-Arabic with MWE annotations, we created AlphaMWE-Arabic, an Arabic edition of the AlphaMWE corpus. This is another step further to facilitate low-resource language processing including dialectal ones and can be useful to both multilingual and monolingual MWE-focused research.

During our creation, we introduced two new error types to the HOPE metric, and the experimental results show that MWE-related errors have a big ratio out of all error types. This reflects that the current state-of-the-art MT systems are still far from reaching human parity as they falsely claimed sometimes, which was partially due to their limited evaluation setting (Läubli et al., 2018; Graham et al., 2020; Han, 2022b).

For the standard Arabic corpus, we had two native speakers who carried out the post-editing and annotation. The corpus quality was ensured by cross-validation, i.e. having the second person check on the output from the other person's first edit. However, to quantitatively measure the inter-annotator agreement (Gladkoff et al., 2023) levels, in the future, we plan to design some experiments on calculating how much chance they agree with each other on the MT output quality and on the post-editing, e.g. to target MWEs vs non-MWEs.

Following the AlphaMWE open-source project, we plan to extend our corpus to a larger size and launch an open research project call where researchers can contribute and volunteer for the extension of the English-Arabic corpus. We have shared tasks in mind by contributing our corpus as a MWE-focused MT challenge, e.g. using human-in-the-loop MT evaluation metric HilMeMe that looks into MWEs (Han, 2022a).

Limitations

In this work, we prepared a small-sized parallel corpus of English-Arabic with multiword expression (MWE) annotations, around 750 sentences directed from AlphaMWE (Han et al., 2020a). While we think this is an important step towards such kinds of resources, we do believe the size of our corpus can be enlarged via further development, such as recruiting volunteering professionals from translation backgrounds. Regarding dialectal Arabic, we offered Tunisian and Egyptian ones with the resources available. However, we can expect more dialectal Arabic to be added to this work if more native speakers are available. We used a human-in-the-loop metric HOPE to evaluate the GoogleMT output which gives a relatively transparent output on how many percents of the errors were made and how many percents of automatic translations fall into minor errors vs major errors. In a possible extensive investigation, we can apply more metrics to generate more diverse evaluation outputs, including fully automatic metrics.

Ethics Statement

There are no ethical issues with the work we carried out in this paper, including the corpus we created. Our Arabic corpus is translated from the source English one that has been validated and checked by the PARSEME shared task organisers and released publicly in 2018 (Ramisch et al., 2020, 2018).

Acknowledgement

We thank Haifa Alrdahi for her helpful advice and input on the Arabic language. We thank the PARSEME (PARSing and Multi-word Expressions) orgnisation https://typo.uni-konstanz.de/parseme/ for open research of their shared task corpus. We thank anonymous reviewers for their valuable comments. This work has been partially supported by grant EP/V047949/1 "Integrating hospital outpatient letters into the healthcare data space" (funder: UKRI/EPSRC).

Abstract

Named Entity Recognition (NER) is a crucial task within natural language processing (NLP) that entails the identification and classification of entities such as person, organization and location. This study delves into NER specifically in the Arabic language, focusing on the Algerian dialect. While previous research in NER has primarily concentrated on Modern Standard Arabic (MSA), the advent of social media has prompted a need to address the variations found in different Arabic dialects. Moreover, given the notable achievements of Large-scale pre-trained models (PTMs) based on the BERT architecture, this paper aims to evaluate Arabic pre-trained models using an Algerian dataset that covers different domains and writing styles. Additionally, an error analysis is conducted to identify PTMs' limitations, and an investigation is carried out to assess the performance of trained MSA models on the Algerian dialect. The experimental results and subsequent analysis shed light on the complexities of NER in Arabic, offering valuable insights for future research endeavors.

1 Introduction

The expression named entities recognition (NER) has been used for the first time at the 6th edition of the Message Understanding Conference (MUC) in November 1995 (Grishman and Sundheim, 1996). The task of NER consisted in using SGML markers to identify entities in texts (names of persons, organizations, or places), temporal expressions, and numerical expressions (”currency” or ”percentages”). Since then, NER has become a starting point and an important part of many applications in natural language processing (Ali et al., 2020), such as: Information Extraction (IE) (Kumar and Starly, 2022), Information Retrieval (IR) (Guo et al., 2009), Semantic Annotation (SA) (Li et al., 2022), Machine Translation (MT) (Babych and Hartley, 2003), Question Answering (QA) systems (Yadav and Bethard, 2018), Text Summarization (Aone, 1999) and Text Clustering (Nagrale et al., 2019).

The process of NER can be done according to three main approaches (Oudah and Shaalan, 2017) (Mansouri et al., 2008), (Gorinski et al., 2019): the symbolic or linguistic (rule-based) approach, where the main idea is to use linguistic knowledge (internal or external clues), dictionaries and gazetteers of proper names to establish a list of knowledge rules (called regular expressions or finite state transducers (Mesfar, 2007)). However, the principal inconvenience of this approach is that the rule-generation process is fastidious and time-consuming. The Machine Learning (ML) approach, is mainly based on a previously annotated corpus. where the recognition problem is converted into a classification problem and employs various ML models to solve it. A hybrid approach which combines the two previous approaches to boost the performance of the models developed have been tried as well.

In recent years, the deep learning approach has proven to be a very powerful for learning feature representations directly from datasets, achieving outstanding results. The approach can learn complex hidden representations without complex feature engineering and rich domain knowledge (Liu et al., 2022).

While the task for Latin scripted language is more advanced (Zhou and Chen, 2021), having features like capitalization gives a clue and differentiates between named entities and other words. Such feature is absent in languages like Arabic. The additional complexity of the task comes from the dialectal variations of Arabic.

In the literature, most of the works on NER in Arabic have been oriented towards the common version MSA, a variant that is both normalized and standardized. However, with the emergence of so-

Proceedings of Recent Advances in Natural Language Processing, pages 458–467
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_051

cial media (Facebook, tweeter, Youtube,...etc.) as a means of communication and also as a source of information. A huge amount of raw data generated every day, which represents a goldmine for many applications in NLP. Therefore, the research on NER has been oriented towards these variants of the Arabic language.

Dialectal Arabic is another form of Arabic language used in everyday' communications, and is generally spoken and written (social networks, advertisements, SMS, etc.). It varies not only from one Arab country to another, but also from one region to another within the same country. Thus, almost all Arab countries have their own dialects. Arabic dialectology generally distinguishes two main areas or families of dialects (Saadane et al., 2018), (Embarki, 2008), (John and Na'ama, 2019):

- The Eastern zone (Mashreq): including Egypt, Syria, and other Middle Eastern countries (Iraq, the Gulf States, Yemen, Oman, Jordan, etc.).
- The Western zone (North Africa): the Maghreb: which includes Algeria, Morocco, Tunisia, Libya, and Mauritania.

Various other granular classification were proposed in literature classify the dialects into five or more variants, namely Gulf, Nile Basin, Levant and Maghreb (Zaidan and Callison-Burch, 2011; Habash, 2010; Abdelali et al., 2021b) to even city level (Bouamor et al., 2018).

The Algerian dialect, also known as Darija ("common language"), is spoken by 70% to 80% of the Algerian population (Saâdane, 2015) (of estimated 45 million people). When we speak about Algerian dialect, we must understand that it is a question of various sub-varieties of local dialect due to the geographical expansion of the country (2.382 million km²), because there is no unified Algerian dialect. There are therefore many varieties of Algerian dialect. It should be remembered that all these sub-varieties are heterogeneously influenced by other languages (e.g. Berber, French, Spanish, Turkish, Italian, etc.) (Harrat et al., 2016). Thus, we can distinguish Algiers dialect (mainly influenced by Berber and Turkish), Oranais dialect (influenced by Spanish), Constantinois dialect (influenced by Italian), Tlemçani dialect (influenced by Andalusian Arabic), etc.

In the context of NLP, the Algerian dialect constitutes a real challenge due to the multitude of constraints it presents, which are either inherited from standard Arabic, such as agglutination, and syntactic flexibility. Or they are due to the dialect itself, such as lack of normalization and standardization (it is common in Algerian dialect as the case of other dialects to find several orthographic transcriptions for the same), code-switching (a consequence of alternating two or more languages (or varieties of dialect) during the production of the same sentences or conversation). ARABIZI is a new spontaneous spelling variant of Algerian dialect, based particularly on Latin characters associated with numbers of special characters.

Such challenges motivated us to explore and focus more on this dialect in an attempt to investigate its particularities in the context of the new deep learning models. Our contributions in this paper can be summarized as follows:

- Answer the inquiry of whether training on the Modern Standard Arabic (MSA) corpus can yield favorable outcomes when testing on the Algerian dialect.
- Benchmark several Arabic pre-trained models and evaluated their performance on a publicly available Algerian dataset.
- Study the impact of using MSA dataset and its performance in reference to the Algerian dataset.
- Apply an error analysis on the best performing pre-trained model in order to figure the challenges and limitations of the model.

The remainder of this paper is organized as follows: the related work for NER in Arabic is presented in section 2. Section 3 gives some indications about Arabic pre-trained models. section 4 and 5 are devoted to experiments and results. The error analysis is described in section 6 and finally, conclusion and future works are presented in section 7.

2 Related Work

The first work on ANER was the TAGARAB system in 1998 (Maloney and Niv, 1998). Since then, many studies have followed covering different approaches: rule-based, machine learning or hybrid. In this section, we will divide the works into two categories: those on the Algerian dialect which are rare and the second category is the works on MSA adopting a Deep learning approach.

2.1 Algerian Dialect

According to our research, the problem with the Algerian dialect is the lack of resources to develop tools based on a machine learning or deep learning approach or even for evaluation (Harrat et al., 2014). For this reason, existing work in Algerian NER focuses more on building corpus (or dataset).

Touileb (2022), build NERDz, Algerian NER dataset. The corpus was an extension of NArabizi treebank (Touileb and Barnes, 2021), which contains initially 1500 sentences containing both Latin and Arabic characters (NERDz is a parallel corpus). statistically, NERDz contains 08 categories of entities, namely: PER for person name (467 entities); GPE for countries and cities (438 entities); ORG represents companies, organizations, and institutions (290 entities); NORP refers to nationalities, political beliefs, and religions (235 entities); EVT includes all types of cultural, political, and sports events (54 entities); LOC all geographical places (41 entities); PROD characterizes objects (23 entities); and MISC other entities with low occurrence in the dataset (18 entities). The author presented preliminary baseline results based on a neural architecture for NER that combines character-level CNN, word-level BiLSTM, and a CRF inference layer.

Adouane and Bernardy (2020), worked on a process that consists of mitigating the problem of the scarcity of labeled data for the Algerian dialect by the creation of a dataset for NER, and an investigation of the settings where it is beneficial to share representations learned between two or several tasks. For building the corpus, they used two corpus initially developed for Code-Switch Detection (CSD) (Adouane and Dobnik, 2017) and Sentiment Analysis (SA) (Adouane et al., 2020). The annotation was done manually by two native speakers, according to 06 predefined classes: person (PER), location (LOC), product (PRO), organization (ORG), and company (COM). They tagged the rest of named entity mentions like time and events as "other" (OTH) to distinguish them from non-named entities (OOO). In order to identify multi-word expressions as one named entity chunk, they use the IOB (Inside-Outside-Beginning) labeling scheme. For the Multi-task, the authors used an encoder-decoder architecture. However, here the encoders are shared between the tasks, while decoders are task-specific. For the experimentation, they proposed four scenarios, the first one NER alone (Macro F-score = 49.68%), the second one NER associated with CSD (Macro F-score = 48.65%), the third one NER associated with Spelling Normalisation and Correction (SPELL) (Macro F-score = 42.05%), and the fourth one NER associated with SA (Macro F-score = 34.60%).

Dahou and Cheragui (2022), studied the impact of normalization and data augmentation on Algerian NER task, using 05 Arabic pre-trained models ARBERT, Arabert v0.2, DziriBERT, MARBERT, and mBERT. For that, they built a corpus based on Facebook's comments, manually annotated according to 03 categories: person (578 entities), location (548 entities), and organization (186 entities). To evaluate the models, the authors set up 04 scenarios, the first one without normalization and data augmentation, in this case, the ARBERT model outperformed the other models with an F1 score of 84.4%. The second scenario is to use normalization, which enabled the DziriBERT model to get the highest F1 Score of 81.9%. The third scenario with data augmentation, where the Arabert v0.2 model yielded the best F1 score with 85.1%. The Arabert v0.2 model again obtained the best F1 Score with 86.2% in the last scenario combining normalization and data augmentation.

Dahou and Cheragui (2023a), presented DzNER, an Algerian dataset for NER, composed of more than 21,000 sentences (over 220,000 tokens) from Algerian Facebook pages and YouTube channels, the process of annotation is done manually by two professional annotators on the Algerian dialect, using the IOB2 scheme for three entities: PER which covers persons names, ORG that includes organizations, companies, institutions, political groups, and football clubs, and finally LOC that represents the geographical places. In order to evaluate the contribution and effectiveness of their corpus, the authors have carried out experiments to analyze the performance of pre-trained Arabic models which are: Arabert and DziriBERT. Where the training is done with DZNER and the test with NArabizi. The Arabert achieved a Macro F1 Score of 75.41% and DziriBERT obtained a Macro F1 Score of 74.69%.

(Dahou and Cheragui, 2023b) studied the impact of two phenomena, the first one was the segmentation and the second one was the use of Latin characters in the Algerian dialect. For this purpose, they pre-training 05 models: AraBERT, MARBERT, ARBERT, DziriBERT, and mBERT. For the experimentation, they use a novel annotated Algerian named entities recognition (DzNER) dataset. The results demonstrate that the ARBERT achieved the best results in Arabic characters with an F1 score of 0.819% on segmented dataset and 0.844% on unsegmented dataset, and the mBERT achieved the best results in Latin characters with an F1 score of 0.676

2.2 Modern Standard Arabic

Bazi and Laachfoubi (2019), introduced a neural network architecture based on bidirectional Long Short-Term Memory (LSTM) and Conditional Random Fields (CRF). The model gets two sources of information about words as input: pre-trained word embeddings and character-based representations and eliminated the need for any task-specific knowledge or feature engineering. For training and testing the authors used ANERcorp, their model achieved an F1 score of 90.6%.

Helwe and Elbassuoni (2019), adopted a semi-supervised co-training approach. Using of a small amount of labeled data, which is augmented with partially labeled data that is automatically generated from Wikipedia. The approach relies only on word embeddings as features and does not involve any additional feature engineering. For the test they used three different Arabic NER datasets: AQMAR, NEWS dataset, and TWEETS dataset, they obtained average F1 scores of 61.8%, 74.1%, and 59.2% respectively.

Ali and Tan (2019), employed a bidirectional encoder–decoder model for addressing the problem of ANER on the basis of recent work in deep learning, in which the encoder and decoder are bidirectional LSTMs. In addition to word-level embeddings, character-level embeddings are adopted, and they are combined via an embedding-level attention mechanism. The model can dynamically determine the information that must be utilized from a word - or character-level component through this attention mechanism. The authors run their experiments on the merged dataset (ANERcorp plus AQMAR). The model achieved a high F-score of 92, 01%.

Alkhatib and Shaalan (2020), proposed a hybrid mechanism based on a conventional neural network, followed by Bi-LSTM and CRF. The model was examined on ANERCorp and Kalimat Corpus. The overall results obtained for the categories: person, location, and organization, in terms of F-measure, are: 93.7%, 95.2%, and 95.3% respectively.

Al-Smadi et al. (2020), used a transfer learning with deep neural networks to build a Pooled-GRU model combined with the Multilingual Universal Sentence Encoder. The proposed model scored 90% with the F1 score, using WikiFANE Gold dataset.

Alsaaran and Alrabiah (2021), proposed a deep learning-based model by fine-tuning BERT model to recognize and classify Arabic-named entities. The pre-trained BERT context embeddings were used as input features to a Bidirectional Gated Recurrent Unit (BGRU) and were fine-tuned using two annotated ANER datasets. For the experimentation, they set up two scenarios, the first using ANERCorp dataset and obtained F1 score of 92.28%. The second merged ANERCorp and AQMAR dataset and achieved an F1 score of 90.68%,

Al-Qurishi and Souissi (2021), proposed an effective model for ANER. The architecture of this model consists of three layers: a transformer-based language model layer, a fully connected layer, and the last layer is a conditional random field(CRF). For the test, the model achieved an F1-macro score of 89.6% on the ANERCorp and 88.5% on the AQMAR datasets.

Boudjellal et al. (2021), presented ABioNER a BERT-based model to identify biomedical named entities in the Arabic text data (specifically disease and treatment named entities) that investigates the effectiveness of pretraining a monolingual BERT model with a small-scale biomedical dataset on enhancing the model understanding of Arabic biomedical text. The model performance was compared with two state-of-the-art models (AraBERT and multilingual BERT cased), and it outperformed both models with 85% F1 Score.

Shaker et al. (2023), proposed long short-term memory (LSTM) units and Gated Recurrent Units (GRU) for building the NER model in the Arabic language. For the experimentation, they built a new dataset in seven different fields (Geography, History, Medical, Sport, Technology, News, and Cooking). The entities' names were labeled in nine categories: Person (PER), Location (LOC), geopolitical (GEO), time (TIM), profession (PRO), organization (ORG), disease (DIS), geography (GEO), and miscellaneous (MISC). The tests show that the LSTM model achieved better accuracy than the GRU model, 80.24% and 77.78% respectively.

3 Arabic Pre-Trained Models

Pre-trained language models, including BERT (Devlin et al., 2018a) and RoBERTa (Liu et al., 2019), have demonstrated significant success across a wide range of NLP tasks in various languages. Arabic NLP has witnessed substantial advancements with the development of dedicated pre-trained language models, achieving state-of-the-art outcomes in both MSA and DA as shown in table 1. However, selecting the most suitable model is challenging due to differences in design decisions and hyperparameters, such as data size, language variant, tokenization, vocabulary size, and number of training steps. Despite fine-tuning being the common approach to choosing the best-performing pre-trained model for a specific task, the reasons behind the superior performance of one model over another and the impact of design choices remain unclear. This study aims to address this question specifically for the Arabic NER task. We selected the following models based on their popularity and coverage for both MSA and DA.

- **AraBERT** (Antoun et al., 2020) is a BERT pre-trained model was trained on around 77GB of Arabic text (8B words) that included Wikipedia Arabic dump, OSCAR corpus (Ortiz Suárez et al., 2020), OSIAN Corpus (Zeroual et al., 2019), Abu El-Khair Corpus (El-khair, 2016) and a large collection from Assafir newspaper articles.

- **MARBERT** (Abdul-Mageed et al., 2021) A large pre-trained model trained and released by the UBC NLP team. The model used a collection of over 1B tweets 128GB of text (15.6B tokens) in combination with 61GB of MSA text (6.5B tokens) from publicly available collections.

- **mBERT** (Devlin et al., 2018b) A Pre-trained model from Google that was built on Wikipedia top 104 languages using a masked language modeling (MLM) objective. Even though this model is not purely trained for Arabic. It's coverage for Arabic is decent as it ranks on the top languages.

- **QARiB** (Abdelali et al., 2021a) The model was pre-trained on Arabic Gigaword Fourth Edition, Abu El-Khair Corpus (El-khair, 2016), Open Subtitles (Lison and Tiedemann, 2016) in addition to 440M unique tweets. This made a total of 14B tokens.

Model	Params	N. Words	Vocab. size
AraBERT	136M	8.6B	64K
MARBERT	163M	6.2B	100k
mBERT	110M	1.5B	106k
QARiB	110M	14B	64k

Table 1: The selected Arabic pre-trained models.

To evaluate the models listed in table 1, we conducted fine-tuning on our datasets and assessed their performance under various scenarios based on the proposed contributions in the introduction. The final architecture utilized consists of an Arabic pre-trained BERT model combined with a straightforward linear layer. Conceptually, the Arabic pre-trained model functions as an embedding layer. We simply augment this with a linear layer to predict the tag for each token in the input sequence. All inputs are simultaneously processed by the pre-trained model, generating individual embeddings for each token. These embeddings are contextually influenced by the other tokens within the sequence, resulting in contextualized embeddings. Subsequently, we passed the output of the pre-trained model to the Linear layer. To predict NER tagging, such as identifying a person, organization, or location, we incorporated a softmax layer on top.

4 Experimental Setup

This section details the experimental setup used in our research. In our experiments, we investigated the performance and limitations of the Arabic pre-trained model in the NER task.

4.1 Dataset

We conducted experiments using two Arabic datasets: the DzNER corpus (Dahou and Cheragui, 2023a)[1], designed for the Algerian dialect NER task and encompassing various domains such as Sports, Travel, Electronics, and Politics. This corpus comprises 220k tokens with 18,387 entities annotated with organization (ORG), person (PER), and location (LOC) tags. The training set accounts for 80% of the total tokens, while the remaining portion is allocated for testing. For MSA NER, we utilized the ANERcorp dataset (Benajiba et al., 2007) using the splitting provided by CAMeL Lab

[1] DzNER Corpus in Github

(Obeid et al., 2020). ANERcorp consists of 316 articles selected from different newspapers to create a diverse corpus, totaling 150k tokens, with 11% of them representing named entities (NEs). The training split comprises 125,102 tokens, and the test split contains 25,008 tokens, all labeled with organization (ORG), person (PER), location (LOC), and miscellaneous (MISC) tags. In our study, we focused exclusively on the three primary entities: person, organization, and location. To accommodate ANERcorp, we replaced the MISC label with the label O. Figure 1 details the overall distribution of the entities in both datasets. Table **??** illustrates the distribution of entities in the training and testing splits for both datasets.

	DzNER		**ANERCorp**	
Entities	**Train**	**Test**	**Train**	**Test**
Person	6189	2204	2721	858
Location	5077	1315	3776	668
Organization	3740	1185	1576	450

Table 2: Statistics of the evaluation datasets.

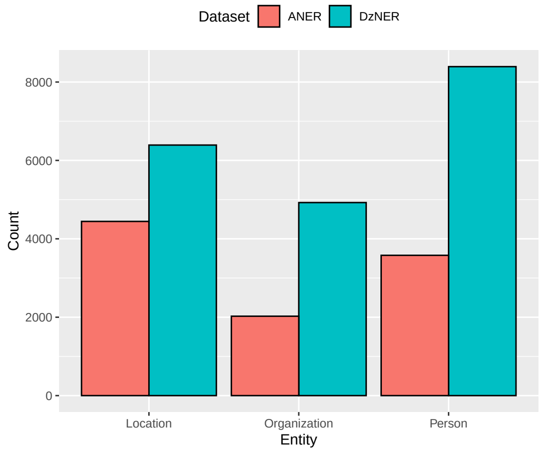

Figure 1: Distribution of NER categories in DzNER and ANERCorp.

4.2 Metrics

The metrics employed in this study include precision, recall, and F1-score. These metrics were selected to evaluate the model's performance in predicting the entity tag.
Precision gauges the ratio of true positives among the instances predicted as positive.

$$Precision = \frac{TP}{TP + FP} \tag{1}$$

Recall assesses the ratio of true positives correctly identified.

$$Recall = \frac{TP}{TP + FN} \tag{2}$$

The F1-score represents the harmonic mean of precision and recall. It provides a measure of the balance between precision and recall, with values ranging from 0 to 1. Higher values indicate superior performance.

$$F1 = \frac{2 \times (precision \times recall)}{precision + recall} \tag{3}$$

4.3 Hyper-parameters

The finetuning and testing processes took place on the Google Colab platform, making use of a Tesla P100 - 16GB GPU. To achieve superior results, we fine-tuned the hyper-parameters by leveraging the test subset of the DzNER dataset. We employed the Adam optimizer (Kingma and Ba, 2014), setting the learning rate to 5×10^{-5}, with a batch size of 16, and a seed of 42 for six epochs. Throughout all our experiments, we utilized the Huggingface Transformers library (Wolf et al., 2020).

5 Results and Discussion

We carried out a battery of experiments in the following order:

5.1 Evaluating DzNER Performance on ANERCorp

We finetuned the selected pre-trained models using the training part of ANERCorp and evaluated both test sets of ANERCorp and DzNER. Table **??** shows the results. It is clear that the DzNER did not perform well on the MSA content. This stress the challenges of dealing with dialectal content and how much models trained only on MSA will underperform, eventhough the original pre-trained models were already exposed to such dialectal content.

5.2 Evaluating ANERCorp Performance on DzNER

The objective of this experiment is to benchmark MSA dataset and its performance when evaluated on dialectal content. Despite that both are Arabic text, the lack of standard orthography and the extensive code-switching in the dialectal content present a major challenge as detailed in section 1. The results in Table **??** similarly to experiment 5.1; the finetuned models performed sub-optimally on the MSA dataset. It is worth to note that the numbers are slightly better than finetuning only on MSA. This indicate that the dialecatal content subsumes the MSA in such task. While most of the MSA features are captured in the dialectal dataset. Extensive code-switching and unstandarized writing is typically absent in MSA.

	ANER		DzNER	
Model	**ANER**	**DzNER**	**ANER**	**DzNER**
AraBERT	0.850	0.639	0.779	0.855
MARBERT	0.827	0.615	0.643	0.827
mBERT	0.776	0.372	0.545	0.790
QARiB	0.820	0.570	0.708	0.828

Table 3: Results of the evaluation cross-datasets using different pre-trained models using micro F1 score. The upper row represents the training data, and the second row represents the testing data.

5.3 Evaluation on Combined Data

Another set of experiments where we attempted to explore whether combining the datasets would have any impact or not on the evaluation. The goal is to see if the Algerian dialect will benifit from the existance of the MSA in the training data or the inverse. After combining both ANERCorp and DzNER training datasets, we evaluated the new finetined models using the test sets of ANERCorp and DzNER separately. Table ?? shows the results of the evaluation. It is clear that the differences are very marginal and not significant as shown in Figure 2. The results are a good indication that both datasets are disjoint and the features present in both are not redundant.

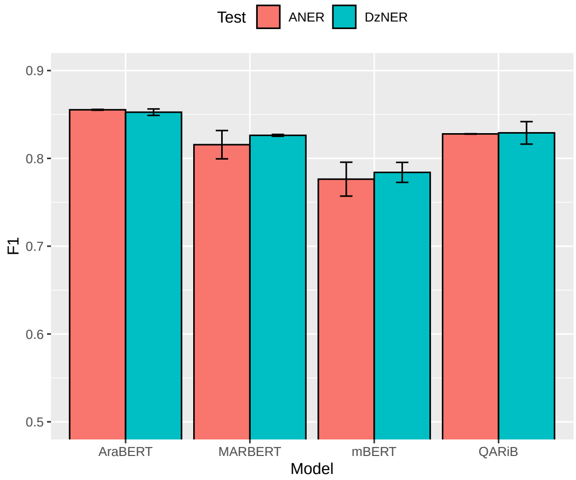

Figure 2: Performance of models per dataset.

Model	ANER	DzNER
AraBERT	0.8557	0.8552
MARBERT	0.8042	0.8255
mBERT	0.7627	0.7921
QARiB	0.8277	0.8381

Table 4: Results of the data combination using different pre-trained models using micro F1 score.

6 Error Analysis

For further investigation, we selected the best performing model AraBERT to probe and examine the shortfall of such class of models. For such task, we inspected the errors on DzNER. Figure 3 shows the confusion matrix for the results of evaluating DzNER on model finetuned with the training set from the same dataset. It is clear that the majority of the errors are caused by not detecting PERS, ORG and LOC respectively on the order of error severity. Looking deeper into the issue, we selected 100 samples among the errors resulted from the classification. We noted that the bulk of these errors are caused by lack of spelling standards such as the case of “ الموووغريب، العرق، بانقلاداش “ which are misspellings for “المغرب، العراق، بنغلاديش ” respectively. Such cases represents over 13% of the errors. While another large set of errors are caused by transliteration, this is mostly when using foreign or entities in another language but transcribing them in Arabic. Cases such as “ڨوقل، الجيري، لألجي “ that represents “ Google, Alger, Algerie “ respectively. Such category of errors represent another 21% among the errors. Errors such missing capitalization in Latin transcribed entities is very common as well. This is the case for “bougara, paris, and zanzibar” that supposed to be transcribed with capitals as “ Bougara, Paris, Zanzibar “. Such issues highlight the challenges dealing with dialectal content that is present in this dataset and similar ones.

7 Conclusion

In this study, we conducted a series of experiments to investigate NER performance in the context of Arabic, with a specific focus on the Algerian dialect. Our findings shed light on the challenges and limitations of existing Arabic pre-trained models trained on MSA and DA when applied to dialectal content. The experiments comparing the performance of ANERCorp on DzNER and vice versa revealed the difficulties posed by the lack of stan-

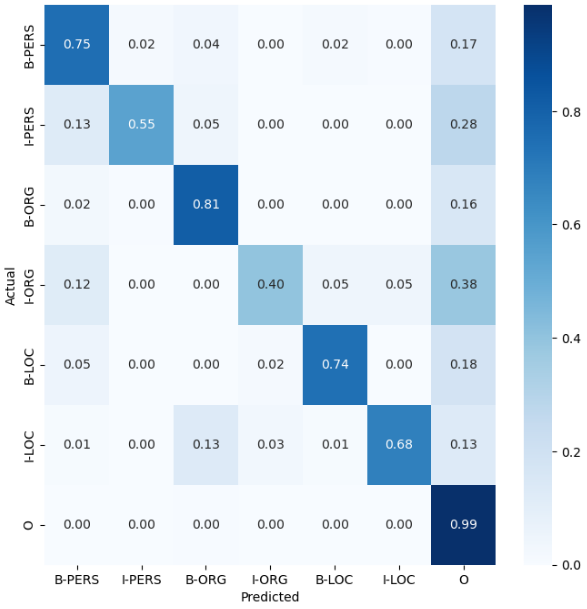

Figure 3: Confusion matrix for the results of evaluating DzNER on AraBERT model finetuned with DzNER train set.

dardized orthography and extensive code-switching in dialectal content. While the fine tuned models showed slightly improved results on the MSA dataset, the dialectal content encompassed MSA features, highlighting the dominance of dialectal data in this task. The combination of the ANERCorp and DzNER datasets did not significantly impact the evaluation results, indicating that the datasets offer non-redundant features and are disjoint from each other. The error analysis, conducted using the best performing model AraBERT, identified common sources of errors in dialectal content, such as spelling variations, transliteration issues, and missing capitalization in latin transcribed entities. These findings emphasize the challenges associated with dialectal content and the need to address spelling variations and non-standardized writing in dialectal Arabic. Future research will focus on: (i) refining NER models to better handle dialectal Arabic; (ii) explore strategies to expand these resources and improve performance in dialectal contexts; and (iii) investigate joint training NER with other auxiliary tasks such as part of speech tagging. Both tasks can mutually benefit from each other and share useful knowledge.

Abstract

In this paper, we investigate the relationship between the use of discourse relations and the CEFR-level of argumentative English learner essays. Using both the Rhetorical Structure Theory (RST) and the Penn Discourse TreeBank (PDTB) frameworks, we analyze essays from The International Corpus Network of Asian Learners (ICNALE), and the Corpus and Repository of Writing (CROW). Results show that the use of the RST relations of EXPLANATION and BACKGROUND, as well as the first-level PDTB sense of CONTINGENCY, are influenced by the English proficiency level of the writer.

1 Introduction

In a world where over 7,000 languages are used, much research has focused on improving methods to teach and learn natural languages. In particular, the field of Natural Language Processing (NLP) has a long history of developing tools to assist language learners and reduce learning barriers. Previous works on surface linguistic features and language learning, such as Webber (2009), Bachand et al. (2014), and Abdalla et al. (2018) have shown significant difference in discourse usage across textual genre and simplicity level. To our knowledge, very few studies have investigated the relationship between discourse structures and language learning.

Corpus research on the use of discourse structures among different CEFR levels can provide valuable insights into how well language learners are able to organize and convey their ideas in written or spoken language. Such an analysis can also identify common patterns of language use that are particularly challenging for learners at different CEFR levels, leading to the development of more effective teaching materials and strategies that target learners' specific needs (Aoyama, 2022), while simultaneously reducing the workload of human graders (Mieskes and Padó, 2018). Findings can also inform the development of more reliable assessment tools that accurately measure learners' proficiency in the use of discourse structures. Accurate assessment is essential for learners to identify their strengths and weaknesses and make informed decisions about their language learning goals and strategies.

In this paper, we investigate the usage of discourse relations using the Rhetorical Structure Theory (Mann and Thompson, 1988) and the Penn Discourse TreeBank (Prasad et al., 2008) frameworks to discover trends in their usage in argumentative English learners across various proficiency levels. Results show that the RST relations of EXPLANATION and BACKGROUND are statistically used more often by writers with a lower CEFR language level, and the use of the PDTB relation of CONTINGENCY decreases as CEFR level increases.

2 Background

2.1 Discourse Analysis Frameworks

In order to analyze the discourse structure of texts computationally, two main frameworks have been developed: Rhetorical Structure Theory (RST), proposed by Mann and Thompson (1988) and Discourse Lexicalized Tree-Adjoining Grammar (Webber and Joshi, 1998), the basis for the Penn Discourse TreeBank (PDTB) (Prasad et al., 2008).

RST describes a text in terms of a tree structure, where leafs are textual units, known as *Elementary Discourse Units* (EDUs). EDUs are the minimal unit of discourse, and are linked to one another to form nodes corresponding to contiguous text spans. The tree describes how each node is related to another via a discourse rela-

Proceedings of Recent Advances in Natural Language Processing, pages 468–474
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_052

tion. Several RST parsers have been developed (e.g. (Heilman and Sagae, 2015) and (Wang et al., 2017)) using the annotated RST-DT dataset (Carlson et al., 2001). The RST-DT uses an inventory of 78 relations organized into 16 major relation groups, namely ATTRIBUTION, BACKGROUND, CAUSE, COMPARISON, CONDITION, CONTRAST, ELABORATION, EVALUATION, ENABLEMENT, EXPLANATION, JOINT, MANNER-MEANS, SUMMARY, TOPIC-COMMENT, TOPIC-CHANGE, and TEMPORAL.

The other main discourse framework is the Penn Discourse TreeBank (PDTB). Three versions of the PDTB have been developed: PDTB-1.0 (Prasad et al., 2006), PDTB-2.0 (Prasad et al., 2008), and PDTB-3.0 (Prasad et al., 2019). We used the PDTB-2.0, as most work has been done with this version and several freely available parsers have been developed (e.g. (Lin et al., 2014; Wang and Lan, 2015)). Unlike RST, the PDTB-2.0 organizes discourse relations (called *senses*) into a 3-tier hierarchy. Four top-level discourse relations (CONTINGENCY[1], EXPANSION, COMPARISON, and TEMPORAL) are further split into second-level and third-level relations.

An important difference between the RST and PDTB frameworks is that RST segments are non-overlapping and cover the entire text as a tree-structure, with every pair of segments assigned an RST relation. On the other hand, PDTB parsing forms a flat structure that links adjacent texts segments (called *arguments*) which may contain segments that overlap. Though the frameworks differ in their structure and inventory of relations, works such as (Demberg et al., 2017) have provided guidelines to compare them.

2.2 Language Proficiency Levels

To assess language proficiency, several measures have been developed. In particular, the Common European Framework of Reference for Languages (CEFR), and the Test of English as a Foreign Language (TOEFL).

CEFR defines six proficiency reference levels: A1, A2, B1, B2, C1, and C2, which represent a progression from basic understanding of a language (A1) to full fluency (C2). Each level of the CEFR provides a general description of what a learner should be able to accomplish to achieve that level, in terms of writing, reading, speaking, and listening proficiency. The TOEFL score, meanwhile, is given to a language learner as a result of taking an official test in English. The test consists of four sections, one of which involves writing an essay based on a reading passage, or based on opinions and personal experiences. A score between 0 (low proficiency) and 120 (full fluency) is given.

The CEFR and TOEFL levels have become standards to evaluate English proficiency, and several datasets of texts have been labelled with these measures. To facilitate their interoperability, in 2010, the Educational Testing Service (ETS) proposed a metric[2] for mapping TOEFL scores directly to CEFR levels.

3 Previous Work

3.1 Discourse Features Across Texts

Differences of discourse structures have been analyzed computationally across textual genres, text complexity, and cognitive abilities.

Webber (2009) and Bachand et al. (2014) showed that the genre of a text influences the choice of discourse relations. Bachand et al. (2014) used articles of various genres to look for common patterns of relations. The researchers observed, for example, that the RST relation of ATTRIBUTION is common in the newspaper article genre, JOINT is comparatively more frequent in online reviews, and TEMPORAL is more frequent in academic paper methodology sections.

Davoodi (2017) evaluated the usefulness of both RST and PDTB relations as features to measure text complexity, and explore how the complexity level of a text influences its discourse-level linguistic choices. It was found, in the case of discourse relations, that there is no statistical difference in their explicit usage across levels of complexity, and that using discourse relations as features for classifying texts based on their complexity did not lead to better performance than the use of other linguistic features. However, the text complexity was shown to influence the usage of discourse connectives (e.g. *but, because*).

Abdalla et al. (2018) identified changes in the usage of discourse relations among patients with Alzheimer's disease. They used the RST parser

[1] For sake of readability, RST relations are indicated in SMALL CAPS; while PDTB relations are in CAPITAL letters.

of Feng and Hirst (2014) to analyze written material by patients with Alzheimer's, from the DementiaBank (MacWhinney et al., 2011) and CCC (Pope and Davis, 2011) datasets, which contain material from patients with Alzheimer's and a control group. Results showed that these two groups displayed a significant increase in ATTRIBUTION relations and a decrease in ELABORATION relations among writers with Alzheimer's disease. To our knowledge, our work is the first to analyze differences in discourse structures across language proficiency levels.

4 Datasets

In order to analyze discourse structures across CEFR levels, we aimed for texts long enough to have rich discourse structures. We used two datasets of argumentative essays: ICNALE (Ishikawa, 2013) and CROW (Staples and Dilger, 2018). We did not use the datasets of Schmalz and Brutti (December 2021) (see Section 3) as these largely consist of short 2-3 sentence texts.

The first dataset we used was the International Corpus Network of Asian Learners (ICNALE) (Ishikawa, 2013). The ICNALE dataset used the ETS mapping (see Section 2.2) to convert TOEFL scores into CEFR scores. The dataset contains essays from 5 CEFR levels: A2, B1.1, B1.2, B2, and C2. In order to be compatible with the second dataset, we merged B1.1 and B1.2 instances to create a single B1 label.

The second dataset we used was the Corpus and Repository of Writing (CROW) (Staples and Dilger, 2018). For the sake of consistency in genre, we only used the argumentative papers from this dataset for comparison with the ICNALE dataset. The CROW dataset is not labelled with CEFR scores, but rather with TOEFL scores. For comparative purposes, we used the ETS mapping on the CROW dataset to determine the CEFR score.

Table 1 shows statistics of both datasets. As the table shows, ICNALE is significantly larger than CROW (5600 essays compared to 1429). However, the essays in CROW are longer with a word-per-essay average of 1057 words vs 231. In addition, as shown in Table 1, the datasets do not contain samples of A1 and C1 CEFR levels, and are not balanced across levels.

5 Discourse Analysis

In order to extract reliable discourse information from the datasets, we used two publicly-available discourse parsers from each framework. For RST, we used the Wang et al. (2017) and the Heilman and Sagae (2015) parsers. We chose these parsers because they use the same set of RST relations, and they achieve high performance for relation tagging. Heilman and Sagae (2015) achieves an F-score of 57.4% on the RST-DT test set, Wang et al. (2017) achieves 59.7%, while human performance is 65.8% (Wang et al., 2017). For PDTB parsing, we used the (Lin et al., 2014) and the (Wang and Lan, 2015) parsers due to their high performance and availability.

We parsed the ICNALE and the CROW datasets (see Section 4) with all four parsers using all 16 RST relations and the 4 level-1 PDTB relations. The outputs of both RST parsers and both PDTB parsers were then compared. In order to have significant statistics, we ignored any discourse relation that appeared in less than 10% of the documents. These included the RST relations of Evaluation, Summary, Topic-Comment and Topic-Change. This left us with the 12 most frequent relations: Attribution, Background, Contrast, Cause, Comparison, Condition, Elaboration, Enablement, Explanation, Joint, Manner-Means, and Temporal. All PDTB level 1 relations appeared in more than 10% of the documents, hence all were considered.

We computed the average frequency of each RST and level 1 PDTB relation for each CEFR label in the dataset: A2, B1, B2, and C2. To determine if there was a statistical difference in the usage of these relations across CEFR levels, we ran a two-tailed t-test with a p-value of 0.95, comparing A2 against C2, B1 against C2, and B2 against C2.

5.1 RST Parser Agreement

Given that each RST parser can make segmentation and labelling errors, we computed their agreement across the two datasets. Much research has addressed the alignment of RST and PDTB annotations (Demberg et al., 2017), but even between two RST parsers with the same labels, computing their agreement on the same dataset can be a difficult task, as the tree structures may not match. To align the annotations, we used the following method. Given 2 EDUs from each parser, $\mathrm{EDU}_{\mathrm{p1}}$ and $\mathrm{EDU}_{\mathrm{p2}}$:

Segment Alignment:

If $\mathrm{EDU}_{\mathrm{p1}}$ and $\mathrm{EDU}_{\mathrm{p2}}$ span the same text (sans punctuation), we align them and keep the pair ($\mathrm{EDU}_{\mathrm{p1}}$, $\mathrm{EDU}_{\mathrm{p2}}$) along with their associated discourse annotations for relation agreement. This case alone led to an inter-parser agreement of over 95%.

Relation Alignment:

1. For each $\mathrm{EDU}_{\mathrm{p}i}$ in the aligned ($\mathrm{EDU}_{\mathrm{p1}}$, $\mathrm{EDU}_{\mathrm{p2}}$),
   - If $\mathrm{EDU}_{\mathrm{p}i}$ was labelled as a satellite by parser pi, or as the second half of a multi-nucleic relation, it is then labelled with its lowest-level discourse relation (see EDUs A and C in Figure 1).
   - Otherwise, if $\mathrm{EDU}_{\mathrm{p}i}$ was labelled as a nucleus by parser pi, it is not assigned a relation.

   For each EDU,

   - If BOTH parsers label the EDU as a satellite, and they have the same relation, mark them as an agreement.
   - If BOTH parsers label the EDU as a satellite, and they have a different relation, mark them as a disagreement.
   - Otherwise, if one or both parsers label the EDU as a nucleus, the EDU is ignored, since its relation has already been considered through its satellite.

Using this method, we were able to verify the agreement between the two parsers on the 11 satellite-nucleus RST relations. The RST relation of JOINT is multi-nucleic, and not considered in the approach. The two parsers on the ICNALE dataset showed an agreement of 80.10% on relation tags, with the full results shown in Table 2.

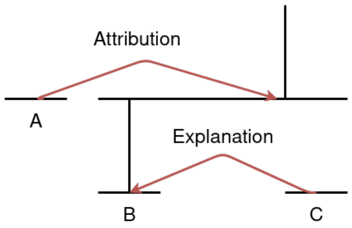

Figure 1: Example RST tree. In our method, satellite A would be labelled ATTRIBUTION, while satellite C would be labelled ELABORATION. Satellite B, as a nucleus, would not receive a label.

As the results show, the parsers disagreed most frequently on CAUSE relations, frequently mislabelling these relations as EXPLANATION. ENABLEMENT relations were also frequently mislabelled as ELABORATION by both parsers. For the following analysis, only the EDUs with an agreed-upon relation between the two parsers were used.

5.2 RST Relations Across CEFR Levels

While many RST relations showed some statistical differences between learner and native speaker essays, only two of the twelve showed the same patterns across the two datasets. For the relation of EXPLANATION, both parsers and both datasets showed a statistical difference in A2 vs C2 and B1 vs C2, but no statistical difference between B2 and C2. The data, shown in Table 3, suggests a general downward trend in the usage of EXPLANATION relations, which flattens out as the learner reaches the B2 level. Intuitively, individuals with lower CEFR levels may have a more limited vocabulary and understanding of complex sentence structures, which can make it more difficult for them to express themselves in a clear and concise way. As a result, they may rely more heavily on the RST relation of EXPLANATION to clarify their meaning and provide additional detail to support their arguments or ideas, or to explain concepts they can not recall the terms for.

For the RST relation of BACKGROUND, both parsers and both datasets show a statistical difference in B1 vs C2 and B2 vs C2, but no statistical difference between A2 and C2. Table 3 suggests that newer learners use BACKGROUND relations at a similar rate to native English speakers (C2), whereas B-level learners show an increase in these relations. The RST relation of BACKGROUND is used to provide information that is important to understanding the main idea or topic of a text. En-

glish language learners may rely more heavily on BACKGROUND to provide necessary context and establish the main topic or theme of their writing. However, A2 level English learners may not have the language skills necessary to effectively attribute a background to the points they are attempting to convey.

Table 3 shows that JOINT relations have an increased usage at the C2 level, while CONTRAST relations have a decreased usage at the C2 level. However, for these relations, the trend in usage among language learners varies.

5.3 PDTB Relations Across CEFR Levels

The relation frequencies of the Lin et al. (2014) and the Wang and Lan (2015) parsers were averaged together. As shown in Table 4, none of the level-1 PDTB relations showed a statistically different usage across CEFR levels that agreed across both datasets. C2-level users use the relation of CONTINGENCY less frequently than lower-level learners, but the trends among learners are not consistent.

5.4 Cross-Framework Results

To compare the usage of discourse relations across frameworks, we used the relation mapping proposed by Demberg et al. (2017). The mapping, shown in Table 5, proposes to map PDTB level 1 relations to RST relations.

Using the Demberg et al. (2017) cross-framework mapping, the PDTB relation of CONTINGENCY showed an interesting comparison with the RST relations of CAUSE+CONDITION+EXPLANATION. Figure 2 compares the percentage of CONTINGENCY (the average of the two PDTB parsers) to the percentage of CAUSE+CONDITION+EXPLANATION (the agreement of the 2 RST parsers) on the ICNALE dataset. The mapping agrees with the pattern that emerges, in which A2 and B1-labelled texts show a statistically significant difference in frequency with C2 essays, whereas B2 essays do not.

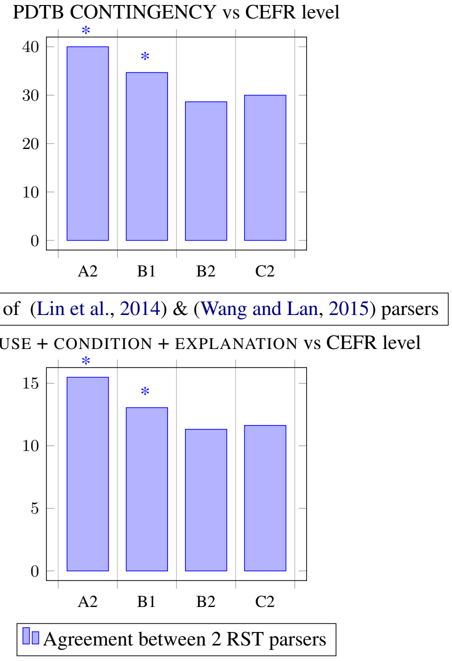

Figure 2: Percentage of CONTINGENCY across frameworks in the ICNALE dataset. The top graph shows the frequency of the level 1 relation CONTINGENCY. The bottom graph shows the average frequency of CAUSE+CONDITION+EXPLANATION. "*" indicates a statistically significant difference with C2 essays.

6 Conclusion and Future Work

In this paper, we investigated the use of discourse information in essays across language proficiency levels. A corpus analysis with state-of-the-art RST and PDTB parsers showed a relation between learner CEFR level and the RST relations of EXPLANATION and BACKGROUND. Using the mapping of PDTB and RST proposed by (Demberg et al., 2017), we showed a decrease in use of CONTINGENCY relations in one dataset at the C2 level.

While discourse relations frequency would not be the sole factor for automatic CEFR assessment tools, the findings of this analysis could serve as a feature for improving the accuracy of these classifications.

Future work could look for differences in discourse relations based on the first language of the English learner, while accounting for the learner's CEFR level. The corpora used in this study provide the native language or country of origin of the learner. Previous work has begun mapping PDTB-3.0 (Prasad et al., 2019) relations to RST relations, such as (Costa et al., 2023), so future work could use inter-framework mapping with the updated PDTB. Finally, future research could expand its focus beyond discourse analysis in argumentative texts and delve into discourse structures across various text genres, including narratives, academic papers, and conversational dialogues. Notably, recent work has explored this avenue in the realm of spontaneous spoken dialogue (López Cortez and Jacobs, 2023). By extending the examination of discourse relations and connectives to diverse genres, a more comprehensive understanding of language learning can be achieved, shedding light on genre-specific discourse patterns.

Reproducibility

Work for this research included the usage of Python and a CoreNLP[3] server. Our code and a detailed description can be found on GitHub[4].

Improving Translation Quality for Low-Resource Inuktitut with Various Preprocessing Techniques

Mathias Hans Erik Stenlund, Matilde Nanni, Micaella Bruton, Meriem Beloucif
Uppsala University
meriem.beloucif@lingfil.uu.se

Abstract

Neural machine translation has been shown to outperform all other machine translation paradigms when trained in a high-resource setting. However, it still performs poorly when dealing with low-resource languages, for which parallel data for training is scarce. This is especially the case for morphologically complex languages such as Turkish, Tamil, Uyghur, etc. In this paper, we investigate various preprocessing methods for Inuktitut, a low-resource indigenous language from North America, without a morphological analyzer. On both the original and romanized scripts, we test various preprocessing techniques such as Byte-Pair Encoding, random stemming, and data augmentation using Hungarian for the Inuktitut-to-English translation task. We found that there are benefits to retaining the original script as it helps to achieve higher BLEU scores than the romanized models.

1 Introduction

While state-of-the-art Machine Translation (MT) systems are achieving close to human-like translations on a restricted set of highly researched languages (Luong et al., 2015; Sennrich et al., 2015; Luong and Manning, 2016; Neubig, 2015; Cho et al., 2014; Luong et al., 2017; Vaswani et al., 2017), they fail to obtain equally good results on languages for which there is a lack of resources (Haddow et al., 2022). In fact, these end-to-end neural encoder-decoder MT systems are quite data hungry, requiring parallel datasets in the tens or even hundreds of millions of sentences to outperform statistical models; datasets which are only available for a few of the spoken languages of the world (Ranathunga et al., 2021). The unavailability of parallel data for most world languages is only the tip of the iceberg because, even when there is data available, the data can be very domain-specific and contain a lot of noise (Haddow et al., 2022). Ranathunga et al. (2021) and Haddow et al. (2022) provide an overview of current research methods tackling low-resource MT, by addressing different aspects and problems. The data and tools scarcity problem in NLP creates the need to simulate low-resource scenarios by taking a small sample of data from a high-resource language so that currently existing tools can be easily tested in low-resource settings (Haddow et al., 2022). The lack of suitable preprocessing tools hinders research on these languages (Haddow et al., 2022). When available, linguistic tools, such as morphological segmentation, are paramount for preprocessing the data and obtaining subword segmentation, to better deal with out-of-vocabulary words; the most common strategies include BPE and SentencePiece (Haddow et al., 2022).

In this paper, we tackle the issue of preprocessing and its effect on translation quality when dealing with a highly agglutinative and morphologically complex low-resource language, Inuktitut. Our goal is to test several preprocessing techniques to determine which yields the best MT results for Inuktitut-English. We experiment with Byte-Pair Encoding (BPE) and Random Stemming, on both the romanized and the original Inuktitut scripts. We also incorporate Hungarian data into training, to determine if additional in-domain data from another language would help increase the translation quality.

2 Related Works

2.1 The Inuktitut Language

One of the many indigenous languages spoken throughout North America, Inuktitut has 33,790 speakers according to the 2021 Canadian census (Government of Canada, 2022). It is one of the official languages of the Canadian province Nunavut, where it is spoken by nearly 60% of the population and used in an official capacity, both in schools and legislative assemblies (Tulloch et al., 2017; Govern-

Proceedings of Recent Advances in Natural Language Processing, pages 475–479
Varna, Sep 4–6, 2023
https://doi.org/10.26615/978-954-452-092-2_053

ment of Nunavut). It is an agglutinative language with a rich morphological system.

A single Inuktitut word could be translated into an entire English sentence as in the case of "ᖃᖓᑕᓲᒃᑯᕕᒻᒨᕆᐊᖃᓛᖅᑐᖓ" [romanized: qangatasuukkuvimmuuriaqalaaqtunga, morphological breakdown: qangata-suu-kku-vim-mu-u-ria-qa-laaq-tunga] meaning "I'll have to go to the airport" (Dench et al., 2011). Written Inuktitut utilizes an adapted version of the Cree syllabary known as Inuktitut Syllabics, an abugida writing system where consonant-vowel pairs are written as a collective unit, with the main consonant letter adapting to the currently attached vowel through movement or additional notation (Government of Nunavut). Romanized orthography of Inuktitut is also available through the use of Qaliujaaqpait (Government of Nunavut).

2.2 NLP for the Inuktitut Language

Low-resource MT of Inuktitut saw a rise in popularity in 2020 when the 3.0 version of the Nunavut Hansard Inuktitut-English parallel Corpus was released (Joanis et al., 2020). Most studies opt for the transliteration of the original Inuktitut script and apply morphological preprocessing on the romanized version of the dataset; one exception is the work by Joanis et al. (2020), who conduct experiments on both the original and the romanized script.

When it comes to MT translation of Inuktitut, the main issue is breaking down words into morphemes. Micher (2018) proposes to combine the UQA·ILA·UT analyzer developed at the Institute for Information Technology within the National Research Council of Canada (Farley), with a segmental recurrent neural network (SRNN) to expand morphological preprocessing coverage of the corpus. They point out that the UQA·ILA·UT analyzer cannot analyze 30% of the types from the corpus so he trains an SRNN model to identify the unrecognized morphemes (Micher, 2018). Joanis et al. (2020) use the same morphological preprocessing as Micher (2018) but they also take an alternative approach and simulate stemming, by choosing prefixes of three characters for Inuktitut words and five characters for English words (Joanis et al., 2020).Ngoc Le and Sadat (2020) build a deep learning-based word segmentation tool for Inuktitut, using a bidirectional long short-term memory neural network for word segmentation. Hernandez and Nguyen (2020) suggest a multilingual approach and train a transformer model on two additional agglutinative languages, Finnish and Estonian. Roest et al. (2020) test eight different segmentation techniques, including Rule-Based with UQA·ILA·UT, but they use a neural segmentation method built on a Transformer architecture instead of RNN. They also employ back-translated Inuktitut data, and additional data from a related language, Greenlandic (Roest et al., 2020), which had no positive effect.

3 Method

3.1 Corpora

In this paper, We use the Nunavut Hansard Inuktitut-English Parallel Corpus 3.0, as described in Joanis et al. (2020). The data consists of aligned sentences from proceedings of the Legislative Assembly of Nunavut. The Inuktitut syllabic data was romanized using a syllabic converter[1] to create a parallel romanized Inuktitut set. All in all, this amounts to a total of around 1.3 million aligned sentence pairs. The data, as provided by the National Research Council of Canada[2], is already divided into a train, dev, and test set for each language.

Although being a relatively large parallel corpus, the language follows mostly legislative assembly debates, which creates a lot of redundancies. For instance, the sentence "Thank you, Mr. Speaker" is found around 17,000 times throughout the entire corpora. Another sign of the debate-style type of language found in the corpus becomes evident as many sentences are very long, presumably due to the turn-taking nature of debates. The provided train, dev and test sets are also very messy in terms of special characters, such as parentheses, full stops etc., that appear in the middle of sentences, seemingly put there by the transcriber to clarify who's talking or where interpretations start and end. There are also many empty lines that divide the different speaker turns as well as many very short lines (1-3 tokens) of audio interpretation.

We use Hungarian data for data augmentation. The Hungarian data is taken from the Hungarian to English EUROPARL parallel corpus v.7[3]. The main advantage of using this data in combination with the aforementioned Inuktitut data is that it is also derived from a similar domain, namely proceedings, and hence follows a similar debate-like

[1] https://www.syllabics.net/convert/inuktitut
[2] https://nrc-digital-repository.canada.ca
[3] https://www.statmt.org/europarl/

type of language. The data also happens to be very clean in terms of special characters littering the sentences and it is free of empty lines.

3.2 General Preprocessing

The data was stripped of special characters as the sheer number of them and their appearances in many sentences were deemed too noisy for training. A selected few sentences and phrases that were very common were also removed. Post-preprocessing the total number of lines in the Inuktitut-English corpus had been reduced to 661,263, which is approximately 26% of the original 2,575,449 lines. Many of these lines were, however, completely empty in the beginning. The full data split post-cleaning is presented in Table 1.

	train	**dev**	**test**	**total**
iu-en	655 765	2 422	3 076	661 263
hun-en	525 725	N/A	N/A	525 725

Table 1: Data split in sentence pairs.

We then used both Byte-Pair Encoding encoding and stemming simulation as segmentation tools. All the experiments were run using default OpenNMT-py parameters to create the vocabularies and to train the model.

3.3 Random stemming

Random stemming is a technique employed to approximate the retrieval of word stems, or root forms, by eliminating part of a word (Dolamic and Savoy, 2008). Stemming can be systematic when consisting of removing inflectional and derivative suffixes, or random, in the event that the suffixes are unknown (Dolamic and Savoy, 2008). In the latter case, one can decide on a set number of characters to approximate stems, 3 and 5 for Inuktitut and English respectively, in Joanis et al. (2020).

4 Experiments

4.1 Baseline

Our core baseline model in the experiments below is based on the Transformer architecture (Vaswani et al., 2017) trained on the iu-en parallel data. The latter, currently the *de facto* standard baseline in NMT, relies on the concept of self-attention, i.e., the ability to learn attending to different positions of the input sequence to compute a representation of that sequence. Another experiment was conducted using OpenNMT-py BPE-tokenizer with 12,000 merge operations, following the preprocessing steps taken by Hernandez and Nguyen (2020) of the same data. They mention that using a fewer number of merge operations for agglutinative languages might be beneficial for MT. For the BPE + Hu experiment, Hungarian data was added when training the model, using the OpenNMT weighting mechanism, to train on batches of training data from different languages. The Inuktitut corpus was given the weight of 8, while the Hungarian corpus was given the weight of 2.

4.2 Random Stemming Experiments

As an alternative to BPE encoding, stemming simulation was also applied, based on previous experiments by Joanis et al. (2020). We start by simulating Inuktitut prefixes, by truncating words at the third character, and English prefixes, by truncating words at the fifth character. Subsequently, a second experiment was conducted where only Inuktitut was preprocessed to simulate stemming and English was left untouched. Inuktitut words were stemmed randomly so that in the end the corpus was composed of stems ranging from two to six characters.

5 Results

We use BLEU (Papineni et al., 2002) for evaluating our models. All the results from the experiments are presented in Table 2.

	Inuktitut Script	Romanized
Baseline	11.3	13.0
Rand: Inuk	14.9	14.5
Rand: Iu_3, En_5	19.4	17.3
BPE	20.6	**20.3**
BPE + Hu	**21.0**	20.2

Table 2: BLEU scores of all experiments

The baseline model achieved a BLEU score of 11.3 on the Inuktitut script and 13.0 on the romanized script. The BPE-only model achieved the best BLEU score of all of the romanized experiments, with a score of 20.3, but was still outperformed by the model trained on the Inuktitut script, which achieved a BLEU score of 20.6. The BPE + Hungarian model achieved the best BLEU score overall, scoring 21.0 on the Inuktitut script. For both initial random stemming and Iu_3 , En_5 stemming experiments, models using the Inuktitut script per-

Reference: “I also encourage all Nunavummiut to remain vigilant in keeping our communities safe in both the physical and virtual worlds”

Figure 2: Model predictions with repetitions

formed best, achieving a BLEU score of 14.9 and 19.4 respectively.

6 Discussion

The overall lack of parallel data to be used during training led to a lack of varied language, resulting both in an abundance of unknown tokens and the repeated use of simplified words in final translations, as displayed in 1. For some translations, it seems as if the model is taking liberties with the original intent of the speaker. See Figure 1.

There are a few cases where the translation does not match the reference sentence, but it still infers a similar meaning, for instance, by congratulating the students in the first example and linking “graduating in the future” to “can look forward to greater opportunities” in the second. For this reason, having fluent human speakers rate final translations may be helpful for future experiments to determine the semantic intent of the original Inuktitut sentence and the differences in speaking these in the original language. The inclusion of the original script during training showed better results in certain contexts, which has often been ignored in other research.

6.1 BPE and Random Stemming

Though the BPE+Hu model outperformed all other models, it is unclear if this is due to the Hungarian data specifically, or more generally having more data due to the overall lack of Inuktitut-English parallel data. For future experiments, it is recommended that additional languages are researched to determine their effects, as well as the inclusion of additional Inuktitut data to provide a clear decision on this matter.

Though performance does not quite match BPE experiments, the Iu_3, En_5 model appears to have potential as a preprocessing method. Further research should be performed using varying stemming configurations to determine the full potential of the effects of random stemming, especially on non-romanized Inuktitut script. Also, stemming the romanized equivalent of the Inuktitut script at the third character might not be the best idea since each Inuktitut syllabic character is transcribed into either two, or even three romanized characters.

7 Conclusion

We show that using BPE and (random) stemming as preprocessing techniques improves the translation quality for Inuktitut when no morphological analyzer is available for the original Inuktitut script, which has not received much attention thus far. We also experiment with data augmentation using Hungarian, which yielded better translation quality on the Inuktitut-English translation task.

Abstract

Detecting the user's intent and finding the corresponding slots among the utterance's words are important tasks in natural language understanding. Their interconnected nature makes their joint modeling a standard part of training such models. Moreover, data scarceness and specialized vocabularies pose additional challenges. Recently, the advances in pre-trained language models, namely contextualized models such as ELMo and BERT have revolutionized the field by tapping the potential of training very large models with just a few steps of fine-tuning on a task-specific dataset. Here, we leverage such models, and we design a novel architecture on top of them. Moreover, we propose an intent pooling attention mechanism, and we reinforce the slot filling task by fusing intent distributions, word features, and token representations. The experimental results on standard datasets show that our model outperforms both the current non-BERT state of the art as well as stronger BERT-based baselines.

1 Introduction

With the proliferation of portable devices, smart speakers, and the evolution of personal assistants, such as Amazon Alexa, Apple Siri, Google Assistant, a need for better natural language understanding (NLU) has emerged. Moreover, many Web platforms and applications that interact with the users depend on the abilities of an internal NLU component, e.g., customer service with social media (Huang et al., 2021), in dialogue systems in general (Zeng et al., 2021), for web queries understanding (Tsur et al., 2016; Ye et al., 2016), and general understanding of natural language interaction (Vedula et al., 2020). The major challenges such systems face are *(i)* finding the intention behind the user's request, and *(ii)* gathering the necessary information to complete it via slot filling, while *(iii)* engaging in a dialogue with the user.

Intent	PlayMusic						
Words	play	music	from	2005	by	justin	broadrick
	↓	↓	↓	↓	↓	↓	↓
Slots	O	O	O	B-year	O	B-artist	I-artist

Table 1: Example from the SNIPS dataset with slots encoded in the BIO format. The utterance's intent is *PlayMusic*, and the given slots are *year* and *artist*.

Table 1 shows a user request collected from a personal voice assistant. Here, the intent is to *play music* by the artist *Justin Broadrick* from year *2005*. The slot filling task naturally arises as a sequence tagging task. Conventional neural network architectures, such as RNNs or CNNs are appealing approaches to tackle this problem. Various extensions thereof can be found in previous work (Xu and Sarikaya, 2013a; Goo et al., 2018; Hakkani-Tür et al., 2016; Liu and Lane, 2016; E et al., 2019; Gangadharaiah and Narayanaswamy, 2019). Moreover, sequence tagging approaches such as Maximum Entropy Markov model (MEMM) (Toutanvoa and Manning, 2000; McCallum et al., 2000) and Conditional Random Fields (CRF) (Lafferty et al., 2001; Jeong and Lee, 2008; Huang et al., 2015) have been added on top to enforce better modeling of the dependencies between the posteriors for the slot filling task. Recent work has introduced other methods such as hierarchical structured capsule networks (Xia et al., 2018; Zhang et al., 2019), and graph interactive networks (Qin et al., 2020).

In this work, we investigate the usefulness of pre-trained models for the Natural Language Understanding (NLU). Our approach is based on BERT (Devlin et al., 2019) and its successor RoBERTa (Liu et al., 2019). That model offer two main advantages over previous ones (Hakkani-Tür et al., 2016; Xu and Sarikaya, 2013a; Goo et al., 2018; Gangadharaiah and Narayanaswamy, 2019; Liu and Lane, 2016; E et al., 2019): (*i*) they are

(a) BERT-Joint.

(b) Transformer-NLU (ours).

Figure 1: Model architectures for joint learning of intent and slot filling: (a) classical joint learning with BERT/RoBERTa, and (b) proposed enhanced version of the model.

based on the Transformer architecture (Vaswani et al., 2017), which allows them to use bi-directional context when encoding the tokens instead of left-to-right (as in RNNs) or limited windows (as in CNNs), and (*ii*) the model is trained on huge unlabeled text collections, which allows it to leverage relations learned during pre-training, e.g., that *Justin Broadrick* is connected to music or that *San Francisco* is a city.

We further adapt the pre-trained models for the NLU tasks. For the intent, we introduce a pooling attention layer, which uses a weighted sum of the token representations from the last language modelling layer. Moreover, we reinforce the slot representation with the predicted intent distribution, and word features such as predicted word casing, and named entities. To demonstrate its effectiveness, we evaluate it on two publicly available datasets: ATIS (Hemphill et al., 1990) and SNIPS (Coucke et al., 2018).

Our contributions can be summarized as follows:

- We enrich a pre-trained language model, such as BERT or RoBERTa, to jointly solve the tasks of intent classification and slot filling.
- We introduce an additional pooling network from the intent classification task, allowing the model to obtain the hidden representation from the entire sequence.
- We use the predicted user intent as an explicit guide for the slot filling layer rather than just depending on the language model
- We reinforce the slot learning with features such as named entity and true casing.
- We present exhaustive analysis of the task-related knowledge in the pre-trained model, for both datasets.

2 Transformer-NLU

We propose a joint approach for intent classification and slot filling built on top of a pre-trained language model. We further improve the base model in three ways: (*i*) for intent detection, we obtain a pooled representation from the last hidden states for all tokens (Section 2.1), (*ii*) we obtain predictions for the word case and named entities for each token (word features), and (*iii*) we feed the predicted intent distribution vector, BERT's last hidden representations, and word features into a slot filling layer (see Section 2.2). The complete architecture of the model is shown in Figure 1b.

2.1 Intent Pooling Attention

Here, the task is to jointly learn the two strongly correlated tasks, i.e., intent detection and slot filling. Hereby, using the pooled representation from the [CLS] token can miss important information about the slots' tags when used as an input for predicting the users' intent. We hypothesise that using the token-level representation obtained from the last layer before the slot projection one can help the model in learning the intent detection task, as these representations contain important task-specific information.

Therefore, we introduce a pooling attention layer to better model the relationship between the task-specific representations for each token and for the intent. We further adopt a global concat attention (Luong et al., 2015) as a throughput mechanism. Namely, we learn an alignment function to predict the attention weights α_{int} for each token. We obtain the latter by multiplying the outputs from the language model $H \in \mathbb{R}^{N \times d_h}$ by a latent weight matrix $W_{int\_e} \in \mathbb{R}^{d_h \times d_h}$, where N is the number of tokens in an example and d_h is the hidden size of the Transformer. This is followed by a non-linear $tanh$ activation. In order to obtain importance logit for each token, we multiply the latter by a projection vector $v \in \mathbb{R}^{d_h}$ (shown in Eq. 1). We further normalize and scale (Vaswani et al., 2017) to obtain the attention weights.

$$\alpha_{int} = softmax(\frac{v \cdot \tanh(W_{int\_e} \cdot H^T)}{\sqrt{d_h}}) \quad (1)$$

$$h_{int} = tanh(\sum_{i=1}^{N} \alpha_{int}^i h_{enc}^i) \quad (2)$$

$$y_{int} = W_{int} h_{int}^T + b_{int} \quad (3)$$

Finally, we gather a hidden representation h_{int} as a weighted sum of all attention inputs, and we pass it through a $tanh$ activation (see Eq. 2). For the final prediction, we use a linear projection on top of h_{int}. We apply dropouts on h_{int}, and on the attention weights (Vaswani et al., 2017).

2.2 Slots Modeling

The task of slot filling is closely related to tasks such as part-of-speech (POS) tagging and named entity recognition (NER). Also, it can benefit from knowing the interesting entities in the text. Therefore, we reinforce the slot filling with tags found by a named entity recognizer (word features). Next, we combine the intent prediction, the language model's hidden representations, and some extracted word features into a single vector used for token slot attribution. Details about all components are discussed below.

Word Features A major shortcoming of having free-form text as an input is that it tends not to follow basic grammatical principles or style rules. The casing of words can also guide the models while filling the slots, i.e., upper-case words can refer to names or to abbreviations. Also, knowing the proper casing enabled the use of external NERs or other tools that depend on the text quality.

As a first step, we improve the text casing using a *TrueCase* model from CoreNLP. The model maps the words into the following classes: *UPPER, LOWER, INIT_UPPER, and O*, where *O* is for mixed-case words such as *McVey*. With the text re-cased, we further extract the named entities with a NER annotator. Named entities are recognized using a combination of three CRF sequence taggers trained on various corpora. Numerical entities are recognized using a rule-based system. Both the truecaser and the NER model are part of the Stanford CoreNLP toolkit (Manning et al., 2014).

Finally, we merge some entities ((job) title, ideology, criminal charge) into a special category *other* as they do not correlate directly to the domains of either dataset. Moreover, we add a custom regex-matching entry for *airport_code*, which are three-letter abbreviations of the airports. The latter is specially designed for the ATIS (Tur et al., 2010) dataset. While, marking the proper terms, some of the codes introduce noise, e.g., the proposition *for* could be marked as an *airport_code* because of *FOR (Aeroporto Internacional Pinto Martins, Fortaleza, CE, Brazil)*. In order to mitigate this effect, we do a lookup in a dictionary of English words, and if a match is found, we trigger the *O* class for the token.

In order to allow the network to learn better feature representations for the named entities and the casing, we pass them through a two-layer feed-forward network. The first layer is shown in Eq. 5 followed by a non-linear PReLU activation, where $W_w \in \mathbb{R}^{23 \times 32}$. The second one is a linear projection f_{words} (Eq. 6), where $W_{proj} \in \mathbb{R}^{32 \times 32}$.

$$s_w^i = W_w[ners; cases] + b_w \quad (4)$$

$$h_w^i = max(0, s_w^i) + \alpha * min(0, s_w^i) \quad (5)$$

$$f_{words}(ners, cases) = W_{proj} {h_w^i}^T + b_{proj} \quad (6)$$

Sub-word Alignment Modern NLP approaches suggest the use of sub-word units (Sennrich et al., 2016; Kudo and Richardson, 2018), which mitigate the effects of rare words, while preserving the efficiency of a full-word model. Although they are a flexible framework for tokenization, sub-word units require additional bookkeeping for the models in order to maintain the original alignment between words and their labels.

We first split the sentences into the original word-tag pairs, we then disassemble each one into word pieces (or BPE, in the case of RoBERTa). Next, the original slot tag is assigned to the first word piece, while each subsequent one is marked with a special tag (*X*). Still, the word features from the original token are copied to each unit. To align the predicted labels with the input tags, we keep a binary vector for the active positions.

Slot Filling as Token Classification As in Devlin et al. (2019), we treat the slot filling as token classification, and we apply a shared layer on top of each token's representations to predict the tags.

Furthermore, we assemble the feature vector for the i^{th} slot by concatenating together the predicted intent probabilities, the word features, and the contextual representation from the language model. Afterwards, we add a dropout followed by a linear projection to the proper number of slots:

$$y_s^i = W_s[softmax(y_{int}); f_{words}^i; h_{LM}^i] + b_s \quad (7)$$

2.3 Interaction and Learning

To train the model, we use a joint loss function $\mathcal{L}_{joint}$ for the intent and for the slots. For both tasks, we apply cross-entropy over a softmax activation layer, except in the case of CRF tagging. In those experiments, the slot loss $\mathcal{L}_{slot}$ will be the negative log-likelihood (NLL) loss. Moreover, we introduce a new hyper-parameter γ to balance the objectives of the two tasks. Finally, we propagate the loss from all the non-masked positions in the sequence, including word pieces, and special tokens ([CLS], <s>, etc.). Note that we do *not* freeze any weights during fine-tuning.

3 Experimental Setup

Dataset In our experiments, we use two publicly available datasets, the Airline Travel Information System (ATIS) (Hemphill et al., 1990), and SNIPS (Coucke et al., 2018). The ATIS dataset contains transcripts from audio recordings of flight information requests, while the SNIPS dataset is gathered by a custom intent engine for personal voice assistants. Albeit both are widely used in NLU benchmarks, ATIS is substantially smaller – almost three times in terms of examples, and it contains fifteen times less words. However, it has a richer set of labels, 21 intents and 120 slot categories, as opposed to the 7 intents and 72 slots in SNIPS. Another key difference is the diversity of domains – ATIS has only utterances from the flight domain, while SNIPS covers various subjects, including entertainment, restaurant reservations, weather forecasts, etc. (see Table 2) Furthermore, ATIS allows multiple intent labels. As they only form about 2% of the data, we do not extend our model to multi-label classification. Yet, we add a new intent category for combinations seen in the training dataset, e.g., utterance with intents *flight* and also *airfare*, would be marked as *airfare#flight*. A comparison between the two datasets is shown in Table 2.

	ATIS	SNIPS
Vocab Size	722	11,241
Average Sentence Length	11.28	9.05
#Intents	21	7
#Slots	120	72
#Training Samples	4,478	13,084
#Dev Samples	500	700
#Test Samples	893	700

Table 2: Statistics about the ATIS and SNIPS datasets.

Measures We evaluate our models with three well-established evaluation metrics. The intent detection performance is measured in terms of accuracy. For the slot filling task, we use F1-score. Finally, the joint model is evaluated using sentence-level accuracy, i.e., proportion of examples in the corpus, whose intent and slots are both correctly predicted. Here, we must note that during evaluation we consider only the predictions for aligned words (we omit special tokens, e.g., [CLS], [SEP], <s>, </s>) and word pieces).

Baselines For our baseline models, we use BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), which we fine-tune. Details about the state-of-the-art model are shown in Appendix A.2. The model's architecture is shown in Figure 1a.

- **BERT** For training the model, we follow the fine-tuning procedure proposed by Devlin et al. (2019). We train a linear layer over the pooled representation of the special [CLS] token to predict the utterance's intent. The latter is optimized during pre-training using the next sentence prediction (NSP) loss to encode the whole sentence. Moreover, we add a shared layer on top of the last hidden representations of the tokens in order to obtain a slot prediction. Both objectives are optimized using a cross-entropy loss.
- **RoBERTa** This model follows the same training procedure as BERT, but drops the NSP task during pre-training. Still, the intent loss is attached to the special start token <s>.

	ATIS			SNIPS		
Model	Intent (Acc)	Sent. (Acc)	Slot (F1)	Intent (Acc)	Sent. (Acc)	Slot (F1)

Table 3: Intent detection and slot filling results on the SNIPS and the ATIS datasets. The best results in each category are in **bold**. Our models are in *italic*; the non-italic models on top come from the literature. Qin et al. (2019, 2020) report single-precision results.

4 Experiments and Analysis

Evaluation Results Table 3 presents quantitative evaluation results in terms of (*i*) intent accuracy, (*ii*) sentence accuracy, and (*iii*) slot F1.The first part of the tables refers to previous work, whereas the second part presents our experiments and is separated with a double horizontal line.

While models become more accurate, the absolute difference between two experiments becomes smaller and smaller, thus a better measurement is needed. Hereby, we introduce a fine-grained measure, i.e., *Relative Error Reduction* (RER) percentage, which is defined as the proportion of absolute error reduced by a $model_a$ compared to $model_b$.

$$RER = 1 - \frac{Error_{model_a}}{Error_{model_b}} \tag{8}$$

Table 4 shows the error reduction by our model compared to the current SOTA (see Appx. A.2), and to a BERT-based baselines (see Section 3). Since there is no single best model from the SOTA, we take the per-column maximum among all, albeit they are not achieved in a single run. For the ATIS dataset, we see a reduction of 11.64% (1.49 points absolute) for sentence accuracy, and 6.25% (0.25 points absolute) for slot F1, but just 4.91% for intent accuracy (see Table 3). Such a small gain can be both due to the quality of the dataset and to its size. For the SNIPS dataset, we see major increase in all metrics and more than 35% error reduction. In absolute terms, we have 0.76 for intent, 4.84 for sentence, and 1.77 for slots (see Table 3). This effects cannot be only attributed to the better model (discussed in the analysis below), but also to the implicit information that BERT learned during its extensive pre-training. This is especially useful in the case of SNIPS, where fair amount of the slots in categories like *SearchCreativeWork, SearchScreeningEvent, AddToPlaylist, PlayMusic* are names of movies, songs, artists, etc.

Transformer-NLU Analysis We dissect the proposed model by adding or removing prominent components to outline their contributions. The results are shown in the second part of Table 3. First, we compare the results of *BERT-Joint* and the enriched model *Transformer-NLU:BERT*. We can see a notable reduction of the intent classification error by 17.44% and 11.63% for the ATIS and the SNIPS dataset, respectively. Furthermore, we see a 19.87% (ATIS) and 17.35% (SNIPS) error reduction in slot's F1, and 11.43% (ATIS) and 11.63% (SNIPS) for sentence accuracy. We also try RoBERTa as a backbone to our model: while we still see the positive effect of the proposed architecture, the overall results are slightly worse. We attribute this to the different set of pre-training data (CommonCrawl vs. Wikipedia). We further focus our analysis on BERT-based models, since they performed better than RoBERTa-based ones. We further report models' variability in Appendix B.1.

Next, we remove the additional slot features – predicted intent, word casing, and named entities. The results are shown as Transformer-NLU:BERT w/o Slot Features. As expected, the intent accuracy remains unchanged for both datasets, since we retain the pooling attention layer, while the F1-score for the slots decreases. For SNIPS, the model achieved the same score as for *BERT-Joint*, while for ATIS it was within 0.2 points absolute.

Finally, we added a CRF layer on top of the slot network, since it had shown positive effects in earlier studies (Xu and Sarikaya, 2013a; Huang et al., 2015; Liu and Lane, 2016; E et al., 2019). We denote the experiment as *Transformer-NLU:BERT w/ CRF*. However, in our case it did not yield the expected improvement. The results for slot filling are close to the highest recorded, while a drastic drop in intent detection accuracy is observed, i.e., -17.44% for ATIS, and -20.28% for SNIPS. We attribute this degradation to the large gradients from the NLL loss. The effect is even stronger in the case of smaller datasets, making the optimization unstable for parameter-rich models such as BERT. We tried to mitigate this issue by increasing the γ hyper-parameter, effectively reducing the contribution of the slot's loss $\mathcal{L}_{slot}$ to the total, which in turn harmed the slot's F1. Moreover, the model does swap interchangeable slots, rather than the *B-* and *I-* prefixes, or slots unrelated to the intent.

BERT Knowledge Analysis As we start to understand better BERT-based large language models (Petroni et al., 2019; Rogers et al., 2020), we also start to observe some interesting phenomena. BERT is trained on Wiki articles, which allows it to learn implicit information about the world in addition to learning knowledge about language itself. Here, we evaluate how that former type of knowledge reflects on the two NLU evaluation datasets. As a first step, we extract all the slot phrases from the training sets, i.e., all the words in the slot sequence. Next, we send the latter as a query to Wikipedia and we collect the article titles. Then, we try to match the phrase with an extracted title. In order to reduce the false negatives, we normalize both texts (strip punctuation, replace digits with zeros, lower-case), allow difference of one character between the two, and finally if the title starts with the phrase, we count it as a match (e.g., *Tampa* vs. *Tampa, Florida*). Overall, 66% of the slots in ATIS and 69% in SNIPS matched a Wikipage title.

Metric	Relative Error Reduction	
	ATIS	
Intent (Acc)	4.91%	17.44%
Sent. (Acc)	11.64%	11.43%
Slot (F1)	6.25%	19.87%
	SNIPS	
Intent (Acc)	40.00%	11.63 %
Sent. (Acc)	35.91%	6.76%
Slot (F1)	37.64%	17.35%
Transformer-NLU	vs. SOTA	vs. BERT

Table 4: Relative error reduction (Eq. 8) comparing *Transformer-NLU:BERT* to the two baselines: *i)* current SOTA for each measure, and *ii)* conventionally fine-tuned BERT-Joint without the improvements.

Next, we evaluate how much of that information is stored in the model by leveraging the standard masking mechanism used during pre-training. In particular, we split each slot in subwords, and then we replace them one by one sequentially with the special [MASK] token. We then sort the predictions for that position by probability and we take the rank of the true word. Finally, we calculate the mean reciprocal rank (MRR) over all the aforementioned ranks: 0.46 for ATIS, and 0.36 for SNIPS. We must note that the BERT's dictionary contains 32K pieces, and the expected uniform MRR is $\sim$1/16,000. Below, we present two examples to illustrate both high- and low-ranked predictions.

High ranked: *play the album jack takes the floor by tom le [MASK] on netflix*, here the model's top predictions are: [**##hrer**, *##rner, ##mmon, ##hr, ##rman*], and the correct token is ranked with the highest probability.

Low ranked: *play some hong jun [MASK]*, here the model's top guesses are mostly punctuation, and general words such as [*to, ;, ##s, and*]. The correct token *##yang* is at position 3,036, which indicates that this term is challenging.

In SNIPS types such as *track, movie_name, entry_name, artist, album* have very high MRR (0.33–0.40), and ones that require numerical value, or are not part of well-known named entities such as object_part_of_series_type (OPST) are the lowest (under 0.1). The same in ATIS for country_name (8e-3), restriction_code (4e-3), meal (4e-3), in contrast to airline_code (0.45), transport_type (0.42), etc. However, ATIS in general does not require such task-specific knowledge, and its MRR is way higher in general, which is reflected by the overall improvement compared to the baseline models.

Error Analysis Here, we discuss what errors the proposed architecture solves compared to the BERT model, and what types of errors are left unsolved. First, we compare the performance of our method (*Transformer-NLU*) to *BERT-Joint (BERT)*. In the intent detection task, the largest improvement (over BERT) comes from examples with slots, indicative for a given intent. This suggests that the model successfully uses the slot information gathered by the pooling attention layer. For the following groups, this is most prominent: (*i*) examples with multi-label intents, e.g., *atis_airline#atis_flight_no – "i need* ***flight numbers*** *and* ***airlines*** *. . . "*, where *BERT* predicted *atis_flight_no*; (*ii*) examples containing distinctive words for another intent class – *"Give me* ***meal*** *flights ...", atis_flight → meal (BERT), "I need a* ***table*** *. . . when it is chiller", GetWeather → BookRestaurant (BERT)*. For all the aforementioned examples, both models filled the slots correctly, but only *Transformer-NLU* captured the correct intent. Moreover, we see a positive effect in detecting *SearchCreativeWork* and *SearchScreeningEvent*, while BERT tends to wrongly fill the slots, and thus swaps the two intents, e.g., *"find* ***heat wave****"*, or *"find* ***now and forever****"*. Finally, we see an additional improvement for *AddToPlaylist* and *atis_ground_fare*.

Next, we compare the performance of the two models on slot filling. As expected, the newly proposed model performs better, when the curated features capture some interesting phenomena. We observe that, when filling code slots (**airport, meal, airfare**) – *"what does . . . code* ***bh*** *mean"*, artists, albums, movies, object names – ***dwele, nyoil, turk*** (*artist → entity_name (BERT)*), locations – *". . . between milwaukee and* ***indiana****", state → city (BERT)*; BERT confuses ***mango*** *(city)* with the fruit (cuisine); *"new york city* ***area****" O → city (BERT)* and time-related ones – ***afternoon, late night, a.m.***.

Finally, we discuss the errors of *Transformer-NLU* in general. For the ATIS dataset, 50% of the wrong intents come from multi-label cases (35% with two labels, and 15% with three), 31% *atis_flight – "how many* ***flights*** *does . . .* ***/have to/leave*** *. . . "* (→ atis_quantity), 11% *atis_city – list la* (→ atis_abbreviation), and the others are mistakes in *atis_aircraft*. For the slots, 50% of the errors come from tags that can have a *fromloc/toloc* prefix, e.g., *city, airport_code, airport_name, etc.*, another 20% are time-related (*arrive_date, return_date*), and filled slots without tag 7%. The errors by the model for the SNIPS datasets are as follows: mislabeled intents *PlayMusic* 11%, *SearchCreativeWork* 22%, *SearchScreeningEvent* 67%, slots – *movie_name* 19%, *object_name* 16%, *playlist* 9%, track 9%, entity_name 5%, *album* 4%, *timeRange* 4%, *served_dish* 2%, filled slots without tag 19%. The model misses 9% (ATIS) and 17% (SNIPS) of all the slots that should be filled. This is expected since SNIPS' slots have a larger dictionary (11K words), with a large proportion of the slots being names, and often including prepositions, e.g., *". . . trailer of* ***the multiversity****"*.

5 Related Work

5.1 Intent Classification

Several approaches have focused only on the utterance intent, and have omitted slot information. For example, Hu et al. (2009) mapped each intent domain and user's queries into a Wikipedia representation space, Kim et al. (2017) and Xu and Sarikaya (2013b) used log-linear models with multiple-stages and word features. Ravuri and Stolcke (2015) investigate word and character n-gram language models based on Recurrent Neural Networks and LSTMs (Hochreiter and Schmidhuber, 1997), Xia et al. (2018) proposed a zero-shot transfer thought Capsule Networks (Sabour et al., 2017) and semantic features for detecting the user intent, without labeled data. Moreover, some work addressed the task in a multi-class multi-label setup (Xu and Sarikaya, 2013b; Kim et al., 2017; Gangadharaiah and Narayanaswamy, 2019).

5.2 Slot Filling

Before the rise of deep learning, sequential models such as Maximum Entropy Markov model (MEMM) (Toutanvoa and Manning, 2000; McCallum et al., 2000), and Conditional Random Fields (CRF) (Lafferty et al., 2001; Jeong and Lee, 2008) were the state-of-the-art choice. Recently, several combinations thereof and different neural network architecture were proposed (Xu and Sarikaya, 2013a; Huang et al., 2015; E et al., 2019). Zhu et al. (2020b) explored label embeddings from slots filling and different kinds of prior knowledge such as: atomic concepts, slot descriptions, and slot exemplars. Zhang et al. (2020) used time-delayed neural networks achieving state-of-the-art performance. Siddique et al. (2021) investigated zero-shot transfer of the slot filling knowledge between different tasks. However, a steer away from sequential models is observed in favor of self-attentive ones such as the Transformer (Vaswani et al., 2017; Radford et al., 2018; Devlin et al., 2019; Liu et al., 2019; Radford et al., 2019; Raffel et al., 2020; Lewis et al., 2020). They compose a contextualized representation of both a sentence, and each of its words, through a sequence of intermediate non-linear hidden layers, usually followed by a projection layer, in order to obtain per-token tags. Such models were successfully applied to closely related tasks, e.g., named entity recognition (NER) (Devlin et al., 2019), part-of-speech (POS) tagging (Tsai et al., 2019), etc.

Approaches modeling the intent or the slot as independent of each other suffer from uncertainty propagation due the absence of shared knowledge between the tasks. To overcome this limitation, we learn both tasks using a joint model.

5.3 Joint Models

Given the correlation between the intent and word-level slot tags, it is natural to train them jointly. Recent surveys covered different aspects of joint and individual modeling of the slot and the intent (Louvan and Magnini, 2020; Weld et al., 2021).

Xu and Sarikaya (2013a) introduced a shared intent and slot hidden state Convolutional Neural Network (CNN), followed by a globally normalized CRF (TriCRF) for sequence tagging. Since then, Recurrent Neural Networks have been dominating, e.g., Hakkani-Tür et al. (2016) used bidirectional LSTMs for slot filling and the last hidden state for intent classification, Liu and Lane (2016) introduced shared attention weights between the slot and the intent layer. Goo et al. (2018) integrated the intent via a gating mechanism into the context vector of LSTM cells used for slot filling.

Qin et al. (2019) used an self-attentive bidirectional LSTM encoder for the input utterances and a dual decoder for the intents and the slots, and they applied both at the token-level. E et al. (2019) introduced a bidirectional interrelated model, using an iterative mechanism to correct the predicted intent and the slot by multiple step refinement. Zhang et al. (2019) tried to exploit the semantic hierarchical relationship between words, slots, and intent via a dynamic routing-by-agreement schema in Capsule Networks (Sabour et al., 2017). Qin et al. (2020) proposed an adaptive graph-interactive framework using BiLSTMs and graph attention networks (GAT) (Velickovic et al., 2018) to model the interaction between intents and slots at the token level. Recently, Qin et al. (2021) introduced a co-interactive Transformer that mixes the slot and the intent information by building a bidirectional connection between them. However, scaling to larger model sizes requires the adopting more efficient approaches (Ren et al., 2019; Zhu et al., 2020a; Kim et al., 2020; Lesci et al., 2023).

Here, we use a pre-trained Transformer, and instead of depending only on the language model's hidden state to learn the interaction between the slot and the intent, we fuse the two tasks together. Namely, we guide the slot filling by the predicted intent, and we use a pooled representation from the task-specific outputs of BERT for intent detection. Moreover, we leverage information from external sources: *(i)* from explicit NER and true case annotations, and *(ii)* from implicit information learned by the language model during its extensive pre-training.

6 Conclusion

We studied the two main challenges in natural language understanding, i.e., intent detection and slot filling. Addressing these tasks is important in a number of scenarios arising on Web platforms and Web-based applications such as customer service in social media, dialogue systems, web queries understanding, and general understanding of natural language interaction with the user.

In particular, we proposed an enriched pre-trained language model to jointly model the two tasks (i.e., intent detection and slot filling), i.e., *Transformer-NLU*. We designed a pooling attention layer in order to obtain intent representation beyond just the pooled one from the special start token. Further, we reinforced the slot filling with word-specific features, and the predicted intent distribution. Our experiments on two standard datasets showed that Transformer-NLU outperforms other alternatives for all standard measures used to evaluate NLU tasks. We found that the use of RoBERTa and adding a CRF layer on top of the slot filling network did not help.

Ethics and Broader Impact

Applicability

Our intent pooling mechanism, as well as the features we introduced, are potentially applicable to other semantic parsing and sequence labeling tasks. They increase the model's size by just few tens of thousands of parameters, which is very efficient in comparison to modern NLP models, which have millions or even billions of parameters.

Biases

On the down side, we would like to warn about the potential biases in the data used for training Transformers such as BERT and RoBERTa, as well as in the ATIS and the SNIPS datasets. Moreover, the use of large-scale Transformers and GPUs could contribute to global warming.

Environmental Impact

Finally, we would also like to warn that the use of large-scale Transformers requires a lot of computations and the use of GPUs/TPUs for training, which contributes to global warming. This is a bit less of an issue in our case, as we do not train such models from scratch; rather, we fine-tune them on relatively small datasets. Moreover, running on a CPU for inference, once the model has been fine-tuned, is perfectly feasible, and CPUs contribute much less to global warming.
